Although less is known about PPAR $\delta$ , this is rapidly changing. Studies into PPAR $\delta$  may have been influenced by the absence of a clinical PPAR $\delta$  agonist in current clinical use. PPAR $\delta$  is expressed widely in essentially all tissues. It was originally characterized in the skin, where it may enhance wound healing during acute inflammation by influencing keratinocyte differentiation and cell survival pathways (75). PPAR $\delta$ -deficient mice are in general not viable, although occasional mice do survive to birth. These PPAR $\delta$ -deficient mice demonstrate significantly smaller body habitus, less adiposity, and abnormal myelination of the nervous system (76,77). Investigators have subsequently shown that PPAR $\delta$  regulates genes involved in fatty-acid metabolism in adipose tissue, skeletal muscle, cardiac muscle, and liver (78). PPAR $\delta$  also has been implicated in regulating inflammation, although these data suggested distinct roles for PPAR $\delta$  in the presence versus absence of ligand. PPAR $\delta$  is expressed in human ECs, but its function in this setting remains obscure (78).

#### POTENTIAL UNTOWARD EFFECTS OF PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\alpha$ AND - $\gamma$ ACTIVATION

In contrast to these various anti-inflammatory and antiatherosclerotic responses, limited reports do suggest some potential untoward effects on the endothelium resulting from PPAR activation. Certain specific oxidized lipids might act through PPAR $\alpha$  to induce inflammation (79,80). In this work,

minimally modified LDL (MM-LDL) and oxidation products of 1-palmitoyl-2-arachidonoyl-sn-glycero-3-phosphocholine (PAPC) activated cultured human ECs to synthesize MCP-1 and IL-8. The authors suggest that this effect may be mediated partly through PPAR $\alpha$ . MM-LDL, Ox-PAPC, or its component phospholipids were capable of activating the PPAR $\alpha$  ligand-binding domain, as well as a consensus peroxisome proliferator-activated receptor response element (PPRE) in transfected ECs. In contrast to earlier studies, these investigators found that the PPAR $\alpha$  activator Wy14643 stimulated the synthesis of IL-8 and MCP-1 by human arterial ECs (HAECs). By contrast, troglitazone, a PPAR $\gamma$  agonist, blunted the induction of IL-8 and MCP-1 gene and protein expression. Ox-PAPC and MM-LDL no longer upregulated MCP-1 in PPAR $\alpha$ -null mice. The reproducibility and in vivo relevance of these findings or of the compounds employed remains unclear but certainly worthy of further study. In clinical practice, the use of TZDs is associated with weight gain, peripheral edema, and heart failure in a small subset of patients, in particular those also taking insulin therapy for diabetes. However, the endothelial effects of PPAR $\gamma$  agonists have not been specifically implicated in the fluid retention that can develop in some patients administered these medications (81).

Interestingly, despite the extensive PPAR $\alpha$ -mediated anti-inflammatory and antiatherosclerotic effects, studies crossing PPAR $\alpha$ -deficient mice with ApoE-deficient mice found less, not more, atherosclerosis (82). Others report that PPAR $\alpha$  agonists could decrease atherosclerosis in LDL receptor-deficient mice (83,84). The reasons for these differences are not clear. One contributing factor may be inherent differences between PPARs in mice versus humans. Indeed, studies of PPAR $\alpha$  agonists in ApoE-deficient mice found a more impressive reduction in atherosclerosis when these mice also expressed a transgene for human apoA1 (83).

### ENDOGENOUS PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR ACTIVATION?

As is apparent from the preceding discussion, considerable insight into PPAR biology has been derived from the identification of the synthetic PPAR agonists for each isoform. The specificity of individual agonists for each PPAR is dictated by the unique structure of both the LBD as well as the chemical structure of the agonist. The large LBD of each PPAR has been exploited in the development of therapeutic agents that can activate two (dual agonists) or all three (pan-agonists) PPARs, simply as a function of steric forces and the available space for agonist occupancy (19).

One of the major unresolved issues in the PPAR field has been the identity of specific natural PPAR agonists that certainly must exist to activate PPARs in vivo (1). Insight into these endogenous PPAR agonists would have major implications, suggesting mechanisms that might protect against the very problems synthetic PPAR agonists are used to treat, such

as diabetes mellitus and dyslipidemia (19). Likewise, defects in pathways that generate natural PPAR agonists also might lead to pathological conditions. Although the prostaglandin derivative 15d-PGJ<sub>2</sub> has been suggested to bind to PPAR $\gamma$ , the presence of this molecule in vivo and its PPAR $\gamma$ -independent effects has tempered enthusiasm for the relevance of this interaction. Leukotriene B<sub>4</sub> has been proposed as an agonist for PPAR $\alpha$  (85), although again the physiological relevance of this has been unclear. Examples of other recent work in this area suggest that lysophosphatidic acid (LPA) (86), tetradecylthioacetic acid (87), and nitrolinoleic acid (88) might also be PPAR $\gamma$  agonists.

An alternative approach to the question of natural PPAR agonists is to identify pathways that might generate natural PPAR ligands, as opposed to pursuing specific candidate molecules. Using this tack, both our group as well as that of Ron Evans, found that lipoprotein lipase (LPL), a key enzyme in triglyceride metabolism, could act on triglyceride-rich lipoproteins to activate PPARs (65,89). Studying murine macrophages, Chawla and colleagues found that LPL interacted with very-low-density lipoproteins (VLDLs) to activate PPAR $\delta$  (89). We found that LPL hydrolyzes VLDL to generate preferentially PPAR $\alpha$  ligands, with significant but lesser effects on PPAR $\delta$  and even less on PPAR $\gamma$  (65) (Figure 87.2). These relative responses were seen both in cell-based as well as more rigorous cell-free radioligand displacement assays. Additional studies demonstrated that LPL-mediated PPAR $\alpha$  activation depended on intact LPL catalysis and did not occur with other lipases tested, despite the release of similar amounts of total free fatty acids (65). Extended further, LPL-treated VLDL repressed TNF- $\alpha$ -induced VCAM-1 induction, but not in PPAR $\alpha$ -deficient ECs (65). This recapitulates the effects of synthetic PPAR $\alpha$  agonists as described earlier. The novel role for LPL in limiting inflammation is an example of the insight that can be derived from probing nuclear receptors through endogenous mechanisms, as opposed to synthetic agonists. Subsequent work has provided additional support for the notion of a transcriptional network through different lipase-lipoprotein substrate interactions, for example as seen with the ability of LPL action to release not only known PPAR $\alpha$  ligands from electronegative LDL, but also to completely reverse electronegative LDL's potent inflammatory effects (23).

Recently, this model for lipolytic PPAR activation has been extended to also include endothelial lipase (90). We initially observed that the widely reported ability of HDL to repress leukocyte adhesion and adhesion molecule expression was lost in the presence of the general lipase inhibitor tetrahydrolipstatin. Subsequent studies led to the demonstration that HDL hydrolysis by endothelial lipase was capable of PPAR $\alpha$  activation and repression of VCAM-1 and leukocyte adhesion. These findings, although in contrast with other lines of evidence in mice that endothelial lipase may promote atherosclerosis (91), support the notion that probing PPARs with more physiologic stimuli like lipase-lipoprotein interactions may shed light on PPARs and lipases, and their role in health and disease.

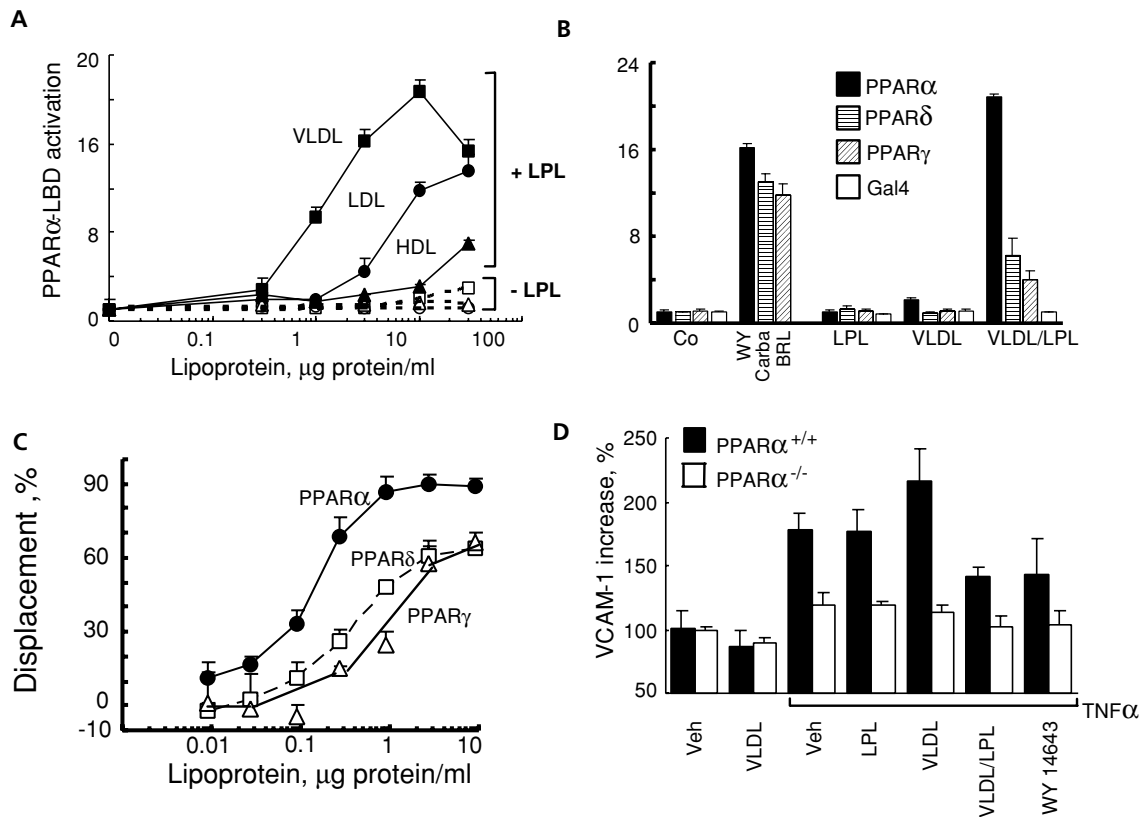

Figure 87.2. (A) LPL treatment of VLDL activates the PPAR $\alpha$  ligand-binding domain (LBD). Standard PPARLBD assays were performed in ECs cotransfected with PPAR $\alpha$ -LBD, the luciferase response pUASx4-TK-luc, and  $\beta$ -galactosidase constructs and stimulated with the lipoproteins shown in either the presence or absence of LPL (30 U/ml). (Details here and in Rossi A, Kapahi P, Natoli G, et al. Anti-inflammatory cyclopentenone prostaglandins are direct inhibitors of IkappaB kinase. *Nature*. 2000;403:103-108.) (B) LPL-treated VLDL (10  $\mu$ g/mL) preferentially activates PPAR $\alpha$ . LBD activation for all three known PPAR isotypes ( $-\alpha$ ,  $-\gamma$ ,  $-\delta$ ) by VLDL in ECs was measured in the presence or absence of LPL using standard LBD-GAL4 assays (as in Figure 87.1), and compared to responses induced by known PPAR isotype agonists as follows: PPAR $\gamma$ -BRL49653 (BRL, 1  $\mu$ M); PPAR $\alpha$ -WY14643 (WY, 100  $\mu$ M), PPAR $\delta$ -carbaprostacyclin (carba, 10  $\mu$ M). (C) LPL-treated VLDL generates PPAR agonists. LPL-treated VLDL was used in radioligand displacement assays. Competition curves were generated by incubating the LPL/VLDL reaction mixture with specific radiolabeled PPAR activators: 5 nM  $^3$ H $_2$  compound A with GST-hPPAR $\alpha$  (circles) or GST-hPPAR $\gamma$  (triangles), or 2.5 nM  $^3$ H $_2$  compound B with GST-hPPAR $\delta$  (squares). Radioligand displacement in the presence of the indicated concentration of VLDL (0.003-10  $\mu$ g protein/mL)/LPL (200 U/mL LPL, 37°C, 1h) is plotted. (D) Similar to synthetic PPAR $\alpha$  agonists, LPL-treated VLDL represses cytokine-induced VCAM-1 in wild-type, but not PPAR $\alpha$ -deficient ECs. VCAM-1 surface expression in ECs obtained from wild-type (black bars) or PPAR $\alpha$ <sup>-/-</sup> mice (white bars) was measured by ELISA using standard protocols. ECs cultured in 96 well plates were stimulated with murine TNF- $\alpha$  (10 ng/mL, 18h). Data represent absorbance at 410 nm after protein concentration normalization. Both WY14643 (100  $\mu$ M) and LPL/VLDL significantly decreased VCAM-1 levels (\*,  $p < .005$ ) in wild-type, but not PPAR $\alpha$ -deficient ECs. Basal VCAM-1 level in PPAR $\alpha$ <sup>-/-</sup> is significantly increased as compared to wild-type ECs (#,  $p < .001$ ), suggesting PPAR $\alpha$  plays a basal role in repressing inflammation.

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS – KEY MEDIATORS OF ENDOTHELIAL TRANSCRIPTIONAL RESPONSES?

PPARs can be considered transcriptional nodal points, controlling the expression of multiple gene targets in a host of different pathways. This characteristic, combined with the fact that all major PPAR isoforms are expressed in vascular ECs,

suggest that PPAR regulation is potentially critical to the roles the endothelium plays in both health and disease. Thus, in addition to the possibility of PPAR activators in clinical use having indirect vascular effects – through improved insulin sensitivity or lower triglycerides and higher HDL – they may also directly influence EC function by activating PPARs present in ECs. Whether these direct effects in ECs as well as other non-metabolic settings are relevant to clinical responses remains

a critical and unsettled issue. Fortunately, some insight into this area may soon be obtained, given ongoing clinical trials examining the effects of PPAR $\gamma$  and PPAR $\alpha$  agonists on cardiovascular events.

### KEY POINTS

- PPARs, as ligand-activated nuclear receptors or transcription factors that control cassettes of target genes involved in energy balance, lipid metabolism, insulin sensitivity, and inflammation, may play a central role in directing transcriptional responses in the endothelium.
- All three PPARs –  $\alpha$ ,  $\gamma$ , and  $\delta$  – are expressed in the endothelium. Considerable evidence suggests the involvement of PPAR $\alpha$  and  $\gamma$  in regulating the expression of target genes important to roles the endothelium is known to play in health and disease.
- Agonists for both PPAR $\alpha$  (lipid-lowering fibrates) and PPAR $\gamma$  (antidiabetic thiazolidinediones) are in current clinical use; some of the proposed benefits of these agents on the cardiovascular system, including anti-inflammatory and antiatherosclerotic effects, may derive from the direct activation of PPARs expressed in the endothelium.
- The action of both lipoprotein lipase and endothelial lipase, respectively, on VLDL and HDL, may represent endogenous mechanisms for PPAR activation, with functional consequences for endothelial responses.

### Future Goals

- To establish if direct PPAR activation in the endothelium, as well as in vascular cells and inflammatory cells, can contribute to clinical cardiovascular benefits, as is currently under study
- To better understand the nature of endogenous PPAR ligands, and the clinical effects and safety of novel synthetic PPAR agonists that are in development

## GATA Transcription Factors

Takashi Minami

*The Research Center for Advanced Science and Technology, The University of Tokyo, Japan*

The GATA family of transcription factors are zinc finger proteins that bind directly to the consensus motif (T/A)GATA (A/G). GATA factors are highly conserved throughout evolution. The mammalian family consists of six members, GATA-1 to -6. The proteins have been classified into two subgroups, according to sequence homology and expression patterns: (a) GATA-1, -2, and -3, which are expressed predominantly in hematopoietic cells; and (b) GATA-4, -5, and -6, which are primarily expressed in heart, gastrointestinal tract, and embryonic endoderm (1,2). Endothelial cells (ECs) have been shown to express GATA-2, -3, and -6. With the exception of GATA-5, disruption of GATA factors in mice results in embryonic lethality. This chapter reviews the role for these proteins in EC biology (summarized in Table 88-1).

### GATA-2

GATA-2 is widely considered to be a critical mediator of hematopoietic cells. Although it is expressed in ECs, its role in this cell type is less well defined. Several *in vitro* studies have demonstrated a role for GATA-2 in mediating basal gene expression in ECs. In the early 1990s, two groups independently cloned human GATA-2 and reported that GATA-2 transactivates the *pre-proendothelin-1* promoter in bovine aortic ECs (3,4). Additional studies have implicated GATA-2 in the basal regulation of von Willebrand factor (vWF) (5), utrophin B (6), platelet-endothelial cell adhesion molecule (PECAM)-1 (7,8), Tie2 (9), and endothelial nitric oxide synthase (eNOS) (10).

In addition to controlling basal expression of EC-specific genes, GATA-2 also serves as an immediate early gene, coupling changes in the extracellular environment to an alteration in EC phenotype. For example, GATA-2 is involved in mediating (a) vascular endothelial growth factor (VEGF)- and thrombin-mediated induction of the angiogenesis-related negative feedback factor, Down syndrome critical region (DSCR)-1 (11); (b) extracellular matrix-mediated induction of matrix metalloprotease (MMP)-2 (12); (c) transforming growth factor (TGF)- $\beta$ 1-inhibitable KDR/FLK-1 (also known as VEGFR2)

expression (13); and (d) thrombin- and native LDL-mediated induction of vascular cell adhesion molecule (VCAM)-1 (14–16).

Null mutation of *GATA-2* is embryonically lethal (E10.5) owing to failure of expansion of early hematopoietic progenitor cells (17). Further evidence for the role of GATA-2 in the hematopoietic stem cell pool was derived from studies of chimeric mice and embryoid bodies (17,18). A recent study suggests an important role for GATA-2 in the induction and expansion of the first hematopoietic stem cells in the aortogonads-mesonephros (AGM) region. Although GATA-2 is expressed in the aortic endothelium and neighboring mesenchymal cells in the AGM at E11.5, the role for GATA-2 in the developing vasculature and intact endothelium remains to be determined.

### GATA-3

GATA-3 is most often implicated in T-cell development (19). However, recent studies from our laboratory point to a potentially important role for this transcription factor in ECs. Using DNA microarrays and RNase protection assays, we have shown that *GATA-3* mRNA is expressed at similar or higher levels than GATA-2 in human umbilical vein ECs (HUVECs). Moreover, incubation of HUVECs with inflammatory mediators, such as thrombin and tumor necrosis factor (TNF)- $\alpha$ , resulted in a downregulation of GATA-3, but not GATA-2, expression (20). Interestingly, GATA-3 is differentially expressed in different types of cultured ECs. For example, compared with HUVECs, GATA-3 expression is lower in human pulmonary artery ECs (HPAECs), although it is undetectable in dermal microvascular ECs (HDMECs) (Figure 88.1).

To date, no published reports exist of GATA-3 target genes in ECs. To gain insights into the GATA-3-dependent transcriptional program, we carried out DNA microarrays of HUVECs infected with adenovirus overexpressing GATA-2 or GATA-3. A total of 60 genes were selectively altered (more than twofold change in duplicate arrays) by GATA-3 (Figure 88.2; for color reproduction, see Color Plate 88.2). Nine of these genes encode

**Table 88-1: Putative GATA Target Genes in ECs**

	Gene Name	Regulation Type	Stimulus
GATA-2	<i>ET-1</i>	Constitutive	
	<i>vWF</i>	Constitutive	
	<i>utrophin B</i>	Constitutive	
	<i>PECAM-1 (CD31)</i>	Constitutive	
	<i>eNOS (NOS3)</i>	Inducible	Glucocorticoid
	<i>DSCR-1</i>	Inducible	VEGF or thrombin
	<i>MMP-2</i>	Inducible	Collagen gel culture
	<i>KDR/FLK-1</i>	Inducible	TGF- $\beta$
	<i>VCAM-1</i>	Inducible	Thrombin
	<i>ICAM-2</i>	Constitutive	
<i>Tie2</i>	Constitutive		
GATA-6	<i>vWF</i>	Constitutive	
	<i>VCAM-1</i>	Inducible	TNF- $\alpha$
	<i>u-PA</i>	Inducible	Laminar shear

proteins related to cell morphology (e.g., cytoskeleton). Interestingly, the angiogenic inducer Cyr 61 and placental growth factor were upregulated significantly with GATA-3 but not GATA-2. A need exists for further studies (e.g., small interfering RNA [siRNA]-mediated knockdown of GATA-3 in vitro and conditional EC-specific knockout of GATA-3 in vivo) to elucidate the role for GATA-3 in EC biology.

### GATA-6

GATA-6 plays an important role in endoderm differentiation (21). In adults, GATA-6 is expressed predominantly in adult heart, aorta, stomach, small intestine, and bladder (21). GATA-6 has been localized in myocardium, lung epithelium, and vascular smooth muscle cells (VSMCs), and has been shown to regulate lung- and heart-specific gene expression. A paucity of data describes a role for GATA-6 in ECs. In our microarray and real-time PCR analyses, GATA-6 is expressed constitutively in cultured ECs (HUVECs, HPAECs, and

human coronary artery ECs [HCAECs]), but not in HDMECs (database from <http://www.lsbm.org>). Indeed, GATA-6 was shown to mediate basal expression of vWF (22) in HUVECs. In HCAECs, laminar flow (fluid shear stress) was reported to upregulate the *urokinase-type plasminogen activator (u-PA)* gene via inducible binding of GATA-6 (23). Others have shown that TNF- $\alpha$  treatment increases the binding of GATA-6 to the *VCAM-1* promoter in cultured ECs (24).

### POST-TRANSCRIPTIONAL MODIFICATION

Extracellular signals, such as thrombin, promote the transcriptional activity of GATA-2 without inducing GATA-2 mRNA expression. Thus, GATA-2 must be subject to post-transcriptional modification. Inducible phosphorylation has been described for GATA-1 in hematopoietic progenitor cells (25), GATA-2 in hematopoietic cells (26), GATA-3 in T cells (25), and GATA-4 in cardiac myocytes (27,28). The extent to which agonist-mediated induction of GATA-2 activity in ECs is mediated by phosphorylation of the transcription factor has not been determined. We have found that treatment of GATA-2 with phosphatase inhibits thrombin-mediated induction of the transcription factor to the *VCAM-1* promoter (T. Minami and W.C. Aird, unpublished observations), arguing against a role for GATA phosphorylation in the thrombin-*VCAM-1* signaling axis.

GATA factors also may undergo acetylation of lysine residues. For example, it has been reported that CREB-binding protein (CBP/p300)-mediated acetylation of GATA-1, -2, and -3 results in increased DNA binding activity and transactivation (29). It will be interesting to determine whether acetylation of GATA and associated chromatin remodeling plays a role in EC signal transduction.

More recently, it was shown that GATA-2 is covalently modified by small ubiquitin-like modifier (SUMO)-1 and -2 (30). In that study, PIASy, a member of the Protein Inhibitor of Activated Stat (PIAS) family of regulators of STAT function, was shown to enhance SUMO (particularly SUMO-2) conjugation to GATA-2, leading to suppression of GATA-2-dependent endothelin (*ET*)-1 promoter activity. Expression of

Figure 88.1. Cell subtype-specific differences in constitutive and inducible GATA expression. Reverse transcription PCR was performed with human GATA-2 or GATA-3-specific primers. Total RNA was purified from each designated ECs in the presence of VEGF (50 ng/mL), thrombin (1.5  $\mu$ /mL) or TNF- $\alpha$  (10 ng/mL). Arrows indicate amplified *GATA-2* or *GATA-3* gene. Cyclophilin was used as a control, showing the integrity and concentration of the isolated total RNA.

Figure 88.2. Color mapping with GATA-3–selective inducible genes. Microarray (Affymetrix U133 plus) analyses were performed in duplicate using HUVECs overexpressing GATA-2 or GATA-3. Genes were filtered according to those that were induced more than twofold by GATA-3 but not GATA-2. Selected genes were analyzed using the GeneTree program. Dark and light panels represent higher and lower expression, respectively, compared with the median for that particular gene. For color reproduction, see Color Plate 88.2.

PIASy is higher in ECs compared with VSMCs and is induced by fibroblast growth factor (FGF) and VEGF (30).

**PROTEIN-PROTEIN INTERACTIONS**

The protein-protein interactions of GATA are summarized in Table 88-2.

**Nonendothelial Cells**

*GATA-1, -2, and -3*

GATA-1 may bind CBP, resulting in transcriptional synergy (31). GATA-1-LMO2 interactions have been shown to play a key role in regulating erythroid gene expression (32). In megakaryocytes and erythroid cells, GATA-1 physically interacts with the Ets family member, Fli-1, and results in the synergistic activation of megakaryocyte-specific promoters (33). A family of proteins, called Friend of GATA (FOG) have been described that mediate both activation and repression of GATA-1, -2, and -3 target genes (1).

In thyrotropes, Pit-1 (a homeodomain protein) and GATA-2 form stable protein-protein interactions, bind to the *TSH* promoter in a ternary complex, and synergistically activate transcription (34). Pit-1 physically interacts with the second zinc finger of GATA-2. Yet another coactivator, MED220, recently has been shown to interact with the Pit-1-GATA-2 complex (35). In hematopoietic cells, GATA-2 interacts directly with the retinoic acid (RA) receptor- $\alpha$ , rendering the transcriptional activity of GATA RA-responsive (29).

*GATA-4, -5, and -6*

Nkx2.1 and Nkx2.5 interact with members of the GATA-4, -5, and -6 subfamily and synergistically act to induce expression of cardiac genes (36,37). GATA-4 and -6 interact with the

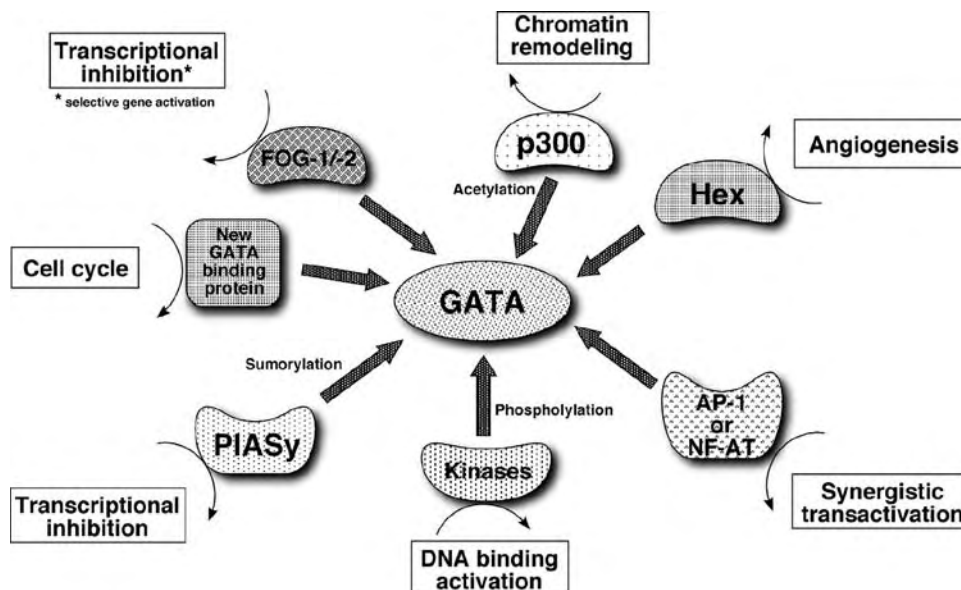

Figure 88.3. Model of GATA function.

cysteine-rich protein (CRP) family of LIM domain proteins to regulate expression in cardiac and vascular smooth muscle (38). GATA-6 interacts with LMCD1/Dyxin. In contrast to most other protein-protein interactions involving GATA factors, which synergistically activate transcription, GATA-6-LMCD1/Dyxin interactions repress GATA-6-dependent gene expression in cardiac cells (39). In VSMCs, p300 is a coactivator for GATA-6 (27). Thyroid transcription factor-1 interacts with the zinc fingers of GATA-6 to regulate the *surfactant protein-C* promoter (40).

### Endothelial Cells

From a functional standpoint, GATA-mediated transactivation of genes in ECs has been shown to be enhanced or repressed by a number of proteins (Figure 88.3). For example, GATA-2 synergizes with AP-1 to induce ET-1 expression in ECs (41). VEGF- and thrombin-mediated induction of DSCR-1 involves the cooperative binding of NF-ATc and GATA-2 and -3 to neighboring consensus motifs in the upstream promoter (11). Recently, we reported that GATA-2 physically interacts with Hex and this interaction inhibits GATA-2-mediated expression of *KDR/FLK-1* gene expression in cultured ECs (42).

#### KEY POINTS

- GATA transcription factors play an important role in mediating basal and modulatable gene expression in ECs.
- ECs express GATA-2, -3, and -6.
- Different vascular beds indicated separate GATA expression patterns.
- GATA proteins are signal transducers, coupling changes in the extracellular environment to changes in gene expression.
- GATA transcription factors are modulated at a post-transcriptional level.

#### Future Goals

- To determine the roles for GATA factors in EC biology in vivo
- To elucidate the mechanisms of post-transcriptional regulation of GATA proteins in ECs

## Coupling

### The Role of Ets Factors

---

Peter Oettgen

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Transcription factors play a pivotal role in the coupling of endothelial gene expression to endothelial function. The tightly controlled regulation of endothelial gene expression is required for several aspects of endothelial biology. During embryogenesis, for example, the normal development of a primary vascular network, or vasculogenesis, requires a series of carefully orchestrated events that are spatially and temporally regulated. These events are largely coordinated by the precisely timed expression of selected sets of transcription factors. In the adult, endothelial cell (EC)-specific genes are differentially regulated in different body organs or tissues. These differences are in large part dependent on paracrine interactions between tissue-specific cell types and the endothelium. These paracrine interactions depend on the coupling of one cell type with another and are largely mediated by specific transcriptional programs. Under changing environmental or pathological conditions, the endothelium in the affected organ or tissue undergoes distinct changes in gene expression. The identification of specific transcription factors involved in the regulation of the endothelium under normal and pathological conditions not only has led to a better understanding of basic underlying mechanisms of endothelial gene regulation, but also may provide novel therapeutic targets for treating patients with a variety of diseases. Indeed, recent studies have demonstrated the feasibility of targeting transcription factors using small molecules (discussed in the section Therapeutic Implications).

We and other investigators have recently demonstrated the importance of selected members of the Ets transcription factor family in regulating endothelial-specific gene expression during normal development, in mediating vascular-bed specific expression in adult endothelium, and in modulating the expression of activation markers under pathological conditions. The goal of this chapter is to review how transcription factors play a central role in coupling endothelial gene expression to endothelial function under normal and pathological conditions, and to explore their potential as therapeutic tar-

gets for drug discovery, with a particular focus on the role of selected members of the Ets transcription factor family in this process.

#### ETS FACTORS

The Ets factors are a family of approximately 30 transcription factors that have been identified in species ranging from flies to humans, and that share a highly conserved DNA binding domain consisting of a helix-loop-helix structure (Figure 89.1; for color reproduction, see Color Plate 89.1) (1). Particular conservation occurs in the third helix, which binds to a minor groove of the DNA, in the region of the core GGAA/T region of the DNA backbone. Additional specificity is mediated by the flanking wings on either side, which bind to and recognize structural elements within the flanking DNA nucleotide sequences. The name *ETS* is derived from a sequence that was detected in an avian erythroblastosis virus, E26, where it forms a transforming gene together with  $\Delta$ gag and c-myc (2). This sequence was called E26 (E Twenty Six) transformation-specific sequence or Ets. The first cellular homologue to be identified was the human Ets-1 protein, which was shown to function as a proto-oncogene in chromosomal translocations from chromosome 1 to 11 in one form of acute monocytic leukemia and, later, acute lymphoblastic leukemia (3,4). The first functional role for Ets-1 was shown to be in thymocytes, where Ets-1 regulates a number of T cell-specific genes. More recently, Ets has been shown to be involved in a wide variety of developmental processes and cell growth. Furthermore, as proto-oncogenes, aberrant expression of selected members of the Ets transcription factor family is associated with the development of a variety of cancers. Over the past several years, a role for different members of the Ets transcription factor family has been demonstrated in the regulation of a wide variety of biological and pathobiological processes including cancer, angiogenesis, and inflammation.

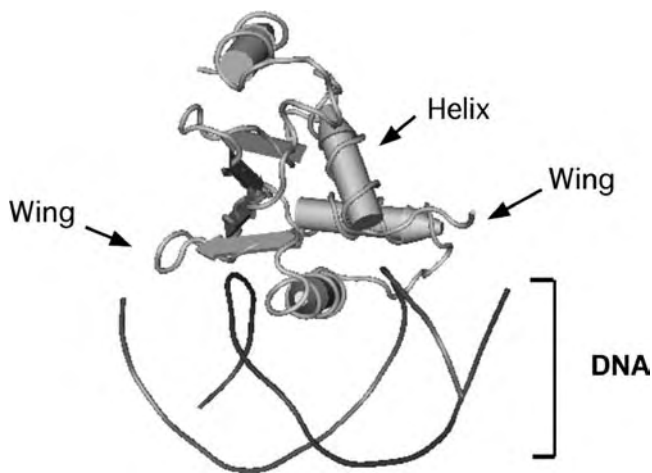

Figure 89.1. Ets DNA binding domain. Schematic of the highly conserved Ets DNA binding domain with a helix-loop-helix structure. Depicted is the structure of the Ets-1 DNA binding domain. Helix 3 is shown in close proximity to the DNA, which is depicted as an overlapping wire-like structure. The flanking wings provide DNA binding specificity among the individual family members. A fourth helix (*top*) can function to inhibit DNA binding. (Reproduced with permission from Garvie CW, Pufall MA, Graves BJ, Wolberger C. Structural analysis of the autoinhibition of Ets-1 and its role in protein partnerships. *J Biol Chem.* 2002;277:45529–45536.) For color reproduction, see Color Plate 89.1.

### REGULATION OF ENDOTHELIAL-SPECIFIC GENE EXPRESSION DURING DEVELOPMENT

Vascular development requires the tightly coordinated expression of vascular-specific genes in a temporal and spatial fashion. Examples of endothelial-specific genes that have been shown to be required for vascular development include several receptor tyrosine kinases, such as the vascular endothelial growth factor (VEGF) receptors, VEGFR1, VEGFR2, and the Tie receptors, Tie1 and Tie2. Targeted disruption of the genes encoding these receptors leads to embryonal lethality at various stages of vascular development (5). Recent studies have supported a role for selected members of the Ets factor family in the regulation of these endothelial-specific tyrosine kinases. Whereas the VEGF receptors VEGFR1 and VEGFR2 are regulated by Ets-1 and Ets-2, the *Tie1* and *Tie2* genes appear to be regulated by a different subset of Ets factors including ELF-1 and NERF2 (Elf-2) (6) (Table 89-1). Further support for a role for these factors during vascular development comes from studies demonstrating increased expression of ELF-1 and ELF-2 in developing embryonic blood vessels (7,8).

Several other Ets factors are involved in regulating endothelial-specific gene expression and function during development. For example, the Ets transcription factor Fli-1 is enriched in the developing blood vessels of zebrafish (9). Targeted disruption of *Fli-1* in mice results in a loss of vascular integrity accompanied by bleeding and embryonic lethality at

day E11.5 (10). The Ets factor Tel was originally identified as a proto-oncogene in the development of human leukemias (11). Interestingly, targeted disruption of this factor led not only to defects in hematopoiesis, but also to defects in extraembryonic angiogenesis that are embryonically lethal (12).

### VASCULAR BED-SPECIFIC GENE REGULATION

Vascular-specific gene expression is also regulated at the level of a particular organ or tissue. Distinct differences in the expression of endothelial-specific genes exist from one organ to another (13–15). For example, the endothelial-specific gene von Willebrand factor (vWF), thrombomodulin (TM), and tissue factor pathway inhibitor (TFPI) exhibit significant differences in expression levels in normal human tissue samples (16). In the heart, vWF and TM are highly expressed, whereas only small amounts of TFPI are detected. The brain expresses undetectable amounts of TFPI and TM, and only small amounts of vWF. TFPI is highly expressed in the placenta, whereas TM and vWF are only weakly expressed. Several endothelial-specific genes, including intercellular adhesion molecule (ICAM)-2, vWF, thrombospondin, and the extracellular matrix protein SPARC depend on the Ets factor Erg for their expression in ECs (17). Ets binding sites also have been identified that are critical for the expression of endothelial-specific molecule (ESM)-1 that is expressed primarily in ECs of the lung, kidney, and gut (18). One particular promising strategy for identifying the molecular basis of vascular bed-specific gene expression has been to study the activity of wild-type and, in some cases mutant, DNA promoter sequences coupled to a reporter gene in transgenic mice. Using this approach, a 1.8-kb fragment of the mouse *Tie1* gene was shown to direct highly reproducible expression of LacZ within the intact endothelium (19). A mutation of a single Ets binding site in the proximal region of the *Tie1* promoter completely abolished the ability of the promoter to direct endothelial-specific gene expression in vivo. Mutation of a second, more distal Ets site leads to a marked reduction of expression in certain vascular beds such as the heart, but not in other organs such as the brain. These findings suggest that selected members of the Ets transcription factor family may be involved in mediating vascular bed-specific expression of the *Tie1* gene. The specific Ets family members that regulate the *Tie1* gene at these sites have not been determined. In addition to their role in regulating the expression of vascular-specific genes, selected members of the Ets transcription factor family also regulate the expression of transcription factors involved in regulating endothelial-specific genes. For example, the gene for transcription factor myocyte enhancer factor 2C (MEF2C) contains an intronic enhancer that directs the expression of this transcription factor in a vascular-specific manner during development. This enhancer contains highly conserved binding sites for Ets-1 (20).

Another approach that has been used more recently to overcome the problems associated with random integration

**Table 89-1: Role of Selected Ets Factors in Endothelial Gene Expression**

	<i>ECs/Vascular Beds</i>	<i>Targets</i>	<i>Inducers</i>	<i>-/- Phenotype</i>	<i>References</i>
Ets-1	Arterial and venous ECs in vitro	VEGFR1, VEGFR2 MMP-1, MMP-3, MMP-9 vWF, urokinase, MEF2	VEGF, HGF, FGF2	Reductions in the number of natural killer cells; no vascular defects	20, 34–37
Ets-2	Arterial and venous ECs in vitro	VEGFR1 VEGFR2, urokinase			6, 38
Elf-1	Arterial ECs in vitro developing embryonic vessels	Tie1, Tie2			6, 8
Elf-2 (NERF-2)	Arterial and venous ECs in vitro; developing embryonic vessels	Tie1, Tie2	Hypoxia		6, 39
Elf-3 (ESE-1)	Not detectable in quiescent ECs in vitro or in vivo, is induced in activated ECs	NOS2, COX2	IL-1 $\beta$ , TNF- $\alpha$ , LPS	Abnormalities in development of small intestine in some strains	29, 40–42
Fli-1	Developing embryonic vessels of zebrafish			Embryonic lethal at E11.5 with loss of vascular integrity and hemorrhage	10
Tel	Yolk sac ECs, broadly expressed in other cells			Defect in extra-embryonic angiogenesis	12
ERG	Arterial and venous ECs	ICAM-2, thrombospondin, SPARC			17

COX2, cyclooxygenase 2; LPS, lipopolysaccharide

observed using standard transgenic approaches is to target the transgene into the *HPRT* locus. This approach has been used to define the role of Ets and other transcription factor binding sites within the *Tie2* promoter (21). Similar studies also have been conducted with the *VEGFR1* and *vWF* genes, which have facilitated the identification of specific regulatory elements that are required for directing the expression of these genes in different vascular beds (22).

Differences in the expression of selected Ets family members also have been observed in different types of primary ECs. For example, whereas the Ets factor ELF-2 (NERF2) is expressed in both arterial (i.e., human aortic ECs [HAECs] and venous ECs [HUVECs]), ELF-1 is only expressed in arterial EC (i.e., HAEC) (6).

### PROTEIN–PROTEIN AND POST-TRANSLATIONAL MODIFICATIONS

Several other mechanisms exist by which gene expression can be further regulated in addition to the binding of specific transcription factors to regulatory elements within these genes. One of the major mechanisms by which the activity of transcription factors can be modified is through protein–protein interactions. For example, Ets-1 has been shown to interact with several different proteins, including the transcrip-

tion factors AML-1, nuclear factor (NF)- $\kappa$ B, GATA3, hypoxia-inducible factor (HIF)-2 $\alpha$ , Pax5, and STAT5 (Figure 89.2) (23). Another mechanism, by which the activity of a transcription factor can be modified, is through post-translational modifications, such as phosphorylation. For example, phosphorylation of Ets-1 by the mitogen-activated protein kinase (MAPK) pathway leads to increased transcriptional activity, whereas phosphorylation through Cam Kinase II decreases Ets-1 activity (24). Other post-translational modifications by which the activity of Ets factors can be modified include sumoylation, ubiquitination, and acetylation (25).

### ANGIOGENESIS

In addition to the regulation of the VEGF receptors during development, Ets-1 also has been shown to be upregulated in the setting of angiogenesis associated with tumor growth. Ets-1 expression in ECs is induced by VEGF, hepatocyte growth factor (HGF), and basic fibroblast growth factor (bFGF). Some of the gene targets for Ets-1 include several members of the matrix metalloproteinase family including matrix metalloproteinase (MMP)-1, MMP-3, and MMP-9 (26). The therapeutic potential of blocking Ets-1 in the setting of angiogenesis recently has been shown. In two animal models of angiogenesis, including a tumor model and a model in which

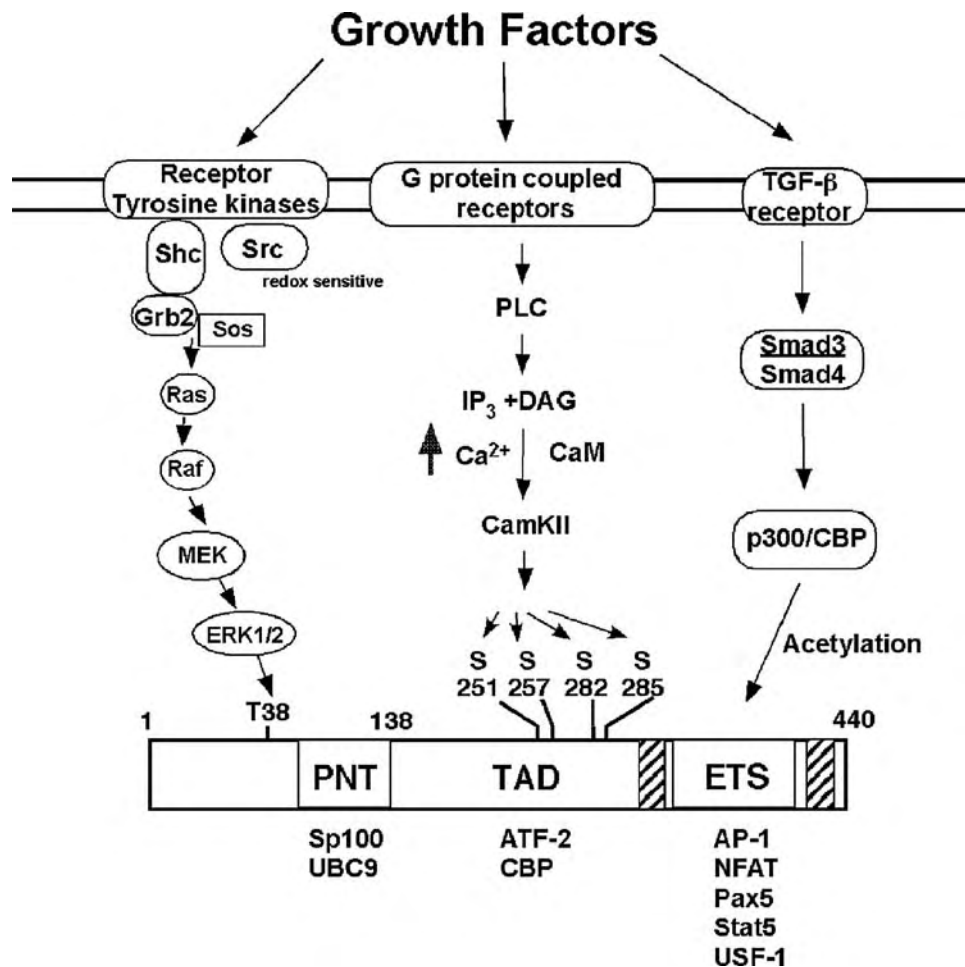

Figure 89.2. Post-translational modifications of Ets factors. An example of the multiple mechanisms by which the activity of Ets factors can be modulated at a post-translational level. The activity of Ets-1 can be positively (MAPK) or negatively (CamKII) regulated through protein-protein interactions with several domains of the protein including the pointed domain (PNT) transactivation domain (TAD) and Ets domain (Ets). (Reproduced with permission Tootle TL, Rebay I. Post-translational modifications influence transcription factor activity: a view from the Ets superfamily. *Bioessays*. 2005;27:285–298.)

bFGF was subcutaneously implanted in the mouse ear, systemic administration of a retrovirus expressing a dominant negative form of Ets-1 resulted in marked inhibition of angiogenesis and tumor growth (27).

## ENDOTHELIAL ACTIVATION

A number of inflammatory mediators can lead to endothelial activation, including proinflammatory cytokines and endotoxin. We recently have identified a novel member of the Ets transcription factor, ESE-1, that has the unique property of having two DNA binding domains: an A/T hook domain and a classical Ets domain (28). ESE-1 is not expressed under normal conditions in cells of vascular origin, such as ECs or vascular smooth muscle cells (VSMCs). However in the presence of proinflammatory cytokines such as interleukin (IL)-1 $\beta$  or

tumor necrosis factor (TNF)- $\alpha$ , ESE-1 expression is rapidly induced in ECs and VSMCs (29). One of the main targets of ESE-1 is the inducible form of nitric oxide synthase (NOS2). In a mouse model of endotoxemia, ESE-1 was induced within the endothelium and first layer of smooth muscle cells within the media (29). In parallel, a similar spatial and temporal induction of NOS2 was observed. Furthermore, ESE-1 functions synergistically with NF- $\kappa$ B to transactivate the NOS2 gene. To further define additional proteins that might interact with ESE-1 to modulate its function, we recently identified CBP/p300 as a protein that cooperates with ESE-1 to upregulate its function (30). More interestingly, we identified another set of proteins, the Ku proteins 70 and 86 that bind to ESE-1 and inhibit its function. The Ku proteins have previously been shown to act as architectural proteins and bind to DNA, but have not been shown to modulate the function of transcription factors.

## THERAPEUTIC IMPLICATIONS

The identification of selected transcription factors that are enriched in the setting of vascular inflammation or angiogenesis not only has implications regarding the understanding of the fundamental underlying molecular mechanisms of these processes, but also has important therapeutic implications. In general, transcription factors do not regulate a single gene, but more often whole sets of genes that may be involved in a particular process or cell type. The inhibition of the function of a particular factor may therefore be therapeutically useful because the activation of whole sets of genes can be blocked, as opposed to a single receptor or enzyme.

In addition to blocking peptides and the use of dominant negative proteins, the identification of small molecules that specifically inhibit selected transcription factors and exhibit therapeutic potential has recently been demonstrated. The transcription factor HIF-1 $\alpha$  is constitutively expressed in many cell types but becomes activated in the setting of hypoxia. HIF-1 $\alpha$  induces the expression of VEGF and is a critical mediator of angiogenesis (31). Two groups have recently identified small molecules that are capable of inhibiting the function of HIF-1 $\alpha$  (32,33). These small molecules not only block the function of HIF-1 $\alpha$ , but have been shown to inhibit the induction of VEGF in the setting of hypoxia and lead to marked reduction in tumor growth of human cancer cell lines in mice, with associated inhibition of tumor angiogenesis in mouse tumor models. The HIF-1 $\alpha$  small-molecule inhibitor was administered after the injected tumor cells reached a size of 120 mm<sup>3</sup> (33). When the HIF-1 $\alpha$  small-molecule inhibitor was administered to animals with the small cell lung cancer cell line SHP-77, it completely abolished the growth of the tumor, with no evidence of any tumors visible after several months. In summary, the results of these and other recent studies clearly demonstrate the therapeutic potential of targeting transcription factors that act as central mediators of the activated endothelium in the setting of pathological processes such as angiogenesis or vascular inflammation. Interactions between basic and clinical scientists, and computational and medicinal chemists, will promote the identification of novel therapeutic compounds that can be used to target the endothelium in a number of human diseases.

### KEY POINTS

- Ets factors are critical transcriptional regulators of endothelial-specific gene expression.
- Several Ets factors, including Ets-1, Ets-2, Elf-1, Elf-2, Fli-1, Erg-1, and Tel regulate vasculogenesis and angiogenesis.
- Critical regulators of endothelial activation in response to inflammatory mediators include the Ets factors Elf-3 and Ets-1.

### Future Goals

- To determine whether inhibition of the function of selected Ets family members in the setting of pathological angiogenesis, using peptide inhibitors or small molecules, can be used therapeutically in a variety of human diseases
- To determine whether inhibition of the function of selected Ets family members in the setting of vascular inflammation can be used therapeutically to treat diseases associated with vascular inflammation, including hypertension, atherosclerosis, and diabetes mellitus

## Early Growth Response-1 Coupling in Vascular Endothelium

Levon M. Khachigian and Valerie C. Midgley

*Centre for Vascular Research, University of New South Wales, Prince of Wales Hospital,  
Sydney, Australia*

Changes in the extracellular environment can trigger alterations in gene expression and eventually phenotype through the activity of transcription factors. One such “coupler” is early growth response (Egr)-1 (also known as Krox-24, zif268, NGFI-A, and TIS8), a 60- to 80-kDa zinc finger transcription factor of the C<sub>2</sub>H<sub>2</sub> subtype and the product of an immediate-early gene (1). It belongs to a family of nuclear regulators that include Egr-2, Egr-3, and Egr-4, and its expression can be induced by a variety of pathophysiologic stimuli in endothelial cells (ECs) and other vascular cell types such as smooth muscle cells (SMCs), monocytes, and macrophages, as well as in a diverse range of nonvascular cells. In 1987, Egr-1 was independently cloned by a number of groups using differential screening strategies (2–5). It is comprised of 533 amino acids and contains an amino-terminal and a carboxyl-terminal activation domain, a repression domain, and a DNA-binding domain consisting of three conserved zinc fingers. Egr-1 also contains a bipartite nuclear localization signal (residues 315–330 and a section of the DNA-binding domain) (Figure 90.1) (1,6).

Egr-1 has been implicated in a panoply of cardiovascular pathologic processes, which include atherosclerosis, restenosis, ischemia, angiogenesis, allograft rejection, and cardiac hypertrophy (7). Triggers such as injury (8), altered biomechanical environment (9), growth factor/hormone and cytokine exposure (10–13), chemical challenge (such as lysophosphatidylcholine) (14), and hypoxia (15,16) are capable of rapidly inducing Egr-1 transcription. Once induced, Egr-1 regulates the expression of many genes through specific interactions with GC-rich motifs in the promoter regions of responsive genes. These include transcription factors, signaling molecules, cell cycle regulatory proteins, cytokines, growth factors, coagulation factors, and even Egr-1 itself. Transcriptional profiling following adenoviral gene transfer in ECs indicates that several hundred genes are differentially expressed in response to Egr-1 overexpression by at least threefold (17) (Table 90-1). We and others have demonstrated that, at least in ECs, Egr-1

controls platelet-derived growth factor (PDGF)-A (9,11,18), PDGF-B (8), fibroblast growth factor (FGF)-2 (19), tissue factor (20), and angiotensin-converting enzyme (21) expression. Moreover, insulin-inducible EC proliferation and regrowth after injury is an Egr-1-dependent process (22). Egr-1 therefore transcriptionally integrates changes in the extracellular environment with altered gene expression and cell phenotype.

It is unlikely that Egr-1 acts alone in its regulation of gene expression; cofactors of Egr-1 have been identified that influence Egr-1 transcriptional activity. For example, cAMP-response-element-binding-protein-binding protein (CBP) and p300 boost Egr-1 transactivation of the *5-lipoxygenase* promoter whereby the N- and C-terminal domains of CBP interact with the transcriptional activation domain of Egr-1 (23). NAB1 and NAB2, on the other hand, serve as Egr-1 corepressors by blocking Egr-1 activity through protein-protein interaction with the inhibitory domain of Egr-1 (24–26). Lessons from our own work investigating PDGF-A (18), PDGF-B-chain (8), and more recently PDGF-C-chain (27) transcription indicate that Egr-1's interaction with DNA involves the displacement of other transcription factors, such as Sp1, from overlapping binding sites in the promoters. However, such interplay need not necessarily have a positive influence on gene expression. Suppression of the expression of hepatocyte growth factor (HGF) receptor (the product of the *c-met* proto-oncogene) by oxidative stress, for example, is mediated through interplay between Egr-1 and Sp1 (28).

The inducible transcription of Egr-1, like that of *c-Fos* (29), is under the control of mitogen-activated protein kinase (MAPK) phosphorylation cascades that phosphorylate ternary complex factor (TCF)<sup>1</sup>/serum response factor (SRF)-dependent gene expression (30), which binds to SRFs to activate serum-response elements (SREs) (31). Several SREs occur in the *Egr-1* promoter (32,33). These interactions are

1 For example, the Ets factors Elk-1, Sap-1a, and Net.

**Table 90-1: Representative Egr-1–Dependent Genes in ECs**

<i>Gene Class</i>	<i>Upregulated Genes</i>	<i>Downregulated Genes</i>
Transcriptional regulatory proteins	<i>NAB1, AP2, Egr-1, GATA-2, p54</i>	<i>Smad6</i>
Signaling proteins	<i>Rad, Notch3, small G protein, bcl-1, RAMP1</i>	<i>BMP2, BMP4, NOS</i>
Growth factors, cytokines, and chemokines	<i>IGF-2, TGF-<math>\beta</math>, PDGF-A, PDGF-B, PDGF-C</i>	<i>TRAIL, CTGF</i>
Cell cycle regulators	<i>p57, Cyclin D1</i>	
Extracellular matrix proteins	<i>VCAM-1, TIMP-1, fibronectin, osteopontin, collagen III <math>\alpha</math>1</i>	<i>VE-Cadherin, PECAM-1</i>
Ion channels	<i>Na<sup>+</sup>-Ca<sup>2+</sup> exchanger, Ca<sup>2+</sup> channel <math>\alpha</math>2</i>	
Other	<i>Apolipoprotein E &amp; D, H0-1, BAI1, hPD-1, tissue factor</i>	<i>Connexin 40, HSP40</i>

responsible for regulating the inducible expression of Egr-1 in response to agonists and conditions as diverse as thrombin (34), lipopolysaccharide (35), and hypoxia (16).

Our understanding of Egr-1's role in ECs and other vascular settings in vivo has, in part, been derived from the use of gene-targeting strategies. The weaponry of synthetic nucleic acid–based gene silencing agents includes antisense oligonucleotides, triplex-forming oligonucleotides, ribozymes, riboswitches, aptamers, silent RNA (siRNA), and RNA-cleaving DNA enzymes (or DNAzymes) (36). Our lab has employed the use of DNAzymes (bearing 9 + 9 nt arms, with a 3'-linked inverted T at the 3'-end) targeting Egr-1 to inhibit vascular EC (19) and SMC (37) growth in culture and to impair the capacity of these cells to regenerate after wounding in vitro. DNAzymes are single-stranded DNA molecules that bind to their target RNA through Watson–Crick base-pairing and cleave between an unpaired purine and a paired pyrimidine

by virtue of a cation-dependent catalytic domain (e.g., the 15 nt long “10–23” domain) (38). Unlike alternative, more costly approaches, DNAzymes are stable in serum and may inhibit through the use of both classic noncatalytic antisense and catalytic mechanisms (39). DNAzymes have provided insights into the roles of Egr-1 in microvascular EC growth, neovascularization, tumor angiogenesis, and tumor growth. For example, we found Egr-1 DNAzymes to perturb spontaneous endothelial tubule formation within hours of plating (19), to inhibit host neovascularization of subcutaneous Matrigel plugs in mice, and to reduce limbal angiogenesis in rat cornea after vascular endothelial growth factor (VEGF) implantation. Furthermore, DNAzymes impaired MCF7 solid tumor (human breast carcinoma) growth in athymic nude mice and reduced vessel density in the tumors, without adversely affecting body weight, wound healing, blood coagulation, or reproduction (19). DNAzyme inhibition of solid tumor

growth in that study was indirect; that is, growth suppression was achieved via inhibition of host EC growth, consistent with Folkman's hypothesis from 30 years ago (40,41). Egr-1 inhibition blocked the expression of FGF2 (19). Interestingly, the injury-inducible endothelial expression of Egr-1 is itself dependent on the release and paracrine activity of endogenous FGF2 (12). The inhibitory properties of DNazymes illustrated by our findings demonstrate the key role Egr-1 plays in EC growth, neovascularization, and tumor growth. Our earlier work demonstrates that Egr-1 DNazymes also inhibit other vascular settings. When delivered adventitiously (from the outside of the vessel in) to the carotid arteries of rats, Egr-1 DNazymes inhibited intimal thickening involving aggressive SMC growth in the arterial intima, 2 weeks after balloon catheter angioplasty (19) and 3 weeks after ligation injury (42). Moreover, when delivered intraluminally in pig arteries using a special catheter, Egr-1 DNazymes blocked in-stent restenosis 1 month after coronary stenting (43). These studies with Egr-1 DNazymes provided the first proof-of-principle evidence that this class of molecule can be used as gene-specific and potentially versatile therapeutic tools (37). DNazymes targeting other "couplers" such as, for example, c-Jun, have been used to inhibit microvascular endothelial growth and angiogenesis, tumor growth (39) as well as SMC growth, and other vascular proliferative settings including intimal thickening in injured arteries (44). Other groups have generated catalytic DNA targeting bcr-abl (45), c-myc (46), integrins  $\beta_1$  and  $\beta_3$  (47,48), protein kinase C (PKC) $\alpha$  (49), PKC $\epsilon$  (50), Twist (51), VEGF receptor-2 (52), laminin  $\gamma_1$  chain (53), human immunodeficiency virus (HIV)-1 (54,55), and platelet-type 12-lipoxygenase (56).

Since its discovery almost two decades ago, many lines of investigation have shown that Egr-1 is indeed a "master-regulator" that controls the expression of multiple growth-regulatory genes and can couple the extracellular environment with cardiovascular pathologic settings.

## KLF2

## A “Molecular Switch” Regulating Endothelial Function

Zhiyong Lin and Mukesh K. Jain

Case Cardiovascular Research Institute, Case Western Reserve University,  
Cleveland, Ohio

Krüppel-like factors (KLFs) are a subclass of the zinc-finger family of transcriptional regulators implicated in the regulation of cellular growth and differentiation and tissue development. The term *Krüppel* is a German word meaning “cripple.” This is based on the observation that *Drosophila* embryos homozygous for *Krüppel* die due to altered thoracic and anterior abdominal segments (1–3). Over the past 13 years, 17 mammalian KLFs have been identified and found to play important roles in diverse cell types. For example, the first mammalian KLF, termed *erythroid Krüppel-like factor* (*EKLF/KLF1*), was found to play a key role in  $\beta$ -globin gene synthesis and erythrocyte development (4,5). Other family members have been shown to play critical roles in diverse processes ranging from epithelial cell differentiation, tumor cell growth, and bone formation (6–10). Recent studies also implicate an important role for these factors in cardiovascular biology (11,12). In this chapter, we discuss published studies to date that support a critical role of lung Krüppel-like factor 2 (LKLF/KLF2) in endothelial biology.

#### IDENTIFICATION AND INITIAL CHARACTERIZATION OF KRÜPPEL-LIKE FACTOR-2

KLF2 was originally cloned in the Lingrel laboratory using a homology screening strategy (13). Subsequent gene targeting studies indicate an essential role for this factor in programming the quiescent phenotype of single-positive T cells and in lung development (14,15). In addition, *KLF2*<sup>-/-</sup> mice exhibit abnormal blood vessel formation due to insufficient smooth muscle cell recruitment, which results in embryonic hemorrhage and death between embryonic (E) day 12.5 and 14.5 (16). The latter observation suggested that KLF2 has an important role in vessel biology. Interestingly, it was shown that within the blood vessel wall, KLF2 expression was lim-

ited to endothelial cells (ECs) (16). However, until recently, the function of KLF2 in this cell type remained poorly understood.

#### FUNCTIONS OF KRÜPPEL-LIKE FACTOR-2 IN ENDOTHELIAL BIOLOGY

The vascular endothelium, which forms the inner lining of cells in all blood vessels, is a critical integrator and transducer of various physiological stimuli (17). The endothelium is a “quiescent” tissue that regulates vascular permeability, blood coagulation, and homing of immune cells to specific sites of the body. Dysfunction of the endothelium is a key pathophysiologic event in the development and progression of diverse vascular disease states. Characteristic abnormalities include impaired endothelium-dependent vasodilation, enhanced expression of leukocyte adhesion molecules, increased elaboration of procoagulant factors, and abnormal vascular remodeling.

Various stimuli can modulate the phenotype of ECs. For example, laminar shear stress (LSS) induces various factors, such as endothelial nitric oxide synthase (eNOS) and thrombomodulin (TM), that confer potent antithrombotic, anti-adhesive, and anti-inflammatory properties (18,19). In contrast, noxious stimuli, such as proinflammatory cytokines or advanced glycation end products, can render the endothelium dysfunctional. As a consequence, eNOS expression is reduced while the expression of adhesion molecules (e.g., vascular cell adhesion molecule [VCAM]-1) and prothrombotic factors (e.g., tissue factor) is induced (20,21). Given the critical function of endothelium in homeostasis, the identification of the regulatory factors that mediate the effects of these stimuli on endothelial (dys)function is of considerable interest. Studies from our laboratory, coupled with others, implicate KLF2 as a molecular regulator of endothelial function (Figure 91.1).

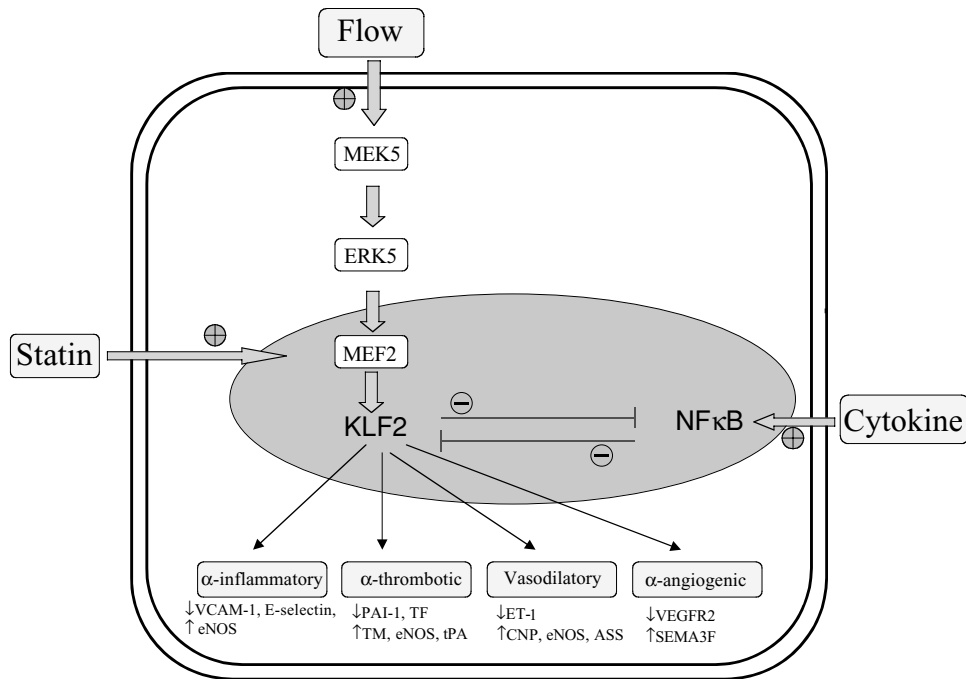

Figure 91.1. Functions and regulation of KLF2 in ECs. KLF2 differentially affects the expression of factors that confer anti-inflammatory, antithrombotic, antiproliferative effects in ECs. Laminar shear stress induces KLF2 expression through the MEK5/ERK5/MEF2 pathway. Cytokines, such as  $\text{TNF-}\alpha$ , reduce KLF2 expression. Statins induce KLF2 expression.

### Krüppel-Like Factor-2 Regulates Endothelial Proinflammatory Activation

In response to inflammatory stimuli, ECs are induced to express adhesion molecules and chemokines that recruit immune cells to the blood vessel wall. This early event then sets the stage for a series of complex interactions between these immune cells and nonimmune cells that dictate disease development and progression (22). Our laboratory first reported KLF2 as a novel transcriptional regulator of endothelial proinflammatory activation. We observed that KLF2 can potently inhibit the expression of VCAM-1 and E-selectin in ECs, resulting in significant attenuation of immune cell adhesion. The effect of KLF2 is specific because, in contrast to VCAM-1 and E-selectin, intercellular adhesion molecule (ICAM)-1 expression was not affected (23).

It is noteworthy that KLF2 inhibits the effects of multiple proinflammatory stimuli including interleukin (IL)- $1\beta$ , tumor necrosis factor (TNF)- $\alpha$ , lipopolysaccharide (LPS), and thrombin (23,24). This raised the possibility that inhibition of a common inflammatory pathway may account for KLF2's favorable effects. Indeed, subsequent studies indicate that KLF2 can inhibit the nuclear factor (NF)- $\kappa\text{B}$  pathway at multiple levels. In the case of stimuli such as IL- $1\beta$  and TNF- $\alpha$ , inhibition occurs via recruitment of transcriptional coactivators (e.g., cyclic adenosine monophosphate [cAMP] response element-binding protein CBP/p300) (23). However, in the case of thrombin, a second mechanism is also operative.

We found that KLF2 potently inhibits the thrombin-mediated induction of multiple cytokines/chemokines (e.g., monocyte chemoattractant protein [MCP]-1, IL-6, and IL-8) by inhibiting the expression of its principal receptor, protease-activated receptor (PAR)-1. As a consequence, NF- $\kappa\text{B}$  nuclear accumulation and DNA-binding are strongly reduced (24). Thus, KLF2 can inhibit endothelial proinflammatory activation by multiple mechanisms that affect the NF- $\kappa\text{B}$  pathway.

### Krüppel-Like Factor-2 Regulates Endothelial Thrombotic Function

Under normal circumstances, the vascular endothelium maintains blood fluidity by producing inhibitors of coagulation and platelet aggregation, modulating vascular tone, and providing a protective barrier separating hemostatic blood components from subendothelial structures (25). Hemostasis may occur if the capacity of inhibitory pathways is impaired or if the capacity of endogenous anticoagulant systems is overwhelmed by a noxious stimulus (25). Recent work indicates that KLF2 can regulate the expression of key factors that regulate vessel thrombosis. Overexpression of KLF2 strongly induced TM, a potent antithrombotic factor. In parallel, KLF2 overexpression also inhibited expression of the prothrombotic proteins plasminogen activator inhibitor (PAI)-1 and tissue factor (in the setting of cytokine activation). Conversely, small interfering RNA (siRNA)-mediated knockdown of KLF2 resulted in antithrombotic effects. Consistent with these gene expression

effects, blood clotting time and flow rates were increased in the presence of KLF2 and reduced by KLF2-deficiency (26).

### **Krüppel-Like Factor-2 Regulates Expression of Factors Implicated in Regulating Vasoreactivity**

Under physiologic conditions, the endothelium regulates vessel tone through the elaboration of several vasodilatory factors such as eNOS or C-natriuretic peptide (CNP). In disease states, the expression of these factors is reduced, whereas that of vasoconstrictive molecules (e.g., endothelin-1) is induced. Several recent studies implicate KLF2 in the regulation of these gene products. KLF2 strongly induces the expression of both eNOS and CNP (27). Furthermore, the expression of argininosuccinate synthase (ASS), a limiting enzyme in eNOS substrate bioavailability (28), also is induced. On the other hand, KLF2 reduced the expression of genes regulating vasoconstriction, such as endothelin-1. In addition, KLF2 decreased the expression of caoveolin-1, a cell membrane protein that serves as a negative regulator of eNOS activity (29). The importance of KLF2 was verified by siRNA studies; reduction of KLF2 significantly attenuated flow-mediated induction of eNOS and CNP while increasing endothelin-1 expression (27).

### **Krüppel-Like Factor-2 Regulates Endothelial Proliferation and Migration**

Under normal conditions, the endothelium retains a highly quiescent phenotype. However, in response to certain stimuli (e.g., vascular endothelial growth factor [VEGF]), ECs can be induced to proliferate, migrate, and establish new blood vessels. Although angiogenesis is of physiologic importance in the adult (e.g., during the menstrual cycle), inappropriate angiogenesis can contribute to serious pathology, such as tumor formation. Studies from our group and others indicate that KLF2 has potent antiangiogenic effects. Bhattacharya and colleagues revealed that forced expression of KLF2 retards VEGF-mediated calcium flux, proliferation, and proinflammatory factor expression. Furthermore, in a nude mouse ear model, KLF2 overexpression dramatically attenuated VEGF-induced new vessel formation and tissue edema. Mechanistically, this reduction was at least in part due to KLF2's ability to inhibit the expression of the key VEGF receptor, VEGFR2/KDR (30). Dekker and colleagues also have provided evidence that KLF2 inhibits EC migration by virtue of its ability to induce the expression of semaphorin 3F (SEMA3F) (31). Thus, by reducing EC proliferation and migration, KLF2 can inhibit angiogenesis.

### **MECHANISMS REGULATING KRÜPPEL-LIKE FACTOR-2 EXPRESSION IN ENDOTHELIAL CELLS**

As noted previously, KLF2 expression in the vasculature is limited to ECs. In this regard, it is noteworthy that expres-

sion in the endothelium is not uniform. Indeed, as elegantly demonstrated by Dekker and colleagues, KLF2 was robustly expressed in linear segments of the human aorta, but expression was notably lower at branch points of aorta (and near the bifurcation in the iliac and carotid arteries) (32,33). Linear segments of the aorta experience laminar flow – a stimulus known to induce KLF2. In contrast, branch points experience disturbed flow and are the regions most susceptible to the development of atherosclerotic lesions (17). Furthermore, branch-point areas also are characterized by heightened NF- $\kappa$ B activity and the expression of VCAM-1 (34). These observations are particularly noteworthy in light of studies discussed in the following sections, regarding the regulation of KLF2 expression.

### **Flow-Mediated Induction of Krüppel-Like Factor-2 Expression**

We and others have demonstrated that LSS can strongly induce KLF2 expression in ECs (23,32,35). The mechanistic basis for this effect has been addressed recently in a series of studies. Promoter deletion studies revealed that the proximal region of *KLF2* promoter can be induced by flow (36). A breakthrough observation first reported by Kumar and colleagues was that this region contains a functional consensus binding site for a family of transcription factors termed myocyte enhancer factor 2 (MEF2) proteins (37). MEF2 factors are members of the MADS box (MCM1, Agamous, Deficiens, Serum response factor) family of transcription factors that bind to A/T-rich sequences (38). Although best known for their role in muscle development, an emerging literature implicates MEF2A and MEF2C as critical regulators of endothelial biology (39–41). For example, Wang and colleagues identified mutations in MEF2A in an inherited disorder with features of coronary artery disease (41) (see Chapter 94). Furthermore, MEF2C has been implicated as a regulator of endothelial integrity and permeability (39). The basis for the favorable effects of MEF2 factors in ECs is not understood, but the link to KLF2 provides a potential explanation. Indeed, this link has been substantiated by two additional studies. First, loss-of-function studies by Sohn and colleagues showed that extracellular signal-regulated kinase 5 (ERK5), a kinase known to activate MEF2 factors, is essential for embryonic KLF2 expression (42). This observation is particularly noteworthy because ERK5 also is known to be activated by laminar flow (43), raising the possibility that LSS-mediated activation of ERK5 stimulates MEF2, which in turn induces KLF2. Consistent with this hypothesis, Parmar and colleagues showed that the overexpression of a dominant negative MEF2 (or mutant MEK5 – an upstream activator of ERK5) prevented flow-mediated induction of KLF2 expression in ECs (27).

In addition to MEF2 factors, observations largely derived from promoter analyses under flow by the Lingrel laboratory implicate a number of additional factors that may contribute KLF2 expression. These factors include p300/CBP-associated factor (PCAF), heterogeneous nuclear ribonucleoprotein D

(hnRNP D), and nucleolin (44,45). However, the importance of these factors in regulating endogenous KLF2 expression under basal conditions or in the context of flow remained to be defined.

### Cytokine-Mediated Inhibition of Krüppel-Like Factor-2 Expression

Proinflammatory cytokines such as TNF- $\alpha$  and IL-1 $\beta$  have been shown to repress KLF2 expression in ECs (23,37). This is an important observation, because reduction in KLF2 expression may lead to unopposed NF- $\kappa$ B activity and endothelial proinflammatory activation. In this regard, a recent study has provided novel insights. Using chemical and genetic inhibitors, Kumar and colleagues determined that the TNF- $\alpha$ -mediated reduction of KLF2 was dependent on both the NF- $\kappa$ B and histone deacetylase (HDAC) pathways. Next, using a combination of promoter deletion and mutation analyses, chromatin immunoprecipitation (ChIP) assays, and siRNA-mediated knockdown studies, evidence was provided that p65 (a component of NF- $\kappa$ B) and HDAC4 cooperate to inhibit the ability of MEF2 factors to induce KLF2 expression (37). These studies, coupled with the observation that KLF2 can inhibit NF- $\kappa$ B, raise the possibility that the balance of these two transcriptional pathways may regulate the state of endothelial activation.

### THERAPEUTIC IMPLICATIONS

Given the favorable properties that KLF2 confers to the endothelium, one would in principle like to identify mechanisms to exploit this in a therapeutically meaningful manner. In this regard, studies from our group and others have identified a novel link between KLF2 and a commonly prescribed class of medications, the statins (46,47). Originally designed to lower cholesterol, these 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors are increasingly recognized as agents that confer favorable properties to the vasculature. However, accumulating information from clinical and experimental studies also indicates that the magnitude of the favorable effects of statins exceed what may be anticipated by lipid lowering alone.

A review of studies assessing the effects of statins on endothelial gene expression revealed a marked overlap with those observed in studies of KLF2. Consistent with this observation, we and others have reported that multiple statins can induce KLF2 expression (23,47). This induction was abrogated by geranylgeranyl pyrophosphate (GGPP) but not farnesyl pyrophosphate (FPP), thereby implicating the Rho pathway. Consistent with this observation, we found that overexpression of a constitutively active form of Rho strongly reduced KLF2 expression. Furthermore, we demonstrated that induction of KLF2 by statins occurs through the MEF2 site in the proximal promoter region (46). Finally, siRNA-mediated knockdown studies demonstrated that the statin-mediated induc-

tion of *e*NOS and *TM*mRNA and protein accumulation within ECs is KLF2-dependent. Taken together, these data identify KLF2 as an important nuclear effector of statin effects in ECs.

### ROLE OF OTHER KRÜPPELS IN THE ENDOTHELIUM

Several other members of the KLF family also may have important roles in endothelial biology. Previous studies indicate KLF6 (also called *zf9*), a ubiquitously expressed factor, is induced in arterial ECs after vascular injury (48). Other studies show that KLF6 can induce urokinase-type plasminogen activator (u-PA) – a key enzyme implicated in tissue remodeling, tumor metastasis, and apoptosis (49). This induction also increased the amount of bioactive transforming growth factor (TGF)- $\beta$ 1 – an important regulator of the vessel injury response. A second KLF factor expressed in ECs is KLF4 (50). Interestingly, KLF4 is induced by both laminar flow as well as thrombin stimulation. However, the role of this factor in endothelial gene expression and function remains unknown.

#### KEY POINTS

- Compelling evidence implicates KLF2 as a “molecular switch” that regulates endothelial gene expression and function.
- KLF2 differentially affects the expression of factors that confer anti-inflammatory, antithrombotic, antiproliferative effects in ECs.
- KLF2 is induced by laminar flow. This occurs via a MEK5/ERK5/MEF2 signaling pathway.
- Cytokines, such as TNF- $\alpha$ , inhibit KLF2 expression through the recruitment of p65/HDAC4 complex to prevent MEF2-mediated induction of KLF2.
- Statins induce KLF2 expression. This induction of KLF2 is critical for the ability of statins to induce key endothelial factors such as *e*NOS and *TM*.

#### Future Goals

- To determine the exact nature of KLF2 function in the vasculature
- To develop *in vivo* gain- and loss-of-function studies to understand the role of KLF2 in vessel biology *in vivo*
- To determine whether statin-mediated induction of KLF2 is operative and functionally important *in vivo*
- To determine whether current statins be modified to develop agents that can more potently induce KLF2
- To determine the existence of a role for other members of this family beyond KLF2

## NFAT Transcription Factors

Takashi Minami

*The Research Center for Advanced Science and Technology, The University of Tokyo, Japan*

The nuclear factor of activated T cells (NFAT) family of transcription factors consists of five family members, four of which are regulated by calcium/calcineurin (NFATc1, -2, -3, and -4) and one of which is calcium/calcineurin independent (NFAT5).<sup>1</sup> Although calcineurin is highly conserved from yeast and humans, NFATc1 through 4 transcription factors appeared later during evolution, with the rise of chordates. The NFAT signaling pathway was first described in T cells. However, most cell types express one or more isoforms of NFAT. Indeed, these proteins have been shown to play a critical role in such diverse processes as the development of skeletal muscle, cartilage, the central nervous system (CNS), and the cardiovascular system. In this chapter, we review evidence for the role of NFAT in endothelial cell (EC) biology. Of particular interest is the recent finding that NFAT signaling in ECs is tightly regulated by a negative feedback inhibitor, the Down syndrome critical region (DSCR)-1.

### STRUCTURE OF NUCLEAR FACTOR OF ACTIVATED T CELLS

NFAT proteins contain a highly conserved DNA-binding domain that is similar to the DNA-binding domain of the Rel family of transcription factors (Figure 92.1). Indeed, all five members of the NFAT family may be classified as members of the extended nuclear factor (NF)- $\kappa$ B/Rel family (1). In contrast to canonical Rel-containing factors, the Rel binding domain of NFAT binds weakly as a monomer or dimer. Instead, NFAT cooperates with other transcription factors to upregulate target genes (discussed in the next section). In addition to the DNA-binding domain, NFAT proteins contain a regulatory domain, which mediates transactivation, and docking sites for calcineurin (CnA) and NFAT kinases. The calcium-dependent NFATs (NFATc1–4) contain 14 conserved phos-

phorylation sites, all but one of which is dephosphorylated by CnA (discussed next).

### REGULATION OF NUCLEAR FACTOR OF ACTIVATED T CELLS SIGNALING

The activity of NFAT is mediated by its phosphorylation state (1,2). The phosphorylation state is controlled by the opposing actions of the calcium ( $\text{Ca}^{2+}$ )-dependent serine/threonine protein phosphatase, CnA<sup>2</sup>, and a number of so-called “maintenance” and “export” serine/threonine kinases, including GSK-3 $\beta$ , casein kinase-1, p38 mitogen-activated protein kinase (MAPK), and c-jun N-terminal kinase (JNK). In resting cells, NFAT is phosphorylated and localized in the cytoplasm. Upon ligand binding to cell surface receptors, a series of linked steps leads to the induction of NFAT transcriptional activity:

1. Activation of phospholipase C (PLC)
2. Release of inositol triphosphate (IP3)
3. Transient release of calcium from intracellular stores through IP3 receptors on the endoplasmic reticulum
4. Influx of calcium through a specialized calcium release-activated calcium (CRAC) channel
5.  $\text{Ca}^{2+}$  binding to calmodulin
6. Calmodulin-dependent activation of CnA

2 Calcineurin was purified during the 1970s, and was named owing to its regulation by calcium and its presence in neural tissue. Mammalian calcineurin consists of three components: calmodulin, a catalytic subunit (CnA), and a regulatory subunit (CnB). There are three isoforms of CnA (CnA $\alpha$ , CnA $\beta$  and CnA $\gamma$ ), and two isoforms of CnB (CNB1 and CNB2). A rise in intracellular calcium concentration leads to increased binding of calmodulin to CnA, and a conformation shift such that the active site of CnA is exposed. Calcineurin interacts with many proteins, including scaffold proteins (e.g., Cabin1), endogenous inhibitors (e.g., Csp1, DSCR-1), and substrates (e.g., NFAT). The classic pharmacological inhibitors of calcineurin, CsA and FK506, both derived from fungi, bind to endogenous immunophilin proteins (cyclophilin in the case of CsA, FKBP12 for FK 506), which then inhibit the catalytic activity of calcineurin, thus blocking both NFAT and non-NFAT calcineurin substrates.

1 NFAT5 (also known as TonEBP, OREBP), the primordial member of the NFAT family, functions in immune response and kidney homeostasis.

Figure 92.1. Schematic diagram of NFAT structure. (Top) Shown is NFATc2. Hatched circles indicate phosphorylated serine residues that are dephosphorylated by calcineurin. Open circles indicate serine residues that are phosphorylated by Cot I and Pim I (left) or RSK and ERK (right). (Middle) Sequences of phosphorylated motifs in NFATc2 (phosphorylated serine residues are underlined). (Bottom) Sequences of the C-calcineurin binding region aligned with the corresponding sequences of each NFAT family protein and the similar region in DSCR-1. NLS, nuclear localization signal.

7. CnA-mediated dephosphorylation of NFAT, which exposes the nuclear localization signal
8. Translocation of dephosphorylated NFAT to the nucleus<sup>3</sup>
9. Binding of nuclear localized NFAT to promoters and activation of target gene expression

As mentioned earlier, NFATs may bind as monomers, homodimers, or heterodimers, but more commonly cooperate with other transcription factors, including AP1, GATA, or myocyte enhancer factor 2 (MEF2) families.<sup>4</sup> The nature of the binding

- 3 Although transcriptional activity of NFAT is regulated primarily by its subcellular localization and by the relative activity of coactivators such as AP1, evidence suggests that NFAT may be post-transcriptionally modified, for example by phosphorylation of the transactivation domain by Cot1/Tpl-2 or Pim1 kinases, or phosphorylation of the DNA-binding region by p60 RSK and MAPK.
- 4 The classical paradigm in the immunology literature involves cooperative interactions between NFAT and AP1. Concomitant activation of the Ca<sup>2+</sup>/calcineurin/NFAT and PKC/Ras/Fos/Jun pathways leads to synergistic activation of many target genes in T cells. GATA–NFAT interactions

partners is determined – at least in part – by the NFAT isoform and the cell type.

CnA is potentially inhibited by the immunosuppressive drugs cyclosporin and FK506, and by a number of endogenous inhibitors, collectively known as calcipressins. These include calcineurin-binding protein 1 (CABIN1), A-kinase anchor protein (AKAP79), and DSCR-1.

## ROLE FOR NUCLEAR FACTOR OF ACTIVATED T CELLS IN THE VASCULATURE

### In Vivo Studies

Targeted disruption of NFAT has demonstrated a role for these transcription factors not only in immunity, but also in a

have been described in T cells, cardiomyocytes and, more recently, ECs. Dephosphorylated NFATc2 (but not other NFAT family members) associates with MEF2 and the coactivator p300, resulting in transcriptional synergy in T cells and skeletal muscle.

number of other critical developmental processes, including the formation of the cardiovascular system.

*NFATc1*<sup>-/-</sup> mice are lethal at embryonic day (E)13.5 to 17.5 and demonstrate abnormal aortic and pulmonary valve development, as well as malformation of the interventricular septum (3,4). The heart valves form through a unique developmental process termed *endocardial-mesenchymal transformation* (EMT), in which ECs within the endocardial cushions delaminate from the endocardial layer and transdifferentiate to become mesenchymal cells (5). These mesenchymal cells proliferate and invade the myocyte-derived basement membrane-like cardiac jelly in the endocardial cushion area. The cushion undergoes a series of morphogenic steps that lead to the formation of the valve. During mouse embryogenesis, NFATc1 expression is restricted to the heart (3) and possibly the thymus (4). Expression in the heart is limited to the endocardium. NFATc1 is localized in the endocardial tubes at E7.5; the endocardium and vitelline vein at E8.5; the endocardium of the ventricles, atria, and outflow tract between E9 and E11.5; and in the lining of the aortic, pulmonary, and AV valves, and endocardial cushion between E11.5 and E13.5 (3). In contrast to the developing heart, studies of newborn and adult hearts did not reveal evidence of NFATc1 expression, suggesting that the gene is turned off at some point during development (3). Immunofluorescence of embryonic hearts revealed nuclear localization of NFATc1 in many, but not all endocardial cells. This pattern was reversed by administration of CsA or FK506 to embryos. These data suggest that NFATc1 activity is mediated by short-range paracrine signals. Vascular endothelial growth factor (VEGF) may represent one such signal; VEGF is produced by cardiomyocytes, and was shown to induce nuclear translocation of NFATc1 in pulmonary valve ECs (6).

*NFATc1*<sup>-/-</sup> embryos displayed multiple abnormalities, including hypertrophied ventricular walls, narrowed/occluded outflow tract, abnormal/underdeveloped valve structure, and persistent interventricular foramen/defective septum formation (3). Vascular endothelium appeared unaffected by loss of NFATc1, as indicated by the normal expression of platelet-endothelial cell adhesion molecule (PECAM)-1. The authors hypothesized that death at E14.5 was caused by valvular incompetence or stenosis, and concluded that the Ca<sup>2+</sup>/calcineurin/NFATc signaling pathway is essential for normal cardiac valves and septum morphogenesis. These findings, along with those of another group (4), suggest that ubiquitous calcium-CnA signaling is channeled into a valve-promoting pathway via the time- and site-specific expression of NFATc1 in endocardial cells.

In a more recent study, the EC-specific deletion of *Cnb1* resulted in cytoplasmic localization of NFATc1 in endocardial cells and valvular defects similar to those observed in *NFATc1*<sup>-/-</sup> mice (7). Tie2-mediated overexpression of NFATc1 rescued the valvular defects and viability of *NFATc1*<sup>-/-</sup> mice, but not the mice deficient in endocardial *Cnb1*. The administration of CsA to embryos at E11 phenocopied the *NFATc1*<sup>-/-</sup> and endocardial-specific *Cnb1*-

knockout. Together, these data support a critical role for endocardial Ca<sup>2+</sup>/CnA/NFATc1 signaling in valve formation. Of note, these genetic and pharmacologic manipulations did not result in defective EMT. Rather, a triple deletion of NFATc2/c3/c4 was required to reduce the numbers of mesenchymal cells in the cushion areas (7).

Combined *NFATc3/c4*-knockout resulted in embryonic lethality (E11.5) owing to impaired blood vessel assembly (8). The phenotype included underdeveloped yolk sac vasculature with enlarged and disordered capillary plexus and poorly developed vitelline vessels, and abnormalities in the major vessels of the embryo proper. Differentiation, proliferation, and formation of the initial vascular plexus were not affected. A reduction of supporting cells occurred, leading to the conclusion that NFATc3 and -c4 are required for the recruitment of vascular smooth muscle and pericyte precursors to the developing vessel wall. A survey of genes involved in vascular development revealed elevated expression VEGF and FLT-1, consistent with the notion that NFAT signaling represses these genes or activates a repressor of their production (a recent study favors the former mechanism [7]). NFATc4 was shown to be expressed preferentially in the neural tube and somites, with minimal expression in ECs. The double mutant embryos demonstrated increased expression of VEGF and blood vessel invasion in the neural tube and somites, suggesting that NFAT signaling normally inhibits vascular overgrowth at these sites (7). Similarly, suppression of myocardial VEGF production by calcineurin was shown to be essential for EMT (7).

### In Vitro Studies

NFAT transcription factors have been localized in cultured ECs. Several NFAT agonists were identified, including phorbol 12-myristate 13-acetate (PMA), VEGF, and histamine (9,10). Many putative NFAT target genes have been described, including *granulocyte monocyte colony stimulating factor* (*GM-CSF*), *tissue factor*, *interleukin (IL)-8*, *E-selectin*, *COX-2*, and *ATP2A3* (9,11).

We recently have shown that thrombin and VEGF, but not tumor necrosis factor (TNF)- $\alpha$ , result in activation of NFATc. In that study, VEGF and thrombin treatment of human umbilical vein ECs (HUVECs) resulted in the induction of DSCR-1 via the coordinate binding NFATc1 or c2, and GATA-2/3 on the promoter (12). To further delineate NFAT target genes in ECs, we carried out DNA microarrays of HUVECs infected with adenovirus overexpressing either GFP (Ad-Control) or a constitutively active form of NFAT (Ad-CA-NFAT). In duplicate arrays, a total of 59 defined genes were upregulated more than fourfold in both experiments (Figure 92.2; for color reproduction, see Color Plate 92.2). These included genes involved in inflammation (*IL-8*, *monocyte chemoattractant protein [MCP]-1*, and *fractalkine*), coagulation (*tissue factor*), leukocyte trafficking (*E-selectin*, *vascular cell adhesion molecule [VCAM]-1*, and *intercellular adhesion molecule [ICAM]-1*), transcription factors (*Egr-1* and nuclear hormone receptor, *RAR $\alpha$* ), and autoinhibition (*DSCR-1*).

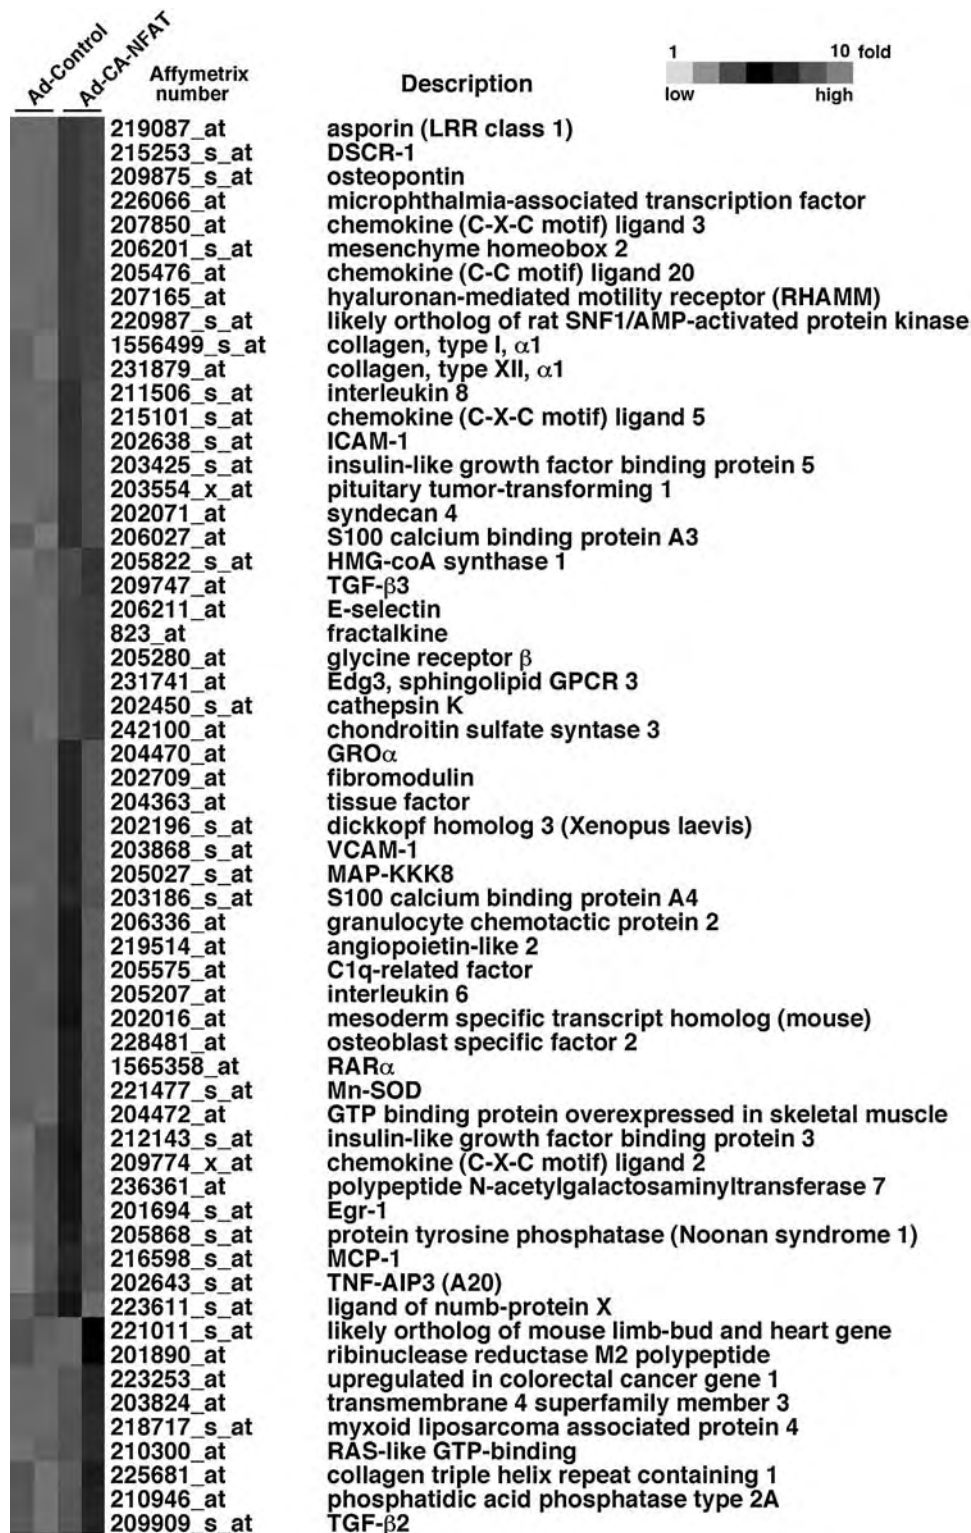

Figure 92.2. NFAT target genes in primary ECs. Microarray (Affymetrix U133 plus) analyses were performed in duplicate using HUVECs overexpressing constitutively active NFAT (CA-NFAT). Genes were filtered according to those induced fourfold by CA-NFAT versus control. Selected genes were analyzed by GeneTree program. Shaded panels represent higher and lower expression, respectively, compared with the median for that particular gene. For color reproduction, see Color Plate 92.2.

Figure 92.3. Schematic model shows the VEGF- or thrombin-calcineurin-NFAT signaling and the DSCR-1-mediated autoinhibition system in ECs.

### DOWN SYNDROME CRITICAL REGION 1

The *DSCR-1* gene (also known as MCIP-1), designated as such because it resides within the Down syndrome critical region of human chromosome 21, encodes a small (~25 kDa) protein that binds to and inhibits the catalytic subunit of calcineurin (13). *DSCR-1* is highly expressed in the CNS in the developing embryo, and preferentially expressed in heart, brain, and skeletal muscle in adults. Overexpression of the *DSCR-1* occurs in patients with Down syndrome (who have an extra copy of the gene), and in patients with Alzheimer disease.<sup>5</sup> The *DSCR-1* gene includes seven exons and six introns. The first four exons are alternative and code for four different isoforms. A 5' promoter regulates expression of the first three isoforms, which are derived from alternative splicing. The most common of these contains exons 1, 5, 6, and 7. An intragenic

region between exons 3 and 4 contains an alternative promoter that initiates transcription of the fourth isoform (exons 4, 5, 6, and 7).

Using DNA microarrays, we showed that, of the various transcripts that were responsive both to VEGF and thrombin, *DSCR-1* was the most highly induced at 1 hour (22-fold with VEGF and 18-fold with thrombin) (12). The inducible *DSCR-1* proved to be the isoform encoded by exons 4 through 7. In contrast to VEGF and thrombin,  $TNF-\alpha$  had little effect on *DSCR-1* levels.

Adenovirus-mediated overexpression of *DSCR-1*, but not control EGFP, inhibited VEGF- and thrombin-mediated nuclear localization of NFATc at 1 hour, and inhibited VEGF-mediated tube formation (12). Overexpression of *DSCR-1* increased the percentage of cells in  $G_0/G_1$  phase and decreased the fraction in S phase, an effect that was reversed by coinfection with Ad-CA-NFAT. *DSCR-1* overexpression in primary ECs resulted in the downregulation of multiple proangiogenic, proinflammatory, and procoagulant genes, including *ICAM-1*, *VCAM-1*, *tissue factor*, *IL-8*, and *E-selectin*. Finally, overexpression of *DSCR-1* in mice blocked matrix neovascularization and tumor progression.

<sup>5</sup> Patients with Down syndrome have decreased incidences of diabetic retinopathies, atheromas, and solid tumors. These conditions are linked to angiogenesis and/or EC activation. It is interesting to speculate that this protection is mediated – in part – by increased *DSCR-1* expression (thus autoinhibition of angiogenesis and EC activation).

Taken together, these data suggest that DSCR-1 serves in a negative feedback loop to inhibit EC proliferation and activation, as well as angiogenesis (Figure 92.3). Such a mechanism is reminiscent of the NF- $\kappa$ B–I $\kappa$ B $\alpha$  autoinhibitory loop. Cellular activation results in phosphorylation-dependent degradation and subsequent ubiquitination of I $\kappa$ B $\alpha$ . As a result, RelA translocates to the nucleus and partners with other members of the NF- $\kappa$ B family to transactivate a multitude of target genes, including proinflammatory mediators. In addition, the NF- $\kappa$ B family induces the early expression of its inhibitor, I $\kappa$ B, which serves to dampen further RelA activity. The NF-AT–DSCR and NF- $\kappa$ B–I $\kappa$ B $\alpha$  negative feedback loops may function to “fine tune” the desired downstream effect of the transcription factor and signal transducer.

#### KEY POINTS

- NFAT transcription factors play an important role in EC biology during development and in the postnatal period.
- NFATc1 is restricted in time and space to developing endocardium, and plays key role in valve formation.
- NFATc3/c4 transcription factors are important for blood vessel development.
- NFATc family members play an important role in adult endothelium, responding to extracellular signals such as VEGF and thrombin, and contributing to multiple phenotypes including angiogenesis and EC activation.
- DSCR-1 is an inducible autoinhibitory protein that turns off NFAT signaling in the endothelium.

#### Future Goals

- To determine the relative roles for NFAT isoforms in physiology and pathophysiology of adult endothelium
- To elucidate the potential for DSCR-1 as a novel therapeutic target

## Forkhead Signaling in the Endothelium

Md. Ruhul Abid and William C. Aird

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Forkhead proteins, members of the winged helix family of transcription factors, have been implicated in a multitude of biological processes. According to conventional views, mammalian forkhead proteins are death-promoting/cell cycle arrest factors whose function must be inhibited to ensure cell survival and growth. In the absence of serum or growth factors, forkhead is dephosphorylated and localized in the nucleus, where it activates proapoptotic and/or antigrowth/cell cycle genes including p27 kinase inhibitor protein (p27<sup>kip1</sup>), Bcl-2-interacting mediator of cell death (Bim), Fas ligand (FasL), growth-arrest and DNA damage inducible gene 45A (GADD45A), and B-cell translocation gene (BTG)-1. Serum or growth factor signaling results in phosphoinositide 3-kinase (PI3K)/Akt-dependent phosphorylation and nuclear translocation of forkhead proteins, with subsequent cell survival and/or proliferation.

Recent studies suggest that this model of mammalian forkhead function is overly simplistic. In addition to their role in promoting cell death and cell cycle arrest, forkhead proteins play a critical role in mediating embryonic angiogenesis, cell differentiation, metabolism, redox state, and immunity.

Most of our current knowledge about forkhead function is derived from studies in the fruit fly (*Drosophila melanogaster*), roundworm (*Caenorhabditis elegans*), and nonendothelial mammalian cell types. In the first part of this chapter, we draw on this extensive literature to review the complex signaling mechanisms underlying forkhead regulation of metabolism, survival, proliferation, longevity, and tumorigenesis. In the second part, we discuss more recent evidence implicating a role for forkhead proteins in endothelial cell (EC) biology.

### FROM FRUIT FLY TO HUMAN

The name *forkhead* was first derived in 1989 from a homeotic gene (*fkf*) that encodes a nuclear protein involved in the development of the terminal regions of the *Drosophila melanogaster* embryo (1). In the following year, a group of liver-specific forkhead-like transcription factors – hepatic nuclear factor

(HNF)-3A, -B, and -C – was discovered (2). HNF3 and *fkf* have been shown to share a highly conserved DNA-binding domain consisting of approximately 100 amino acids. Since their original discovery, forkhead genes have been identified in a wide variety of species ranging from yeast to humans.

Initial clues about forkhead signaling pathways and the molecular mechanisms of forkhead function were derived from studies in *C. elegans*. The *C. elegans* forkhead transcription factor, DAF-16 (the orthologue of mammalian FoxO [Forkhead box-containing protein, O subfamily]), was shown to be downstream of an intracellular signaling cascade involving DAF-2 (insulin/insulin growth factor [IGF]-1 receptor homologue)-AGE-1 (PI3K homologue)-Akt1 and Akt2 (Akt homologues), and to regulate lifespan, reproduction, and metabolism, including response to oxidative stress (3–5).

Since these early reports, more than 100 members of the forkhead family have been identified in different species. Recently, a new nomenclature, based on the structure of these transcription factors, has been adopted in which all FOX proteins are organized into 15 subfamilies or classes. The three mammalian homologues of DAF-16 – namely FKHR/FoxO1, FKHL1/FoxO3a, and AFX/FoxO4 – belong to the ‘O’ subfamily of FOX proteins. All the members contain a highly conserved DNA-binding domain (FKH), the relative location of which may vary among different members. Forkhead proteins are often described as “winged helix” due to the presence of helical sections flanked by a double-wing structure that resembles a butterfly, as resolved by crystal structure analysis. Although commonly known as transcription factors due to their ability to bind DNA, forkhead proteins may act as activators (transactivators) or inhibitors (repressors) of gene transcription (discussed next).

A role for forkhead in human cancer was suspected during the cloning of the mammalian counterparts of forkhead transcription factors AFX/FoxO4, FKHR/FoxO1, and FKHL1/FoxO3a. AFX (ALL1 fused gene from chromosome X, 1; new name, FoxO4) was originally identified as a fusion partner of the mixed-lineage leukemia (*MLL*) gene

in acute leukemia, whereas FKHR/FoxO1 (forkhead homolog in rhabdomyosarcoma; new name, FoxO1) was shown to be fused with PAX3 (paired box 3) or PAX7 in rhabdomyosarcoma (6–9). Another mammalian homolog of forkhead, FKHL1 (forkhead homolog in rhabdomyosarcoma-like 1; new name, FoxO3a) was also identified (10).

More recently, all three mammalian orthologues of DAF-16 (FKHR/FoxO1, FKHL1/FoxO3a and AFX/FoxO4) were shown to be substrates for Akt (11–17). These and subsequent studies in mammalian cells uncovered a critical role for the forkhead family of transcription factors in coupling extracellular signals (particularly insulin and IGF-1) to downstream changes in gene expression in primary nonendothelial cells and cell lines originated from fibroblast, muscle, liver, and adipose tissues. As mentioned earlier, the conventional model of forkhead function holds that, when cells are exposed to growth factors or serum, there occurs the activation of PI3K/Akt, secondary phosphorylation, and nuclear exclusion of forkhead transcription factors; downregulation of target gene expression; and enhanced cell survival and proliferation (11–15,17). Putative forkhead-responsive genes include insulin-like growth factor binding protein (IGFBP)-1, glucose-6-phosphatase, phosphoenolpyruvate carboxykinase, pancreatic duodenal homeobox (Pdx)-1, mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase, FasL, tumor necrosis factor apoptosis related ligand (TRAIL), GADD45A, transforming growth factor (TGF)- $\beta$ , B-cell lymphoma (BCL)-6, Bim, and p27<sup>kip1</sup> (18–27). In contrast, the withdrawal of serum or growth factors leads to nuclear translocation of forkhead proteins, transcriptional activation of target genes, and subsequent cell cycle arrest and/or apoptosis.

## REGULATION OF FORKHEAD PROTEINS

### Phosphorylation and Subcellular Localization

Forkhead proteins are regulated by two major post-translational events: phosphorylation and acetylation. Phosphorylation is initiated upstream by PI3K, which in turn is activated by G-proteins and tyrosine kinases, including the receptors for insulin, IGF-1, platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF) (28–31). On activation, PI3K triggers a signaling cascade that includes downstream serine-threonine kinases, PI3K-dependent kinase (PDK1), Akt, and serum and glucocorticoid-regulated kinase (SGK) (28). Akt is the main downstream signaling molecule that phosphorylates and inactivates proapoptotic and cell cycle inhibitory proteins, including BAD (displaces Bax from binding to Bcl-2 resulting in cell death) and forkhead proteins. Akt-mediated phosphorylation occurs at Thr32, Ser253, and Ser315 in FKHL1/FoxO3a; at Thr24, Ser256, and Ser319 in FKHR/FoxO1; and at Thr28, Ser193, and Ser258 in AFX/FoxO4 (13,32,33). Each of these sites in forkhead contains the highly conserved Akt-recognition motif, RXXRXS/T, where *R* denotes arginine, *S* and *T* denote serine and threonine, respectively, and *X* denotes any residue.

All forkhead transcription factors require phosphorylation of the N-terminal (T24 in FKHR/FoxO1, T32 in FKHL1/FoxO3a, and T28 in AFX/FoxO4) and the DNA-binding domain/nuclear localization sequence (NLS) (S256 in FKHR/FoxO1, S253 in FKHL1/FoxO3a, and S193 in AFX/FoxO4) for translocation from nucleus to the cytoplasm. Phosphorylation of the N-terminal threonine and the NLS serine residues also is required for recognition by and association with 14–3–3 proteins that retain forkhead in the cytosol. The second Akt phosphorylation site (within the NLS) is thought to disrupt the nuclear localization signals (34). The third or C-terminal phosphorylation site (S319 in FKHR/FoxO1, S315 in FKHL1/FoxO3a, and AFX/FoxO4) is a substrate for both Akt and SGK. Although all the Akt motifs in forkhead can be phosphorylated by Akt and SGK (because they have similar substrate recognition motifs), only the third or C-terminal site appears to be preferred by the kinase, SGK.

Two additional serine residues exist immediately after the third (C-terminal) Akt/SGK serine phosphorylation site, which are phosphorylated by casein kinase 1 (CK1) (Figure 93.1) (35). These two serine residues are recognized and phosphorylated by CK1 only when the third Akt motif (S315 in FKHR/FoxO1; S319 in FKHL1/FoxO3a; S258 in AFX/FoxO4) is already phosphorylated – i.e., the phosphorylation by CK1 appears to be a “primed” event. Another serine phosphorylation site exists, immediately after the CK1 sites, which is phosphorylated by dual-specificity tyrosine-phosphorylated and –regulated kinase 1A (DYRK1A) (36). Together with the C-terminal Akt/SGK and CK1-substrate serine residues, this DYRK1A phosphorylation site appears to form a patch of four acidic residues in the vicinity of the nuclear export sequence (NES) of the forkhead proteins. The precise functional importance of these phosphorylation events requires further study.

A small GTPase, Ras, also has been implicated in the regulation of forkhead function (37). Ras is recruited to the receptors of growth factors by adaptor proteins and is loaded with GTP. Ras activates GEF (guanine exchange factor) that activates Ral, and Ral modulates Ras-mediated induction of cellular proliferation. Ras–Ral signaling has been shown to phosphorylate threonine residues at 447 and 451 in AFX/FoxO4, which appears to influence transactivational activity of the forkhead protein (18,38). It is not clear at the moment whether other forkhead proteins require this Ras–Ral activity, because this phenomenon was studied only with AFX/FoxO4. In addition, phosphorylation of T447 and T451 did not influence subcellular localization of AFX/FoxO4 (Figure 93.2).

The nuclear export and import of forkhead proteins are active processes, because these proteins have an estimated molecular mass of more than 50 kDa (ranging from 75 kDa to 125 kDa). To date, several *cis*- and *trans*-acting factors that are involved in the regulation of subcellular localization of forkhead proteins have been identified. In addition to phosphorylation events, two important *cis*-acting elements exist that have been demonstrated to be involved in the relocation of forkhead. As shown in Figure 93.1, all FoxOs contain a

Figure 93.1. The mammalian forkhead proteins, FKHRL1/FoxO3a, FKHR/FoxO1 and AFX/FoxO4, and their functional sites. Shown are the putative phosphorylation sites and their respective kinases (AKT/PKB; SGK, serum glucocorticoid kinase; IKK,  $\text{I}\kappa\text{B}$  kinase; JNK, c-jun N-terminal kinase; CK1, casein kinase 1; DYRK1, dual-specificity tyrosine-phosphorylated and -regulated kinase 1), the acetylation sites and the proteins responsible for acetylation (CBP, CEBP binding protein) and deacetylation (SIRT1, silent information regulator). T, threonine; S, serine; K, lysine.

lysine-rich NLS situated in the C-terminal end of the DNA-binding domain. This NLS region has been shown to be responsible for nuclear localization (34). The second Akt-substrate phosphorylation site (e.g., S256 in FKHR/FoxO1) is believed to alter the conformation and function of this NLS motif. In addition, all three mammalian forkhead contain another *cis*-acting element in the C-terminal NES (34,39).

Importins and exportins are *trans*-acting factors involved in mediating the nuclear-cytoplasmic distribution of forkhead proteins. Importins recognize the NLS and mediate the translocation of forkhead to the nucleus. Ran-GTP binds to importin and releases the transported protein in the

nucleus. Exportins, such as chromosomal region maintenance 1 (CRM1) protein, bind to the NES and facilitate the export of forkhead from the nucleus to the cytosol. It has been demonstrated that a phosphorylation-resistant mutant of AFX/FoxO4 is amenable to nuclear export (34), suggesting that the association between forkhead and CRM1 is independent of forkhead phosphorylation status (34,40).

Additional *trans*-acting factors involved in the regulation of subcellular localization of forkhead are 14-3-3 proteins that have a molecular mass of 30 kDa. 14-3-3 proteins are homodimers and can also form heterodimers with other members of the same family of proteins, assuming a U shape.

Figure 93.2. Mechanism of subcellular localization of the FoxO proteins. (A) Proteins mediating active transport of FKHR/FoxO1 from the nucleus to the cytoplasm. 14–3–3 dimers bind to the Akt-phosphorylation sites in FKHR, threonine 24 (T24) and serine 256 (S256). Chromosomal region maintenance protein 1 (CRM1) binds to the nuclear export sequence (NES). CRM1 and Ran-GTP mediate nuclear export of forkhead. (B) Nuclear and cytoplasmic shuttling of FoxO proteins. Importins bind to the nuclear localization sequence FoxO and mediate transport of FoxO from the cytosol to the nucleus. Once in the nucleus, Ran-GTP binds importin and releases forkhead which then becomes available for CRM1 binding. CRM1 binds to the NES of FKHR/FoxO1 in the nucleus. CRM1, in conjunction with Ran-GTP, mediates nuclear exclusion of forkhead.

The phosphorylated serine residues (pS) followed by an X (any residue)-proline in RSXpSXP and RXXXpSXP motifs are recognized by 14–3–3. The N-terminal (threonine) Akt-substrate sites of the mammalian forkhead proteins contain an overlapping optimal site for 14–3–3 binding. It has been demonstrated that phosphorylation by Akt of the N-terminal threonine and DNA-binding-domain serine is essential for 14–3–3-mediated cytosolic sequestration of the transcription factor (34,39). It is plausible that the two “arms” of the U of 14–3–3 recognize and bind to these two Akt phosphorylation sites in forkhead proteins. In addition, phosphorylated forkhead was reported to be degraded by ubiquitin-proteasome (41), suggesting another level of complexity in the regulation of forkhead translocation and stability.

I $\kappa$ B kinase has also been found to cause phosphorylation and cytoplasmic translocation of FKHL1/FoxO3a (42). Hu and colleagues demonstrated that, in some phospho-Akt-negative tumors, forkhead exclusion from the nucleus was associated with higher levels of I $\kappa$ B kinase  $\beta$  (42). This group further showed that I $\kappa$ B-mediated phosphorylation was followed by ubiquitination and proteosomal degradation of FKHL1/FoxO3a. In addition, overexpression of forkhead

could inhibit I $\kappa$ B-induced cellular proliferation in vitro and tumor growth in mice.

Recently, Oh and associates showed that the c-jun N-terminal kinase (JNK) pathway acts in parallel with the insulin-like signaling pathway to regulate lifespan in *C. elegans*, and both JNK and insulin pathways converge onto DAF-16 (43). They also showed that JNK-1 directly interacts with and phosphorylates DAF-16 in *C. elegans*, and in response to heat stress, JNK-1 promotes the translocation of DAF-16 into the nucleus. These findings raise the possibility that a similar pathway exists in mammals where interaction between two well-conserved proteins, JNK-1 and forkhead, may provide a mechanism by which JNK regulates longevity and stress resistance.

### Transcriptional Activity

Transcriptional activity of forkhead proteins is primarily dependent on their subcellular localization – i.e., whether forkhead is present in the nucleus. In addition, regulation of transcriptional activity by modification of the DNA-binding domain and/or transactivational domain has been reported. Other transcriptional proteins and coactivators have been shown to interact with forkhead, thereby altering its function. Finally, recent reports of acetylation of forkhead protein have uncovered another level of complexity in the regulation of the activity of these transcription factors.

The DNA-binding domain of forkhead proteins recognizes and binds to a conserved forkhead-responsive element (FHRE) that is present in forkhead target genes (12,13,22,23). The second Akt phosphorylation site that is located adjacent to the DNA-binding domain has been shown to be critical for forkhead’s ability to bind DNA. DNA binding is hindered by phosphorylation of this serine residue (12,17).

The C-terminus was reported to be involved in the transactivational activity of the forkhead transcription factor (FKHR/FoxO1) in rat hepatoma cells (44). In this study, a series of serine residues in the C-terminus (at 319, 499, and residues within a stretch of 350 to 364) were found to be phosphorylated by insulin, which increased the transactivation potential of FKHR/FoxO1. The DAF-16 Ser-Ala mutant, in which the Akt phosphorylation sites are mutated, was also demonstrated to have increased PI3K-dependent, 14-3-3 independent transcriptional activity (45), suggesting the presence of a PI3K-dependent transactivational domain in the C-terminus besides the classical Akt-dependent sites in forkhead proteins.

Forkhead proteins have been found to interact with other proteins that modulate their activity. FKHR/FoxO1, FKHL1/FoxO3a, and DAF-16 interact with p300/CREB binding protein (CBP) and enhance the glucocorticoid-stimulated transcription by CBP (46–48). FKHR/FoxO1 was found to interact with CCAAT/enhancer binding protein (C/EBP)- $\beta$  in a DNA-independent manner (49). However, DNA-binding was essential for the additive action of C/EBP- $\beta$

and FKHR/FoxO1 on the decidual prolactin (*dPRL*) promoter (50). DYRK1A and DYRK1B, in addition to DYRK1A's kinase activity on forkhead, were shown to increase the transcriptional potential of FKHR/FoxO1 in inducing expression of glucose-6-phosphatase via a direct physical interaction (50–52). Additionally, DNA-binding-independent interaction of FKHR/FoxO1 with proliferation-activated receptor gamma coactivator (PGC)-1 $\alpha$  was demonstrated to enhance transcription of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase 1 genes by PGC-1 $\alpha$  (53).

The nuclear receptors interact with and act as inhibitors of forkhead transcription factors (54). Forkhead transcription factors contain an LXXLL domain in the C-terminus that plays an important role in their interaction with the nuclear receptors. It has been shown that estrogen receptor (ER) and androgen receptor (AR) repress the function of FKHR/FoxO1 (55). In turn, interaction of FKHR/FoxO1, FKHL1/FoxO3a, and AFX/FoxO4 steroid and nonsteroid nuclear receptors may either activate or repress the transcriptional activity of these receptors. Such interactions have been described for ER, AR, HNF-4, progesterone receptor, thyroid hormone receptor, retinoic acid receptor (RAR), glucocorticoid receptor, and peroxisome-proliferator-activated receptor (PPAR) (55–59). FKHR/FoxO1 binds to and negatively regulates HNF-4 activity (59). Akt-mediated phosphorylation of FKHR/FoxO1 by insulin decreases physical interaction of HNF-4 and FKHR/FoxO1 (59). Interaction of forkhead with the nuclear receptors can be independent or dependent of nuclear receptor ligand binding. For example, ligand binding of RAR is not required for RAR-FKHR/FoxO1 interaction, whereas estrogen facilitates binding of ER to FKHR/FoxO1 (56).

Very recently, SIRT1, a human homolog of silent information regulator (Sir) 2, has been demonstrated to deacetylate mammalian FoxO proteins, resulting in either potentiation (60) or deactivation (61) of forkhead activity. Daitoku and colleagues showed that Sir2 deacetylates the CBP-induced acetylation of FKHR/FoxO1 at the lysine residues K242, K245, and K262 and potentiates transcriptional activity of forkhead (62). Sir2 also serves as a transcriptional coactivator of FKHR/FoxO1. In contrast, Motta and associates demonstrated that SIRT1-mediated deacetylation of FKHL1/FoxO3a reduced both Bim and p27<sup>kip1</sup> expression and enhanced cell survival (61). On the other hand, Brunet and colleagues showed that deacetylation of forkhead by SIRT1 shifted the balance from proapoptosis to a cell-cycle arrest and stress-resistance phenotype with a corresponding reduction in Bim but increase in p27<sup>kip1</sup> expression (62). These findings are in accordance with the previous findings in *C. elegans* that overexpression of *Sir2* gene could increase lifespan in the roundworm. The discrepancy between the functional activities of forkhead upon deacetylation by SIRT1 demonstrated by these three groups indicates that further study will be required to understand the effect of deacetylation on forkhead at the functional level.

## Transcriptional Repression

Forkhead proteins have also been reported to act as transcriptional repressors. Two members of the murine forkhead gene family that belong to a different subclass P, Foxp1 and Foxp2, were shown to be expressed in the lung and to act as transcriptional repressors (63). *Xenopus* forkhead protein, FoxD5a, acts as a transcriptional repressor in axis formation and neural plate expansion (64). The latter study showed that expression of *en2*, *Krox20*, proneural genes (*Xnrgn1*, *neuroD*), and a neural differentiation gene (*n-tubulin*) is repressed in FoxD5a-expressing cells. Recently, cell cycle inhibition by FKHL1/FoxO3a was shown to be mediated by transcriptional repression of cyclin D1 and D2 by forkhead (65). In addition, a forkhead transcription factor of subclass L, FoxL2, known to be associated with premature ovarian follicle in a subset of women, was shown to be a repressor of the human steroidogenic acute regulatory (StAR) and other follicle differentiation genes (66–68). Mutation or disruption of FoxL2 was demonstrated to accelerate follicle development, resulting in increased recruitment of dormant follicles and subsequent premature ovarian failure. Thus, an increase in the expression or activity of forkhead proteins may not necessarily be translated into an increase in a generalized expression of forkhead target genes (69).

## PATHOPHYSIOLOGICAL ROLE OF FORKHEAD PROTEINS

Although most of our earlier knowledge about forkhead functions was derived from the studies in the roundworm, *C. elegans*, forkhead has been implicated in many cell-type-specific and signal-specific functions. To examine forkhead functions in mammals, several groups have focused on different cell lines and primary cells in culture. Currently, the physiological functions of forkhead are being studied using loss-of-function (by ablation of one or both alleles) or gain-of-function mutants (overexpression of wild-type or constitutively active) in mice.

### Role in Metabolism

Adenovirus-mediated overexpression of FKHR/FoxO1 in mice increases gluconeogenesis (glucose production) in liver through PPAR- $\gamma$  coactivator PGC-1 $\alpha$  (53). Because hepatic glucose production is a key issue in the development and treatment of diabetes, forkhead may be a therapeutic target in this disease. In contrast to the *in vitro* findings in cell-based systems, overexpression of a constitutively active FKHR/FoxO1 did not result in any observable increase in apoptosis in transgenic mice (70). On the other hand, diabetes due to ablation of IRS2 (insulin receptor substrate 2) was rescued by haploinsufficiency (deletion of one allele) of FKHR/FoxO1 (27), suggesting that a decrease in forkhead gene

dosage can alleviate the effects of a lack of insulin-mediated downstream signaling. These findings support the notion that insulin resistance or failure of propagation of inhibitory signaling of insulin to downstream forkhead results in a phenotype that resembles overexpression or constitutive activation of forkhead in mice – i.e., increase in hepatic gluconeogenesis. Accordingly, Nakae and colleagues showed that haploinsufficiency of FKHR/FoxO1 protected against insulin resistance (70). On the contrary, *FKHR/FoxO1*-null mice die at E10.5 due to incomplete vascular development (71,72).

Deletion of FKHL1/FoxO3a showed age-dependent infertility due to premature ovarian failure as a result of accelerated differentiation and consequent depletion of primary ovarian follicles (71). In contrast, *AFX/FoxO4*-null mice did not show any observable abnormalities (71). These findings suggest that the forkhead gene products, FKHR/FoxO1, FKHL1/FoxO3a, and AFX/FoxO4 are functionally diverse (i.e., nonredundant) in mammals.

### Role in Cell Differentiation

A role for forkhead in cellular differentiation was derived from the *in vitro* (using cell culture) and *in vivo* (transgenic mice) observations. FoxOs were shown to couple extracellular cues with intracellular signals that regulate differentiation of myoblasts (73,74), preadipocytes (75), pancreatic  $\beta$  cells (27), and thymocytes (76). Recently, two independent studies demonstrated that the ubiquitin ligases, Atrogin-1 (MAFbx) and MuRF1, that cause muscular atrophy are FoxO targets, and that inhibition of forkhead activity prevents the induction of these ligases (77,78).

### Role in Neoplasia

Forkhead's involvement in tumorigenesis and cancer was first suspected from its role in cell cycle regulation. Forkhead modulates several cell cycle checkpoint genes that regulate G<sub>0</sub>/G<sub>1</sub> (e.g., p27<sup>kip1</sup> [18,79], BTG1 [80], cyclin D [25]) and G<sub>2</sub>/M (e.g., GADD45A [25,81]). However, a role for forkhead proteins in cancer was confirmed with the discovery of two chromosomal translocations associated with human cancer. A chromosomal translocation resulting in the fusion of the coding region of either PAX3 or PAX7 to FKHR/FoxO1 was shown to be involved in the pathogenesis of rhabdomyosarcoma (82). In addition, AFX/FoxO4 was shown to be fused with the transcription factor MLL in leukemia (83). To explain the molecular mechanisms of forkhead-mediated tumorigenesis, two opposing models have been proposed. The first model assumes that a gain-of-function of forkhead predisposes to tumor formation. The finding that the PAX3-FoxO1 fusion is a more potent transcriptional activator than PAX3 alone supports this model (82). On the other hand, failure of the PAX3-FoxO1 transgenic mice to develop tumors (84–86) called for an alternate model. In this model, a loss of function mutation of forkhead is thought to be responsible for tumorigenesis, suggest-

ing that a critical forkhead target gene with roles in both cell cycle arrest and apoptosis may contribute to cell survival and transformation (87). In addition, PTEN, an endogenous negative regulator of PI3K and a tumor suppressor, was shown to positively regulate forkhead through the PI3K/Akt pathway, resulting in induction of apoptosis or cell cycle arrest by upregulating p27<sup>kip1</sup> expression (18,79,88). More than 60% of prostate cancer tumors are known to have loss of function mutations in PTEN. Modur and associates demonstrated that forkhead overexpression in these PTEN mutant tumors resulted in apoptosis (and thereby inhibition of tumor progression) through direct induction of a proapoptotic member of the tumor necrosis factor (TNF) family, TRAIL (89).

In breast cancer, overexpression of FKHL1/FoxO3a was found to increase expression of Bim, an apoptotic protein. An antineoplastic drug, paclitaxel, appears to increase the expression of FKHL1/FoxO3a, which subsequently decreases cell survival through induction of Bim expression and thus contributes to the tumor suppressive actions of the drug (90). In contrast, estrogen enhances survival in mammary cancer cell lines by stimulating p21-activated kinase (Pak)-1 that induces phosphorylation and nuclear exclusion of forkhead (91).

Seoane and colleagues demonstrated that in mammalian cells, forkhead coordinates signals at the intersection of Smad, FoxG1, and PI3K pathways (92). A complex of forkhead and Smad proteins activates p21<sup>Cip1</sup>, a growth arrest gene; Smad proteins are mediators of TGF $\beta$  signaling. This Smad- and forkhead-mediated upregulation of p21<sup>Cip1</sup> is inhibited by PI3K and positively regulated by FoxG1, a member of a different subfamily of forkhead. Seoane and colleagues also showed that the presence of increased PI3K/Akt activity and FoxG1 expression in neuroepithelial and glioblastoma cells resulted in the reduction of p21<sup>Cip1</sup> levels and concomitant increase in cell survival and proliferation. Moreover, Nakae and associates reported that the FoxO target gene, p21<sup>Cip1</sup>, is involved in preadipocyte differentiation (75).

Taken together, these findings suggest that inactivation of forkhead proteins is crucial in the development and/or progression of a variety of cancers, raising the possibility that forkhead activity may be targeted therapeutically. Recently, Kau and colleagues devised several chemical molecules that act to inhibit nuclear export of FKHR/FoxO1 in PTEN-deficient (thus, with a high level of PI3K/Akt activity) tumor cells (93). Interestingly, many of the molecules identified in this study are inhibitors of nuclear export receptor CRM1, an PI3K/Akt-mediated export pathway.

### FORKHEAD PROTEINS IN ENDOTHELIAL BIOMEDICINE

The quest to elucidate the role of forkhead in endothelium has just begun. Most of our understanding about FoxOs in endothelium is currently derived from *in vitro* studies using primary human ECs. A small number of studies

have addressed *in vivo* functions by either overexpressing or deleting one or more of the mammalian isoforms of FoxO proteins in mice. The first evidence suggesting a role for forkhead in the vasculature came from a study of non-FoxO forkhead proteins, Foxc1 (Mf1) and Foxc2 (Mfh1). Mice null for *Foxc1/Mf1* had severe defects in the anterior segment of the eye with a complete failure of differentiation of the inner corneal endothelial layer (94). Deletion of another forkhead homolog in mice, *Foxc2/Mfh1*, resulted in severe cardiovascular defects (95). Kalinichenko and associates showed that the newborn mice heterozygously null for the forkhead box f1 (*Foxf1*) transcription factor developed lethal alveolar hemorrhage due to defective mesenchyme–epithelial interaction during lung morphogenesis (96). Mutations in *FoxC2/Mfh1* were also reported to be responsible for the lymphatic vascular disorder, lymphedema-distichiasis (97). However, until recently, evidence was lacking for a role of FoxO proteins in EC biology.

### In Vitro

The first studies to demonstrate FoxO expression in ECs were published in 2003 and 2004 (30,98,99). FKHR/FoxO1, FKHL1/FoxO3a, and AFX/FoxO4 were shown to be expressed in human coronary artery ECs (HCAECs) and umbilical vein ECs (HUVECs) (30). This study also demonstrated for the first time that VEGF induced phosphorylation of FKHR/FoxO1 and AFX/FoxO4, nuclear export of FKHR/FoxO1 and FKHL1/FoxO3a, and downregulation of transcriptional activity of FKHL1/FoxO3a in ECs in a PI3K/Akt-dependent manner. VEGF-mediated cell survival, promotion of DNA synthesis, and cell cycle progression from G1 to S were shown to be forkhead-dependent in ECs (30). Forkhead-mediated induction of the cell cycle inhibitory gene *p27<sup>kip1</sup>* was partly implicated in all these VEGF effects in ECs. This study clearly demonstrated that VEGF inhibited expression of *p27<sup>kip1</sup>* at the mRNA and protein levels through a forkhead-dependent pathway. Interestingly, the forkhead isoforms, FKHR/FoxO1 and AFX/FoxO4, but not FKHL1/FoxO3a, were detected in HCAECs and HUVECs at the protein level by western blots; FKHL1/FoxO3a was only detectable by RT-PCR in HCAECs, HUVECs, and human pulmonary artery ECs (30). Other studies have shown that FoxO factors lie downstream of epoxyeicosatrienoic acid (99), and angiopoietin 1 (Ang1) (100) in ECs and modulate the expression of several forkhead-target genes including *p27<sup>kip1</sup>*, *survivin*, and *TRAIL*. An elegant study by Skurk and colleagues showed for the first time that FKHL1/FoxO3a could also act as a transcriptional repressor in ECs (98). They found that FKHL1/FoxO3a inhibited transcription of FLICE inhibitory protein (FLIP), a dominant-negative inhibitor of caspase-8 function (101), resulting in the activation of the “extrinsic” or caspase-dependent apoptotic pathway in HUVECs (98). Thus, as was observed in non-ECs, forkhead may function as a transcriptional activator or repressor in ECs.

A recent study from our lab has demonstrated that VEGF-PI3K/Akt-mediated regulation of phosphorylation and transcriptional activity of forkhead in ECs is dependent on NADPH oxidase-derived redox signaling (102). Hepatocyte growth factor (HGF) also induced phosphorylation and inactivation of FKHR/FoxO1 in HCAECs in a PI3K-dependent manner. However, HGF-mediated induction of forkhead phosphorylation was found to be redox-independent in these cells (102). These findings suggested that the requirement of NADPH oxidase/redox activity in ECs is specific to the growth factor/agonist and not to the forkhead protein per se.

In contrast to non-ECs, where insulin suppresses manganese superoxide dismutase (MnSOD) levels via a PI3K/Akt-forkhead-dependent signaling pathway, VEGF was shown to induce expression of MnSOD in ECs. The importance of forkhead as a positive regulator in this pathway was evidenced by the observation that VEGF-mediated induction of MnSOD was enhanced by inhibition of PI3K or Akt or by overexpression of TM-FKHL1/FoxO3a. Because both insulin and VEGF phosphorylate and inhibit forkhead, these data suggested that VEGF-mediated induction of MnSOD must involve an overriding positive pathway. Indeed, we demonstrated that VEGF-mediated induction of PKC-nuclear factor (NF)- $\kappa$ B was responsible for the net positive effect of VEGF on MnSOD expression. We have recently identified a number of other VEGF-responsive genes whose net response depends on the relative activities of positive signaling pathways (e.g., NF- $\kappa$ B) and negative signaling pathways (namely, the PI3K/Akt-mediated exclusion of forkhead from the nucleus) (103).

Potente and associates (104) recently reported that FKHR/FoxO1 and FKHL1/FoxO3a are abundantly expressed in HUVECs and that overexpression of constitutively active TM-FKHR/FoxO1 and TM-FKHL1/FoxO3a significantly inhibited EC migration and tube formation *in vitro*. This study also demonstrated that FKHR/FoxO1 and FKHL1/FoxO3a regulate overlapping yet distinct (i.e., nonredundant) target genes, including those involved in angiogenesis and vascular remodeling. For example, FKHR/FoxO1, but not FKHL1/FoxO3a, was implicated in transcriptional induction of *Ang2*, whereas both FoxO proteins were shown to downregulate endothelial nitric oxide synthase (eNOS) expression. In addition, TM-FKHL1/FoxO3a deficiency increased eNOS expression and enhanced postnatal vessel formation in mice.

### In Vivo

In 2004, two groups independently demonstrated that mice null for *FKHR/FoxO1*, but not *FKHL1/FoxO3a* or *AFX/FoxO4*, died on embryonic day 10.5 as a consequence of defects in the branchial arches and impaired vascular development of the embryo and yolk sac (71,72). Deletion of *FKHR/FoxO1* did not appear to affect EC differentiation or vasculogenesis but rather impaired vascular sprouting (i.e., angiogenesis). Whereas *FKHL1/FoxO3a*-null mice exhibited an

age-dependent infertility due to ovarian failure, *AFX/FoxO4*-null mice did not show any obvious phenotype (71,105).

Furuyama and associates (72) examined *FKHR/FoxO1*<sup>-/-</sup> versus *FKHR/FoxO1*<sup>+/+</sup> mice for differences in gene expression. In quantitative PCR, transcripts of *VEGF*, *FLT-1*, *FLK-1*, *Ang1*, *Ang2*, *Tie1*, *Tie2*, *EphB2*, *EphB3*, and *EphB4* were comparable in mutant and wild-type E9.5 yolk sacs. In contrast, mRNA levels of *connexin-37*, *connexin-40*, and *ephrinB2* were significantly lower in the mutant samples. In embryoid bodies, comparable differentiation was noted of mutant and wild-type ES cells into ECs and, consistent with the in vivo data, no difference in expression of *FLT-1*, *FLK-1*, *Tie1*, and *Tie2*. VEGF-mediated induction of proliferation and migration of was not impaired in *FKHR/FoxO1*<sup>-/-</sup> ECs. VEGF induced an elongated or spindle-shaped phenotype in polygonal ECs isolated from wild-type mice and cultured in vitro. In contrast, a significant percentage of ECs isolated from the *FKHR/FoxO1*-null mice remained flat and polygonal even after treatment with VEGF. These observations led to the conclusion that the defective vascular development was attributable to either a failure of response or an abnormal response of ECs to growth factors or angiogenic stimuli in the *FKHR/FoxO1*-null embryos (72).

As noted earlier, our current understanding of forkhead physiology in vivo is heavily based on the observations made from the studies in the roundworm, *C. elegans*. In this meta-

zoan, regulation of the mammalian forkhead homologue, DAF-16, by the insulin-receptor homologue, DAF-2, has been shown to modulate several physiological functions (4,5,106). It is not clear whether insulin/IGF-1, the major signaling pathway that regulates the *C. elegans* forkhead (DAF-16), plays a similar role in the regulation of the mammalian vascular system. A study using vascular EC-specific *insulin receptor (IR)*-knockout mouse demonstrated that inactivation of the IR on EC had no major consequences on vascular development or glucose homeostasis under basal conditions but altered expression of vasoactive mediators (eNOS, endothelin-1) and may play a role in maintaining vascular tone and regulation of insulin sensitivity to dietary salt intake (107). These results contrast with the embryonic lethality and abnormal vascular development of *FKHR/FoxO1*<sup>-/-</sup> mice (71,72). Taken together, these results suggest that, unlike the metazoan DAF-2/DAF-16 signaling, the link between insulin and *FKHR/FoxO1* signaling pathways in the mammalian vascular development has been modified during evolution.

**CONCLUSION**

Forkhead signaling has been implicated in many cellular and organismal functions including cell survival, proliferation, differentiation, metabolism, redox regulation, and longevity.

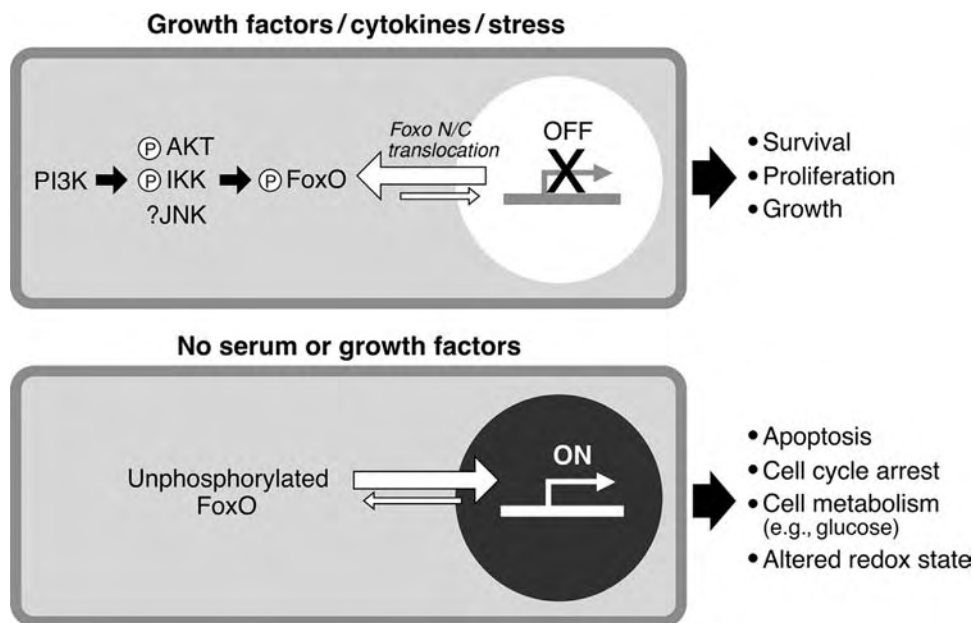

Figure 93.3. Regulation of FoxO proteins by extracellular agonists. *Upper panel*, exposure of ECs to growth factors, cytokines or stress results in PI3K/Akt-dependent phosphorylation of FoxO, nuclear exclusion of phospho-FoxO, and attenuation of FoxO-dependent gene expression. The net effect is increased EC survival, proliferation, and/or growth. *Lower panel*, in the absence of these agonists (e.g., in serum-free medium), there is no stimulation of the PI3K/Akt pathway. Thus, FoxO remains unphosphorylated and is localized to the nucleus where it exerts transcriptional activity (shown is FoxO-mediated target gene activation, although FoxO may repress certain target genes). The net outcome is apoptosis, cell cycle arrest, and/or altered cell metabolism/redox state. N/C, nuclear cytoplasmic.

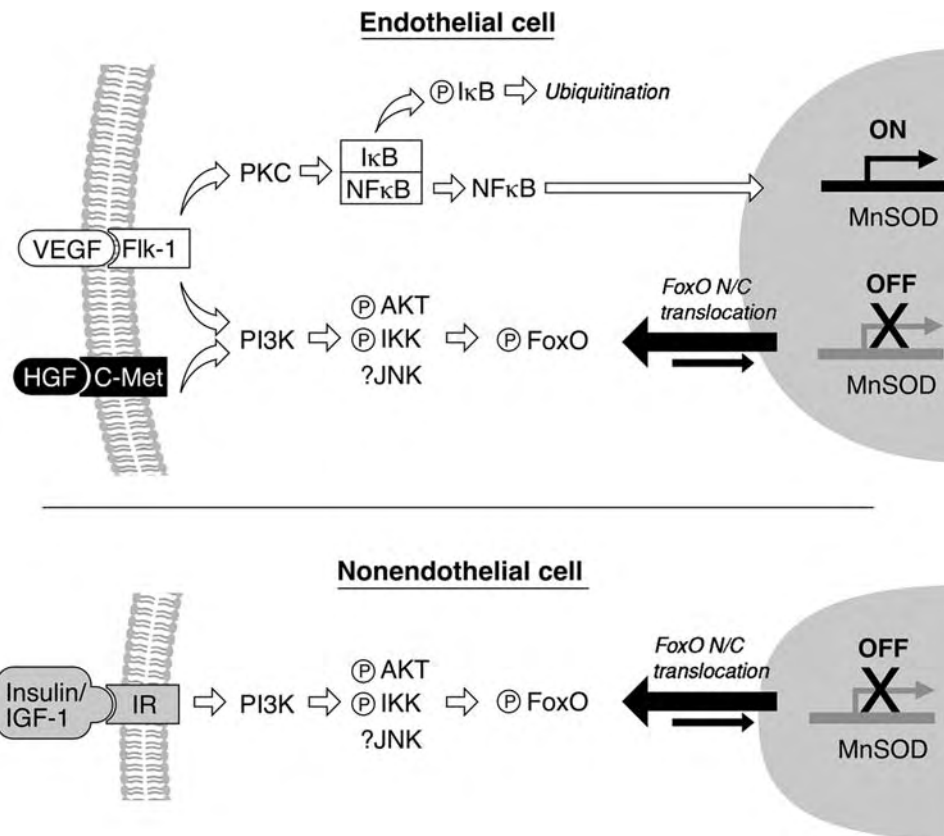

Figure 93.4. Role for FoxO proteins in cell signaling is agonist- and cell type-specific. In ECs, VEGF and HGF result in PI3K/Akt-dependent phosphorylation and inactivation of FoxO. In the case of HGF, nuclear exclusion of FoxO results in reduced expression of the FoxO target gene, MnSOD. In the case of VEGF, concomitant activation of NF- $\kappa$ B overrides the negative effect of FoxO translocation, leading to net induction of MnSOD. In non-ECs, the effect of insulin/IGF-1 parallels that of HGF in ECs, with phosphorylation-mediated inactivation of FoxO and downregulation of MnSOD expression. N/C, nuclear cytoplasmic.

Forkhead performs all these important cellular functions by serving as an intracellular signal transducer that couples information in the extracellular environment through cell surface receptors for growth factors, cytokines, hormones, and stress, to downstream changes in phenotype.

Existing evidence supports a critical role for forkhead proteins in ECs. In addition to the classical model in which agonist-mediated phosphorylation and nuclear exclusion of FoxO proteins results in downregulation of death-promoting/cell cycle arrest genes, these transcription factors also participate in complex transcriptional regulation of health-promoting genes (e.g., MnSOD) whose net expression depends on interacting positive and negative influences (Figure 93.3). In vitro and in vivo studies suggest that FoxO proteins are involved in multiple EC functions, including survival/apoptosis, cell cycle progression, proliferation, migration, and blood vessel formation. Whether forkhead is involved in other functions of ECs (e.g., metabolism) awaits further study. Moreover, the extent to which endothelial FoxOs contribute to vascular hemostasis will require the generation and analysis of lineage-specific knockouts.

#### KEY POINTS

- FoxO transcription factors play an important role in EC biology (Figure 93.4).
- In vitro, several agonists have been shown to phosphorylate FoxO, including VEGF, epoxyeicosatrienoic acid, and Ang1.
- Phosphorylation of FoxO leads to nuclear exclusion of the transcription factor and hence reduced transcriptional activity (which may be activating or repressing in nature).
- FoxO target genes in the ECs include proapoptotic and cell cycle arrest genes, as well as genes involved in metabolism and health.
- Under in vivo conditions, mammalian forkhead family members FKHR/FoxO1, FKHL1/FoxO3a, and AFX/FoxO4 have nonredundant roles in vascular development.

**Future Goals**

- To understand the pathophysiological roles of FoxO proteins in adult endothelium
- To determine the potential for FoxO proteins as therapeutic targets in cardiovascular diseases

**ACKNOWLEDGMENT**

This work was supported by NIH grant HL077348.

# Genetics of Coronary Artery Disease and Myocardial Infarction

## The MEF2 Signaling Pathway in the Endothelium

---

Coronary artery disease (CAD) is the leading cause of death and disability in the United States and other developed countries (1). CAD is characterized by the formation of atherosclerotic plaques in the walls of the coronary arteries (2–5). The structure of a normal coronary artery consists of the endothelium (a single layer of endothelial cells [ECs]) on the luminal side; followed by the intima, consisting of collagens and proteoglycans; the middle layer (media) of smooth muscle cells (SMCs); and the outside layer (adventitia), consisting of connective tissues, fibroblasts, and more SMCs (Figure 94.1). Development of CAD starts with binding of blood monocytes to the endothelium through cell adhesion molecules including vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1, followed by infiltration of lipoproteins and monocytes into the media region, which attract oxidized lipids and form foam cells, the hallmark of an arterial lesion. Necrosis and apoptosis of foam cells lead to a necrotic core with a mass of cell debris and lipids. Macrophages and the foam cells secrete cytokines, inflammatory molecules, and growth factors that induce SMC migration, proliferation, and the production of extracellular matrix-forming plaques with fibrous caps. When the plaques are stable, the patient may not experience any symptoms of chest pain. However, plaque rupture may lead to thrombosis and secondary unstable angina, acute myocardial infarction (MI), or sudden death (6,7).

This overview of the pathophysiology of CAD and MI represents the current prevailing mechanism for the pathogenesis of CAD and MI and suggests that CAD is an inflammatory process affecting the endothelium (i.e., endothelial dysfunction) in addition to a disease of lipid metabolism, SMC proliferation and migration, and upregulation of immune

responses. Recent advances in molecular genetic studies of CAD and MI have, however, provided new insights into the pathogenic mechanisms of CAD and MI. The discovery of *myocyte enhancer factor 2A (MEF2A)*, as a gene associated with CAD and MI, identifies one member of the MEF2 family in the abnormal development of the endothelium in the disease process (6,7). This chapter reviews the structure and function of MEF2 transcription factors, with emphasis on their roles in vascular development and their involvement in the development of CAD and MI.

### MEF2 STRUCTURE AND FUNCTION

The MEF2 family of transcription factors has been studied most extensively in muscle cells, where they play a key role in myogenesis and morphogenesis of cardiac or skeletal muscle (8). MEF2 proteins have been implicated in neuronal cell survival, T-cell apoptosis, and cellular responses to growth factors, cytokines, and environmental stressors (8–18). Recent studies, as discussed later, suggest that MEF2 proteins also regulate vascular morphogenesis, including endothelial function and development.

The MEF2 family consists of four members: MEF2A, MEF2B, MEF2C, and MEF2D. They are nuclear phosphoproteins belonging to the MCM1 agamous deficiens serum response factor (MADS) superfamily of DNA binding proteins. The four MEF2 proteins share approximately 50% amino acid identity overall but have more than 95% similarity at the N-termini. MEF2 proteins have an identical structure of functional domains (Figure 94.2). The N-termini of the MEF2 proteins contain the MADS domain responsible for specific

Figure 94.1. A schematic diagram of a coronary artery. It consists of the endothelium and intima, internal elastic lamina, media, and adventitia. MEF2A is expressed in the endothelium. Mutations detected in this gene lead to a dysfunctional EC layer and culminate in the generation of atherosclerosis.

DNA binding and dimerization, followed by the MEF2 domain, which increases DNA binding and mediates interactions of MEF2 proteins with other cofactors. The C-termini of MEF2 factors contain the transcriptional activation domains, which are also the targets of mitogen-activated protein kinase (MAPK) activation pathway and intracellular signaling cascades activated by calcium (19–22). The C-terminal end also contains the nuclear localization signals for transporting these transcription factors into the nucleus.

The MEF2 proteins bind as homo- and heterodimers to a *cis*-element with the consensus sequence (C/T)TA(A/T)<sub>4</sub>TA(G/A) in the promoter of many cardiac and skeletal muscle-specific genes. The three-dimensional structure of a complex between DNA and the core dimeric DNA binding domain of MEF2A (residues 1–85; containing residues 1–58 for MADS domain and residues 59–73 for MEF2 domain) has been determined. The MADS domain mediates recognition and specificity of DNA binding, and both the major and minor grooves of DNA are involved in this interaction (23).

Figure 94.2. The domain structure of MEF2A and locations of CAD-associated mutations in MEF2A. The N-terminal end of the MEF2A protein contains the MADS domain responsible for specific DNA binding and dimerization, followed by the MEF2 domain that increases DNA binding and mediates interactions of MEF2 proteins with other cofactors (GATA, ERK5, HDAC, etc.). The C-terminal region of MEF2A contains the transcriptional activation domains, which are also the targets of MAP kinase activation pathways and intracellular signaling cascades activated by calcium. The C-terminal end of MEF2A contains the nuclear localization signal (NLS).

MEF2 proteins interact with many different cofactors, which may be a mechanism by which MEF2 factors control many different cellular processes. These factors, which can bind and stimulate MEF2 activity, include MyoD, GATA, nuclear factor of activated T cells (NFAT), TH receptor, p300/PCAF, 14–3–3, and extracellular signal-regulated kinase 5 (ERK5) and other proteins that suppress MEF2 function such as histone deacetylase (HDAC)4, HDAC5, HDAC7, HDAC9, interacting transcription repressor (MITR), and Cabin (23). In addition, the interaction of MEF2 with MyoD regulates skeletal muscle differentiation, and the interaction of MEF2 with GATA factors may be important for cardiovascular development (24).

MEF2 is also a key player in the transduction of signals from extracellular environment. It is involved in the induction of the *c-jun* promoter in response to signals originating from multiple cell surface receptors including G-protein-coupled receptors (24), epidermal growth factor receptor (25–27), the lipopolysaccharide receptor (28), and the CD28 costimulatory receptor in T lymphocytes (29). In response to increased intracellular calcium concentration mediated by T-cell receptor signaling, MEF2 stimulates the expression of the gene encoding the orphan nuclear hormone receptor Nur77 (30), also known as TR3, which is a potent activator of cytochrome c-mediated apoptosis (31). And finally, angiotensin II stimulates the DNA-binding activity of MEF2A and its expression at the protein level without affecting the expression level of MEF2A transcription, suggesting a post-transcriptional regulation of MEF2A expression by angiotensin II in vascular SMCs (32). The p38 MAPK-dependent pathway mediates this process. It is apparent that MEF2 is involved in several pathways triggered from the binding of ligands to cell surface receptors. Furthermore, MEF2 also targets over 30 genes that specifically bind to the promoters in nearly all skeletal and cardiac muscle (33).

## MEF2A IS ASSOCIATED WITH CORONARY ARTERY DISEASE AND MYOCARDIAL INFARCTION

### Association between MEF2A Mutations and Coronary Artery Disease/Myocardial Infarction

Genetic studies of a human pedigree with CAD and MI identified a seven-amino acid deletion of MEF2A that causes CAD and MI (7,34). The family studied was from Iowa (in the Midwestern United States) and has been plagued for generations by incidents of CAD and MI. Thirteen family members were affected with CAD; nine of them developed acute MI, five patients required percutaneous coronary angioplasty, and four underwent coronary artery bypass surgery. The disease in this family is inherited in an autosomal dominant fashion. The disease gene was localized to the telomeric region of the long arm of chromosome 15, designated 15q26. This is the first genetic locus mapped for autosomal dominant CAD and MI, thus the locus was designated as *adCAD1*.

The specific CAD/MI gene at this locus was identified as *MEF2A*. It contained a deletion of seven amino acids ( $\Delta Q_{440}P_{441}P_{442}Q_{443}P_{444}Q_{445}P_{446}$ ) located close to the nuclear localization signal of MEF2A protein (Figure 94.2). All participants were screened for mutations by single-stranded conformational polymorphisms (SSCP) analysis in this gene (whether they had symptomatic heart disease or not), and the presence or absence of atherosclerosis was documented by a cardiac angiogram (6,7). The MEF2A mutation was present in every family member with detectable CAD and was absent in relatives and unrelated individuals without evidence of heart disease.

Further screening of the *MEF2A* gene with SSCP in 207 living patients in the general population with CAD/MI identified three novel missense mutations, N263S, P279L, and G283D in four patients (1.93%) (Figure 94.2) (6). None of these mutations was detected in 191 control individuals without CAD/MI as documented by direct assessment of the coronary arteries by an angiogram. The CAD cases and controls were matched for ethnicity, age, and body mass index (6). These results suggest that nearly 2% of the CAD/MI population may carry an MEF2A mutation. The P279L variant in exon 7 was independently confirmed to be associated with MI in a Spanish population (odds ratio 3.1) (34). In sum, the *MEF2A* gene has been established as the first non-lipid-related gene in which mutations have been linked to CAD and MI, connecting the MEF2 signaling pathway to an important human disease.

#### MEF2A Mutation Molecular Mechanisms in Coronary Artery Disease and Myocardial Infarction

The MEF2A mutations have been functionally characterized in detail. The seven-amino acid deletion disrupts the nuclear localization of MEF2A, reduces MEF2A-mediated transcrip-

tion activation, and abolishes synergistic activation between MEF2A and the transcription factor GATA-1 (11). Mutant MEF2A with the seven-amino acid deletion interferes with the function of wild-type MEF2A protein, indicating that the deletion acts via a dominant negative mechanism (7). The three missense mutations have similar functional effects on MEF2A, and they reduce the transcriptional activation activity of MEF2A or synergistic transactivation by MEF2A and GATA-1 as demonstrated in HeLa cells (7). In contrast to the deletion, each of the three missense mutations acts by a loss-of-function mechanism and does not interfere with the function of wild-type MEF2A protein. Interestingly, consistent with genotype-phenotype correlation studies, the seven-amino acid deletion has a dominant negative effect in that it is associated with a much more severe clinical outcome (9 of 13 patients developed MI) compared with the missense mutations (none of the four carriers have developed MI yet) (6,7).

Because mutations in MEF2A are associated with CAD, we hypothesized that MEF2A contributes to a dysfunctional or abnormal development of the endothelium, rendering ECs then prone to inflammation and thrombosis, ultimately leading to the development of CAD and MI. Immunostaining studies with an anti-MEF2A antibody detected MEF2A protein in the endothelium of human coronary arteries (7), which co-localizes with the expression signal of platelet-endothelial adhesion molecule-(PECAM)-1/CD31, an EC marker (Figure 94.3). MEF2A protein was also detected in cultured human umbilical vascular ECs and intact human coronary arteries by Western blot analyses (Figure 94.4). And finally, MEF2A mRNA was also detected in rat SMCs in vitro (35). MEF2A protein expression was detected in proliferating SMCs but not in differentiated SMCs in a rat model of arterial injury and clinical restenosis (35). We have also detected expression of MEF2A protein in the nuclei of proliferating human SMCs

Figure 94.3. The expression of MEF2A in the coronary endothelium. (A) Immunostaining studies with an anti-MEF2A antibody detected a high level of expression of MEF2A protein in the endothelium of coronary arteries. (B) MEF2A colocalized with the expression signal of CD31, an EC marker. (Reproduced with permission from L. Wang et al. *Science* 2003;302:15780–15781.)

Figure 94.4. Detection of MEF2A protein in ECs and coronary arteries by Western blot analysis. (A) MEF2A protein was detected in protein extracted from cultured human umbilical vascular ECs. (B) MEF2A protein was detected from protein extracted from intact human coronary artery tissue.

(7). These results suggest that MEF2A protein is present in the target organ of CAD – namely the endothelium and SMCs of the coronary artery.

Expression of MEF2A has been previously studied in mice. *MEF2A* mRNA was detected in blood vessels during mouse early embryogenesis (36). Expression of MEF2A protein was detected as early as day 8.5 postcoitum in cells of embryonic vasculature, and the pattern is similar to that of vascular endothelial growth factor receptor 2 (VEGFR2) and von Willebrand factor (both are EC markers) (37). These expression studies suggest that MEF2A may play an important role in vascular morphogenesis.

Mice deficient in MEF2A have been created (38). Homozygous *MEF2A*<sup>-/-</sup> mice in the 129sv genetic background die suddenly within the first week of life. However, mice on mixed genetic backgrounds survive (38). No structural heart defects have been detected before death, but dilation of the right ventricle was detected in homozygous *MEF2A*<sup>-/-</sup> mice with sudden death at necropsy. The cause of the sudden death phenotype in homozygous *MEF2A*<sup>-/-</sup> mice remains largely unknown.

Based on the findings that MEF2A mutations are associated with CAD and that MEF2A is upregulated in cultured ECs and in coronary endothelium, we proposed a novel function of a transcription factor that contributes specifically to dysfunctional or abnormally developed endothelium, thus triggering the development of CAD (7). We expect that future studies will uncover a role for MEF2A in controlling the expression of many genes in the coronary endothelium. Mutations in

MEF2A will alter the expression of some subsets of genes and thus reprogram the transcriptional profile in the endothelium, leading to EC dysfunction. As the endothelium forms a barrier between blood and the arterial wall, defects in this cell layer may render it more susceptible to the invasion of monocytes and macrophages and to the formation of atherosclerotic plaques. Once the arterial wall integrity is lost, a cascade of events culminates in unstable angina, MI, or sudden cardiac death. It is important to note that this hypothesis remains to be further validated.

In sum, the molecular pathway of MEF2A plays an important role in the complex pathogenic mechanisms that generate CAD and MI. It is likely that the MEF2A signaling pathway will be found to contribute to the regulation of endothelial development and function and may also be a key player involved in the complex disease process of atherosclerosis.

#### MEF2B, A POTENT TRANSACTIVATOR EXPRESSED IN EARLY MYOGENIC LINEAGES

Like other MEF2 members, MEF2B also binds to A/T-rich DNA sequences and regulates gene expression through interactions with other coactivators and corepressors in several tissues. In muscle cells, MEF2B is the only member of MEF2 family that regulates smooth muscle myosin heavy chain gene expression (39). In neuronal cells, MEF2B and MEF2C, together with adhesion related kinase (Ark), repress the expression of gonadotropin-releasing hormone (GnRH) (40). Although there has been no report on MEF2B in ECs, MEF2B was detected in SMCs and neointima (41).

MEF2B is the most divergent member of the vertebrate MEF2 family of transcription factors. It shares significant amino acid sequence with other MEF2 members within the MADS/MEF2 domains, whereas the C-terminal region (transactivation domain) shows relatively little similarity (42).

Members of the MEF2 family are generally kept in an inactive state when directly associated with the class II HDACs. HDACs repress transcription by deacetylating core histones, which results in chromatin condensation. In T lymphocytes, MEF2 activity is also repressed by Cabin1, which recruits class I HDAC to MEF2 target genes. Recently, there have been advances in understanding how MEF2 interacts with HDACs and Cabin1. Han and colleagues solved the crystal structure of the MADS-box/MEF2 domain of human MEF2B bound to a motif of Cabin1 and DNA (43). A stably folded MEF2 domain was shown to be on the surface of the MADS domain, and Cabin1 binds a hydrophobic groove on the MEF2 domain. The structure of the complex between MADS-box/MEF2 domain of MEF2B and the MEF2-binding motif of class II HDAC9 was also determined and is similar to the structure of the Cabin1/MEF2/DNA complex (44). Thus, MEF2 proteins recruit transcriptional corepressor Cabin1 or HDACs to specific DNA sites through the MEF2 domain.

The functional role of MEF2B remains largely unknown. Unlike other MEF2 members, MEF2B is not phosphorylated

by p38 MAPK or big MAPK1 (BMK1, also called ERK-5). Thus, how MEF2B is phosphorylated still needs to be elucidated (45,46). MEF2B also binds the MEF2 consensus sequence with reduced affinity relative to the other family members, whereas MEF2A, -C and -D have similar DNA specificity (42).

### MEF2C, CRITICAL FOR THE DEVELOPMENT OF THE VASCULAR SYSTEM

The *MEF2C* gene is expressed in multiple cell types, including skeletal, cardiac, and SMCs as well as the neural crest and the vascular endothelium (47–49). It plays an important role in vascular development and is required for cardiac myogenesis and morphogenesis (49–51). *MEF2C*-null mice exhibit profound cardiac defects, including a near complete loss of the right ventricle and its outflow tract, defective aortic arch looping, and a disorganized endocardium (50). Consequently, mouse embryos lacking MEF2C fail to form a functional vascular system and have major defects in vasculogenesis that are lethal by embryonic day E9.5. Although ECs do develop, they fail to organize normally into a vascular plexus, suggesting a potential role for MEF2C in EC differentiation. At the same time, SMCs do not differentiate. It is not clear whether MEF2C has a primary role for SMC differentiation or whether a defect in signaling between ECs and pericytes is responsible for this failure of SMCs to differentiate. These vascular defects are similar to that of knockout mice for VEGF or its receptor VEGFR1 (49).

Bi and colleagues, showed that MEF2C deficiency results in a complex set of vascular malformations, including the arrest of the yolk sac capillary network and the eventual disruption of the yolk sac vessels (51). The embryonic vasculature fails to remodel into a more complex vasculature of diversely sized vessels by E9.5. The vessels in the head and those caudal to the heart have enlarged lumens and a reduction in the number of capillaries, whereas the vessels located dorsally and anterior to the heart have smaller lumens compared with normal control animals. Furthermore, ECs in this region are rounded with erratic orientations with respect to the underlying myocardium (51). This suggests that a defect in EC differentiation or angiogenesis occurs and has been attributed to the decreased angiopoietin 1 (Ang1) and VEGF expression by the myocardium (51). This in turn suggests that an essential function of MEF2C in the myocardium is the regulation of proper expression of these cytokines to direct endocardial formation.

Similar embryonic abnormalities were also detected in mice null for big MAPK-1 (BMK1, also called ERK-5) and MAPK kinase kinase-3 (MEKK3) (49–54). The MAPK signaling pathways start with activation of MEKK by G-protein-coupled receptors. Activated MEKK phosphorylates a subordinate MAPK kinase (e.g., MEK5), which further activates a MAPK (e.g., BMK1 or ERK5) by phosphorylation. BMK1 can stimulate transcriptional activation of MEF2 factors by phos-

phorylating the transcription activation domains or by direct interactions with MEF2 factors.

Studies with *BMK1* conditional knockout mice provided direct genetic evidence that a BMK1–MEF2C pathway is critical for EC survival and blood vessel integrity (55). Cre-recombinase-mediated ablation of *BMK1* in adult mice results in the degeneration of the cardiovascular system and is accompanied by hemorrhages in multiple organs. The EC lining of blood vessels become round, irregularly aligned, and eventually apoptotic. The in vitro removal of BMK1 protein also leads to the death of ECs due in part to the deregulation of MEF2C. Additionally, endothelial-specific *BMK* knockout leads to cardiovascular defects identical to those of global *BMK* knockout mutants, whereas surprisingly, mice lacking BMK1 in cardiomyocytes develop to term without any apparent defects. Moreover, normal ECs proliferated and underwent a mesenchymal transformation in cardiac explant cultures, whereas explanted ECs from *BMK1*<sup>-/-</sup> mice failed to proliferate in vitro. Infection of *BMK1*-knockout ECs with an adenovirus encoding a constitutively active form of MEF2C fused to the VP16 activation domain provided considerable protection from apoptosis for these cells. Taken together, these results provide direct genetic evidence that the BMK1 pathway delivers survival signal through MEF2C in ECs (55).

In sum, these targeted inactivation studies of the MEF2C have demonstrated that MEF2C is an early marker of the vascular development that mediates EC organization and angiogenesis.

### MEF2C Is Regulated by Ets-1

Screening for transcriptional enhancers from the mouse *MEF2C* gene identified an EC-specific, intronic enhancer that binds transcription factor v-ets erythroblastosis virus E26 oncogene homolog 1 (avian) (*Ets-1*), which is a transcription factor that is sufficient to drive MEF2C expression in the developing vascular endothelium. *Ets-1* is active from the earliest stages in vasculogenesis in the yolk sac of the embryo and remains robustly active throughout embryonic development and into maturation to the adult form. The EC-specific enhancer of MEF2C contains four highly conserved *Ets*-binding sites that are efficiently bound by *Ets-1* protein in vitro, and two of these sites are required for the enhancer function in embryos. The MEF2C enhancer does not drive its expression in vascular SMCs, indicating that the enhancer is specific for ECs and additional discrete elements within the *MEF2C* locus will direct expression in SMCs (56).

### MEF2D, A MEMBER OF MEF2 FAMILY WITH A KEY ROLE IN APOPTOSIS

Breitbart first cloned human *MEF2D* in 1993 using a *MEF2B* cDNA probe to screen human cardiac ventricle cDNA. It was later mapped to human chromosome 1q12–23. MEF2D

is ubiquitously expressed with several alternatively spliced forms (57,58). MEF2D has been shown to play a key role in T-cell receptor (TCR)-mediated apoptosis during thymic negative selection. It mediates calcium-dependent transcription of *Nur77*, a transcription factor involved in TCR-mediated apoptosis of thymocytes (30,59). MEF2D binds two calcium-responsive DNA elements in the *Nur77* promoter and mediates the calcium-dependent induction of *Nur77* (30). It remains to be determined whether MEF2D plays any role in vascular development.

#### KEY POINTS

- The *MEF2* genes encode members of the MEF2 family of transcription factors. Four members in this family exist: MEF2A, MEF2B, MEF2C, and MEF2D. MEF2 proteins bind to a conserved A/T-rich sequence element bearing the consensus sequence CTA(A/T)<sub>4</sub>TAG in the promoters of many skeletal and cardiac muscle genes and regulates their expression.
- MEF2 proteins share high sequence similarity in an N-terminal MADS (MCM1, agamous, deficiens, serum response factor) domain and an adjacent MEF2-specific domain. The MADS domain mediates DNA binding and dimerization and the MEF2-specific domain influences DNA-binding affinity and is responsible for interactions with transcriptional cofactors. The C-terminal regions of MEF2 factors, which are more divergent, act as transcription activation domains and contain signals that are necessary for nuclear localization.
- Although it is established that MEF2 factors play a critical role in muscle differentiation and development, subsequent studies have demonstrated that they are expressed ubiquitously and might have additional functions apart from their involvement in myogenesis.
- *MEF2A* is the first disease-associated gene identified for autosomal dominant CAD and MI. The first genetic locus for autosomal dominant CAD/MI, *adCAD1*, is in the chromosome 15q26 region.
- *MEF2A* protein is highly expressed in coronary endothelium, suggesting that the pathogenesis of CAD may involve deregulation of transcriptional programs in the endothelium. Dysfunctional or abnormally developed endothelium has been proposed as a triggering mechanism for development of CAD.
- MEF2B is the only member of the MEF2 family that regulates smooth muscle myosin heavy chain gene expression. It is the most divergent member of the vertebrate MEF2 family of transcription factors.

- Several studies of knockout mice of *MEF2C* have established it as a critical gene for normal development of the vascular system. An intronic enhancer of *MEF2C* is responsible for its expression in ECs. The enhancer is EC specific and a site for transcription factor Ets-1.
- MEF2D plays a role in T-cell apoptosis.

#### Future Goals

- To further associate MEF2A in the genesis of CAD/MI and validate these findings in the patient population at large
- To define a specific mechanism of action of MEF2A in the generation of disease
- To create the MEF2A seven-amino acid deletion in a transgenic mouse model to observe a genotype-phenotype correlation with CAD/MI

## Vezf1

### A Transcriptional Regulator of the Endothelium

Frank Kuhnert\* and Heidi Stuhlmann†

\*The Scripps Research Institute, La Jolla, California;  
Stanford University Medical Center, Stanford, California;

†Weill Medical College of Cornell University, New York City, New York

This chapter summarizes our current knowledge of vascular endothelial zinc finger 1 (Vezf1) and its human orthologue DB1 and their role in vascular biology. We describe the unique features of the *Vezf1* gene and its homologues, and we will present evidence that Vezf1 acts as a transcription factor. Finally, we discuss possible roles that Vezf1 plays in the endothelium during development and in angiogenesis.

Mouse *Vezf1* originally was identified using a retroviral “gene trap” screen for early cardiovascular genes in mouse embryonic stem (ES) cells and embryos (1–4). During embryogenesis, Vezf1 expression is localized in vascular endothelium (4), as well as neuronal and mesodermal tissues. Under in vitro conditions, Vezf1 expression has been reported in cultured endothelial cells (ECs) such as human umbilical vein ECs (HUVECs), mouse EOMA and yolk sac-derived ECs, hematopoietic cell lines (T, pre-B, erythroleukemia cells, macrophages) (4), and a fetal liver-derived stromal cell line (5). The human orthologue, DB1 (also termed ZF161), was first isolated from Jurkat T cells as a protein that binds to a GT/GC-rich region in the human *interleukin (IL)-3* promoter (6). In addition, DB1 was found to be upregulated during differentiation of dendritic cells from monocytes by cDNA microarray analysis (7).

#### VEZF1 IS HIGHLY CONSERVED AMONG VERTEBRATES

One of the striking features of *Vezf1* is the high extent of conservation of the gene structure and the nucleotide and amino acid sequences (4; F. Kuhnert and H. Stuhlmann, unpublished observations). The murine *Vezf1* gene contains six exons and five introns and spans a total length of 16.3-kb on chromosome 11. The human orthologue *DB1/ZNF16* maps to a syntenic region at 17q23.2 and shows the same gene structure with respect to the number, the position, and the size of the cod-

ing exons, as well the nucleotide sequences at the exon–intron boundaries. The mouse cDNA is 4,578-bp in length and contains 1,557 bp of coding sequences. The human *DB1* cDNA is 4,652-bp in length with an open reading frame of 1,566 bp. Alignment of mouse and human cDNAs reveals an 85% to 92% sequence identity in the coding and most of the 5′ and 3′ untranslated regions, suggesting the presence of conserved functional and structural elements in the mRNA.

The Vezf1 and DB1 open reading frames encode 518- and 521-amino-acid proteins, respectively, with a predicted molecular mass of 56 to 58 kDa. The two sequences differ only in six amino acids and in additional three glutamine residues in the human DB1 polyglutamine stretch (Figure 95.1). Amino acid alignment of putative Vezf1 orthologues from various vertebrate species illuminates a striking conservation from fish through mammals and few nonconservative changes from amphibia through mammals (Figure 95.1) (F. Kuhnert and H. Stuhlmann, unpublished observations). Thus, it is likely that crucial functional domains of Vezf1 were conserved during the evolution of vertebrate species.

#### FUNCTIONAL DOMAINS OF VEZF1

Vezf1 displays hallmarks of a bona fide transcription factor (Figure 95.2). For example, it contains six internal zinc fingers of the Cys2/His2 (Kruppel-like) type, a motif known to promote DNA binding. The zinc finger domain is 65% identical to mouse PUR-1, a protein that binds to purine-rich sequences and transactivates the *insulin* promoter (8,9). Its human orthologue, MAZ/SAF-1, is a zinc finger transcription regulator of c-Myc, CD4, serotonin 1 $\alpha$  receptor, and  $\gamma$ -fibrinogen (10,11) and shares 65% amino acid identity in the zinc finger region with DB1/ZNF161 (Figure 95.2). No other genes with significant sequence similarities exist in the databases, defining Vezf1/DB1 and PUR-1/MAZ as the only

Figure 95.1. Amino acid sequence alignment of mouse Vezf1 and its orthologues from key vertebrate species.

Figure 95.2. Structural and functional domains of mouse Vezf1, human DB1/ZBF161 and related proteins.

members of a small subfamily of Cys2/His2 transcription factors. In addition to the zinc finger domain, *VeZF1* contains a polyglutamine stretch and a proline-rich region, known mediators of transcriptional repression and activation, respectively, at its C-terminus. The functional domains of *VeZF1* were delineated by a combination of mutagenesis, transactivation, DNA-binding and subcellular localization analyses (Figure 95.2). The dissection of the *VeZF1* domain structure identified a N-terminal nuclear localization sequence (NLS) KKPSKPVKK, spanning residues 164 to 172, and a strong C-terminal transcriptional transactivation domain (amino acids 421 to 518) encompassing the proline-rich region, that is functional both in endothelial and heterologous cell lines. Interestingly, this transactivation domain is activated only after deletion of the N-terminal portion of *VeZF1*, but is inactive in the context of the full-length protein. A similar “unmasking” process of a C-terminal transactivation domain has recently been reported for Smad proteins. The DNA binding activity was mapped to the central five-zinc finger motif. This region was found to be capable of forming specific DNA-protein complexes with oligonucleotide probes containing sequence motifs derived from the *IL-3* and the endothelial-specific *FLK-1* and *FLT-1* promoters. In addition, the central five-zinc finger domain of DB1 was shown to interact with a novel GTPase-activating protein, p68RacGAP, via yeast two-hybrid screening (12). Finally, the N-terminal region upstream of the DNA binding domain of DB1, including the first zinc finger, functions as a RhoB binding site (13).

### VEZF1 TARGET GENES

Human *DB1* was cloned based on its binding activity to the CT/GC-rich region of the human *IL-3* promoter (6). In transient transfection assays DB1 augments Tax-dependent transcription without displaying any detectable effect on the transcription activity of the *IL-3* promoter by itself (6). The interaction of *VeZF1* with members of the Rho GTPase machinery may represent a novel mechanism to modulate *VeZF1* activity. For example, sequestration of DB1 by a prenylated, nuclear-localized form of the RhoB GTPase results in the inhibition of transcriptional potentiation of Tax-mediated transcriptional activation of the *IL-3* promoter (13). Moreover, recent studies demonstrate a RhoB interaction-dependent transactivation of the *neuropilin 1 (NRP1)* promoter by DB1 via canonical DB1 binding sites in primary ECs.

*VeZF1* was shown to bind in a sequence-specific manner to the same CCCC GC core sequence in the murine promoters of *IL-3*, *FLK-1*, and *FLT-1* but failed to activate transcription of these promoters in transient transfection assays in ECs (D. Lemons, F. Kuhnert, and H. Stuhlmann; unpublished observations), suggesting that *VeZF1* functions in the context of these promoters in concert with additional coactivators. *VeZF1/DB1* was found, however, to transactivate the EC-restricted human *endothelin-1 (hET-1)* promoter in transient

transfection assays (14). In fact, a novel *VeZF1*-responsive element, ACCCCC, was identified 47-bp upstream of the transcriptional start site of the *hET-1* promoter. Cotransfection of p68RacGAP potentially inhibits *VeZF1*-dependent transcriptional activation of the *hET-1* promoter (12). *Stathmin/ oncprotein 18 (OP18)*, a microtubule-destabilizing protein, was identified as another putative *VeZF1* target gene by cDNA microarray analysis of ECs treated with *VeZF1* antisense oligodeoxynucleotides (AS-ODNs) (15). Downregulation of *VeZF1* in proliferating ECs by AS-ODNs resulted in a 50% reduction of stathmin/OP18 expression, whereas overexpression of *VeZF1* in ECs increased the expression of stathmin/OP18. Furthermore, downregulation of stathmin/OP18 phenocopied the effect of *VeZF1* knockdown on EC proliferation, migration and network formation in vitro (15). Lastly, the analysis of a large canon of potential vascular targets, including vascular endothelial growth factor (VEGF), angiopoietin, ephrin, Notch, and transforming growth factor (TGF)- $\beta$  signaling pathways, in *VeZF1*<sup>-/-</sup> embryos by microarray and RNA in situ hybridization analysis is ongoing but thus far has not revealed any genes whose expression is regulated by *VeZF1* in vivo (16).

### FUNCTION OF VEZF1 DURING VASCULAR DEVELOPMENT – LOSS-OF-FUNCTION STUDIES IN MICE

Gene-targeting studies in mouse ES cells and mice established that *VeZF1* function is required for the development of the blood vascular and the lymphatic system in a dose-dependent manner (16). Loss of *VeZF1* function resulted in an incompletely penetrant, haploinsufficient embryonic lethal phenotype. Homozygous mutant embryos can be subdivided into two classes. Class I embryos display an early phenotype that is characterized by defective angiogenic remodeling, particularly in the developing vasculature of the aortic arch system, the head and neck, and in the intersomitic vessels, and by the loss of vascular integrity. In contrast, class II embryos display apparently normal vascular patterning but are subject to midgestation hemorrhaging (Figure 95.3A; for color reproduction, see Color Plate 95.3). Immunohistochemical and ultrastructural analysis demonstrated normal vascular smooth muscle cell/pericyte coverage in *VeZF1* mutants but revealed defects in EC adhesion, tight junction formation, and extracellular matrix (ECM) organization in mutant vessels as the molecular basis for observed hemorrhaging (16).

Furthermore, haploinsufficiency was detected in about 20% of the heterozygous embryos. Affected heterozygous mutant embryos displayed dramatic lymphatic hypervascularization at midgestation, accompanied by hemorrhaging and edema in the jugular region, the first site of lymphatic sprouting from the venous system (Figure 95.3B). A low incidence of the lymphatic phenotype also was observed in class II homozygous mutant embryos. Apparently, the early lethality

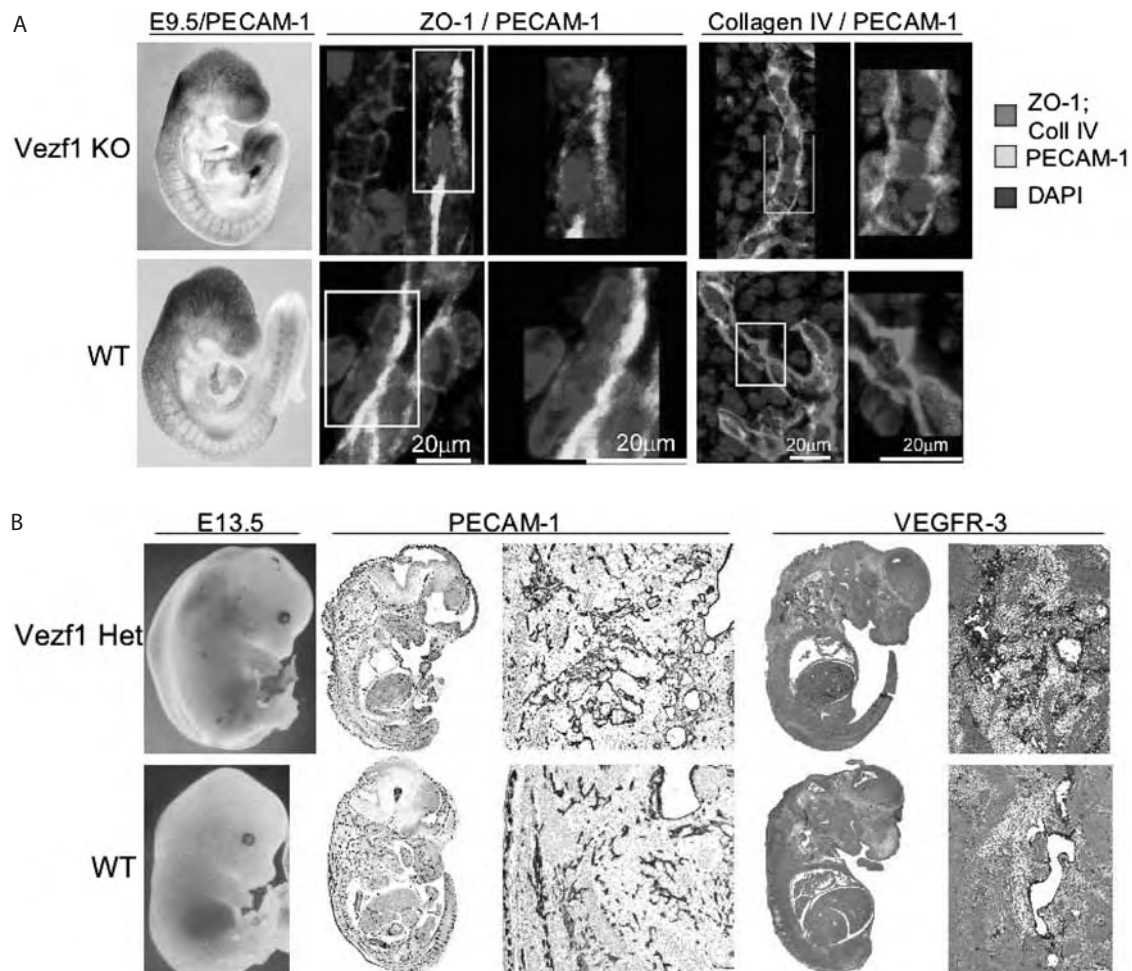

Figure 95.3. Blood vascular and lymphatic phenotypes in *Vezf1* loss-of-function embryos. (A) Hemorrhaging *Vezf1* KO embryos with EC defects. (B) Lymphatic hypervascularization, hemorrhaging, and edema in *Vezf1* heterozygous embryos. For color reproduction, see Color Plate 95.3.

in *Vezf1*<sup>-/-</sup> embryos precluded a more robust detection, both in frequency and severity, in homozygous mutant embryos. The lymphatic system phenotype is highly reminiscent of the human congenital malformation syndrome cystic hygroma. Furthermore, it indicates that *Vezf1* functions as a negative regulator of lymphatic differentiation and/or proliferation during embryonic development. This conclusion is supported by recent studies in which knockdown of the human orthologue DB1 in primary ECs lead to an increase in lymphatic phenotype and gene expression (I. Adini and L. Benjamin, personal communication). Importantly, it raises the question of whether loss of *Vezf1* function can be correlated with other known hyperplastic conditions thought to arise by excessive proliferation of lymphatic ECs, such as lymphangioma, lymphangiosarcoma, and Kaposi sarcoma.

The *Vezf1* loss-of-function studies suggest that the primary defect lies in the lymphatic and blood ECs – i.e., that *Vezf1* acts cell-autonomously in ECs. However, because *Vezf1* expression is present but not restricted to the developing endothelium, additional defects in other *Vezf1* expressing cells, such as

mesenchymal cells, may contribute to the mutant phenotype. Recently, we have demonstrated that EC-specific expression of *Vezf1* under the control of the *Tie-2* promoter rescues the *Vezf1*<sup>-/-</sup> phenotype, suggesting that endothelial *Vezf1* is the most critical determinant of survival (F. Kuhnert, Z. Zou, and H. Stuhlmann; unpublished observations).

#### FUNCTION OF VEZF1 DURING IN VITRO DIFFERENTIATION – LOSS-OF-FUNCTION STUDIES IN EMBRYONIC STEM CELLS

In vitro ES cell differentiation into embryoid bodies recapitulates the endothelial differentiation program and maturation steps observed during vasculogenesis and angiogenesis in the embryo. Studies using ES cells in which one or both *Vezf1* alleles are genetically inactivated were consistent with the vascular phenotypes observed in mice, strongly indicating the endothelium as the primary target of *Vezf1* function. Embryoid bodies derived from *Vezf1*<sup>-/-</sup> ES cells failed to form

a well-organized and differentiated vascular network. Abnormal ECM deposition on mutant ECs was found, similar to the phenotype detected in mutant embryos. In addition, *VeZF1*<sup>-/-</sup> ECs showed dramatic spouting defects in a three-dimensional collagen matrix. Finally, *VeZF1*<sup>-/-</sup> teratocarcinomas displayed delayed differentiation and reduced and abnormal vascularization.

### INTERACTION OF VEZF1 WITH RHO GTPases

Increasing evidence implicates *VeZF1* interaction with Rho GTPases and associated regulatory proteins as a novel mechanism to modulate *VeZF1* function. Nuclear localization of a prenylated form of RhoB and specific binding of *VeZF1*/DB1 to prenylated RhoB via its N-terminal region was demonstrated by Lebowitz and Prendergast (13). Sequestration of DB1 by RhoB resulted in the inhibition of transcriptional activation of the *IL-3* promoter by DB1. Recent studies demonstrate a positive effect of RhoB–*VeZF1*/DB1 interaction on the transactivation of certain endothelial genes such as *NRP1*. *VeZF1* also was shown to bind to a novel GTPase-activating protein, p68RacGAP, in ECs (12). Rac1-specific p68RacGAP colocalizes with *VeZF1* in the nucleus and the cytoplasm, inhibits *VeZF1*-dependent transcriptional activation of the *hET-1* promoter, and modulates EC capillary tube formation in vitro. It is unknown whether transcriptional inhibition of the *hET-1* promoter, similar to the *IL-3* promoter, is mediated by sequestration of *VeZF1*. The interaction between *VeZF1* and components of the Rho GTPase machinery may represent an important and novel paradigm for the regulation of physiological and pathological angiogenesis, especially in light of the recent implication of RhoB in the regulation of endothelial sprouting and apoptosis (17).

### CONCLUSION

Recent functional studies provided us with new insights into the biological role of *VeZF1* during the development of the mammalian vascular system. These studies suggest that *VeZF1* is a transcription factor that controls in a strictly dosage-specific manner normal blood vessel and lymphatic vessel development. Molecular studies suggest that interaction of *VeZF1* with other cofactors, specifically Rho GTPases and Rho/Rac associated proteins are crucial to modulate its function in the endothelium.

#### KEY POINTS

- *VeZF1* is a transcription factor that in a strictly dosage-dependent manner regulates the development of the blood and lymphatic vasculature.

- *VeZF1* regulates EC adhesion, tight junction formation, and ECM organization.
- *VeZF1* is a negative regulator of lymphatic EC proliferation/differentiation.
- Putative *VeZF1* EC target genes include *ET-1*, *NRP1*, *FLT-1*, *FLK-1*, *IL-3*, and *stathmin/OP18*.
- The interaction between *VeZF1* and components of the Rho GTPase machinery may represent a novel paradigm to modulate *VeZF1* transcriptional activity.

#### Future Goals

- To determine if loss of *VeZF1* function can be correlated with known lymphatic EC hyperplasia, such as cystic hygromas, lymphangioma, lymphangiosarcoma, and Kaposi sarcoma
- To identify genes that function in the same transcriptional regulatory circuits as *VeZF1*

## Sox Genes

### At the Heart of Endothelial Transcription

---

Neville Young and Peter Koopman

*Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia*

The endothelium is not well understood as a fully functional organ, yet a surprising amount of data exist regarding vascular development during embryogenesis. During mouse development, endothelial cells (ECs) alone make up the vasculature until around halfway through gestation. A large number of knockout and mutant mice exist in which severe defects in the endothelial vasculature at these early stages lead to embryonic lethality. The use of these animals to dissect the genetic interactions within ECs during development has led to an increased understanding of the endothelium.

The central thread of this chapter is the transcriptional regulation of ECs by members of the *Sox* gene family, but it also will incorporate relevant information gained from other signaling hierarchies. We have amassed substantial data implicating SOX18 in vascular development (1,2). In situ analysis of *Sox18* has demonstrated expression in the condensing mesenchyme underlying the developing hair follicle, in the developing heart, and in the ECs of the vasculature. Mutations in *Sox18* lead to mice with defective hair, skin, and vasculature. The vascular defects can be particularly life-threatening, leading to generalized edema due to the leaky vasculature that can result in embryonic or postnatal lethality. Here, we review the data bearing on the molecular and cellular roles of SOX18 and related genes in regulating endothelial phenotype and function.

#### SOX GENES

*Sox* genes encode a family of transcription factors, characterized by the presence of a 79 amino acid DNA-binding high mobility group (HMG) domain, similar to that found in mammalian testis-determining factor gene (3). HMG domains can be found in a number of proteins involved in chromatin organization, general transcription and transcriptional regulation. HMGB1, for example, is a non-SOX HMG domain containing protein involved in chromatin packaging but also is secreted from necrotic cells and activated macrophages to

induce angiogenesis (4). *Sry* is located on the Y chromosome and triggers the development of the testis. To date, based on sequence conservation of the HMG domain, *Sox* genes have been identified exclusively in the animal kingdom: in insects, nematodes, reptiles, birds, amphibians, and fish, with at least 20 members currently recognized in mammals (5). SOX transcription factors have both classical and architectural modes of action: they are able to bind to promoter regions to activate the transcription of target genes directly and also are able to bend DNA to an angle of between 70 and 80 degrees, thus bringing together other proteins and *cis*-acting DNA regulatory sequences to facilitate transcription.

*Sox* genes have diverse temporal and spatial expression patterns during embryonic development and are implicated in many cell fate decisions during early embryogenesis. Their diverse roles are best illustrated by the variety of phenotypes associated with spontaneous mutations in *Sox* genes. In humans, mutations in *Sry* cause male-to-female sex reversal and gonadal dysgenesis (6); SOX9 mutations result in camp-tomelic dysplasia, a skeletal dysmorphogenesis (7); SOX10 mutations result in Waardenburg-Shah syndrome, leading to deafness, hypopigmentation, and aganglionic megacolon, all due to defects in neural crest migration (8). Thus, SOX transcription factors seems to be involved in a variety of tissue-specific switching events that control changes in the expression of suites of genes involved in cell-type specification and differentiation.

The vast majority of SOX transcription factors appear to act as transcriptional activators; however, in a small number of cases, transcriptional repression has been ascribed to SOX proteins. Experiments to date suggest that efficient SOX protein regulation of target gene transcription requires recruitment of cofactors and partner proteins to their transactivation domains. Evidence exists in vitro suggesting that some *Sox* genes can partially activate transcription independently but that this activation is potentiated in the presence of cofactors (9). However, in vivo, it is difficult to imagine how the abundance of SOX binding motifs would be regulated efficiently

in the absence of cofactor modification. Recruitment to these SOX functional domains of non-DNA binding transcription factors or other cofactors has been postulated to be a probable mechanism to generate SOX target gene specificity (10).

### PHYLOGENY OF SOX GENES

Before addressing the structural and functional groupings of the various *Sox* genes, it is important to define exactly what a *Sox* gene is. *Sox* genes can be found scattered throughout the genome and were originally classified as encoding proteins having more than 50% amino acid sequence identity to SRY in the HMG domain; however, this definition is no longer accurate or particularly useful in distinguishing a bona fide *Sox* gene from other classes of HMG-box genes. For example, human *SOX30*, a gene with obvious structural features of a *Sox* gene, encodes a protein with only 48% identity to human SRY in the HMG domain. Present criteria for defining *Sox* genes use the conservation of key motifs within the HMG domain, such as the signature sequence motif RPMNAFMVW, which appears to be conserved in all non-SRY SOX proteins. The original concept of reference to SRY was a historical, and, in retrospect, poor choice for defining *Sox* genes, especially as *Sry* is present only in mammalian lineages. In addition, due to its location on the rapidly evolving Y chromosome, *Sry* is highly divergent, even between closely related species (5).

The 20 *Sox* genes found in mammals are arranged into groups A through H, based on their HMG box similarities and additional information on non-HMG domain structural motifs (5). Vertebrates typically express several members of each group, whereas invertebrate species have a single ancestral sequence for each group (the exception being Group B, where four sequences have been identified in *Drosophila*).

Relationships between members of the *Sox* family shed light on the evolutionary process as they display traits of both slow divergence and rapid change. The HMG domain, the motif that forms the core of all SOX family proteins, has accumulated relatively few sequence changes due to selection pressures to retain DNA binding and is therefore well conserved across all SOX groups. In contrast, the regions outside of the HMG domain show more rapid stochastic evolutionary changes that must have occurred via the apparent co-option of functional domains and motifs of other proteins (11). As a result of this, sequence and structure outside the HMG domain is highly divergent between SOX groups, yet conserved to a recognizable extent between members within the same SOX group. The degree of conservation correlates loosely with the degree of similarity of function between members of the same SOX group. For example, members of *Sox* group D include *Sox5* and *Sox6*, which have similar expression profiles, are thought to act redundantly in spermatogenesis and chondrogenesis, and show a high degree of structural conservation. In contrast, group E *Sox* genes are less similar in structure and have very different expression patterns and roles in development and disease.

In mammals, *Sox18* is related to two other *Sox* genes, *Sox7* and *Sox17*, which together form *Sox* group F. These three genes have similar structures and overlapping temporal and spatial expression profiles in several but not all cell types. This suggests that although the three genes are regulated differently in some tissues, they could potentially function redundantly in cells where they are coexpressed – for instance, in ECs during vascular development.

### DISCOVERY OF SOX18

*Sox18* was first identified as part of an effort to identify novel *Sox* genes expressed in mouse embryonic tissue. A gene with an open reading frame of 1404 base pairs, encoding a protein 468 amino acids in length, was identified and mapped to distal chromosome 2 (12,13). The encoded protein, SOX18, was found to bind to the sequence 5'-AACAAAG-3' and to be capable of activating transcription via this sequence in GAL4 reporter assays in vitro (14) possibly via a transactivation domain mapped to a region C-terminal to the HMG domain (Figure 96.1) (5). Further study revealed that this in vitro activation could be significantly increased in the presence of known binding partners (15). It therefore seems unlikely that in vivo SOX18 activates transcription in the absence of cofactors. Much more probable is that proteins such as myocyte enhancer factor 2 (MEF2C), which are known to interact with the C-terminal region of SOX18 in ECs, will have a crucial role in regulating transcriptional specificity and efficiency. Otherwise the ability of any *Sox* gene to activate any gene bearing a SOX binding motif at would cause transcriptional chaos.

The sequence of *Sox18* is generally well conserved between species, suggesting a conserved and important function for the protein. However, subtle differences exist between SOX18 proteins from mouse, human, and chicken, and these may reflect different functions required of the gene product in different species. For example, murine SOX18 has a longer C-terminus than either human or chicken, whereas chicken SOX18 has a divergent *trans* activating domain when compared to the other two (Figure 96.1). It has been postulated that mouse SOX18 may recruit more DNA-binding partners in its extended C-terminus, and that chicken SOX18 may recruit a different suite of cofactors to its *trans* activation domain.

	HMG BOX	Transactivation Domain	C-terminus

### SOX18 IS EXPRESSED IN ENDOTHELIUM OF DEVELOPING BLOOD VESSELS

Blood vessels in an embryo are initially assembled from endothelial precursors (vasculogenesis), which subsequently undergo remodeling via endothelial sprouting and branching (angiogenesis). Initially, *Sox18* expression was observed in the developing vascular endothelium and condensing mesenchyme of hair follicles in mouse embryos (1,16). Close examination revealed that at embryonic day (E)7.5, *Sox18* is expressed in the allantois and within yolk sac blood islands. At 8.0 dpc expression was observed in angioblasts of mesodermal origin (nascent ECs) around the foregut and in the presumptive endocardial cells of the cardiogenic plate. At E8.5, expression was detected throughout the developing heart and early vasculogenic network and by E9.5 could be observed in vessels forming by angiogenesis (Figure 96.2A).

The expression of *Sox18* coincides with that of other known EC markers, such as vascular endothelial growth factor (VEGF) receptor 1 (VEGFR1/FLT-1) and VEGF receptor 2 (VEGFR2/FLK-1). Interestingly, in *Flk-1*-knockout mice, in which ECs fail to differentiate, *Sox18* expression is absent, yet in *Flt-1*-knockout mice, where ECs do differentiate but fail to organize into vessels, there is *Sox18* expression.

The vasculature at these early developmental stages consists entirely of ECs prior to the appearance of other components of the vasculature such as smooth muscle cells and pericytes. Thus, the onset of expression in endothelial precursors from as early as E7.5 and the absence of expression in *Flk-1*-knockout mice indicate that SOX18 is associated with the initial events of endothelial differentiation and subsequent vascular development.

Interestingly, *Sox18* expression is transient in ECs, lasting for about 48 hours during early vasculogenic and angiogenic events before being extinguished in established vessels. This pattern of expression also is conserved between species (it

is also observed in the chicken embryo) and strengthens the case for the role of SOX18 as a regulator of vascular development (16). After its initial embryonic expression SOX18 is not observed again in the vasculature except in adult tissue undergoing angiogenic remodeling – e.g., during wound healing, post myocardial ischemia, or in de novo tumor endothelium.

### MUTATIONS IN SOX18 REVEAL ITS FUNCTION

Nearly all of the work relating to the role of SOX18 in EC biology has been undertaken in the developing embryo, and it is at this time that defects in SOX18 function can be seen to influence EC biology. The vascular system is one of the earliest organs to be established in the developing embryo, and its formation is critical for successful embryogenesis. Given its pattern of expression during blood vessel development, the removal of SOX18 function from the embryo would have been postulated to have grave consequences during embryogenesis. It was surprising, then, to find that *Sox18*-knockout mice are normal and viable (1). The lack of major phenotype of *Sox18*-knockout mice may be explained by the fact that other members of the *Sox* group F, namely *Sox7* and *Sox17*, have spatial and temporally overlapping expression patterns in the vasculature permitting them to act redundantly to compensate for its loss.

Somewhat fortuitously, the location of *Sox18* on mouse chromosome 2 coincided with the mapped locus of a classical, spontaneous, semidominant mouse mutant, *ragged* (*Ra*) (Figure 96.2B). *Ra* mice exhibit defects in hair and vascular development (they are bald) and although the vascular network seems to form normally, these mice suffer from edema, chylous ascites, and cyanosis. Further study revealed point mutations in *Sox18* in all four known allelic variants of *ragged*; these mutations are predicted to result in missense translation of the SOX18 C-terminus and premature truncation of the protein

Figure 96.3. A schematic of murine SOX18 protein compared to the RaOp mutant version. Note intact HMG box and transactivation domain in RaOp mutant.

(Figure 96.3) (17). These truncated proteins were found to be unable to activate transcriptional target sequences relative to wild-type controls in GAL4 *in vitro* assays (14). These studies provide a ready explanation for the etiology and biochemical underpinnings of the *Ra* mutant phenotype and its semidominant mode of action: *Ra* mutant forms of SOX18 are presumably able to bind to their normal transcriptional targets but are unable to appropriately engage cofactors and partner proteins required for proper function in endothelial development. Evidence for the importance of cofactors in SOX18-targeted transcription is seen in work on the MADS box transcription factors *Mef2C*. Both *Mef2C* and *Sox18*-null mutants display overlapping phenotypic abnormalities. Further work has demonstrated that these proteins interact directly and are coexpressed in EC nuclei. MEF2C also potentiates SOX18-mediated transcription *in vivo* but this activation is reduced with *Sox18 ragged* mutants where the activation domain is truncated and the protein interactions disrupted (15).

Three of the four *Ra* mutant alleles have mutations within the defined transcriptional transactivation domain of SOX18, however, the fourth allele, termed *ragged opossum (RaOp)* has a mutation 3' of the activation domain and yet, despite having this domain intact, is unable to activate transcription. This suggests that either a further functional domain exists in the C-terminus of murine SOX18, or that the activation domain extends further than previously thought, or both. The three *ragged* mutant mice with point mutations in the transactivation domain all exhibit edema, chylous ascites and cyanosis at birth in the homozygous state. However, the *RaOp* mutant mice exhibit these symptoms in the heterozygous state, whereas homozygotes die at around E13.5 due to severe hemorrhage of the vascular network. Therefore, somewhat paradoxically, the *RaOp* gene product, although apparently a more intact protein than that encoded by the other three mutant alleles, causes the most severe mutant phenotype. It has been postulated that this paradox is due to the *RaOp* gene product more efficiently sequestering cofactors and/or partner proteins required for normal regulation of endothelial development (18).

The contrast between the lack of phenotype in the *Sox18*-null mouse and the severe vascular phenotype observed in the *RaOp* mice was initially difficult to explain. However, subsequent cell transfection experiments showed that *Ra*-expressing constructs can interfere with the ability of SOX18, SOX17, and SOX7 to activate their target genes (9). Evidence

also has been uncovered suggesting that all three Group F *Sox* genes are coexpressed in the vascular endothelium at the same time (19). Thus, it seems that the ragged proteins are able to act in a dominant negative fashion to interfere with the normal function of SOX18, SOX17, and SOX7, emphasizing the importance of the function of these genes in endothelial and vascular development. This also suggests that a common repertoire of cofactors exists in ECs for a short space of time when the initial vascular network is being established.

More recently, mutations in the human form of *SOX18* have been found to underlie both recessive and dominant hypotrichosis–lymphedema–telangiectasia, suggesting a role for SOX18 in the development and/or maintenance of lymphatic and blood vessels in humans (20). Interestingly the most severe of these mutations closely resembles the *ragged* mutations seen in mice.

## THE SOX18 MOLECULAR PATHWAY

Signaling pathways that mediate vascular development during embryogenesis have been well characterized in recent years, and the importance of cell trophic factors such as VEGF, platelet-derived growth factor (PDGF), fibroblast growth factors (FGFs), epidermal growth factor (EGF), and their receptors have been well documented (21). However, much less is known about transcriptional regulation within ECs. SOX18 is only one of a handful of transcription factors that have been identified with a defined role in vascular development and can thus provide important clues into how endothelial phenotype is regulated.

Some insights into the function of SOX18 have been provided by analysis of *Sox18* expression in null mutants of *Flt-1* and *Flk-1* which also have severe vascular defects (22,23). FLT-1 is essential for organization of the embryonic vasculature but it is not required for EC differentiation. As mentioned earlier, normal *Sox18* expression is observed in the ECs of *Flt-1*-knockout embryos, even though they do not assemble into a normal vascular network. In contrast, no *Sox18* expression is observed in *Flk-1*-knockout mice, in which endothelial precursors do form but do not seem to differentiate into ECs. This lack of expression of *Sox18* in endothelial precursor cells (which at this stage would normally express *Sox18*) in FLK-1-deficient embryos, along with the luminal position of *Sox18*-expressing cells indicate that *Sox18* expression is associated

with early vascular endothelial development. These studies suggest that *Sox18* expression is downstream of, but not necessarily directly controlled by, the VEGF–FLK-1 pathway where it may be involved in preliminary EC differentiation.

What genes are regulated by SOX18 and how is the regulation controlled? Recent findings have started to shed light on both how SOX18 mediates transcription and what genes it targets. Based on an overlapping expression pattern and the phenotypic effects observed in *Mef2C*-knockout mice, a relationship between MEF2C and SOX18 was identified (15). MEF2C is a transcription factor demonstrated to have a role in vascular development; it is expressed in ECs during development and *Mef2C*-knockout mice exhibit vascular defects similar to those observed in *VEGF* and *VEGFR1/Flt-1*-knockout mice (23) (see Chapter 32). Subsequently, SOX18 and MEF2C proteins were found to interact biochemically, and the two proteins are coexpressed in the nuclei of ECs in vivo (15). The expression of *Mef2C* enhances SOX18-mediated transcription and regulates the activity of the SOX18 activation domain, suggesting that MEF2C and SOX18 may be partners in transcriptional regulation during early vascular development.

Further work in our laboratories has revealed that SOX18 is able to activate the transcription of the *vascular cell adhesion molecule (VCAM)-1* gene (9). VCAM-1 is a member of the immunoglobulin superfamily of adhesion molecules, and is an important molecule involved in cell-cell contacts. VCAM-1 is expressed on the surface of ECs, and *VCAM-1*-knockout mice have disrupted chorioallantoic fusion and die in utero at E13.5. SOX18 activates transcription of this gene via a classical SOX binding motif in the *VCAM-1* promoter. It is therefore possible to hypothesize that the *Ragged* mutant phenotype is caused, at least in part, by an absence of VCAM-1 expression due to a lack of functional SOX18, resulting in poor cell-cell contacts in the vascular endothelium, in turn causing vascular leakage and edema. Activation of VCAM-1 by, and binding of MEF2C to, SOX18 are indeed defective in *RaOp* heterozygous mice, reaffirming the role of SOX18 in a regulative pathway governing the early development of ECs in the vasculature (9,18).

Other targets of SOX18 remain to be identified, and many candidates exist. For example, the Tie2 receptor, required for angiopoietin (Ang)-induced signaling, is expressed in ECs subsequent to *Sox18* expression. SOX binding sequences exist in a region of the *Tie2* promoter shown to be critical for endothelial expression. It also is of interest to note that the putative SOX site in the *Tie2* promoter is adjacent to an octameric binding sequence motif. OCT transcription factors previously have been demonstrated to interact with SOX factors to enhance transcription in other cell types (24).

### SOX18 FUNCTION AND ENDOTHELIAL CELL PHENOTYPE

The cell type specificity, timing, and transient nature of *Sox18* expression suggests that it is involved in the initial specification

of ECs. However, endothelium is clearly able to form in *RaOp* mutant mouse embryos but appears to generate vessels with impaired integrity, causing edema and hemorrhage. Further, the only transcriptional target so far identified for SOX18 is one that is implicated in regulating vascular integrity. What, then, is the true cellular function of SOX18?

Evidence from other model systems in which similar defects are observed to those seen in *Ra* mice offers clues to possible targets of, or proteins interacting with, SOX18. One important feature to note when using a candidate gene approach to identify partner proteins of SOX18 is to observe whether they are expressed at the same time in the same cells. Mice with disrupted Tie2/Ang1 signaling have phenotypes similar to *RaOp* homozygotes. Mice with disrupted Tie2 signaling initially develop a normal vasculature, but the embryos die at between E9.5 and E12.5 due to malformations of microvessel structure (25). *Tie2* is coexpressed with, and a potential target of, SOX18 in ECs and the similarities between the mutant phenotypes suggest that they may interact in the same pathway. Ultrastructural analysis of *Tie2*- and *Ang1*-knockout mice suggests that initially ECs in these mice form normal networks but that angiogenic sprouting is defective, contributing to vessel stenosis, and embryonic lethality. Interestingly, and entirely hypothetically, this may be a case where two different but important vascular signaling pathways may intersect. Earlier we suggested that the VEGF/FLK-1 pathway was upstream of SOX18, therefore the possibility exists that in the absence of SOX18 the Tie2/Ang1 pathway will not be activated, contributing further to defective EC differentiation.

Comparisons between *RaOp* homozygotes and these knockout mice show distinct phenotypic similarities, but it remains to be seen if ECs in the *RaOp* homozygotes are affected similarly to those in *Tie2*- and *Ang1*-knockout mice. However, the ultrastructural defects observed in *Tie2*-knockout mice, such as the rounding of the ECs and capillary stenosis, may in turn explain some of the gross defects observed in these as well as the *RaOp* homozygotes. If ECs do not differentiate, migrate, or proliferate normally at these early stages, then they may not interact correctly with each other or the extracellular matrix later on, preventing stabilization and maturation of the vasculature. In addition, it is known that in *PDGF*-knockout mice, a lack of recruitment of pericytes to the vasculature can lead to microaneurysms and subsequent edema similar to that observed in the *RaOp* homozygotes (26). Therefore, it also may be the case that ECs from *RaOp* homozygotes do not differentiate correctly and are unable to recruit the correct companion cells, contributing to the observed hemorrhagic phenotype.

It also may be true that SOX18 affects multiple steps in the endothelial differentiation pathway. It will be informative to study in detail the extent and patterning of the vasculature in *Ra* mutant mice, measure vascular integrity in dye leakage experiments, and examine the vasculature in *Ra* mutants at the ultrastructural level, complementing these in vivo observations with in vitro studies of the effects of SOX18 on EC migration, proliferation, and ability to generate tubes.

## SOX18 AND ENDOTHELIAL DISEASE

Point mutations in SOX18 have been found to underlie the human disease hypotrichosis–lymphedema–telangiectasia (HLT) (20). The most severe, dominant forms of this disease closely resemble the phenotype of the *RaOp* mouse mutant and are caused by similar molecular lesions that would be expected to act in a dominant-negative manner. Curiously, other disease mutations can occur in the HMG-box region of SOX18, and are likely to result in a loss of function, consistent with their recessive mode of inheritance. The discrepancy between the loss-of-function phenotype in mice (mild coat color effects) and in humans (HLT) points to molecular differences in the involvement of *Sox18* and/or other group F *Sox* genes between the two species or differential dosage requirements between the two species. The spectrum of phenotypes in HLT further suggests that, in addition to its role in angiogenesis, SOX18 plays an important role in the development and/or maintenance of lymphatic vessels in humans.

The transient expression of *Sox18* during embryogenesis is not only a developmental phenomenon required for the initial formation of a vascular network in the embryo; *Sox18* expression also is observed transiently in adults, but only during de novo vessel formation, such as occurs during excisional wound healing (27).

Pathological neovessel formation also occurs during tumor growth. Evidence abounds that tumor growth is dependent on neovessel formation and that the molecular pathways employed by tumor cells to generate a de novo vascular network are a recapitulation of the developmental process. In 1994, a dominant-negative version of the *Flk-1* receptor was expressed in mice in which aggressive subcutaneous tumors were induced. This resulted in mice that grew tumors, but at a greatly reduced rate compared to their wild-type litter mates (28). As *Flk-1* is expressed in ECs, this work suggested that targeting the VEGF-FLK-1 pathway in EC function could be effective as an antiangiogenic tumor therapy. However, it has taken 10 years for this work to advance to successful Phase III clinical trials of a humanized monoclonal antibody, bevacizumab, directed at VEGF (29).

One of the problems with targeting ECs in antiangiogenic strategies is their physiological importance maintaining overall host homeostasis; many antiangiogenic therapies may inadvertently target existing blood vessels in the body. The specific expression pattern of *Sox18* during neovessel formation suggests that it forms the basis of a novel strategy for targeting only nascent endothelium to inhibit tumor angiogenesis. As *Sox18* expression is transient and only on in ECs participating in new growth, then targeting SOX18 function would only affect the subset of ECs participating in tumor neoangiogenesis.

Overall, the transcriptional regulation of ECs is still not well understood; however, increasing efforts from many different groups have begun to shed light on this subject. What is clear is that SOX18 plays an important role in the initial differentiation of ECs and that defects in this role compromise embryo development and survival. As work in this field

advances, exciting opportunities are arising to translate knowledge of EC development during embryogenesis into treatments for patients with diseases in which pathological angiogenesis is a marker of poor prognosis.

### KEY POINTS

- The transient function of SOX18 during EC differentiation in the embryo is vital for the formation of a fully functional vasculature.
- *Sox18* is one of a group of *Sox* genes involved in endothelial biology.
- Loss of function of SOX18 may be masked (in mice) by the action of the other group F *Sox* genes, *Sox7*, and *Sox17*.
- Dominant-negative mutations in SOX18 result in vascular and lymphatic dysfunction in mice and humans. In these cases, the mutant SOX18 protein is thought to interfere with the functions of wild-type SOX18 protein, and with SOX7 and SOX17 proteins.
- At least one target of SOX18, VCAM-1, is involved in determining vascular integrity.
- The activity of SOX18 is important also for adult neoangiogenesis.

### Future Goals

- To identify further downstream targets of SOX18
- To study in detail the vasculature, EC phenotype, and lymphatic integrity in the *RaOp* mouse model
- To study the effects of SOX18 gain- and loss-of-function on EC migration, proliferation, and tubulogenesis in vitro
- To explore SOX18 as a novel target for pro- or antiangiogenic therapies

### ACKNOWLEDGMENTS

We are grateful to Jo Bowles and Alisa Poh for critical reading of the manuscript. ## Id Proteins and Angiogenesis

Robert Benezra and Erik Henke

*Memorial Sloan-Kettering, Cancer Center, New York City, New York*

The Id proteins were the first identified naturally occurring dominant negative antagonists of a transcription factor class. They have been shown to control a wide range of cell fate decisions in embryonic and adult development in organisms ranging from fly to man (1,2). The four related members of the family (called Id1–4) all contain a helix-loop-helix (HLH) dimerization motif. The 40- to 50-amino acid HLH domain is found in many transcription factors, including the myc family of cellular oncogenes, MyoD, other E-box (CANNTG)-binding proteins, and hypoxia inducible factor (HIF)-1 $\alpha$ . Most of these HLH-containing transcription factors have an extra basic region (hence the term *bHLH proteins*) that specifically binds to DNA. In contrast, the Id proteins lack the basic region. Consequently, Id proteins bind to and sequester bHLH proteins, preventing their homo- or heterodimerization with other bHLH factors and their association with DNA. Principal targets of the Id proteins are the ubiquitously expressed bHLH E-proteins, which cooperate with tissue-restricted bHLH proteins to regulate gene expression (1,3,4). Thus Id–E-protein interactions provide a unifying mechanism for controlling cell-type-specific gene expression in multiple cell lineages.

Loss-of-function mutations in Id1 and Id3 have been shown to lead to embryonic and adult angiogenic defects, suggesting an important role for these proteins in blood vessel formation (5). Based on a consideration of underlying transcriptional mechanisms, it seems likely that such defects are related to the liberation of otherwise Id-sequestered E-proteins and the inappropriate activation of genes under the control of bHLH transcription factors. Although the identification of E-protein partners in endothelial cells (ECs) remains elusive, certain downstream consequences of Id loss are gradually coming to light. In addition, the biological consequences of Id loss on EC mobilization and maturation, as well as the consequences of Id loss on murine models of carcinogenesis, are shedding important new insights into basic and possibly translationally meaningful questions. This chapter reviews these recent advances.

### ANGIOGENESIS DEFECTS AS A RESULT OF ID LOSS

Mice that are null for *Id1* or *Id3* develop normally and display only mild phenotypic alterations. *Id1*-null mice show some defects in T-cell migration, and *Id3*-null mice have defective B-cell proliferation (Table 97-1). However, mice in which both copies of *Id1* and *Id3* are disrupted die in utero at embryonic day (E)13.5 with a characteristic hemorrhage in the forebrain. Grossly dilated vessels are apparent in the ganglionic eminence at E11.5, but by E12.5 these vessels appear to collapse upon themselves to form an aggregate of endothelium (5). Interestingly, a similar, albeit less severe phenotype than that of the *Id1/3*-double knockouts is observed in mice lacking integrin  $\alpha_v$ , an integrin implicated in angiogenic processes (6). In the case of Id loss of function, it seems reasonable to hypothesize that the specific localization of the vascular defect to the brain is due to compensation by Id2 in vessels outside the brain (7). Indeed, animals with loss-of-function mutations in Id1, -2, and -3 (*Id1*<sup>-/-</sup> *Id2*<sup>+/-</sup> *Id3*<sup>-/-</sup>) develop more widespread hemorrhage that is not restricted to the brain. In addition, animals that lack both *Id2* copies and both copies of either *Id1* or *Id3* (*Id1*<sup>-/-</sup> *Id2*<sup>-/-</sup> and *Id2*<sup>-/-</sup> *Id3*<sup>-/-</sup>) die at E13.5 from cardiac malformations without showing forebrain hemorrhage (8). Why the ganglionic eminence is so susceptible to the vascular perturbation in the *Id*-knockout and integrin  $\alpha_v$ -knockout mice is not understood, but the findings provide a striking example of site-specific vasculopathy (Table 97-1).

The embryonic vascular defect in *Id1/3*-double knockout mice raised the possibility that these proteins are important for postnatal angiogenesis. In contrast to the double knockout animals, mice that are missing one, two, or three copies of the *Id1/3* pair are viable, and the expected number of animals is born. When transplanted with tumor allografts, these animals demonstrate significant reductions in tumor microvessel density and loss of integrin  $\alpha_v\beta_3$  and matrix metalloproteinase (MMP)-2 on the surface of the remaining vessels (37). These changes are associated with a dramatic decrease in the growth

**Table 97-1: Id Expression Pattern and Knockout Phenotypes**

<i>Gene</i>	<i>Embryonic Expression (Refs.)</i>	<i>Adult Expression and Expression in Tumors (Refs.)</i>	<i>Angiogenic Expression (Refs.)</i>	<i>Knockout Phenotype (Refs.)</i>
<i>Id1</i>	Roofplate of neuronal tube, later in dividing neuroblasts Gut (mesenchyme), endocardiac cushion, lung, kidney, tooth, glandular structures, heart (9)	Not expressed in normal tissue, some evidence of expression in tumor cells – breast (10,11), colon carcinoma (12), thyroid cancer (13)	Most tumor endothelium; poorly differentiated, but not well differentiated, prostate tumors (14–16)	Normal development, defects in T-cell migration (17,18), animals smaller than wild-type
<i>Id2</i>	Roofplate of neuronal tube, later in maturing neurons Gut (endothelium), endocardiac cushion lung, kidney, tooth, glandular structures, heart (9)	Purkinje cells (cerebellum) (5,19), overexpressed in colon adenocarcinoma (12) and neuroblastoma (20)	No evidence for expression in tumor endothelium, expression in neuroectodermal tumors leads to upregulation of VEGF (21)	25% embryonic lethality, lack of lymph nodes, Peyer's patches. Reduced killer, Langerhans, and splenic cells (22,23); hydronephrosis (24) and enteric neoplastic lesions (25), immature mammary glands, lactation defects (26)
<i>Id3</i>	Roof and floorplate of neuronal tube, later in dividing neuroblasts, olfactory system, branchial arches, limbs, sclerotome, endocardiac cushion, outer lining of the gut (mesenchyme), lung, retina, kidneys, teeth, heart (9)	Not expressed in normal tissue; evidence of expression in colon adenocarcinomas (12)	Most tumor endothelium (14–16)	Normal development, defects in B-cell proliferation, thymocyte maturation, and humoral immunity; animals smaller than wild-type (27,28)
<i>Id4</i>	Absent in early neurogenesis, expressed in maturing neurons, ventral epithelium of developing stomach (9) Oligodendrocyte precursors (29)	Purkinje cells (cerebellum), testis, spleen, kidney, BM. Overexpressed in glioblastoma, oligodendrogliomas (30) and bladder cancer (31) Inactivated in highly metastatic breast tumors (32), colorectal carcinoma (33), and gastric adenocarcinoma (34) Potential tumor suppressor in leukemia (35)	No evidence for expression in tumor endothelium	Premature differentiation, neural proliferation defects, defective differentiation in oligodendrocyte lineage, malformation of different brain regions (36)

*Id1*<sup>-/-</sup>/*Id3*<sup>-/-</sup>, forebrain hemorrhage, cardiac development defective, embryonic lethal (E13.5).

*Id1*<sup>-/-</sup>/*Id2*<sup>-/-</sup> cardiac malformation, embryonic lethal (E13.5).

*Id2*<sup>-/-</sup>/*Id3*<sup>-/-</sup> cardiac malformation, embryonic lethal (E13.5).

*Id1*<sup>-/-</sup>/*Id2*<sup>-/-</sup>/*Id3*<sup>-/-</sup>, widespread hemorrhage, cardiac development defective, embryonic lethal (E11.5).

of some tumor allografts (e.g., B6RV2 lymphoma), but surprisingly others (e.g., Lewis lung carcinoma) continue to grow, albeit more slowly, despite severe hypoxic stress, internal hemorrhage, and necrosis. Depending on the allograft model, a dose effect of Id loss also is observed. Whereas in the case of B6RV2 grafts deletion of one copy (*Id1*<sup>+/-</sup>/*Id3*<sup>+/+</sup>) is sufficient to block tumor growth completely, Lewis lung carcinoma and murine breast carcinoma (B-CA) transplants show a stepwise stronger reduction in growth rate by subsequent deletion of *Id* alleles. In the case of Lewis lung carcinoma, despite primary tumor growth in the absence of the Ids, metastatic growth

to the lung was severely perturbed (5). So, in this case at least, allograft growth in the face of reduced Id dosages and hypoxic stress was very much different from that observed at metastatic sites. Whether this is due to a global sensitivity of metastatic lesions to the type of angiogenic stress imposed by Id loss or other antiangiogenic treatment warrants further analysis.

Transplanted tumors may behave very differently from more physiologically relevant models of cancer with respect to their response to antiangiogenic intervention. A critical next step in the analysis of Id proteins as potential therapeutic

targets was to determine the effect of Id loss on the vascularization and growth of spontaneous murine tumors. Three informative model systems have been employed to date and each, remarkably, provides unique insights into the effects of angiogenic stress on tumor growth and progression. The model systems include (a) mice that develop breast tumors initiated by the overexpression of the *her2/neu* oncogene (MMTV-*her2/neu*); (b) mice missing one copy of the *phosphatase and tensin homolog deleted from chromosome 10* (*PTEN*) tumor suppressor (*PTEN*<sup>+/-</sup>), which develop multiple neoplasias; and (c) mice that develop prostate tumors as a result of overexpression of the SV40 T-antigen oncoprotein in the prostate epithelium (Tramp) (14–16). Each of these strains was crossed with the *Id*-knockout mice and assayed for changes in tumor phenotype.

In contrast to the allograft models in which *Id*<sup>+/+</sup> tumor cells are transplanted into *Id*-null recipients, the spontaneous tumors will carry the same *Id* profile as the mouse bearing the tumor. Therefore, it is important to consider the potential confounding effects of *Id* loss in the tumor cells themselves. Careful analyses of spontaneous tumors in *Id*<sup>+/+</sup> mice failed to reveal evidence for *Id1/3* expression in tumor cells in any of the three tumor models. In contrast, prominent *Id1* expression was detected in the nuclei of the ECs infiltrating those tumors (14–16). These findings strongly suggest that any effect of *Id* loss is likely to be a reflection of perturbations of the vasculature.

In the case of MMTV-*her2/neu* animals bearing breast tumors, the loss of *Id* resulted in a dramatic change in the morphology of the tumors. Tumors in animals with intact *Id1* and *Id3* genes presented as dense cellular masses with little necrosis. However, when one, two, or three copies of the *Id1/3* pair were missing, a dramatic increase in cystification was observed. Fluid-filled cavities surrounded by a viable rim of cells at the periphery frequently were observed. These cells at the periphery may have “escaped” the hypoxic stress caused by the vascular defects imposed by *Id* loss. This hypoxic stress is manifested by the increase in HIF-1 $\alpha$  protein present during the early stages of cyst growth. However, the volumetric growth of the cysts was equal to or greater than the dense lesions observed in the *Id* wild-type background. In an attempt to target the viable rim of cells at the periphery of the cysts, animals were treated with the Hsp90 antagonist 17-AAG. Hsp90 has been shown to act as chaperone for both *her2/neu* (the oncogene driving the growth of the tumor) and HIF-1 $\alpha$ , which may be driving the “escape” from hypoxic stress by inducing very high vascular endothelial growth factor (VEGF) expression and recruitment of vessels to the viable rim. Whereas treatment with 17-AAG in the *Id* wild-type background led only to a modest suppression of growth, remarkably, *Id* loss in combination with 17-AAG administration led to the first reported complete suppression of growth of these breast lesions. Withdrawal of 17-AAG after 8 weeks led to regrowth of the tumors (despite the lesions being extremely small during treatment), making this an excellent model for further analysis of tumor dormancy (14).

Loss of one copy of *PTEN* leads to an accumulation of phosphatidyl-inositol-triphosphate and activation of the growth-promoting Akt kinase. Mice harboring this mutation develop a spectrum of tumors and hyperplastic lesions, such as lymph node hyperplasias, uterine carcinomas, prostate intraepithelial neoplasias (PIN), and pheochromocytomas (38). In situ hybridization and immunohistochemistry showed that *Id1* and *Id3* expression was confined to the endothelium of lymph hyperplastic lesions and uterine carcinomas, whereas the vessels of PINs, pheochromocytomas, and non-neoplastic tissue stained negative. *Id1* and *Id3* were either not expressed at all or only weakly expressed in the tumor cells. *Id*-knockout mice were crossed into the *PTEN*<sup>+/-</sup> background, and the effect on the vascularization of multiple tumors was examined. In all tumors in which *Id* was expressed in the endothelium, *Id* loss (*Id1*<sup>-/-</sup> *Id3*<sup>+/-</sup>) led to a loss of vascular integrity. The consequences of this, however, varied dramatically from lesion to lesion. The lymphoid hyperplasias, for example, showed pinpoint hemorrhages resulting from *Id* loss, but lesions grew at normal rates. Intrauterine carcinomas, on the other hand, showed such extensive hemorrhage and necrosis that most of the disease was eliminated by *Id* loss (16). Thus, this model clearly demonstrates that the effects of *Id* loss on tumor biology depend on tumor type, a result which may pertain to other antiangiogenic interventions.

Finally, loss of *Id* function in the Tramp model of prostate cancer has yielded another novel insight into the effects of antiangiogenic stress on tumor growth and progression. Studies in the Tramp model prior to crossing with *Id*-null mice revealed *Id1* and *Id3* expression in the nuclei of those ECs infiltrating poorly differentiated, but not well differentiated, prostate tumors – a result corroborated in human specimens. These data suggest that the expression of *Id* in tumor-associated ECs is not only dependent on the type of tumor, as shown in the *PTEN* model, but also on tumor grade. (Furthermore, as described later, only those ECs infiltrating the poorly differentiated tumors are bone marrow-derived.) As predicted from this analysis, when the *Id* loss-of-function mutations (*Id1*<sup>-/-</sup> *Id3*<sup>+/-</sup>) were introduced into the Tramp background, only the poorly differentiated tumors displayed a dramatic increase in hemorrhage and necrosis (15). As in the case of the *her2/neu* cross, this disruption of vascular integrity was not followed by a dramatic suppression of tumor growth, suggesting again that combination therapy aimed at targeting hypoxia “escapees” will ultimately be the most effective therapeutic antiangiogenic strategy in human cancer.

## ID PROTEINS AND PROGENITOR CELL MOBILIZATION

The inhibition of allograft tumor growth in the *Id*-knockout model allowed for a rapid determination of the functional role of bone marrow-derived endothelial progenitor cells (EPCs) in tumor vascularization. Previous studies have shown that EPCs may contribute to neoangiogenesis (39–41).

Interestingly, *Id1*<sup>+/-</sup>*Id3*<sup>-/-</sup> animals were first shown to have a defect in their ability to mobilize a CD11b<sup>-</sup>/VEGF receptor (VEGFR2)<sup>+</sup> EPC population in response to VEGF administration (42). In these experiments, it also was shown that VEGF administration leads to an upregulation of Id1 in the bone marrow. Together with the observation that Id knock-down attenuates the growth of some tumors, these data raised the interesting possibility that Id-mediated tumor growth depends on mobilization and subsequent uptake of EPCs in tumor vasculature. To test this hypothesis, lethally irradiated *Id1*<sup>+/-</sup>*Id3*<sup>-/-</sup> and *Id*-WT animals were transplanted with bone marrow from *Id*-WT *Rosa26-LacZ*<sup>(+)</sup> mice. Four weeks after bone marrow reconstitution, the transplant recipients were injected subdermally with B6RV2 cells. In the *Id1*<sup>+/-</sup>*Id3*<sup>-/-</sup> mice, bone marrow transplantation reversed the attenuating effect of the *Id*-null background on tumor growth and vasculature (42). Indeed, nearly 100% of tumor vessels after 2 days were LacZ<sup>+</sup>, indicating their derivation from the donor bone marrow. Importantly, the percentage of LacZ<sup>+</sup> vessels declined over time, suggesting the replacement of the endothelium with host-derived ECs. The utilization of the bone marrow-derived cells was not simply due to the “freezing” of the peripheral vasculature in the *Id*-null animals, because bone marrow from *Rosa26-LacZ*<sup>(+)</sup> mice transplanted into irradiated wild-type animals produced similar results (42).

But is the same phenomenon observed in spontaneous tumors which, we have argued, are much more physiologically relevant with respect to angiogenesis? Here, as in the tumor growth analysis, significant differences are observed. In the *PTEN*<sup>+/-</sup> tumor model, the utilization of ROSA26-LacZ<sup>+</sup> bone marrow-derived progenitors is clearly dependent on the tumor type: Lesions in the lymph nodes are never observed to contain bone marrow-derived ECs; however, in intrauterine carcinomas, between 10% and 20% of the ECs incorporated into the vessels are donor-derived. Importantly, even this relatively low level of bone marrow progenitor incorporation was shown to be of functional significance because, after transplanting the *Id*-null mice with wild-type ROSA26-LacZ<sup>+</sup> bone marrow, the hemorrhage and necrosis observed in the uterine tumors in the *PTEN*<sup>+/-</sup> background was significantly reduced (16). The low percentage of progenitor incorporation, which also has been observed in human tumors marked with bone marrow from gender-mismatched transplants (43), may reflect replacement of progenitors with mature endothelium from the periphery (see next section). In the Tramp prostate model, incorporation of bone marrow-derived progenitor cells was shown to correlate with tumor grade; high-grade (poorly differentiated) tumors recruited Id-positive bone marrow-derived progenitors to about 15% of the vessels, whereas low-grade (well-differentiated) tumors utilized Id-negative host-derived endothelium (15). Here again, even low incorporation of EPCs had functional relevance, because wild-type (but not Id mutant) bone marrow significantly reduced the hemorrhage observed in the prostate tumors in the *Id*-knockout background, but had – as expected – no influence on tumor

progression. In addition, Id mutant bone marrow increased the hemorrhage observed in the prostate tumors when transplanted into wild-type animals, suggesting that these cells are both necessary and sufficient to renormalize the vasculature that results from Id loss (15). Taken together, these results and recent, unpublished data obtained from treatment experiments using VEGF, support a model in which upregulation of Id in the bone marrow in response to VEGF leads to the mobilization of EPCs, which incorporate into a functionally significant subset of vessels in some tumor types (Figure 97.1). Whether the utilization and presence of these EPCs in the tumor bed varies significantly with time (as in the allografts) remains to be determined.

Recently, several other observations have provided support for the EPC hypothesis. First, Kerbel and coworkers have shown that EPC concentrations in peripheral blood can predict the angiogenic potential of various mouse strains (44). In humans, gender-mismatched bone marrow transplants yielded approximately 2% donor ECs in the skin and gut (43,45).

Several studies recently have called into question the importance of bone marrow-derived progenitor cells for the formation of tumor vessels. First, Naldini and coworkers, by performing careful confocal microscopy studies with mice transplanted with Tie2-driven green fluorescent protein (GFP)-marked bone marrow, showed quite convincingly that only rare platelet-endothelial cell adhesion molecule (PECAM)-1/CD31<sup>+</sup> ECs are GFP-positive and that the contribution from the marrow is more pronounced in the hematopoietic compartment (46). This latter population of cells may contribute to angiogenesis without becoming an integral part of the vessel. In a separate study, Begley and colleagues marked the endothelium by introducing both a LacZ Cre-lox-activatable allele and a tamoxifen-inducible Cre recombinase driven by the SCL-promoter/enhancer (47). In this way, only upon tamoxifen stimulation would SCL-expressing cells be marked with  $\beta$ -galactosidase. These investigators found that, although these animals did not display  $\beta$ -galactosidase-positive cells in the bone marrow upon tamoxifen treatment (presumably because SCL is not expressed until later in the development of the lineages), they did develop  $\beta$ -galactosidase-positive vessels in the tumor (47). They reasoned that, if these cells were derived from bone marrow-derived progenitors, then transplantation of wild-type animals with bone marrow from the transgenics should show  $\beta$ -galactosidase-positive vessels upon tamoxifen treatment and tumor challenge. None, however, were observed.

How can these results be reconciled with the earlier mentioned data that showed a clear involvement of bone marrow-derived ECs in tumor angiogenesis? We would propose that all of these findings are concordant if we assume that an early EPC migrates from the bone marrow to the site of a tumor or ischemic injury and is required for the establishment of the very early vascular network. These cells, however, gradually become replaced with more mature endothelium from the periphery (Figure 97.2). This model predicts that in the

Figure 97.1. Role of Id proteins in peripheral and bone marrow-derived ECs. In the periphery, Ids are required for maintaining the expression of FGFR1, MMP-2, laminin 5, and integrin  $\alpha6\beta4$ , which form a promigratory network. This network depends on the engagement of integrin  $\alpha6\beta4$  with an MMP-2 cleavage product of laminin 5. In the bone marrow, Ids are required for the mobilization and proliferation of EPCs, which enter the blood stream as circulating endothelial progenitors (CEPs) and migrate to the site of the tumor. Id1 and Id3 in the bone marrow are upregulated in response to VEGF, and it is speculated that this may lead to the upregulation of the chemokine receptor CXCR4. These cells may then be competent to engage stromal-derived factor (SDF)-1 from the tumor (or tumor-associated stromal cells), which facilitates their mobilization.

$\beta$ -galactosidase-marked bone marrow transplant experiments of Lyden and colleagues (42), there would be a gradual drift of tumor endothelium from LacZ<sup>+</sup> to LacZ<sup>-</sup>, and this trend was indeed originally reported. The Begley experiment might be interpreted as having failed to mark the early progenitors

that initially migrate to the site of the tumor because these cells do not develop into mature endothelium, but rather are replaced by it from the unmarked periphery. Finally, Naldini and coworkers might have found a higher percentage of GFP-positive progenitors if an endothelial-specific marker earlier

Figure 97.2. Temporal changes in bone marrow-derived contribution to the tumor vasculature. A speculative scheme is proposed whereby the early vascular network in a tumor is primarily composed of circulating endothelial progenitors (CEPs), which fuse to form blood vessels. These cells in these vessels are gradually replaced with more mature endothelium from the periphery.

than CD31 was utilized in the analysis. Although this interpretation is speculative at this point, it nonetheless provides a model compatible with most of the data published and a readily testable hypothesis.

### ID1 PROTEINS AND ENDOTHELIAL CELL BIOLOGY

Because the Id proteins are themselves regulators of transcription, it seems reasonable to assume that the angiogenesis phenotype of Id loss is mediated by changes in the transcription of key mediators of EC migration and vessel assembly. Lymph hyperplastic lesions that develop in the *PTEN*<sup>+/-</sup> animals have a severely perturbed vascular network in the *Id1*-null background, and changes in Id-dependent gene expression profiles in the tumor endothelium were determined (16,48). Four key players in an integrin signaling pathway were all shown to be downregulated in response to Id1 loss in vivo: integrins  $\alpha 6$  and  $\beta 4$ , fibroblast growth factor receptor 1 (FGFR1), MMP-2, and laminin 5 (16). When FGFR1 engages FGF2, it leads to an upregulation and enhanced secretion of MMP-2 in some cell types (49), as well as upregulation of integrins  $\alpha 6$  and  $\beta 4$  (48). MMP-2, in turn, cleaves laminin 5 to yield a promigratory proteolytic fragment that engages integrin  $\alpha 6\beta 4$  (50). Downregulation of all four components is predicted to short-circuit this pathway and prevent proper EC migration. Inhibition of these signaling molecules, in Matrigel plug assays, was shown to phenocopy the loss of Id, demonstrating a functional significance of the array findings (16). Importantly, this model has received support from an independent genetic analysis, in which it was shown that hypomorphic mutations in integrin  $\beta 4$  also lead to impaired angiogenesis (51). It is of note that the lesions from which the Id-deficient ECs were derived do not recruit bone marrow-derived EPCs. It will be of interest, therefore, to determine if the same promigratory pathway is affected in the bone marrow to explain the defect in EPC mobilization observed in the *Id*-knockout animals.

The antiangiogenic protein thrombospondin (TSP)-1 has been reported to be upregulated in response to Id1 loss in murine embryonic fibroblasts, and suggests another mechanism whereby Id1 loss in the vasculature might lead to angiogenesis inhibition (52). No upregulation of TSP-1 in the vasculature of spontaneous tumors or xenografts in *Id1*-null mice has been reported, however, making such a mechanism unlikely. A genetic analysis of the *TSP-1*-knockout in the *Id1*-knockout background could be performed because both strains are viable and, if the mechanism is playing any role in tumor angiogenesis, a reversal of the *Id*-null phenotype should be observed in the *TSP-1/Id1*-double null mice.

The chemokine stromal derived factor (SDF)-1 has been shown to be upregulated by ECs in response to ischemia, which leads to the mobilization of EPCs. If the observation that the SDF-1 receptor, CXCR4, is regulated by Id1 in T cells (17) also applies to EPCs in the bone marrow, it would suggest that VEGF induction of Id1 may in turn lead to the compe-

tence of EPCs to receive an SDF1 signal from the periphery. A careful analysis of CXCR4 expression in the EPCs is clearly an important next step in providing support for this intriguing possibility.

But what controls Id expression in the neovasculature? It has been shown that VEGF in the circulation leads to a dramatic upregulation of Id1 and Id3 in the bone marrow, presumably in the progenitor cells that become mobilized (42). Activation of the mitogen-activated protein kinase (MAPK) pathway by VEGF receptor stimulation could impinge on the *Id1/3* promoters at the Egr1 site, as has been demonstrated in other cell types (53,54). Validation of this idea in ECs by transfecting appropriate *Id* promoter-reporters should be established, and other transcription factors mediating the response could be identified. Integrin engagement also has been reported to impinge on the *Id1* promoter, independent of growth factor stimulation, and, here again, analysis in ECs needs to be performed to confirm this idea. The proangiogenic statin, fluvostatin, but not VEGF also has been reported to upregulate Id1 in human dermal microvascular ECs (HDMECs) in culture (55), although VEGF does apparently upregulate Id1 expression in human umbilical vein ECs (HUVECs) (56), suggesting differential Id regulation depending on the endothelial subtype.

Another signaling cascade that impinges on the Id protein in EC cells is the transforming growth factor (TGF)- $\beta$  pathway. Both bone morphogenic protein (BMP) 2 and 6 (through the BMP receptor) and low concentrations of TGF- $\beta$  (through type I receptor activin-like kinase [ALK]-5) lead to an upregulation of Id1 expression via Smad1 and 5 and enhanced proliferation and migration of ECs in culture (57–59). BMP6 and TGF- $\beta$ -induced stimulation of migration is inhibited by antisense Id1 treatments, demonstrating the requirement for Ids in these responses (57,58). Ectopic expression of Id1 in ECs in culture enhances cell migration and tube formation (57), demonstrating the sufficiency of Id1 expression for these effects. High concentrations of TGF- $\beta$  (through the type I receptor ALK1), on the other hand, lead to an inhibition of cell proliferation and migration, the downregulation of Id1, and upregulation of the antiangiogenic plasminogen activator inhibitor (PAI)-1 (58). An important in vivo correlate of these findings is the observation that mice lacking the BMP-specific Smad1 or -5 die at midgestation with enlarged blood vessels (57,60,61) similar to those observed in the *Id1/3*-double knockout embryos. Together then, these studies indicate that the development and maturation of ECs in mice is at least in part mediated by the TGF- $\beta$ /Id pathway connections.

### CONCLUSION

The prevailing evidence suggests that Id proteins, and/or their upstream or downstream effectors, are potential targets for novel anticancer drug design. In particular, genetic manipulation of Id levels has validated Id as an important target in several spontaneous murine tumors that are physiologically

much closer to human disease than transplanted tumors. The fact that the Ids are expressed at low levels in most normal adult tissue, but are reactivated in the tumor vasculature (and possibly in some cancers in the tumor cells themselves), suggests that targeted therapy will be associated with low toxicity. The advantage of targeting Id itself is that the transcription factor is selectively expressed in tumors. Moreover, the genetic mouse models indicate that partial loss of Id function is sufficient to inhibit tumor growth. The disadvantage is the challenge inherent in inhibiting nuclear proteins. One approach is to inhibit interactions between Id and other proteins. Over the past few years, progress has been made in targeting protein–protein interactions using small molecules. In particular, agents effective at inhibiting the Myc–Max interaction (62) or  $\beta$ -catenin (63) have been reported. Other approaches include the use of inhibitors targeted at mediators of Id expression or downstream effectors of Id. The unique phenotype of Id loss in these tumor models, as well as the role of the EPC as a surrogate marker, promise to facilitate drug screening.

The advantage of targeting upstream and/or downstream mediators of the Id pathway is their relative accessibility and amenability to downregulation. However, these intermediates are not in and of themselves specific to the tumor. For example, whereas MMP-2 and integrin  $\alpha 6\beta 4$  have been identified as Id target genes, they are also expressed in Id-negative cell types, presumably through the influence of other transcriptional networks. Thus, by targeting one or another of these downstream genes, tumor specificity would be lost.

In summary, novel drug design to inhibit the activity of the Id proteins, even acknowledging the difficulty of the challenge, is a goal worthy of pursuit for the management of human cancer.

#### KEY POINTS

- Id proteins are negative regulators of transcription and are essential for the mobilization, migration, and proliferation of ECs to and within a tumor.
- Loss of Id in tumor ECs leads to the inactivation of key elements of a promigratory pathway involving the cleavage of laminin 5 and engagement of integrin  $\alpha 6\beta 4$ , and may account for the vascular phenotype observed in Id-knockout animals.
- The effects of Id loss and antiangiogenic stress depend on the tumor type and tumor grade. Identifying and characterizing the Id-dependent events in the bone marrow during tumor growth is an important next step.
- Targeting Id may be an important antiangiogenic therapeutic strategy, because it is not expressed in normal ECs and most normal adult tissue.

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

A major theme, or organizing principle, of this book is the analogy of the endothelial cell (EC) to an input–output device. Input arises from the extracellular environment and includes numerous biochemical and biomechanical forces. These environmental cues trigger signaling in ECs through receptor-dependent and receptor-independent mechanisms. Intracellular signaling then results in post-transcriptional and/or transcriptional changes, ultimately leading to an alteration in output, or phenotype. Other sections in this book cover topics related to input and signaling. The chapters in the current section focus on the output side of the equation. An important qualification when discussing output is the scale of investigation that is being considered. For example, at the level of the single cell, ECs may undergo a change in calcium flux, cell shape, protein or mRNA expression, migration, proliferation, and/or apoptosis. Monolayers of ECs express barrier properties and may be assayed for adhesion and transmigration of leukocytes. Other (emergent) properties of the endothelium are only appreciated at the level of the whole blood vessel, organ, or organism. These include endothelial regulation of vasomotor tone and formation of new blood vessels.

In this section, we begin with novel *in vivo* proteomic approaches that underscore the remarkable heterogeneity of EC phenotypes at the level of the cell surface (Chapters 99 and 100). The next series of chapters focus on the role of the endothelium in hemostasis, beginning with an overview of coagulation (Chapter 101), followed by detailed discussions of specific procoagulant and anticoagulant molecules (Chapters 102–109). Another important function of the endothelium is the regulation of vasomotor tone. We have not included an overview chapter related to this topic. Rather, we focus on the pivotal role of nitric oxide (NO) in EC biology (Chapter 110). For thematic purposes, this chapter is followed by one on heme oxygenase and carbon monoxide (CO) (Chapter 111). NO and CO are produced by *and* signal in ECs. Another example

of an autocrine factor that serves as both input and output are the prostanoids (Chapter 112). As reviewed in Chapter 113, the endothelium plays an important role in mediating permeability. The role for endothelium in governing leukocyte adhesion and transmigration is discussed in Chapter 114, and the component parts underlying this process are detailed in Chapters 115–118. Proliferation and migration of ECs are critical aspects of angiogenesis and are covered in a later section on health and disease. ECs display a balance between pro-survival and pro-apoptotic factors (Chapter 119). Finally, there is increasing evidence for the role of the endothelium in antigen presentation, as reviewed in Chapter 120.

The chapters in the current section offer a representative spectrum of endothelial outputs. Many of these may be considered core (or unifying) properties of the endothelium – in other words, phenotypes that are common to more than one vascular bed. For example, every EC in the body contributes to hemostatic balance (albeit through site-specific formulas of procoagulants and anticoagulants). NO is produced by many ECs, particularly those that line arterioles. All vascular beds display barrier properties. Although leukocyte adhesion occurs primarily in postcapillary venules, these blood vessel types are distributed across the body. The regulation of programmed cell death is common to all ECs.

It is well established that many (if not most) EC phenotypes are restricted in their tissue distribution. Some of these regional phenotypes are discussed in organ-based chapters in Part III. There is little question that many site-specific properties of the endothelium await discovery. Indeed, a survey of existing proteomic (see Chapters 99 and 100) and genomic data indicate a wealth of novel vascular bed–specific transmembrane and secreted proteins. Deciphering these so-called *vascular zip codes* is an important goal for the future. Finally, when considering outputs, it is important to recognize that in the human body, ECs may communicate with one another and with other tissues over large distances. For example, ECs may

secrete soluble mediators or release microparticles that signal to ECs from another vascular bed. Alternatively, circulating blood cells may “pick up” information from one site of the vasculature and transfer that information to another site (for

an interesting example, see Chapter 62). Future work in this area may uncover previously hidden “information highways” that further underscore the need to approach the endothelium as an integrated system.

# Proteomic Mapping of Endothelium and Vascular Targeting in Vivo

Lucy A. Carver and Jan E. Schnitzer

*Sidney Kimmel Cancer Center, San Diego, California*

Endothelial cells (ECs) are highly adapted to meet the needs of local tissue and therefore acquire molecular and functional variation according to their location in the body. Although there is little question that the microenvironment of the tissue surrounding the blood vessels significantly influences EC phenotype, very little molecular information exists about vascular endothelium and the degree to which EC expression is modulated within different organs in vivo. Elucidating molecular expression and topography for ECs in multiple tissues constitutes the first step in a systems biology approach to gain a fundamental understanding of functional differences across organ systems and to frame future studies investigating how environmental inputs alter EC gene/protein expression and physiology. This information is vital also for tissue engineering, in which persists a critical lack of understanding of the properties of ECs in the context of normal tissues. By knowing EC expression in a given organ, researchers gain important topographical and functional knowledge, define the set of functional players in each endothelia, and gain key markers both to discover the factors leading to a particular phenotype and maybe to someday re-create the necessary tissue environment in culture. Finally, defining the endothelial proteome in healthy and diseased tissues may reveal further microenvironmental modulation and may prove clinically useful by identifying new disease biomarkers and, perhaps more importantly, novel targets for site-directed delivery of functional and molecular imaging agents as well as nanomedicines, gene vectors, and drugs. In this chapter, we discuss technical barriers to mapping comprehensively the vascular endothelium in vivo and how various promising discovery and validation platforms that integrate state-of-the-art global analytical techniques have overcome some of these difficulties to reveal distinct molecular signatures in normal and neoplastic tissues.

## ULTRASTRUCTURAL DIVERSITY OF ENDOTHELIA IN TISSUE

### Morphological Heterogeneity

The endothelium is a key gatekeeper controlling the exchange of molecules from the blood to the tissue parenchyma. It largely controls the permeability of a particular vascular bed to blood-borne molecules. The permselectivity of the EC barrier is strongly dependent on the structure and type of endothelium lining the microvasculature in different vascular beds. ECs lining the microvascular beds of different organs exhibit extensive structural differentiation that can be grouped into three primary morphologic categories: sinusoidal, fenestrated, and continuous. Sinusoidal endothelium, found in liver, spleen, and bone marrow, has large intercellular gaps (here, also termed *discontinuous endothelia*) and no basement membrane, allowing for minimally restricted transport of molecules from the capillary lumen into the tissue (or vice versa). Other endothelia are characterized by the presence of a large number of circular transcellular openings, called *fenestrae*, with a diameter of 60 to 80 nm. Fenestrated endothelia frequently have thin diaphragms and are found in organs that require rapid exchange of small molecules, such as kidney glomeruli, endocrine glands, and intestine. Continuous endothelia form a barrier with an uninterrupted cell monolayer and basement membrane with neither fenestrae within ECs nor large gaps between ECs. Most endothelia fall into this latter category.

Permeability in continuous endothelia is regulated by intercellular junctions and vesicular transcytosis. In general, water, solutes, and other small molecules are transported paracellularly (e.g., between ECs) via diffusion and convection; however, specialized proteins (aquaporins and ion channels) at the EC surface membrane may facilitate transmembrane transport into ECs and perhaps even across in select tissues (1).

Most continuous endothelia, including lung, heart, and skeletal muscle, have abundant caveolae that function for select blood proteins as vesicular carriers into and across the cell. Caveolae can constitute 50% to 70% of the cell surface plasma membrane and occupy 10% to 15% of the total cell volume (about 500–600 vesicles/ $\mu\text{m}^3$ ) (2–4). Other continuous endothelia located in brain and testes form a very restrictive barrier by having few, if any, caveolae and by forming epithelial-like, tight junctions that prevent even small solute transport. To meet the metabolic demands of the brain tissue cells, endothelia of the blood–brain barrier must express specific transporters, even for molecules as small as glucose and amino acids (5,6).

Although originally derived from normal blood vessels, tumor vascular endothelium undergoes considerable alterations. Early tumor development is accompanied by extensive neovascularization with an increased number of intraendothelial organelles, such as vesiculo–vacuolar organelles (VVOs), and extensive distortions of its capillaries forming a chaotic network of dilated vessels that lack segmental differentiation and the strict organization of the vasculature of normal organs (7,8). Other distinctions include reduced basement membrane development with altered composition (7), increased proliferation rate of the ECs (9), and even altered cellular composition of the blood vessels themselves (7). The altered development and morphology of tumor ECs is discussed in detail in Chapter 158.

### Distinct Glycocalyx and Transport Pathways

Both passive, pressure-driven transport pathways and active pathways exist for blood molecules to cross endothelium. Passive pathways include paracellular transport through highly regulated intercellular junctions for convective filtration of water, and solutes (10) as well as transcellular transport through fenestrae or transendothelial channels that may form transiently in very attenuated regions of the cell by the fusion of two or more caveolae each located on apposing plasma membranes (11). Active pathways include both coated (i.e., clathrin dependent) and noncoated (e.g., caveolae) plasmalemmal vesicles that transport plasma macromolecules bound or adsorbed from blood by shuttling their contents either into the cell (endocytosis) or from the luminal to abluminal aspect of the endothelium or vice versa (transcytosis) (12–15). The endocytic and transcellular pathways may include both fluid-phase and receptor-mediated processes. Caveolae are discussed in more detail in Chapter 73.

Capillary permeability also depends on the interaction of blood proteins such as albumin and orosomucoid with the endothelial glycocalyx (10,16–19). The luminal surface of the endothelium is exposed directly to the blood and is covered by an elaborate carbohydrate-containing, proteinaceous, polyanionic surface coat called the glycocalyx, which also includes plasmalemmal components such as the glycosylated ectodomains of integral membrane proteins, proteoglycans, glycolipids, and adsorbed blood proteins. The absence

of serum proteins in vascular perfusates increases capillary permeability (10,16,18,20,21). Blood protein binding within the glycocalyx may restrict transendothelial transport via the “serum effect”<sup>1</sup> or may enhance specific transport of molecules by receptor- and caveolae-mediated processes (22). Serum also may reduce the coupling of macromolecular transport with hydraulic conductivity (23), thereby reducing paracellular “leakiness” in vivo and increasing the relative importance of transcellular transport. This phenomenon is not simply secondary to the effects of oncotic pressure. Protein binding is thought to form a molecular filter within transport pathways (16) that can electrostatically (24) and sterically (25) restrict the transvascular transport of water, small solutes, and macromolecules. Binding specific receptors mediating transmembrane signaling to produce transient calcium influxes, nitric oxide (NO) production, and other intracellular responses also contributes to regulating EC barrier function, probably by modulating both paracellular and transcellular transport.

This obvious and extensive morphological diversity is likely to reflect tremendous molecular heterogeneity in ECs from different organ vascular beds. Yet expression profiling has been challenging to perform, especially in vivo, where tissue microenvironmental factors influence EC phenotype. In the next sections, we discuss recent large-scale developments on establishing the molecular diversity of endothelia as well as its underlying mechanisms and possible consequences both in studying EC physiology and in the discovery of tissue-specific EC markers for site-specific imaging and drug delivery.

### TECHNICAL HURDLES IN STUDYING AND MAPPING ENDOTHELIAL CELLS

#### Difficulty in Sampling Endothelial Cells in Vivo

Little is currently known about EC molecular expression (i.e., its proteome) and even less about differential expression among the various organ capillary beds. In part, the current paucity of data on EC proteins may relate to methodological problems in interrogating vascular endothelium in vivo. Although it appears logical to study vascular endothelia in vivo (due to morphological and molecular heterogeneity of ECs among tissues), it has been quite difficult to analyze ECs as they exist in their native state in tissue. Even in highly vascularized tissue, the endothelium represents only a very small percentage of the cells constituting each tissue. It appears critical therefore to extract EC samples from the tissue to have any chance to unmask EC molecular expression that otherwise is beyond the dynamic range of detection and is effectively “swamped out” by the much stronger signals from other cell types in the tissue and the nearly 100,000 other, more abundant, tissue proteins. ECs are not localized clumped in a region

1 The serum effect is the phenomenon by which adsorption of serum proteins within the glycocalyx of ECs renders the EC barrier impermeable to solute transport. E.g., ferritin (see Schneberger and Hamelin. *AJP* 1984;247:206.)

of the tissue but rather exist as a very thin attenuated monolayer lining blood vessels disseminated throughout the organ, thereby making microdissection or isolation to obtain purified, uncontaminated material quite difficult. This in turn greatly hinders detection, identification, and purification of EC-specific proteins as well as any comparisons of endothelia between tissues.

### Endothelial Cell Isolation

Given these realities, it is not surprising that scientists have attempted for nearly half a century to isolate ECs from the rest of the tissue/organ (26–28). As early as the 1920s, attempts were made to isolate ECs from tissue (29). With the discovery of reasonable EC marker proteins, such as angiotensin-converting enzyme (ACE) and von Willebrand factor (vWF), the first demonstrable and reproducible isolation of ECs from tissue occurred 35 years ago and constituted a major breakthrough in the field (27,30). The development of effective EC isolation techniques heralded a new era in vascular biology where, far from being a passive lining to the blood vessel, the endothelium was discovered to be an active participant in many physiological and pathological functions, including coagulation, angiogenesis, atherosclerosis, and inflammation. The ability to isolate and grow ECs in cell culture permitted many of the pathways involved in the various EC functions to be characterized in detail. ECs isolated from many different tissues showed some diversity in protein expression but yielded little tissue specificity (31).

### Phenotypic Drift

Unfortunately, the successful isolation of ECs for growth in culture is not the sought-for panacea for obtaining material for mapping EC protein expression. ECs are highly plastic cells that clearly alter their phenotype according to microenvironmental cues. For example, avascular brain tissue transplanted into the coelomic cavity of chick embryos undergoes vascularization to form a competent blood–brain barrier; conversely, when avascular coelomic tissue was transplanted into the brain, the ECs that invade the mesenchymal tissue grafts form leaky capillaries and venules (32,33). ECs also change considerably when removed from their native tissue environment for isolation and growth in culture. The significant microenvironmental perturbation contributes to morphologically obvious phenotypic drift and the loss of native functions as the cells de-differentiate and adapt their metabolism and protein expression to ex vivo and cell culture conditions (22,34,35). For example, the signaling molecule tumor necrosis factor (TNF)- $\alpha$  stimulates neovascularization in rabbit corneas whereas it inhibits proliferation of ECs grown in culture (36). Many distinctive characteristics found in vivo are lost, including expression of tissue-specific proteins and the usual abundance of caveolae, which decreases 30- to 100-fold in cultured ECs and even in ECs freshly and rapidly isolated from tissue (37–40). The rapidity of this change when isolating ECs from

tissues is rather remarkable and may be indicative of the acute sensitivity and responsiveness of ECs to environmental cues in vivo.

Despite ample evidence for significant phenotypic change, the extent of the molecular chasm between ECs in vivo and in vitro is only beginning to be elucidated (37,39,40). Comparison of the cell surface proteome of ECs existing natively in vivo versus rat lung microvascular ECs (RLMVECs) grown under standard cell culture conditions has revealed significant differences in expression, including those proteins apparently induced by the tissue microenvironment (37). Of the 450 proteins identified in vivo, only 263 were found at all in vitro (58%), suggesting modulation by the unique tissue microenvironment not reproduced in cell culture (37). Out of 73 known EC marker proteins, 65 were found at the EC surface in rat lung versus only 32 in cultured RLMVECs. Forty-one known EC markers were detected only in rat lung.<sup>2</sup> Last, ~20 EC proteins showing tissue-restricted expression among endothelia were not detected in isolated ECs (37). Thus, the in vivo tissue microenvironment, which cannot yet be duplicated ex vivo, appears to significantly regulate distinct protein expression in ECs.

A number of biological mechanisms may account for differences in EC morphology and protein expression in vivo versus in vitro. Physical factors from hemodynamic forces can greatly influence EC phenotype, including induction and redistribution of protein expression with translocation from intracellular compartments to the cell surface (41). Cultured cells or even freshly isolated cells ex vivo lack the natural cues from the surrounding basement membrane, perivascular cells, and the tissue parenchyma to maintain expression of specific proteins. ECs interact with and respond to circulating hormones, carrier proteins, underlying perivascular cells, and the surrounding matrix of the tissue. During isolation from tissue, ECs are often subjected to harsh chemical treatment (digestion by proteolytic enzymes), mechanical disruption (mincing, mixing, centrifugation), and environmental (hypoxia) conditions. It is not surprising that this gross perturbation of ECs caused by tissue disruption can greatly alter molecular expression.

### ANALYSIS OF ENDOTHELIAL CELL PROTEIN EXPRESSION AND TOPOGRAPHY

Antibodies, peptides, and ligands represent probes potentially useful for analyzing EC protein expression in cell culture and in vivo using a wide variety of techniques, including staining of tissue sections or cell monolayers, Western analysis, and whole body imaging after intravenous injection of the probe.

2 There were 73 total known EC markers. Some of these 73 proteins were identified in both the lung P and lung cultured cells; i.e. a subset of the 73 were identified in both samples; some proteins were unique to lung (not found in cultured cells) (41 of the 73 were unique to lung with 24 being identified also in cultured cells –  $41 + 24 = 65$ ) and some were unique to cultured cells (not found in the lung).

Proteins also can be analyzed indirectly through mapping of gene expression and mRNA levels using a wide variety of genomic techniques. The application of mass spectrometry (MS) to peptide sequence analysis has created a powerful means to identify directly proteins expressed by vascular ECs. Table 99-1 summarizes several direct and indirect methods to map the EC proteome (as discussed later) and describes some of their strengths and weaknesses. Analysis *in vivo* or *in situ* is greatly preferred but technically burdensome.

### Cell- and Ligand-Based Approaches

Some of the first indications that EC diversity existed came from incubating cultured ECs under different conditions with a wide variety of protein ligands as well as tumor, immune, or other cells (42). Possible differences in cell surface expression were readily evident. In fact, after laborious protein purification or expression cloning, many very important EC cell adhesion molecules were identified through approaches pioneered by Gimbrone, Pober, Bevilacqua, Auerbach and others (43–47). Albumin binding proteins and important receptors to a wide variety of growth factors (e.g., vascular endothelial growth factor [VEGF], platelet-derived growth factor [PDGF], transforming growth factor [TGF]- $\beta$ ) ultimately have been identified by ligand-based searches of cultured ECs (18,48–53). Intravenous injection of cells<sup>3</sup> and ligands also has confirmed EC heterogeneity *in vivo* but such an approach has yielded little in the way of new molecular discoveries (54).

### Monoclonal Antibody-Based Approaches

Over the last quarter century, various attempts to map EC protein expression utilized isolated ECs and their membranes or cell lysates as immunogens in mice for monoclonal antibody production (30,31,55–61). These early pioneering studies provided new antibodies to ECs and the first direct evidence for differential protein expression for endothelium from different organs. They also uncovered useful markers for comparative and functional studies of ECs but ultimately failed to yield tissue-specific antibodies or target proteins useful for targeting a single organ selectively. Such an outcome is not surprising given that organ-associated EC phenotypes are largely dependent on the tissue microenvironment (62). The hybridoma-based technology is also inherently limited by its ability to screen only a small portion of the immune repertoire and by its reduced ability to generate antibodies directed to self-antigens or to highly conserved epitopes.

### Phage-Based Techniques

The concept of phage display was developed initially by the pioneering work of George Smith, who first demonstrated the

ability of filamentous bacteriophage to display at their outer surface foreign polypeptides fused to a coat protein, either g3p or g8p (63). Since then, phage display has proven to be a valuable tool in the display of small polypeptides as well as large proteins. The most significant accomplishment of phage display in recent years is its success in displaying antibody fragments and manipulating large antibody libraries for the generation of monoclonal antibodies (64,65). Unlike antibodies produced from mice using hybridoma technology, phage display permits a very large repertoire of antibodies to be displayed in a library created and analyzed *in vitro* without necessarily a need for immunization. After successive rounds of selection and amplification of a phage library against a target, the few clones that bind to the target can be rapidly identified. With phage libraries, there is no more need for laboratory animals, human antibodies can be generated directly for medical use, and antibodies with novel specificities such as antibodies to self-antigens or to highly conserved epitopes can be generated.

Many variations of phage display screening have been used to identify EC surface proteins. Screening phage libraries by *in vitro* bacterial panning (66) or after intravenous injection to search for tissue-homing peptides has been reported (67–69), but so far the yield has been rather modest with few promising tissue-specific targets or validated targeting probes. Reported targeting of adipose tissue with a proapoptotic peptide that binds to prohibitin resulted in selective ablation of white fat (70). Doxorubicin conjugated to RGD- and NGR-containing peptides bind integrins and can substantially improve the therapeutic index of this common chemotherapeutic agent (68). Animal survival increased many months, consistent with tumor regression and fewer metastases seen in the treated mice. Other peptides apparently targeting prostate, brain, and kidney tissue have been identified by *in vivo* panning of peptide-phage display libraries (67,69). Typically, when peptides are injected intravenously, only 0.2% or less of the injected dose of organ- and tumor-specific peptides is found in the target tissue (67,68). In one study, tumor accumulation was only 2- to 10-fold more than in the control brain tissue whose highly restrictive endothelium should greatly minimize any nonspecific uptake (68). Unfortunately, most of the vascular targets recognizing these peptides remain elusive, probably because such small peptides lack the specificity and affinity necessary for purifying a single target molecule (71). The mechanism responsible for the reported beneficial responses with peptides and peptide-drug conjugates remains unclear (71), in part because, when known, the targeted proteins can be found on multiple endothelia and other cell types (38).

The *in vivo* panning strategy appears limited inherently by the rather poor binding capacity and specificity of short peptides as well as the difficulty in achieving intravascular conditions needed to delineate large libraries. The rapid transit of blood through tissue vessels and the rapid scavenging of intravenously injected phage by the liver and spleen (reticuloendothelial system) within seconds to minutes works against phage selection by *in vivo* panning. Unlike classical screening where phage are incubated with an isolated protein or even

3 For example, B16 murine melanoma cells injected IV into normal mice selectively colonize the lung suggesting that there is something present in the lung EC that permits binding of the B16 cells to the EC surface.

**Table 99-1: Techniques to Study Protein Expression and Topography of ECs**

*Indirect Methods I*

- Uses and/or generates probes to putative EC molecules that can then be used to assess specificity of expression and then to identify molecular interactions with a probe (i.e., antibody–antigen).
- Requires identification of probe interaction partner, which can be difficult for some probes such as peptides that can interact with multiple proteins.

<i>Technique</i>	<i>Advantages</i>	<i>Disadvantages</i>
Cell- and ligand-based approaches	1. Can identify useful EC markers	1. Laborious process to identify cell-surface binding proteins 2. Low throughput
Hybridoma technology	1. Can identify useful EC markers 2. Readily generates probes for comparative and functional EC studies	1. Target protein not readily identified 2. Cannot generate antibodies directed to self-antigens or to highly conserved epitopes 3. Can only screen small portion of immune repertoire
Phage display libraries	1. Allows rapid screening of large, randomly paired antibody light and heavy chain libraries 2. Readily generates probes for comparative and functional EC studies 3. Can screen naïve or host immune response repertoire	1. Clones often of low affinity due to loss of original light and heavy chain pairing, structural changes brought about by connecting linkers 2. Optimal conditions known for classic screening on cells and proteins in vitro
In vivo panning of phage or viral libraries (peptide or antibody)	1. Allows rapid screening of large peptide combinatorial libraries 2. Readily generates peptides for comparative and functional EC studies	1. Limited by poor binding capacity of peptides 2. Short peptides with low specificity 3. Phage rapidly removed from blood by the reticulo-endothelial system (RES) 4. Glycocalyx and hydrodynamic forces in vivo may hinder access and prevent equilibrium binding to EC surface in vivo 5. scFv have lower affinity than whole IgG

*Indirect Methods II*

- Identifies mRNAs to putative EC molecules. mRNA levels can be compared to other tissues to determine induction or downregulation
- Requires generation of probes for use in validating specificity of expression and targetability

<i>Technique</i>	<i>Advantages</i>	<i>Disadvantages</i>
Genomic analysis	1. Allows large-scale, quantitative, high-throughput molecular profiling of ECs 2. Readily detect alterations in gene expression among various tissues or under different conditions 3. Human genome largely complete for straightforward sequence identification	1. Large number of genes identified requires laborious validation 2. Provides only indirect analysis of protein expression; lacks information regarding abundance, localization, or post-translational modification

*Direct Methods*

- Analyzes protein expression directly
- Requires validation usually through generation of new specific probes (antibody, peptide, oligonucleotide, DNA) for testing expression in multiple cells and tissues.

<i>Technique</i>	<i>Advantages</i>	<i>Disadvantages</i>
MS analysis	1. Allows large-scale, high-throughput molecular profiling of ECs 2. Readily compare protein expression across tissues 3. Provides direct analysis of protein expression and post-translational modification	1. Large number of proteins identified requires laborious validation 2. Dynamic range limitations may reduce identifications 3. Quantitative analysis currently is challenging
Protein arrays (antibodies, ligands, other)	1. Can be large-scale and high-throughput 2. Rapid screening 3. Sensitive and highly differential screen	1. Requires very specific probes 2. Ultimately need probe for each distinct protein (>100,000) 3. Protein interaction may interfere to yield false-negatives 4. Depends on sample screened for EC specificity

cells in culture for sufficient time to allow equilibrium binding, *in vivo* most of the phage (>90%) are removed before having sufficient time “to experience” and reach equilibrium binding to the EC surface. Moreover, large carriers, such as phage or viral vectors, will experience significant streamlining to concentrate in a central coaxial distribution profile in the blood vessel tube. This effectively reduces interactions with luminal EC surfaces and probably increases the need for longer circulation times to achieve binding. In addition, the glycocalyx can function as a barrier to larger entities from binding the ECs resulting in restriction of transendothelial transport (72). Finally, validation of candidate targeting peptides has been difficult with an over-reliance on tissue staining techniques, which, for reasons discussed later, are difficult to perform in a quantitative or qualitatively rigorous manner. Further technical development is clearly needed to harness more effectively the power of phage display in creating new EC binding probes and in allowing more comprehensive mapping of endothelium *in vivo*.

Not surprisingly, very recent approaches from the labs pioneering this technology have begun to include several rounds of *in vitro* prescreening with cells or tissue components to enrich the sublibrary before *in vivo* panning (73,74). Another more recent phage-based strategy has been described to rapidly identify not only probes but also their cognate antigens for targeting vascular endothelia of specific organs *in vivo* (75). Phage libraries are differentially screened against luminal EC plasma membranes (isolated directly from tissue) by *in vitro* phage screening techniques using standard, well-controlled screening conditions more akin to the classic phage approaches of the past (75). Numerous phage clones reactive to EC surface determinants in lung have been identified and rapidly validated by *in vivo* molecular imaging. Unfortunately, rapid liver and spleen uptake has been observed for all phage tested within seconds of intravenous injection, thereby precluding validation efforts of phage targeting *in vivo*. To avoid this, scFv were cloned from the phage to produce minibodies that showed rapid and selective targeting after intravenous injection. Finally, the high degree of antibody specificities and affinities permit rapid and immediate identification of organ-selective endothelial target antigens by MS analysis of immunoprecipitates and Western analysis. Such novel, comprehensive strategies may provide new promise for harnessing the power of phage display for mapping vascular endothelia natively in tissue and for achieving vascular targeting of specific tissues *in vivo*.

### Mass Spectrometry–Based Analysis

Two-dimensional (2D) gels have a long history of use in comparing protein expression across tissues but require large amounts of starting material and are time consuming and labor intensive to run (76). In addition, separation of hydrophobic, highly charged, or transmembrane proteins as well as intergel reproducibility can be problematic. High-throughput analysis can be achieved through the use of robotic gel anal-

ysis and spot-picking coupled to automated sample preparation and MS loading technology, which reduces error and radically decreases the amount of hands-on time for technical personnel. Multidimensional HPLC protein separation and identification technologies (77) coupled to database searching have been developed to analyze samples with significant diversity (>1,000 proteins). These effective MS-based “shotgun” approaches to protein identification (78) may greatly speed the discovery process by obviating the need to apply time-consuming and labor-intensive gel-based separation techniques. Various techniques, such as isotope-coded affinity tags (ICAT) (79), have been elaborated to achieve accurate quantification and sequence identification of peptides within a complex mixture.

For rapid and reproducible profiling, protein arrays are being developed that lend themselves well to high-throughput screening (80). Protein arrays are analogous to DNA arrays in that antibodies, small molecules, phage, or protein baits are immobilized on a slide that is then incubated with tagged sample proteins to estimate the concentration of specific proteins in the original sample. The success of these arrays is largely dependent on the affinity and specificity of antibody or protein probes used. In addition, the reactivity of the probe to the target protein may be decreased or abolished upon protein conformational change, protein interactions, or aggregation.

Most cell types, including ECs, are likely to express >10,000 genes and contain >100,000 distinct proteins. In this regard, shotgun MS approaches are probably better than 2D gel-based approaches, but to date no technology can effectively handle this level of molecular diversity and complexity to identify all such proteins in a cell. Multiple studies have been published describing a somewhat limited but direct proteomic analysis of ECs. Two MS analyses of whole cultured ECs (human umbilical vein ECs and a cell line designated RHE) subjected to 2D gel analysis recently identified a few proteins (<60 all together) and no cell surface enzymes or transmembrane proteins (81,82). A third study used shotgun MS approaches to identify 450 proteins (using stringent identification criteria of  $\geq 3$  peptides) in luminal EC surface membranes isolated from rat lungs using the silica-coating technique (described in Chapter 73) (37). This included  $\sim 80$  known EC markers and a wide variety of protein types such as transmembrane, enzymes, signaling molecules, and cytoskeletal elements. About 60% of these proteins expressed *in vivo* also were detected in rat lung ECs *in vitro*, consistent with modulation of expression by the tissue microenvironment not reproduced *ex vivo* or in cell culture (37).

Various chemical techniques that enzymatically label proteins have been applied to selectively radiolabel cell surface proteins of cells in culture (83–87) or on the EC surface of blood vessels *in situ* (86–89). Enzymatically driven intravascular radioiodination of rat heart endothelium *in situ* is quite cumbersome and difficult because it requires perfusing isolated rat hearts for 15 minutes with  $\geq 10$  mCi of  $^{125}\text{I}$  and microspheres covalently coated with lactoperoxidase and glucose peroxidase (86). Although useful in many ways, including

evaluating the carbohydrate nature of cell surface glycoproteins by lectin analysis (84,86) or defining the presence of a protein or a ligand-receptor interaction by affinity chromatography using specific antibodies and ligands (e.g., albumin-binding proteins) (84,85), direct global isolation of the radiolabeled EC surface proteins away from the more abundant other tissue proteins is quite difficult.

Chemical biotinylation using lipid-impermeable hydrophilic labeling agents improved comparative mapping of the EC surface and was first done in 1987 *in vitro* (90) and then 10 years later *in vivo* (91). One approach entails direct detection of the biotinylated proteins by avidin blotting after protein separation by SDS-PAGE. Perhaps a better strategy is to first perform avidin-based chromatography before separating the proteins in the eluate by SDS-PAGE for protein staining to detect all proteins or avidin blotting to visualize only biotinylated proteins. With the development of MS techniques to identify proteins, these biotinylation techniques have been used again nearly two decades later, this time to identify many of the biotinylated proteins in cell culture (92) and by perfusion *in situ* (93). Unfortunately, because chemical reagents such as biotin can easily and rapidly extravasate into the tissue, this technique must be applied with caution for the mapping of endothelium in tissue and with the understanding that many proteins on non-EC tissue cells are accessible for labeling. It becomes difficult to prolong the reaction time necessary to permit uniform chemical conjugation of all EC surface proteins yet limit reagent permeation into the tissue (which occurs within seconds). Thus, such chemical labeling *in situ* in fact extends significantly beyond just EC surface proteins to proteins of other cells and extracellular matrix further inside the tissue. This is readily evident by avidin staining of tissue sections of *in situ* biotinylated organs and by some of the biotinylated proteins identified that related to non-ECs in the tissue – e.g., cadherin-16, which is selectively expressed in epithelial cells in the adult kidney (93). Such *in vivo* biotinylation is based on the enhanced statistical probability for labeling luminal EC surface proteins over other tissue proteins and ultimately, for EC analysis, is clearly superior to starting with all proteins in the tissue homogenate. Lastly, both radioiodination and biotinylation techniques only label a small subset of EC proteins.

Modern “omic” analysis techniques are being utilized in attempts to identify all proteins and genes expressed within a given tissue or subset of cells within a tissue often for the purpose of discovering new drug targets. Genomic and proteomic approaches can complement each other to facilitate the generation of accurate maps of total protein/gene expression of any given cell type or tissue. Proteomic analysis offers an important advantage over DNA microarray or other genome technologies because it allows the preferential identification of gene products specifically expressed in the tissue or cell of interest. Despite many strengths, including improved precision and high throughput, a major weakness of exclusively using genomic approaches for mapping protein expression is that mRNA analysis provides only an indirect analysis of proteins as gene products. Transcriptional activity does not nec-

essarily correspond to the abundance, structure, or activity of its protein product for various reasons, including molecular half-life of mRNA versus protein product, synthesis rate, multigenic and epigenetic phenomena, as well as environmental influences, such as cell cycle, stress, and disease (94–96). Direct genomic identification seems unlikely for proteins not simply induced in expression but rather becoming new disease-induced targets primarily through post-translational modification (i.e., phosphorylation, sulfation, glycosylation, proteolytic cleavage) and/or translocation/redistribution (i.e., from poorly accessible intracellular cytosolic or membrane compartments to the outside cell surface). Thus, the importance of analyzing expression directly at the protein level is being more widely recognized, and various techniques have been developed to achieve this type of analysis. Also defining protein expression at the subcellular level is required for context, function, and targeting purposes.

## VASCULAR TARGETING

A major goal of modern medical research is the discovery of new targets for detecting disease through molecular imaging (97,98) and for treating disease through directed delivery *in vivo* (99,100). With the completion of the human genome project, it is estimated that the human genome encodes 25,000 genes. However, because of extensive RNA processing, post-translational modification, and the formation of functional protein complexes, this gene pool expands in size to several hundred thousand to perhaps a million possible distinct proteins (101). Past genomic and proteomic analyses of samples from normal and diseased tissues have yielded thousands of candidate drug targets for diagnostic as well as potential therapeutic targeting (99,100). Yet the sheer number of candidates appears to have overwhelmed the required but time-consuming *in vivo* validation process (100,101) so that the dilemma in drug target discovery today has become identifying which few of these many candidates are the most meaningful and targetable in treating and imaging disease.

Unfortunately, the potential value of identifying tissue-specific targets is offset by the difficulty in gaining access to that tissue owing to the endothelial barrier (15,102). Most known tissue- and tumor-associated gene products are expressed by the cells primarily constituting the tissue (e.g., tumor cells, cardiomyocytes, hepatocytes, alveolar epithelial cells) and, as such, these potential targets remain inside tissue compartments that are poorly accessible to many agents injected into the circulation, including gene vectors, nanoparticles, and even most biological agents, such as antibodies. This lack of tissue delivery and penetration prevents effective therapy *in vivo*. It has become apparent that new analytical strategies are required to reduce data complexity and to focus the power of global identification technologies (“omics”) to permit rapid discovery and validation of truly accessible targets *in vivo*.

Vascular targeting has been proposed as an alternative strategy for site-directed delivery that bypasses many of the

problems associated with direct tissue/cell targeting. This approach diverts analytical focus from the poorly accessible surface of cells inside the target tissue to the luminal EC surface of blood vessels feeding the tissue/tumor. This interface is directly exposed, and thus inherently accessible, to agents circulating in the blood (103,104). The strategy is predicated on the existence of luminal EC surface proteins expressed selectively in one tissue to the extent necessary to achieve its goal. Vascular targeting of antibodies may be applied not only to the delivery of drugs for therapy but also to imaging where targeting antibodies conjugated to imaging agents may provide useful diagnostic and prognostic tools for detection and assessment of primary and metastatic lesions. But to be useful for many drug-delivery applications, this strategy still requires a means by which to cross the vascular wall for access to underlying tissue cells (15,22,71,105). A new aspect to the vascular targeting strategy (discussed in detail in Chapter 73) is the potential utility of the caveolae transcytosis pathway in endothelium for selectively overcoming this key barrier to facilitate tissue-directed delivery to underlying tissue cells (15,71,104).

To reach its potential, vascular targeting requires the discovery of tissue-specific (i.e., vascular bed-specific), accessible endothelial targets. Many attempts have been made to identify such targets and develop probes (56,67–70,106–109) but, so far, without technologies for comprehensive analysis, most directed delivery *in vivo* has not met theoretical expectations (71). A lung-targeting antibody has been reported (106), but the antigen was subsequently found to be thrombomodulin (110), which is expressed by many different cell types, including the EC surface of most organs. Immunotargeting the panendothelial marker, platelet-endothelial cell adhesion molecule (PECAM)-1, can improve delivery to the lung after IV injection from the usual <1% to nearly 4% of the injected dose (2- to 4-fold over liver delivery) but only when the antibody is biotinylated and complexed with streptavidin (111). Although ACE is expressed on certain epithelial cells, macrophages, and ECs, some antibodies to ACE show 10- to 20-fold greater targeting of lung than other organs and blood (112) and have been used to enhance drug delivery to the lung (113) as well as lung gene delivery and expression using adenoviral vectors (114). Tissue-homing peptides, discovered primarily via *in vivo* panning of phage display libraries, also have provided a modest increase in tissue delivery (67), but the levels of targeting were <1% of the injected dose and many times were just compared to delivery to brain with relative targeting indices of 6- to 20-fold. Brain uptake *in vivo* is notoriously low because its endothelium has very tight junctions and few caveolae, both contributing to a high resistance to even very small molecules.

VEGF and its receptors are currently being exploited as sites for tumor imaging and/or therapy (8). Antibodies to VEGF injected intravenously in tumor-bearing rodents accumulate preferentially within neoplastic tissue (115). VEGF conjugated to toxin is also effective in reducing tumor size in rodents (116). Unfortunately, because VEGF and its recep-

tors are expressed in various normal human tissues, such as kidney, it is unclear how selective these targets will be clinically. When used with chemotherapy, Bevacizumab (Avastin; a humanized murine mAb to VEGF) has shown promise by extending median survival time by about 8 months in patients with metastatic colon cancer and 2 to 3 months in patients with non-small cell lung cancer (117,118). Thrombotic complications are evident but may be avoided through exclusion of high-risk patients.

Table 99-2 lists the tissue distribution of these and other potential tumor EC targets currently being investigated for tumor immunotherapies. They include roundabout 4 (Robo4) expressed at sites of active angiogenesis in tumor ECs, in adults (119). Robo4 is an EC-specific member of the roundabout receptor family that binds slit to inhibit EC migration in primary EC cultures (120). It has a critical role in embryonic angiogenesis, is generally absent in normal adult ECs, and is upregulated in ECs of various solid tumors (120–123). Delta 4 is a Notch ligand located in the plasma membrane that is induced by hypoxia on the endothelium at sites of active angiogenesis, including tumor ECs (124). Nucleolin is a well-known nuclear protein that can be expressed on tumor cells and on the EC surface in tumor blood vessels but not generally normal vessels (38,125). Intravenous injection of homing peptides or nucleolin antibodies accumulate in tumor vessels as well as in angiogenic vessels of implanted “matrigel” plugs (125). CD44 is a highly heterogeneous cell surface receptor with specific variants highly expressed in tumor ECs as well as in other tissues (126). A monoclonal antibody recognizing a widely distributed isoform CD44H conjugated to chemotherapeutic agents has shown promise in suppressing solid tumor growth in rats (127,128) and mice (129).

Endoglin is a RGD-containing glycoprotein (130) that is a component of the TGF- $\beta$  receptor system (131). Although endoglin is expressed by a variety of different cells and on the endothelia of many organs (132), endoglin antibodies conjugated to deglycosylated ricin A chain have shown strong anti-tumor and anti-angiogenic efficacy when injected into mice bearing human breast tumors (133,134).

Several integrins, including  $\alpha\nu\beta 3$ ,  $\alpha\nu\beta 5$ , and  $\alpha 5\beta 1$ , may be induced by tumors and may be a useful target site for inhibiting the growth of tumors (135,136). Integrin  $\alpha 5\beta 1$  may regulate the function of  $\alpha\nu\beta 3$  during EC migration *in vitro* or angiogenesis *in vivo* (137). Antibodies, peptides, and antagonists of  $\alpha 5\beta 1$  inhibit growth factor-induced angiogenesis and cause regression of human tumors in animal models (138). Antibodies recognizing  $\alpha\nu\beta 3$  and RGD-peptides to  $\alpha\nu$  integrins cause tumor regression by preventing normal engagement which induces apoptosis selectively in proliferating ECs (68,136). Recently nanoparticles targeting  $\alpha\nu\beta 3$  integrins in the tumor vasculature have been shown to direct gene therapy to ablate tumors (135). Selective dual  $\alpha\nu\beta 3$  and  $\alpha\nu\beta 5$  antagonists inhibited angiogenesis in the chick chorioallantoic membrane assay and significantly inhibited tumor growth in mice bearing subcutaneous human melanoma tumors (139).

\*This expression profile is only for this protein as it is expressed at the surface on the outside of the EC (not elsewhere; e.g., nucleolin is expressed fairly ubiquitously in nuclei of all cells including ECs) and integrins expressed on outside of many cell types including blood cells, fibroblasts, and epithelial cells.

<sup>†</sup>May be regulated by physiological angiogenesis in endometrium and ovaries (wound healing?)

<sup>‡</sup>Unclear if expressed at the luminal EC surface or mostly in extracellular matrix.

ND; not determined.

Prostate-specific membrane antigen (PSMA), is upregulated in neoplastic prostate epithelium (108,140–142) and neovasculature (143–146) as well as in metastatic lesions (141, 146,147). Although its expression also is observed in brain, salivary gland, and intestine (108,140,146,148,149), antibodies to PSMA ( $^{111}\text{In}$ -7E11; ProstaScint) are currently being used as an imaging agent for detecting soft-tissue metastases in prostate cancer patients at high risk of metastatic disease, and studies are underway to determine potential utility in targeted therapy (150–153).

A 165 kDa sialoglycoprotein named endosialin is found in various carcinomas, sarcomas, neuroectodermal tumors but not lymphomas (154). Monoclonal antibodies to endosialin recognize endothelium in tumors but not in normal tissues (154). Endosialin was discovered independently to be expressed in tumor ECs by SAGE analysis of normal versus colon tumor ECs, which revealed several genes upregulated in the tumor vessels (109). Tumor endothelial marker 1 (TEM1) (eventually found to be endosialin), TEM5, TEM7, and TEM8 are all transmembrane proteins whose expression is highly upregulated in tumor ECs and/or in mouse embryonic vasculature (155–157). A splice variant of TEM8 has been identified as the anthrax toxin receptor (158). Re-engineered anthrax toxin that is activated by cell-surface urokinase has been shown to cause regression of subcutaneous tumors in mice (159).

Intercellular adhesion molecule (ICAM)-1 is an adhesion molecule expressed normally on ECs, where it functions in leukocyte attachment and migration to sites of inflammation (160). During tumor angiogenesis, cytokines produced by the tumor cells activate ECs to produce increased amounts of ICAM-1 and to shed the soluble form (sICAM)-1 into the blood (161). sICAM-1 stimulates EC migration, differentiation, and vessel sprouting *in vitro* as well as angiogenesis and tumor growth promotion *in vivo* (162,163). ICAM-1 may mediate EC migration via endothelial NO synthase (eNOS) activation and actin cytoskeleton reorganization (164). Serum sICAM-1 levels are elevated in cancer, and there is a positive correlation with tumor progression (165,166). In addition, a monoclonal antibody directed against another well-known cell adhesion molecule, vascular cell adhesion molecule (VCAM)-1, when conjugated to human tissue factor, selectively induces vascular thrombosis and inhibited tumor growth in mice bearing solid, human Hodgkin tumors (167).

Lastly, there are several proteins associated with select endothelia but not necessarily located at the luminal EC surface for immediate access to circulating targeting agents. Developmentally regulated endothelial locus (Del)-1 is an extracellular matrix protein expressed in ischemic tissue that stimulates angiogenesis (168). Del-1 contains two discoidin I-like domains and may act to promote adhesion of ECs through interaction with the  $\alpha\nu\beta 3$  integrin receptor (169). Stanniocalcin (STC)-1 is a secreted glycoprotein that acts with hepatocyte growth factor to regulate EC maturation (170). STC-1 is highly expressed in tumor blood vessels and may be an effective tumor vascular target (171). The EDB domain of fibronectin is highly expressed by the ECs of many

tumor types but undetectable in normal adult tissues (172–175). Radioiodinated EDB antibodies have recently been tested in the clinic and have shown the ability to target tumors (176). The primary location of these proteins in the extracellular matrix adjacent to the endothelium may require passive leakage of targeting agents across the vascular wall, which ultimately may slow targeting. Tenascin C is a highly upregulated extracellular matrix protein in brain and lung tumors but undetectable in normal adult tissues (177). Antibodies recognizing tenascin C have been used for many years in the clinic for imaging tumors (178–182).

### Applying Proteomic Mapping to Vascular Target Discovery

Most of these vascular targets are expressed by, or proximal to, ECs in tissue and, in fact, have been identified by studying isolated ECs and tissue sections with genetic-, ligand-, and/or antibody-based probes. More direct MS-based proteomic mapping of vascular ECs *in vivo* is desirable and may, at least theoretically, be even more fruitful, but it is technically complex and difficult. One approach to reduce the tremendous molecular complexity of the starting analyte (the tissue with its hundreds of thousands of proteins) and to rapidly and directly identify and validate accessible vascular targets is to integrate multiple technologies – including subcellular tissue fractionation, subtractive proteomics, *in silico* bioinformatics, expression profiling, *in vivo* biodistribution assay, and molecular imaging – into a comprehensive analytical system for determining the proteins expressed at the cellular site of interest (e.g., ECs in the tissue). To focus the power of proteomic technology to a small subset of tissue proteins, namely the accessible vascular targets (i.e., the proteins expressed on the EC surface directly exposed to the blood circulation), tissue subfractionation has been applied to isolate the pertinent luminal EC plasma membranes and thereby to promote the unmasking of a small subset of proteins on the EC surface from the several hundred thousand proteins in the tissue or individual but whole ECs. This magnitude of data complexity reduction at the beginning of the analysis greatly reduces the background of nonaccessible tissue targets, thus potentially decreasing the failure rate and the overall work necessary to find valid targets.

Such an integrated approach has recently been used to discover tissue-modulated proteins showing promise in tissue-specific imaging and pharmacodelivery (37,38) (Table 99-2). A subtractive comparison of proteins expressed in rat lung ECs *in vivo* versus *in vitro* in cultured cells has been performed to discover possible tissue-restricted EC surface proteins and even identify potential lung-specific EC proteins *in vivo* (37). The list of proteins identified *in vivo* using a stringent criteria of  $\geq 5$  peptides versus *in vitro* using minimal criteria of one peptide were subtracted *in silico* based on the working hypothesis that tissue-dependent EC protein expression may be reduced in cell culture, which does not duplicate conditions *in vivo*. The list of differentially expressed candidate proteins

was reduced further by bioinformatic interrogation of structure, glycosylation, and membrane orientation to yield 11 proteins likely to have domains outside the cell and therefore targetable from the bloodstream. Expression profiling with specific antibodies revealed that each protein is indeed expressed on the EC plasma membrane and that each exhibits a different restricted expression pattern among the organs tested. None of these proteins is expressed equivalently on the EC surface membranes in each organ. Endothelia in many organs other than lung lack detectable expression. A distinct molecular signature for each vascular bed is quite apparent from the expression levels of these 11 EC marker proteins in each organ. Two proteins, aminopeptidase P and OX-45, appear specific for lung endothelium. Antibodies to aminopeptidase P show lung-exclusive targeting after intravenous injection. Antibodies to OX-45 do not because leucocytes express this protein also.

A similar subtractive approach has been used to compare diseased versus normal tissue to uncover potential targetable tumor-induced EC proteins (38). Fifteen differentially expressed proteins have been identified as being enriched on the EC surface in tumor vessels (AnnexinA1, AnnexinA8, ephrinA5, ephrinA7, myeloperoxidase, nucleolin, transferrin receptor, and vitamin D-binding protein), including several proteins already implicated in tumor angiogenesis (VEGF receptor [VEGFR]-1 and -2, Tie2, aminopeptidase-N, endoglin, C-CAM-1, neuropilin 1). Although clearly expressed or even induced on the tumor EC surface *in vivo*, nearly all of the proteins also are found expressed restrictively in normal endothelium of select major organs. One of the identified proteins was a 34 kDa protein recognized by AnnexinA1 (AnnA1) antibodies only on tumor endothelium. *In vivo* imaging using radioiodinated AnnA1 antibodies shows tumor-selective imaging and targeting within one hour of intravenous injection. This unprecedented rapidity in tumor targeting probably relates to its immediate accessibility at the luminal EC surface in tumors. Targeted radioimmunotherapy is effective with survival studies showing complete remission in 80% of the animals after a single treatment with radioiodinated AnnA1 antibodies versus 100% mortality within 7 days without treatment or when using control nontargeting antibodies (38). Thus, an integrated approach to proteomic analysis is capable of identifying a potential tumor-induced vascular target capable of directing immunotargeting of tumor neovasculature to achieve significant remission even in advanced disease.

Validation of EC expression and targeting *in vivo* is essential. *In vivo* imaging techniques, such as gamma scintigraphy, SPECT, PET, and luminescence imaging are fast becoming the new "gold standard" for noninvasively obtaining information pertaining to target organ selectivity, structure and organ function, and receptors and enzymes within normal and diseased tissues (97,98). Biodistribution analyses using radioactive probes specific for the target protein are laborious but definitive in showing the tissue distribution of the probe based on the limited sample pool. Other techniques, such as immunohistochemical analyses of tissue sections, lack

the dynamic range and statistical power to quantify target expression and probe targeting *in vivo* after intravenous injection. They tend to yield false-negative results, especially when poorly performed and controlled. However, such techniques, including immunofluorescence and electron microscopy, can provide key information about ECs and tissue processing *in vivo* and thus should be used only after targeting conditions are established so that more detailed information on probe transport in tissue can be obtained. Of course, probe specificity must be established for the studies to be at all meaningful.

At this time, we know very little about how drugs, gene vectors, nanoparticles, antibodies, and other agents are processed by the endothelium of each tissue and then by the cells inside the tissue. Without this fundamental knowledge, it will be difficult to achieve, in a directed fashion, the desired goals of *in vivo* targeting. Nanomedicine, gene therapy, and even many standard drug and biologic therapies, such as antibodies, may be greatly limited. Development of new imaging technologies as well as advanced and optimized application of current imaging modalities, such as intravital and multiphoton microscopy, will also help accelerate this vision. Better probes are also much needed, both for sensitive *in vivo* detection and for achieving tissue targeting *in vivo*.

Before site-directed therapies can approach their theoretical potential, the extent of EC heterogeneity must be determined and potential tissue-specific EC protein targets must be identified (15,71,104). Table 99-2 lists several EC surface proteins as potential targets for specific organs and solid tumors. For additional useful, accessible vascular targets to be discovered, it will be necessary to systematically and comprehensively map and compare protein expression on the endothelium of major organs and tumors, so that tissue-modulated and even organ- or tumor-specific EC surface markers may be uncovered. The development and application of more robust technologies for both discovery and validation efforts appear to be needed to achieve such goals and concretely determine the true potential for vascular targeting.

Vascular targeting is likely to go beyond application to site-directed delivery and penetration into tissue. It may someday result not only in altering the EC phenotype *in vivo*, for instance to address a disease, but also the effect of endothelium on the underlying tissue cells. Directing signaling modifiers to specific endothelia is likely to yield tissue-specific responses, for instance, by targeting the endothelium to change its behavior in such a way that it alters signaling to underlying tissue.

## CONCLUSION

Elucidating the molecular topography of the EC surface in multiple tissues constitutes the first step in gaining a better fundamental understanding of functional differences across organ systems and forms the basis for future studies into how environmental inputs alter EC gene/protein expression and physiology. This information is vital as well for tissue engineering

where there is a critical lack of understanding of the properties of ECs in the context of normal tissues. By knowing EC expression in a given organ, researchers gain markers to discover the factors leading to a particular phenotype and thus will be able to recreate the tissue environment in culture with higher fidelity. Finally, defining this vascular proteome is expected to uncover new functions and to discover clinically significant tissue-modulated and possibly even organ-specific molecules that may be useful as targets for site-directed delivery of drugs, genes, or imaging agents. We are just at our infancy in defining molecular expression of ECs in vivo. The next decade should yield very significant progress toward defining the molecular topography and diversity of endothelium in many normal and diseased tissues. The process of induced and restricted expression creates much impetus for overcoming technical barriers to map comprehensively vascular endothelium in vivo.

#### KEY POINTS

- ECs lining the microvascular beds of different organs exhibit extensive morphological, ultrastructural, and molecular differentiation.
- The broad molecular heterogeneity of ECs contributes to numerous technical difficulties in characterizing their physiology and expression profile but also provides the basis for discovering novel vascular targets for site-directed delivery of functional and molecular imaging agents, nanomedicines, gene vectors, and drugs.
- Numerous approaches have been used to attempt to identify proteins directly that are expressed by ECs, most recently through the use of mass spectrometric-based techniques to analyze peptide sequences exposed on the luminal EC surface.
- Vascular targeting focuses on targeting proteins on the luminal EC surface of blood vessels feeding the tissue/tumor that is directly exposed and thus inherently accessible to agents circulating in the blood and bypasses many of the problems associated with direct tissue/cell targeting.
- Proteomic analysis of luminal EC plasma membrane proteins has identified lung- and tumor-induced proteins that can be targeted by monoclonal antibodies for rapid and efficient accumulation into the tissue/tumor.

## A Phage Display Perspective

Amado J. Zurita, Wadih Arap, and Renata Pasqualini

*M.D. Anderson Cancer Center, The University of Texas, Houston*

The vascular system is a complex network of vessels connecting the heart with organs and tissues to maintain homeostasis in response to physiological and pathological stimuli. Blood vessels are composed of endothelial cells (ECs), mural cells (pericytes or smooth muscle cells), and basement membrane. ECs lining the inner surface of blood and lymphatic vessels play important roles in the control of vascular tone, hemostasis, tissue growth, capillary exchange, inflammation, immune response, and angiogenesis. Even though these functions, along with other anatomical and molecular features, are common to all ECs, substantial structural and functional heterogeneity is seen among them. For example, ECs in the brain form a tight continuous monolayer required for a critical barrier function (blood–brain barrier), but those in the kidney, spleen, liver, and bone marrow display fenestrations or intercellular gaps for the rapid exchange of fluids and/or cells. This diversity is clearly a result of molecular differences between EC populations, which allow complex interactions with very distinctive microenvironments. Recent studies have identified transcriptional diversity between ECs in different types of blood vessels (arteries vs. veins, vessels of different caliber) and different anatomical locations (1–4). Not surprisingly, lymphatic ECs also display distinct characteristics (5).

Blood vessels can grow from endothelial progenitors (vasculogenesis), from the sprouting and subsequent stabilization of these sprouts by mural cells (angiogenesis and arteriogenesis), or from the expansive growth of preexisting vessels (collateral growth) (6). When vessel growth is altered, in particular when excessive angiogenesis occurs, new blood vessels contribute to a long (and growing) list of disorders, including cancer, arthritis, retinopathies, obesity, atherosclerosis, and asthma (6). However, it is in solid tumors where an abnormal vasculature is a hallmark (7,8). Tumor blood vessels clearly differ both structurally and functionally from normal vasculature and from newly formed blood vessels in sites of physiological angiogenesis or chronic inflammation (9). Most tumor vessels are tortuous, leaky, and discontinuous; have an altered blood flow; and although mural cells and basement membrane are present, they are profoundly abnormal (10–12). Tumor lymphatics are also anomalous (13). These

abnormalities are determined by an imbalance between levels of pro- and antiangiogenic molecules in cancer, thus activating the so-called angiogenic switch from vascular quiescence, which can occur at different stages of tumor progression depending on the tumor type and the environment (14). It is the continuous nature of the changes related to the tumor environment – forming new vessels or remodeling existing ones – that explains the tremendous heterogeneity that exists between tumors, between a primary lesion and its metastases, between different moments in single lesions, and sometimes even between different locations in single lesions (9,15). In addition, recent reports have challenged the traditional assumption that tumor-associated ECs (TECs) are genetically stable, providing further evidence for the existence of phenotypic differences between normal ECs and TECs and for heterogeneity among TECs (16–18).

Characterizing differences between diverse normal EC populations and between normal and pathological ECs is crucial for understanding vascular development, physiology, and pathophysiology, and for the development and delivery of targeted therapies. A variety of approaches have been applied to identify *molecular* markers for specific vascular beds, including the Stamper–Woodruff assay for lymphocyte homing, monoclonal antibodies, differential display, serial analysis of gene expression (SAGE), genomic microarrays, subtractive or covalent modification proteomics, and phage display. In this chapter, we review recent progress that has been made in using phage display libraries (in particular peptide libraries) as a proteomics tool to map heterogeneity of the vascular system. We focus on applications of phage display technology related to normal and tumor vasculature, mainly in vivo phage display and vascular targeting.

### PHAGE DISPLAY TARGETING STRATEGIES AND THE VASCULATURE

Phage display libraries are commonly used to obtain defined peptide sequences interacting with a particular molecule of interest with high affinity (19). Typically used libraries consist

of genetically encoded polypeptides or proteins (including antibodies) expressed within a coat protein, usually pIII (a minor coat protein located at one tip) or pVIII (the major coat protein forming the body), of a filamentous bacteriophage (of which the most widely employed is M13). Billions of different sequences can be displayed, allowing exposure of a vast number of individual phage clones and subsequent affinity selection of those displaying peptides that bind specifically to a given molecular target of almost any chemical nature. The typical procedure for affinity purification or (bio)panning involves incubation of a primary or amplified existing library with the target molecule, removal of unbound phage by washing or perfusion, and recovery and propagation of the bound phage by bacterial infection. Several consecutive rounds of panning, usually three to four, are typically performed to improve selection. Finally, sequencing the corresponding viral DNA in the region encoding the displayed peptide reveals the sequence displayed by a binding phage. The selected phage and cognate peptides are then used for further analysis of the ligand–target interaction.

Through different strategies, phage display has been widely used in the last decade in vascular biology, in particular in the context of angiogenesis (9,20). Originally developed to map epitope-binding sites of antibodies (21), the search for peptide fragments with new or improved specificity or affinity has led to a number of technical advances in the construction of libraries, phage screening methodologies, and sequence affinity maturation (19,22,23).

Generally speaking, phage display is carried out either *in vitro* (on purified molecular targets or on cells) or *in vivo*.

## In Vitro Targeting

### *Cell-Free Screening on Isolated Molecular Targets*

The primary application of phage display has been the isolation of high-affinity ligands for previously characterized protein targets (24–26). These procedures require the use of purified or recombinant marker molecules attached to a solid support. Phage libraries displaying cyclic random peptides or antibody fragments (single-chain Fv or Fab) have been widely used. Interestingly, it has been shown over the years that a high number of isolated ligands bind to biologically relevant sites and act as agonists or, more frequently, antagonists of the function of the target molecule (27). Quite often, the primary structures of the selected peptides resemble those within known or potential interacting proteins, a useful characteristic in mapping protein–protein interactions. Phage-borne peptides demonstrate a broad mimicking potential to linear, conformational, and nonprotein binding sites (28). In peptide libraries, it is common to observe motifs consisting of three amino acids appearing several times in difference sequence contexts and being responsible for binding. This number provides the minimal framework for the overall fold of polypeptide chains and protein–protein interactions (29). Some examples of tripeptides acting as binding motifs include RGD, LDV, and LLG (to integrins) (30,31); GFE (to membrane dipepti-

dase) (32,33); and NGR (to aminopeptidase N[APN]/CD13) (34).

Panning on purified blood vessel-associated molecules has led to the successful isolation of ligands (peptides or antibody fragments) to vascular targets. The vast majority of targets have been angiogenesis-related markers. For brevity's sake, we only list markers without further discussion. This includes the selection of ligands against:

- Receptors, such as vascular endothelial growth factor (VEGF)-receptor 1 (VEGFR1) (35,36), VEGFR2 (37–40), VEGFR3 (41), EphA2 (42), Tie2 (43–45), and NG2 (46)
- Adhesion molecules, such as integrins (31,47–51), galectin-3 (52), intercellular adhesion molecule (ICAM)-1 (53), P-selectin (54), and E-selectin (55)
- Growth factors or extracellular matrix molecules associated with angiogenesis, such as VEGF (56–59), angiotensin 2 (60), membrane type-1 matrix metalloproteinase (MT1-MMP) (61), matrix metalloproteinase (MMP)-2 and MMP-9 (62), thrombospondin-1 (63), and the ED-B fragment of fibronectin (64)

### *Screening the Molecular Diversity of Surfaces of Cells in the Vasculature*

The isolation and characterization of ligands recognizing receptors on the surface of endothelial or vascular wall-associated cells is critical for the development of vascular-targeted agents. Not only that, but targeted ligands display in many cases specific functions that can be used for diagnostic or therapeutic purposes, or to gain insight into ligand–receptor interactions. The identification of ligands binding to cell membrane-embedded receptors has several advantages over cell-free strategies. As opposed to purified receptors, those on cell surfaces are more likely to preserve their natural or biologically active conformation, which can be lost upon purification and immobilization. Also, many cell surface receptors are active as complexes whose formation may require vitality of the cell, and this sometimes provides an additional advantage for targeting specificity or ligand function. An additional advantage is that these procedures can be performed in an unbiased manner, potentially allowing the recognition of receptors of unknown distribution or previously unrecognized existence. Nevertheless, the isolation of highly specific ligands to complex cell surface molecules remains challenging in many cases (65). Moreover, ECs in culture may not truly represent the cell phenotype *in vivo*. Although some characteristics seem to be stable when ECs are cultured for several passages (66,67), rapid changes in gene expression programs and de-differentiation can occur *ex vivo* (68,69).

Various groups have reported the successful identification of specific peptide or antibody ligands after biopanning on vascular cells or even blood vessel surfaces *ex vivo*. In a few cases, new ligands for established cell surface receptors were sought, as in the case of VEGFR2/KDR (70),  $\alpha_v$  integrins (71), LOX-1 receptor (72), vascular adhesion molecule (VCAM)-1 (73) and ICAM-1 (74). However, most biopanings on cells

have been completed with no prior information about the cell surface receptor repertoire. This is the case for those performed on human umbilical vein ECs (HUVECs) either in culture or obtained ex vivo (65,75–77), brain microvascular ECs (78), dermal microvascular ECs (79), coronary artery ECs (80), rat retinal ECs and aorta (81), and rat heart ECs and histological sections of collateral blood vessels (82).

A typical problem associated with the use of phage display on cell surfaces is the high number of nonspecific binder clones and the loss of low affinity specific binders with the washes to reduce background. Our laboratory has developed a novel technology termed *Biopanning and Rapid Analysis of Selective Interacting Ligands* (BRASIL) for the screening of cell-surface binding peptides from phage libraries (83). Using a single-step differential centrifugation to separate specific phage–cell complexes from unbound phage, this methodology allows for fast selection of peptide binders and shows an improved sensitivity and specificity over conventional methods. As a proof of principle, we used BRASIL to screen a phage display random peptide library on activated, VEGF-A<sub>165</sub>-stimulated HUVECs after a library subtraction step on quiescent ECs (83). This work showed that BRASIL is well suited for characterizing vascular targets in EC membranes in vitro and recognizing functionally relevant epitopes on target molecules. BRASIL also can be used to screen phage antibody or other types of phage display libraries. Moreover, as several rounds of selection can be performed on multiple samples in a relatively short time in tandem with cell-sorting techniques, this methodology can be automated and used for high-throughput screening – for example, of circulating vascular cell populations coming from patients.

### In Vivo Targeting

Vascular targeting in vivo takes advantage of blood vessel heterogeneity. In normal blood vessels, functional and structural multiplicity are linked at the organ, tissue, and single vessel level. In diseased tissues, environmental pressure also creates differences among blood vessels. Structural and functional diversity is associated with molecular differences between vascular cell populations.

The molecular diversity of the vasculature provides a rational foundation for the development of site-specific targeted bioactive molecules. Plasma-membrane antigens or receptors can be used to target diagnostic or therapeutic agents directly to normal or diseased sites. Targeted diagnostics should improve sensitivity and specificity for detection of disease. Targeted therapies should improve efficacy with reduced toxicity.

### In Vivo Phage Display

In vivo phage display allows for the identification of ligand–receptor pairs specific to given sites and functional status of the vascular system (84). This technology employs the same phage selection procedures used in vitro but accomplishes it in vivo by injecting a random phage library intra-

venously into a living organism. After a predetermined circulation time, biopsies from the sites of interest, whole organs or tumors are taken. Phage displaying peptides or antibody fragments that home to specific organs, tissues, or vascular beds are recovered. This process can be repeated several times to improve targeting specificity and affinity. Finally, ligands are isolated, identified, and further characterized. The homing ability of individual ligands also can be validated by this methodology (32,84,85).

Although the majority of in vivo studies have been performed using random peptide libraries, some recent work has shown that it is possible to screen libraries displaying antibody fragments on phage. For example, screening a phage-scFv library led to the isolation of fragments selective for murine thymic endothelium (86). Other investigators have described biodistribution and in vivo homing ability of phage displaying a specific antibody Fab (87) and scFv (65), respectively.

One of the most important advantages of in vivo phage display over other high-throughput profiling approaches is that information on focal distribution of receptor targets is preserved up to the single cell level, which is particularly applicable in heterogeneous systems such as the vasculature. In distribution studies and using immunohistochemistry to localize phage homing, it is not uncommon to see, within a population of cells, cell surface differences that are related to target distribution and level of expression. Compared with in vitro selection, in vivo phage display provides further advantages. Cell specificity in vitro may not be stringent enough in complex systems, especially if affinity is low for an abundant cell type. Ligands isolated in vivo have shown the ability to home selectively to the site of interest and bind under the physical conditions of circulation at the target location. As a consequence, peptides that recognize plasma and ubiquitous cell surface proteins are “counterselected” from the circulating phage pool, improving homing selectivity. In addition, by adjusting the time in which the phage pool is allowed to circulate, one can favor the selection of specific peptides for the endothelium or other vascular and perivascular cells or structural components. This is particularly useful in situations in which the vascular integrity is disrupted, as in the case of cancer-associated vasculature (several examples of nonendothelial molecular targets will be discussed later in the chapter). However, despite all its powerful characteristics, in vivo phage display is technically challenging because of the difficulty in monitoring after-injection events, in particular contact time between phage and endothelial surfaces. A careful optimization of circulation times based on targeted organ and pharmacokinetic properties of distinct phage display libraries is critical with this technology (88).

Since the first description of the in vivo phage display in 1996 (84), numerous peptide ligands and corresponding vascular markers have been discovered by our laboratory and others (20,89). In many cases, selected molecular targets, although specifically expressed in a vascular bed, also were found in other locations outside the vasculature in a manner not

**Table 100-1: Structure and Activity of Vascular Homing Peptides Identified by in Vivo Phage Display with Established Receptors**

necessarily tissue- or cell-specific. These results illustrate an essential characteristic of in vivo phage display for target discovery: Both accessibility and target expression influence the outcome. In this respect, the vasculature provides unique accessibility to agents that are given intravenously. Another significant aspect is that, as noted earlier in this chapter, many of the peptide ligands bind to functionally important regions of their target molecules and thus play a functional role to add to their targeting capability. Some examples will be discussed in the next paragraphs.

#### *Normal Tissue-Specific Vascular Targets*

Peptide ligands targeting brain and kidney (84), skin, intestine, uterus, adrenal gland, retina (32), pancreas (32,90), lung (32,91), muscle (92), prostate (93,94), breast (95), lymph nodes (96), and fat (97) have been described. These and other results obtained with unrelated technologies are demonstrating that ECs in diverse environments exhibit different sets of cell surface markers, or similar markers displaying site-specific features.

In vivo phage display is uncovering a vascular address system of homing ligands and corresponding receptors (so-called *zip codes*) that provides unique opportunities for targeted clinical applications. It also improves our understanding of molecular interactions in vascular beds. In this regard, the identification of targeted receptors is critical (Table 100-1). Integrating the isolation of ligands from in vivo screenings with complementary biochemical approaches has yielded an array of tissue-specific vascular receptors. Two proteases have been identified by in vivo phage display as markers of the vasculature in normal tissues: membrane dipeptidase in the lung (33) and aminopeptidase P in the breast (95). How-

ever, other types of molecules also have been described. For example, we recently established prohibitin (a multifunctional membrane-associated protein) as a vascular marker of adipose tissue (97).

Organs such as the adrenal gland, kidney, pancreas, and brain contain structurally and functionally distinct regions that exhibit a unique vascular organization. To determine whether a differential expression of vascular addresses could be recognized by in vivo phage display within focal regions of the microvasculature, Yao and colleagues combined this technology with laser pressure catapult microdissection on murine pancreatic islets of Langerhans (90). Among several candidate proteins exhibiting structural homology with the peptide sequences recovered, two ephrin A-type ligand homologues, A2 and A4, were identified. Significantly, the vast majority of peptides that were isolated from the microvasculature of microdissected islet sections were not found among those from the acinar pancreas. Furthermore, sequences obtained from the acinar pancreas were also unique. This work further showed the ability of in vivo phage display to recognize molecular vascular heterogeneity.

Although the previously described studies were performed on mouse models and still allowed the identification of many putative human ligand and target homologues (34,85,98), mouse-derived probes might not always be useful for targeting applications in humans. Moreover, level of expression and distribution of targets can change among different species (94). This potential species-related diversity in ligand specificity, affinity and accessibility, and target expression and distribution should prompt careful evaluation of results obtained from animal studies before considering human applications. With this in mind, the construction of a human molecular

vascular map is clearly required to obtain human-relevant data in the field of vascular proteomics and to successfully translate vascular targeting into clinical practice.

We have recently taken the first steps toward such a fundamental task (94). A brain-dead patient with an end-stage B-cell lymphoproliferative disorder received an intravenous infusion of a CX<sub>7</sub>C (C = cysteine, X = any amino acid) random phage display peptide library. Fifteen minutes later, tissue biopsies were obtained from bone marrow, prostate, liver, fat, skeletal muscle, and skin to provide histopathological diagnosis and to recover phage from various organs. Phage isolated from each tissue were recovered for identification of the corresponding peptide inserts. To analyze the distribution of inserts, we designed a high-throughput pattern-recognition software for the comparison of short amino acid residue sequences (tripeptide motifs) retrieved both from phage recovered from the biopsies and from the unselected library. Analysis of the approximately 50,000 tripeptide motifs obtained from the recovered phage showed that their distribution to the different organs was not random. Some of the tripeptide motifs were recovered from a single tissue, whereas others were found in several, probably indicating binding to differentially expressed endothelial markers for the former and to ubiquitous endothelial molecules for the latter. Further analysis of shared motifs isolated from single organs (four to six amino acids long) found matches with known human proteins, potential circulating ligands (either secreted proteins or surface receptors present on circulating cells) for EC surface receptors. Among candidate human proteins potentially mimicked by selected peptide motifs, we identified interleukin (IL)-11 as a ligand mimicked by a peptide specifically enriched in prostate. The prostate-endothelium homing phage was shown in phage overlay assays to recognize the endothelium and epithelium of normal human prostate, but not other tissues, such as skin. Furthermore, it bound specifically to IL-11 receptor (IL-11 $\alpha$ ) *in vitro*.

These studies may form the basis of a targeted pharmacology, which could be particularly useful in the context of angiogenesis-dependent diseases.

#### *Vascular Targets in Tissues Undergoing Angiogenesis*

We have previously discussed the changes occurring in the vasculature of tissues undergoing angiogenesis. *In vivo* phage display is being used to investigate molecular differences between normal microvasculature and that with a dysregulated growth. Novel vascular markers have been identified, especially in the context of cancer-associated angiogenesis. Their tissue and cell distribution and accessibility to the circulation have been specifically addressed, and in some cases expression has even been correlated with disease/tumor stage. In addition, many of the vascular markers found in angiogenic blood vessels not only serve as target receptors for circulating ligands but also are functionally relevant and their activity can be modulated.

Exploring the vasculature in chronic inflammatory diseases has revealed site-specific ligands. Houston and colleagues

isolated peptides that home to atherosclerotic blood vessels in low-density lipoprotein receptor-deficient mice (99). Similarly, Liu and associates probed atherosclerotic lesions in *ApoE*<sup>-/-</sup> mice (100). Glucose-regulated protein 78 (GRP78), a cell-surface expressed chaperone identified by our group as the molecular target for autoantibodies associated with metastatic prostate cancer (101), was recognized as the endothelial surface receptor of one selected peptide (100). In addition, another peptide with sequence similarity to tissue inhibitor of metalloproteinase (TIMP)-2 showed specific binding to atherosclerotic endothelium *in vivo* (100). Targeting restenotic lesions after angioplasty, using a sequential *in vitro*-*in vivo* approach, Michon and colleagues selected phage binding to proliferating vascular smooth muscle cells and, after three rounds, to physically denuded common carotid artery in *ApoE*<sup>-/-</sup> mice (exposing the vascular smooth muscle cell layer) (102). An interesting strategy is being pursued by a group of investigators in the United Kingdom (89). These authors performed *in vivo* phage display selection on human synovial tissue from patients with rheumatoid arthritis or osteoarthritis transplanted subcutaneously into SCID animals (103). Based on their previous observation of the formation of functional anastomoses between human graft and murine subdermal blood vessels (104), they claim this model allows selection on human vasculature. Further validation of homing specificity in nongrafted human tissues, functionality, and additional results on different disease models are expected. Finally, exploring the effect of aging on cardioprotection from myocardial infarction, Cai and associates found a decrease in cardiac microvascular homing of tumor necrosis factor (TNF)- $\alpha$  mimic peptides *in vivo*, which was attributed to age-related downregulation of TNF-receptor 1 in murine heart (105).

*In vivo* screening of phage libraries has generated a panel of diverse peptide motifs that recognize markers in tumor-associated vasculature. The first ligand motifs identified by *in vivo* phage display in cancer, nowadays extensively validated, were RGD (arginine-glycine-aspartic acid, embedded in a double-cyclic peptide designated RGD-4C) and NGR (asparagine-glycine-arginine) (85). The RGD-4C peptide is a selective binder of the  $\alpha v \beta 3$  and  $\alpha v \beta 5$  integrins (106), which are known to be selectively expressed in human tumor blood vessels and many human tumor cells (107). Similar to some of the markers described for normal tissues, peptides containing NGR bind to a peptidase/protease: APN, also known as CD13 (34). Tumor homing by RGD-4C- and NGR-containing peptides is independent of the tumor cell's origin.

APN/CD13 and aminopeptidase A (APA), another vascular protease accessible to circulating ligands with known upregulation in tumor-associated pericytes (108), are functional targets in angiogenic vasculature in that they modulate angiogenesis (34,98). Their enzymatic activities contribute to proangiogenic pathways, because their functional ablation, either through genetic or biochemical methods, significantly reduces the formation of new blood vessels in several

angiogenesis-dependent conditions, including cancer and retinopathies.

By using phage libraries expressing random peptides or cDNA-encoded protein fragments, Ruoslahti and colleagues have been using an *ex vivo*–*in vivo* approach for screening of tumor angiogenesis in recent years. The phage library is first incubated on cell suspensions prepared from the target tissue, and then the enriched library is used *in vivo*. In one screen, phage were initially selected for binding to bone marrow cells *ex vivo* and subsequently in tumor-bearing mice, obtaining a ligand mimic of a fragment of the nuclear protein high mobility group (HMG) protein 2 (HMGN2) (109). A derived 31-aa synthetic peptide (F3) showed preferential accumulation in the nuclei of tumor-associated ECs and certain tumor cells. In a subsequent report, the target receptor for F3, also expressed in a nontumor angiogenesis model, was identified as cell surface nucleolin (110). Using the same strategy for screening but favoring the recognition of nonendothelial targets (by depleting the cell suspension of them), a new peptide homing to tumor cells and associated lymphatic vessels, LyP-1, was uncovered (111). LyP-1 showed no recognition of lymphatic vessels in normal tissues. Intriguingly, binding to a subset of cultured tumor cells correlated with the ability of LyP-1 to recognize the putative tumor lymphatics in orthotopic xenografts and metastatic lesions derived from them (112). Moreover, LyP-1 presented an intrinsic proapoptotic effect (112). However, the surface molecule to which LyP-1 binds, which may be implicated in the peptide's activity, has not yet been identified. As an additional proof of the molecular specialization of the vasculature and the sensitivity of *in vivo* phage display to detect it, two studies have shown molecular signatures associated with different stages of tumor progression, from dysplasia to invasive cancer (113,114). By using transgenic mouse models for multistage tumorigenesis (K14-HPV16 squamous [113] and RIP-Tag2 pancreatic islet [114] carcinomas), different tumor-type and tumor-stage-specific vascular homing peptides were obtained.

*In vivo* phage display also has made possible the identification of other peptide sequences targeting tumor vasculature, including those accompanying irradiated tumors (115), a model of rat glioblastoma (116), and human gastric cancer transplanted to the subrenal capsule of immunosuppressed mice (117).

By validating the IL-11/IL-11R $\alpha$  ligand–receptor pair in human prostate cancer (94), we have recently shown that ligand–receptor pairs in the context of a normal tissue can still be present and functional in cancer, even when the cancer has metastasized (118). We found the expression of IL-11R $\alpha$  in the blood vessel and tumor compartments (and its recognition by our IL-11 mimic sequence) progressively increased with prostate cancer progression. Furthermore, a proapoptotic peptide guided by the IL-11 mimotope specifically targeted and internalized in IL-11R $\alpha$ -expressing prostate cancer cells, inducing apoptosis (118). Our results further illustrate the value of *in vivo* phage display for the identification of relevant targets in the context of human disease.

## VASCULAR ADDRESSES FOR TARGETED DELIVERY

There is an obvious pharmacokinetic advantage in making use of the molecular differences in the vasculature for targeting. We have reviewed several examples of targeted ligands identified by phage display exhibiting an intrinsic functional capability. In the majority of cases, however, ligands selected for homing to blood vessels have been used to guide the delivery of coupled therapeutic and diagnostic agents. Cytotoxic drugs (85,119,120), proapoptotic peptides (93,97,121,122), thrombogenic agents (123), metalloprotease inhibitors (62), cytokines (124,125), genes (80,126–129), and liposomes (130,131) have been addressed to receptors in the vasculature. Although most of the experiments have been performed in cancer (85,93,112), other experimental models of disease also have been explored (97,132). This approach, in general, showed enhanced therapeutic efficacy and decreased side effects for targeted versus parental untargeted agents, clearly illustrating the value of the targeting technology for therapy. Tumor-targeting peptide ligands also have been used to guide and deliver imaging agents, in particular RGD (133–137).

Several factors influence the success of a targeting strategy (138). Among them, features that explain the specificity achieved for vascular targets identified by *in vivo* phage display have to be considered, including preferential expression of the target in an organ or tissue of interest, accessibility of the target from the circulation, and environment-dependent modifications in the target. An additional feature achieved by many targeting peptides, internalization capability, can be important for homing selectivity and intracellular delivery of functional moieties. An illustrative example is APN/CD13, which has been extensively targeted for tumor therapy in animal models (85,121,124). APN/CD13 was recognized as the principal receptor for the NGR peptide motif, a tripeptide sequence previously identified by *in vivo* phage display that homes strictly to the endothelium of angiogenic blood vessels (34,85). APN/CD13 is expressed in epithelial cells in the liver, intestine, bile duct, brain, kidney, prostate, and lung; in fibroblasts and smooth muscle cells; and in the normal and leukemic progeny of myeloid cells (139). Although some of these locations (in particular those in hematopoietic compartments) are accessible from the circulation, NGR-containing peptide ligands mostly recognize the endothelial and periendothelial cell compartment of angiogenic blood vessels. The basis for this restricted recognition pattern appears to be the existence of different APN/CD13 forms in normal epithelial cells, tumor-associated vessels, and myeloid cells, so that a tumor vessel-related APN/CD13 form, but not those associated with epithelial and myeloid cells, functions as an NGR receptor (139). Moreover, it has been reported that APN/CD13 has multiple enzymatic activities depending on the tissue microenvironment. Studies using antibodies and natural peptide substrates indicate that APN/CD13 undergoes conformational changes and exposure of cryptic epitopes upon binding, which regulate

enzymatic activity (140). Factors present only in the tumor microenvironment might cause a differential reactivity or accessibility to different APN/CD13 ligands, such as the tumor vasculature-targeting NGR peptides. This example clearly demonstrates the importance of using a functional proteomics method, such as in vivo phage display, for the identification of ligands that target molecules with complex regulatory mechanisms and expression patterns in time and space.

#### KEY POINTS

- The recognition of heterogeneity in the vasculature is longstanding. However, the significance, extent, molecular diversity, and potential utility of this heterogeneity in health and disease are now being more fully appreciated and exploited thanks to the in vivo phage display technology.
- In vivo phage display provides novel tools for selective vascular targeting and identifies corresponding vascular cell surface receptors accessible to the circulation.
- In vivo phage display also improves our understanding of organ and tissue vascular specificity in health and disease and contributes to a definition of the functional role that new targets play in the pathogenesis of the many angiogenesis-related diseases.

#### Future Goals

- To proceed from the ligands identified by in vivo phage display to new targets in blood vessels, sophisticated state-of-the-art array proteomic technologies and precise target validation methods are needed.
- To construct, using in vivo phage display technology, a detailed map of the molecular specificities of the human vasculature that can be used to improve our understanding of human disease and to develop clinical applications

#### ACKNOWLEDGMENTS

Our work was funded by grants from the NIH and DOD to R. P. and W. A., and the Gillson-Longenbaugh Foundation. A.J.Z. received a fellowship from the Instituto de Salud Carlos III, Spain.

## Hemostasis and the Endothelium

William C. Aird

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Vascular thrombotic disorders are the leading causes of mortality in the Western world. It is interesting to note that most, if not all of these disorders, although consisting of a systemic imbalance in hemostasis, are characterized by the development of focal thrombotic lesions (Tables 101-1 and 101-2). For example, microangiopathic hemolytic anemia (e.g., hemolytic uremia syndrome and thrombotic thrombocytopenia purpura) affect every microvascular bed with the notable exception of the liver and lung (see Chapter 146). The congenital hypercoagulable states, as exemplified by the factor V Leiden mutation, are associated with systemic changes in clotting factor level and/or activity, yet generally predispose patients to an increased risk of venous, and not arterial, thrombosis (1,2). In patients with warfarin-induced skin necrosis (a rare complication of coumarin treatment), a systemic imbalance occurs in vitamin K–dependent clotting factors (circulating protein C is disproportionately low compared with circulating factors II, VII, IX, and X). Remarkably, fibrin deposition is limited to postcapillary venules of the dermis (3,4). In the final analysis, very few, if any, thrombotic diseases affect the entire vasculature (2). This observation is supported by genetic mouse models, in which the deletion of one or another natural anticoagulant mechanisms results in vascular bed–specific fibrin deposition and thrombosis (5). An important question that arises from these clinical and animal studies is how a systemic imbalance in hemostasis is ultimately manifested by local rather than diffuse vasculopathic lesions. As discussed herein, the endothelium provides an important clue to the answer.

### CLASSIFICATIONS IN HEMOSTASIS

*Hemostasis* is strictly defined as the arrest of bleeding. *Coagulation* is the transformation of a liquid into a semisolid or solid, coherent mass. In day-to-day practice, the terms *hemostasis* and *coagulation* are used interchangeably to describe the physiological process by which blood is maintained in a fluid state within the closed circulation. Hemostasis may be classified

according to several schemes, some of which are outlined here (notably absent is a discussion of congenital versus acquired hemostatic defects).

### Primary versus Secondary Hemostasis

Primary hemostasis refers to the platelet response, whereas secondary hemostasis refers to the soluble circulating clotting factors that converge in a cascade of enzymatic reactions to generate the end product, fibrin. In reality, the cellular and protein components of hemostasis are highly coordinated and interdependent; they function in unison in both space and time. Nevertheless, a conceptual distinction between these two compartments is helpful when considering mechanisms, diagnosis, and therapy. Platelets arise through the membrane budding of terminally differentiated precursor cells, termed *megakaryocytes*, which are located in the bone marrow. The megakaryocyte is one of the largest cells in the mammalian body and one of the few cells in the animal kingdom with a hyperdiploid or polyploid nucleus. Once released into the blood, platelets circulate freely as small discoid-shaped anucleate cells. When activated, platelets undergo a change in shape, adhere, and aggregate. During this process, they present a newly activated cell surface for assembly of the clotting cascade – just one example of the cross-talk that occurs between primary and secondary hemostasis. (The dialogue between platelets and endothelial cells is further detailed in Chapter 64). Assays for primary hemostasis include an inspection of the peripheral blood smear, platelet count, and a small number of ancillary tests, including platelet aggregation studies and heparin-induced thrombocytopenia (HIT) antibodies.

Secondary hemostasis consists of circulating proteins that are synthesized primarily in the liver. Exceptions include factor VIII (whose source is still debated), tissue factor (TF), and some of the anticoagulant proteins (discussed later). Clotting is initiated by TF-mediated activation of factor VII (extrinsic pathway) (Figure 101.1). TF is a transmembrane protein expressed on the surface of activated monocytes, in the subendothelial layers of the blood vessel wall, and by certain subsets

**Table 101-1: Hypercoagulable States Associated with Disorders of Primary Hemostasis<sup>†</sup>**

	<i>Disease/Disorder</i>	<i>Site of Thrombosis</i>
<b>Acquired</b>	TTP	All organs except lung and liver
	HUS	Predominantly kidney
	MPD	Portal/hepatic veins
	PNH	Portal/hepatic veins
	DIC	Microvessels; all organs are susceptible
	HIT	Arteries, veins, often in unusual sites
	APS	Arteries and veins
	Atherosclerosis	Conduit arteries
<b>Congenital</b>	Sickle cell disease	Microvessels, especially joints

TTP, thrombotic thrombocytopenia purpura; HUS, hemolytic uremic syndrome; MPD, myeloproliferative disorder; PNH, paroxysmal nocturnal hemoglobinuria; DIC, disseminated intravascular coagulation; APS, antiphospholipid antibody syndrome

<sup>†</sup>Primary and secondary hemostasis are integrally linked; therefore most of these diseases also are associated with activation of the clotting cascade. This is particularly true in the case of DIC, HIT, and APS.

of endothelial cells. Interestingly, the precise source of TF that is responsible for initiating coagulation in physiological states is still an open question – one that ultimately will be addressed by studying genetic mouse models lacking TF in one or another cell lineage. The clotting cascade is amplified through the intrinsic pathway via mechanisms that involve cross-talk (factor VIIa of the extrinsic pathway activates factor IX of the intrinsic pathway) and feedback (thrombin activates factors XI and VIII of the intrinsic pathway). The clotting cascade consists of a series of linked reactions in which a serine protease, once activated, is capable of activating its downstream substrate. These enzymatic reactions are phospholipid-dependent and take place on activated cell surfaces. Some reactions are accelerated by the presence of cofactors, namely factor VIIIa (which accelerates factor IXa-mediated activation of factor X) and factor Va (which accelerates factor Xa-mediated activation of prothrombin). In the final step of the clotting reaction, the serine protease, thrombin, cleaves the structural protein, fibrinogen, to generate fibrin. Fibrin is ultimately cross-linked through the activity of factor XIIIa.

For every procoagulant reaction, a natural anticoagulant response occurs. The anticoagulant mechanisms are regulated primarily by the endothelium. The endothelium expresses tissue factor pathway inhibitor (TFPI) (6), which forms a quaternary structure with TF, VIIa, and Xa, thus inhibiting the extrinsic pathway. The endothelium synthesizes heparan, a cofactor for antithrombin III (ATIII), which neutralizes each of the serine proteases in the clotting cascade (7,8). Protein C is converted to activated protein C in the presence of endothelial membrane-bound thrombomodulin (TM) and endothelial protein C receptor (EPCR) (9). Once activated, protein C inactivates the cofactors of the clotting cascade (factors VIIIa

and Va), a process that is accelerated by the cofactor protein S. Finally, the fibrinolytic system may be thought of as a natural anticoagulant mechanism, in which plasmin degrades preformed fibrin. The endothelium synthesizes several proteins involved in fibrinolytic balance, including tissue-type plasminogen activator (t-PA) and plasminogen activator (PAI)-1.

Assays for secondary hemostasis include mixing studies, partial thromboplastin time (which measures the integrity of the intrinsic pathway), prothrombin time (which measures activity of the extrinsic pathway), and specific clotting factor assays. On the anticoagulant side, assays exist for ATIII, protein C, and protein S (TFPI levels also can be measured, but provide little in the way of useful information). In addition, genetic screening is available for diagnosing the factor V Leiden mutation and the prothrombin 20210 mutation, both of which are associated with increased risk for thrombosis. Routine assays do not presently exist for those anticoagulants that are bound to the endothelium, including TM, EPCR, and heparan (for an example of a study that describes expression of TM and EPCR in human subjects, see Ref. 10).

### Hemostasis as a Finely Tuned Balance

Hemostasis may be viewed as a finely tuned balance between procoagulant and anticoagulant forces (1). On the procoagulant side is the monocyte, the platelet (primary hemostasis), and the clotting cascade (secondary hemostasis). The anticoagulant side includes the four mechanisms described in the previous section (TFPI, heparan/ATIII, protein C/protein S/TM, and fibrinolysis). In addition, blood flow (or lack of stasis) facilitates clearance of activated proteases and provides the endothelium with protective levels of shear stress. The maintenance of vascular integrity (intact endothelium) and the attenuation of negatively charged membrane surfaces limit the activation of primary and secondary hemostasis. Depending on which side the scale tips toward, abnormalities in hemostasis clinically manifest either bleeding (hemorrhage) or thrombosis (clotting).

### Virchow's Triad

Virchow's triad represents a time-honored approach to hypercoagulability. The triad consists of a change in the blood vessel wall (namely loss of vascular integrity), a reduction in blood flow (namely stasis) or an alteration in blood constituents. Impairment in vascular integrity and/or local alterations in blood flow – as occur, for example, following hip surgery – are sufficient to explain many causes of focal or site-specific thrombosis. It may be argued that low flow in the deep veins of the leg render this site particularly vulnerable to thrombosis in patients with congenital hypercoagulable states. Moreover, patients with congenital hypercoagulable states have an increased risk of venous thromboembolism following trauma, surgery, or immobilization (11,12). However, Virchow's triad – as it is usually interpreted – fails to explain certain thrombotic phenotypes (e.g., the lack of correlation between congenital

**Table 101-2: Hypercoagulable States Associated with Disorders of Secondary Hemostasis**

	<i>Disease/Disorder</i>	<i>Virchow's Triad*</i>	<i>Site of Thrombosis</i>
<b>Acquired</b>	Pregnancy	S/B	DVT
	Immobilization	S	DVT
	OCP	B	DVT
	V/A catheters	T	Site of catheter
	Trauma	T	Site of trauma
	Surgery	S/T	Site of surgery, DVT
	Sepsis	S/T/B	Multiple (but not all) organs
	Congestive heart failure	S	DVT
	DIC	B	Multiple (but not all) organs
	HIT	T/B	Arteries and veins
	APS	B	Arteries and veins
	Cancer	S/T/B	DVT
	Atherosclerosis	T/B	AMI, stroke, peripheral artery
	Organ transplantation	S/T/B	Transplanted organ
	Hyperhomocysteinemia	B	Venous and arterial
Nephrotic syndrome	B	DVT, renal vein thrombosis	
<b>Congenital</b>	ATIII deficiency	B	DVT
	PC deficiency	B	DVT
	PS deficiency	B	DVT
	Prothrombin mutation	B	DVT
	V Leiden	B	DVT
	Fibrinolytic defects (e.g., plasminogen deficiency)	B	DVT
	Dysfibrinogenemia	B	DVT
	Sickle cell disease	S/T/B	Different organs
	Hyperhomocysteinemia	B	Arteries and veins

OCP, oral contraceptive pill; V/A, venous or arterial; PC, protein C, PS, protein S; DVT, deep venous thrombosis; AMI, acute myocardial infarction

\*Listed are the major contributors in Virchow's triad (as originally defined). S, stasis; B, blood constituents; T, trauma to blood vessel wall. Virtually every disease has an endothelial component.

hypercoagulable states and arterial thrombosis). Assuming that such individuals have the same incidence of atherosclerosis and plaque rupture as the normal population, then Virchow's triad would predict a higher rate of acute myocardial infarction. Another example worth considering is warfarin-induced skin necrosis. The fundamental abnormality is a disproportionate reduction in *circulating* protein C. According to Virchow's triad, the predilection for dermal clots must be explained by local stasis and/or damage in the microvasculature of the skin. No evidence supports either of these mechanisms.

When Virchow proposed his triad in 1845, virtually no understanding existed of the biology of the vessel wall or the nature of the blood constituents. However, as argued in the sections that follow, a modified version of Virchow's triad, which takes into account the critical role of the endothelium in modulating hemostatic phenotypes, provides a conceptual framework for approaching the local nature of thrombotic disorders.

## SPATIAL AND TEMPORAL DYNAMICS OF THE ENDOTHELIUM

The endothelium plays a critical role in mediating hemostasis (1,13–15). As discussed earlier, ECs express TFPI, heparan, TM, EPCR, t-PA. Other endothelial-derived anticoagulants include ecto-ADPase, prostacyclin, and nitric oxide. On the procoagulant side, ECs synthesize TF, PAI-1, von Willebrand factor (vWF), and protease-activated receptors (1). Importantly, endothelial-derived anticoagulant and procoagulant molecules are unevenly distributed throughout the vasculature (Table 101-3). For example, TFPI is expressed predominantly in capillary endothelium, EPCR in large veins and arteries, endothelial nitric oxide synthase (eNOS) on the arterial side of the circulation, vWF in veins, and TM in blood vessel types of every caliber in all organs except the brain (1,16–18). TF is not detectable in normal endothelium, whereas in a baboon model of sepsis, the gene is upregulated in a subset of endothelial cells in the marginal zone of splenic follicles (19),

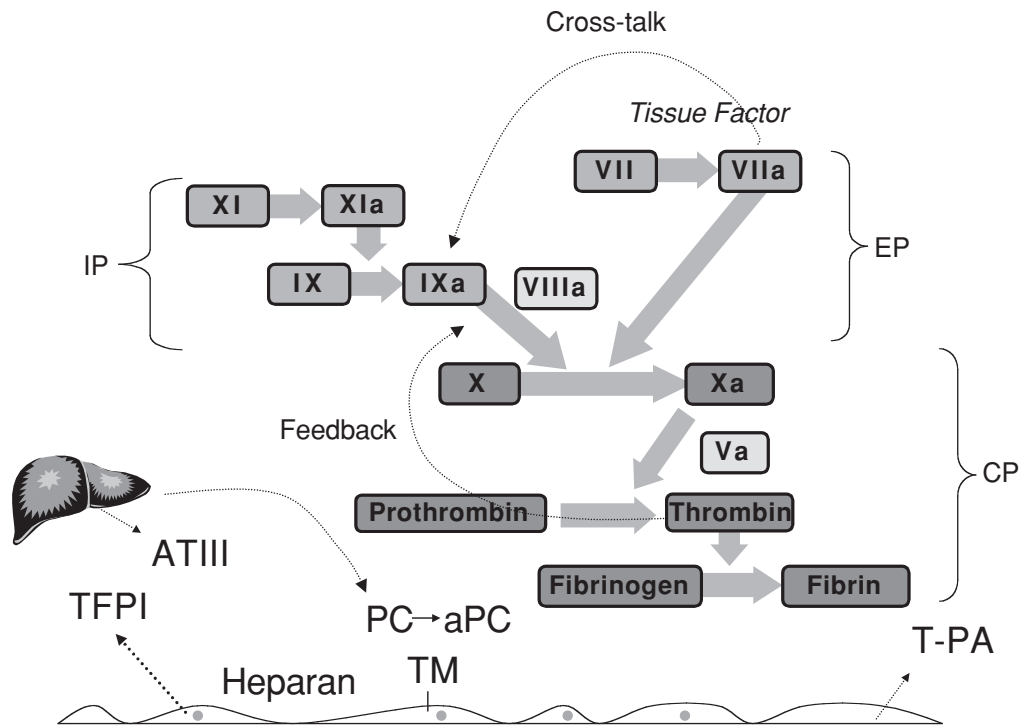

Figure 101.1. The coagulation pathway. The clotting cascade consists of an extrinsic pathway (*EP*; tissue factor, factor VII), an intrinsic pathway (*IP*; factors XI, IX, VIII), and a common pathway (*CP*; factors X, V, (pro)thrombin, and fibrinogen). Factors VII, XI, IX, X, II (thrombin) are serine proteases; factors V and VIII are cofactors; fibrinogen is a structural protein. Shown are the four major classes of natural anticoagulants: antithrombin III (ATIII)-heparan (which inhibits the serine proteases of the clotting cascade), protein C (PC)/protein S (not shown) and thrombomodulin (TM) (which inhibits the cofactors of the clotting cascade), tissue factor pathway inhibitor (TFPI) (which inhibits the extrinsic pathway), and the fibrinolytic system (A activates plasmin, which degrades fibrin). The liver and endothelium (the cell lining at bottom) both contribute to the synthesis and release of hemostatic factors. Note that factor XII is not included in the scheme. This factor, which can activate factor XI in vitro, is important to consider when interpreting results of coagulation assays. However, it does not play a critical role in mediating in vivo hemostasis. Two key links connect the extrinsic and common pathways with the intrinsic pathway. First, factor VIIa activates factor IX (cross-talk). Second, thrombin activates factors XI and VIII (feedback). t-PA; tissue-type plasminogen activator. The activated form of the serine protease is indicated by the suffix “a”.

and in regions of disturbed flow (20). These data suggest that endothelial cells from different sites of the vascular tree employ site-specific “formulas” of procoagulants and anticoagulants to balance local hemostasis. These observations provide a powerful foundation for an integrated model of hemostasis (for review, see Ref. 21).

### INTEGRATED MODEL OF HEMOSTASIS

The liver synthesizes a relatively constant amount of fibrinogen, serine proteases, cofactors, and anticoagulants (protein C, ATIII, protein S) (Figure 101.2). The bone marrow produces and releases into the circulation a relatively fixed number of monocytes and platelets, cells that are capable of either expressing TF or promoting clotting reactions. This net output of liver-derived proteins and marrow-derived cells is systemically distributed and integrated into the unique hemostatic

balance of each and every vascular bed. Thus, when an alteration occurs in the net output of proteins (e.g., protein C or factor V Leiden deficiencies) or cells (e.g., increased activation of monocytes and/or platelets in sepsis), the changes affect the hemostatic balance in ways that differ among various sites of the vascular tree. To return to the example of warfarin-induced skin necrosis, it seems likely that the site-specific hemostatic balance of the postcapillary venular endothelium in the skin renders the dermal microvasculature particularly vulnerable to the systemic imbalance in vitamin K-dependent factors, particularly protein C. Interestingly, a similar pattern of thrombosis is seen in purpura fulminans associated with congenital homozygous protein C deficiency or meningococemia-induced acquired protein C deficiency (22). Based on the sensitivity of dermal microvessels to protein C deficiency, it is interesting to speculate that dermal endothelium expresses lower levels of other natural anticoagulants (e.g., TFPI, heparan, and/or t-PA) compared with other

**Table 101-3: Distribution of Representative Endothelial-Derived Hemostatic Factors**

<i>Factor</i>	<i>Distribution</i>
vWF	Veins
eNOS	Arteries
TFPI	Capillaries
EPCR	Large veins and arteries
t-PA	Highest levels in brain; in lung in bronchial but not pulmonary circulation
TM	Absent in brain

vascular beds or that factors V and VIII are preferentially activated at this site.

Adding another layer of complexity (and heterogeneity) to the model is the fact that the endothelium may be differentially activated between sites of the vasculature. For example, sepsis may be associated with the local accumulation of cytokines and secondary changes in leukocyte adhesion, thrombin generation, barrier function, blood flow, and oxygenation, each of which may affect the local endothelial-derived hemostatic balance.

This revised scheme offers certain advantages over older models. First, it is more inclusive in that it recognizes the

involvement of four functionally linked organ systems in mediating coagulation: namely, the liver, bone marrow, cardiovascular system, and endothelium. In this way, we are reminded of the importance of the hepatocyte in synthesizing the serine proteases, the two cofactors, fibrinogen, and the natural anticoagulants, ATIII, protein C, and protein S; the critical role of the TF-expressing monocyte in initiating coagulation; the participation of the platelet in localizing and perpetuating the coagulation response; and the importance of the EC as a manufacturer of hemostatic factors and regulator of the hemostatic balance. Second, the scheme incorporates both primary and secondary hemostasis. All too often, the cellular and soluble phases of coagulation are perceived as separate and independent entities that operate in series, when in fact they are highly integrated, parallel processes. Finally, the paradigm provides a useful conceptual framework for understanding the local nature of thrombotic diathesis. The very existence of vascular bed-specific phenotypes is enough to explain how a systemic imbalance in proteins and/or cells may be channeled into local clot formation.

It is not difficult to reconcile this model with that of Virchow. Two observations have not changed over the past 150 years. First, stasis of flow (e.g., secondary to obesity, tumor, congestive heart failure, pregnancy, or immobility) when introduced into the system, may lead to the accumulation of activated clotting factors, reduction in protective

Figure 101.2. Integrated model of hemostasis. The liver (*left*) produces the serine proteases, cofactors fibrinogen of the clotting cascade (shown as Y-shape), and many of the circulating natural anticoagulants. Shown are protein C (C), protein S (S), antithrombin III (ATIII). The bone marrow (*right*) releases monocytes (Monos) and platelets (PLT), which are capable of expressing tissue factor and/or an activated cell surface. The liver and bone marrow-derived proteins and cells are systemically distributed and integrated into the unique hemostatic balance of each vascular bed (shown are balances in two hypothetical vascular beds). (Adapted with permission from Aird WC. *Crit Care Med*. 2001 July; 29:S28–34.)

hemodynamic forces, and downstream hypoxia – all of which may tip the balance to the procoagulant side. Second, frank disruption or denudation of the endothelium (e.g., as occurs in trauma, surgery, or catheter placement) may result in the exposure of blood to subendothelial adventitial TF and secondary thrombosis. However, two new observations warrant emphasis. First, when talking about blood constituents, we now appreciate the importance not only of the soluble clotting factors, but also of the cells – and not just the platelet, but also the monocyte, perhaps the single most important initiator of blood coagulation. Second, we now understand that the endothelium is far from a passive barrier; it is highly active, very much alive, rich in diversity, and steeped in complexity – and as a result is a critical determinant of local hemostatic balance. Based on our new knowledge, Virchow's triad may be modified – slightly – to incorporate not only of the structural but also the functional integrity of the vessel wall, particularly as it relates to the endothelium.

## CONCLUSION

Virchow's triad has withstood the test of time and continues to provide a working foundation for approaching patients with thrombotic disorders. However, the strict application of nineteenth-century principles to a modern-day understanding of thrombosis neglects important advances in the fields of hemostasis and vascular biology. In this chapter, we have proposed an integrated model that honors the spirit of the original triad, while at the same time recognizing the critical role of the endothelium in mediating hemostasis.

### KEY POINTS

- The endothelium is a key regulator of hemostasis and serves to channel systemic imbalances in hemostasis into focal thrombotic phenotypes.
- The endothelium synthesizes many procoagulant and anticoagulant molecules.
- Each vascular bed expresses a unique repertoire of procoagulant and anticoagulant molecules.
- The endothelium is part of an integrated model of hemostasis that includes the activity of multiple organs, cells, and soluble proteins.

### Future Goals

- To determine the primary source of TF
- To elucidate/catalogue vascular bed-specific balances of procoagulant and anticoagulants
- To use that information to develop site-specific anticoagulant therapies

## Von Willebrand Factor

---

Tom Diacovo

*Columbia University, New York City, New York*

von Willebrand factor (vWF) is a large glycoprotein of complex multimeric structure. It is synthesized exclusively by vascular endothelium and megakaryocytes, and is stored and secreted by these cell types as well as by circulating platelets. In blood, it serves not only as a carrier for factor VIII, protecting it from proteolysis, but also plays a critical role in hemostasis by promoting platelet deposition at sites of endothelial cell (EC) injury. To accomplish this task, vWF must form a “bridge” between components of the subendothelial matrix or the surface of inflamed venular endothelium and receptors expressed on circulating platelets. One remarkable feature of this plasma glycoprotein is its ability to support significant interactions with platelets only upon surface immobilization and under specific hemodynamic conditions. This avoids the disastrous consequences of platelet–vWF aggregate formation in flowing blood. The importance of vWF in hemostasis is underscored by the occurrence of clinical bleeding when plasma levels fall below 50 IU/dL or when functional defects are present in the protein due to spontaneously occurring or inherited mutations. Such abnormalities result in von Willebrand disease (vWD), the most common inherited bleeding disorder in humans, with an estimated prevalence of 1% in the general population (1,2).

### HISTORICAL ASPECTS

Recognition that certain families may have a predisposition to bleeding has been described in the Talmud and other Hebrew writings as early as the second century A.D. (3). These Jewish texts decreed that offspring were exempt from circumcision if deaths due to hemorrhage occurred in other male siblings undergoing this procedure, suggesting that these individuals suffered from hemophilia. Yet, it was not until 1926 that the Finnish physician, Dr. Erik von Willebrand identified a new bleeding disorder he termed *hereditary pseudohemophilia* (4). In his initial study, he described a hematological disorder, affecting several families, which was transmitted in an autosomal dominant fashion and presented mainly as recurrent episodes of mucosal bleeding but occasionally as fatal hem-

orrhages. Although bleeding time was prolonged despite relatively normal platelet counts in afflicted individuals, there was a lack of a male gender bias, distinguishing it from hemophilia. Unfortunately, the etiology of this newly defined bleeding disorder remained elusive to Dr. von Willebrand throughout his career. It would eventually be named in his honor, vWD.

It was not until 45 years later when immunologic assays were devised to measure the levels of clotting factors in blood that a deficiency in a plasma protein distinct from factor VIII, termed vWF, was identified as the cause for this bleeding disorder. Subsequent cloning of the *vWF* gene, together with knowledge pertaining to its synthesis, secretion, and ligand-binding characteristics have been instrumental in elucidating the molecular mechanisms that contribute to this disorder, as well as in the development of a classification system for vWD. More recently, crystallographic analysis of specific regions contained within this plasma protein has provided important insights into potential structural mechanisms that may regulate its hemostatic properties.

### VON WILLEBRAND FACTOR GENE

The gene encoding for human vWF has been cloned and located on chromosome 12p13.2, while its murine counterpart has been identified on chromosome 6. It spans 178 kb and contains 52 exons corresponding to 8.7 kb of mRNA (5). A noncoding, highly similar pseudogene has been identified on chromosome 22q11–13 in higher primates and includes a region spanning from exon 23 to 34 (6). However, it is not believed to yield functional transcripts because of the presence of a splice site and nonsense mutations. Distinct modifier genes and cell type–specific transcription factors are believed to regulate plasma levels of vWF and account for its restricted expression in megakaryocytes and ECs (7–10).

The primary translation product is a 2,813-residue precursor polypeptide, referred to as prepro-vWF, which consists of a 22-residue signal peptide, a 741-residue propeptide, and the mature subunit of 2,050 residues (molecular weight ~278 kDa) (Figure 102.1). The nascent vWF protein is highly

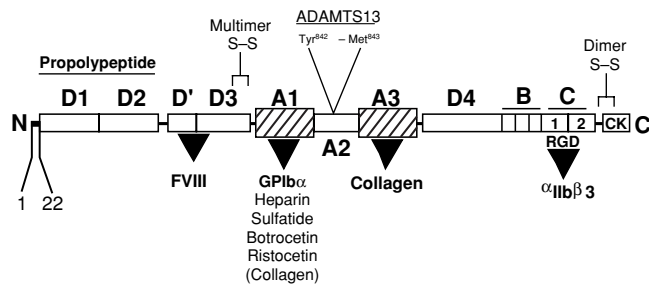

Figure 102.1. Schematic representation of prepro-vWF. The vWF precursor consists of a signal peptide (residues 1–22), a propeptide (residues 23–763), and the mature subunit (residues 764–2050). The location of the five types of conserved structural domains is indicated, as well as their respective ligands or receptors (boldface designates a major receptor or ligand). Location of intersubunit disulfide bonds yielding pro-vWF dimers or multimers of the mature protein also is indicated.

glycosylated (10%–19%), containing 22 carbohydrate side chains, 10 of which are *O*-linked to Ser or Thr residues and 12 *N*-linked to Asn residues (11). The *N*-linked oligosaccharides of vWF synthesized in endothelium are unusual in that they contain ABO blood group antigens (12). Although the presence of these blood group antigens appears to impact on vWF levels, they only account for a fraction of the total variation in the population (20%–30%). Evidence is mounting, however, that the pattern of vWF glycosylation may be important in regulating its stability and function in the circulation. This is supported by the shortened half-life of circulating vWF in animals lacking oligosaccharide branch-specific sialylation because of a deficiency in ST3Gal-IV sialyltransferase (13).

### VON WILLEBRAND FACTOR PROTEIN

To provide effective hemostasis, vWF must exist in a multimeric form composed of dimers of the mature peptide. Considerable progress has been made in understanding the biochemistry of this process in endothelium, which appears to occur in an analogous manner in megakaryocytes (14). Pro-vWF subunits are assembled in the endoplasmic reticulum, “tail-to-tail” through disulfide bonds formed between their carboxy termini. Specifically, a cysteine knot (CK) domain comprised of 90 residues has been implicated in dimerization, based on a naturally occurring mutation in humans and site-directed mutagenesis studies (15). After the formation of this dimeric building block, the glycosylated, pro-vWF dimers are transported to the Golgi, whereupon multimerization occurs through the formation of “head-to-head” intersubunit disulfide bonds at the amino-termini ends of dimers. This process requires the presence of the propeptide, which is comprised of domains D1 and D2, because multimer formation in, but not transport to, the Golgi is abolished in its absence. The D1 and D2 domains possess CXXC motifs found in thiol:disulfide oxidoreductases, enzymes known to promote the rearrangement

or the formation of disulfide bonds. Recent evidence has suggested that the propeptide may indeed function in this capacity (16). Ultimately, this process can yield vWF multimers that contain more than 40 subunits, exceeding 20,000 kDa in size; these are comparable in length to the diameter of a platelet ( $4 \mu\text{M}$ ). The highest-molecular-weight multimers are most functionally active in hemostasis, and are ultimately stored in Weibel-Palade bodies in endothelium and in  $\alpha$ -granules in platelets (17). In the case of the former, vWF appears to have a heterogeneous pattern of expression in blood vessels, as determined by immunohistology, with the strongest staining intensity exhibited in veins, followed by arteries, arterioles, capillaries, and venules (18).

### STORAGE AND SECRETION IN ENDOTHELIUM

Two distinct pathways of secretion exist for vWF produced by endothelium: one constitutive, which is linked to synthesis and is directed toward both the apical and luminal surfaces; the other inducible, relying on storage and subsequent release from an intracellular, membrane-bound organelle known as a Weibel-Palade body, in response to physical trauma or physiological agonists (Figure 102.2). This latter pathway is most efficacious in terms of platelet recruitment. This is explained by the fact that the majority of high-molecular-weight multimers synthesized by endothelium are retained in Weibel-Palade bodies. In response to agonists that raise either intracellular  $\text{Ca}^{2+}$  (i.e., thrombin) or cyclic adenosine monophosphate (cAMP) levels (i.e., epinephrine and vasopressin), Weibel-Palade bodies undergo exocytosis in a basolateral direction, resulting in an increase in the effective concentration of large multimers in the extracellular matrix (ECM) (14). By contrast, this unique polarity appears to be lost upon the biomechanical disruption of the endothelium, which has been reported to result in the bidirectional release of high-molecular-weight multimers of vWF. This alteration in secretion may prevent further

Figure 102.2. Secretion of vWF from endothelium. (A) Constitutive secretion to plasma and extracellular matrix (ECM). (B) Storage in Weibel-Palade body (WPB). (C) Exocytosis of WPB in response to circulating agonists. (D) Exocytosis of WPB in response to biomechanical disruption of the endothelium.

dislodgement of damaged endothelium by anchoring it to the ECM, while simultaneously providing an effective substrate for platelet deposition. In either case, this ensures that the resulting thrombogenic response will be maximal at the site of injury. vWF storage, however, is not limited to ECs because megakaryocytes and platelets also possess this capability (stored in organelles known as  $\alpha$ -granules); however, this source of vWF contributes minimally to plasma levels (19). Release of  $\alpha$ -granule contents requires platelet activation, which occurs in response to agonists generated or exposed at sites of vascular injury. Both the constitutive and inducible secretory pathways in endothelium contribute to plasma levels of mature vWF, which average approximately 100 IU/dL (range 50–200 IU/dL), with a circulating half-life of approximately 12 hours (20,21). Because the distribution of vWF in the subendothelial matrix may be variable throughout the vascular system, this circulating pool of vWF is believed to be important in ensuring rapid platelet deposition wherever injured tissue comes into contact with circulating blood.

#### REGULATION OF PLASMA VON WILLEBRAND FACTOR MULTIMER SIZE

Once released into the circulation, vWF is then subjected to proteolysis that converts the large multimers into a series of smaller ones. This involves cleavage of a single bond between residues Tyr842 and Met843 of its A2 domain, a process that relies on the activity of a metalloprotease known as ADAMTS13 (a disintegrin and metalloprotease, with thrombospondin-1-like domains, member 13) (22) and is enhanced in the presence of fluid shear force (23). The gene encoding this protein has been identified and localized to chromosome 9q34 in humans. The importance of vWF proteolysis is exemplified by genetic mutations or circulating autoantibodies that result in loss of protease activity, contributing to chronic thrombotic thrombocytopenic purpura (TTP). This disorder is characterized by the presence of unusually large vWF multimers (ULvWF) in plasma and the formation of thrombi in the microcirculation. It is believed that these ULvWF multimers are responsible for spontaneous platelet clumping in TTP.

#### STRUCTURE AND FUNCTION OF PLASMA VON WILLEBRAND FACTOR

The majority of the mature vWF protein (>90%) consists of four domains, each of which is present in multiple copies and exhibits internal homologies with one another. They are arranged in the following order: D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2 (see Figure 102.1). In general, each domain performs a specific function, but may interact with several ligands. In regard to hemostasis, the A1 domain of vWF is solely responsible for supporting the initial capture of circulating platelets, while the primary function of its A3 domain

is to anchor the vWF-platelet complex to the site of injury. Significant progress has been made in terms of elucidating the structural elements contained within these two domains that form direct contacts with or regulate their interactions with ligands.

For vWF to commence platelet recruitment to a region of vascular damage, it must first become immobilized by interacting with a reactive surface. The A3 domain (residues 910–1111 of mature vWF) is well suited for this process because it contains a functional binding site for collagen, a major component of exposed ECM (24). Evidence to support this claim is provided by an *in vivo* animal study demonstrating a reduction in arterial thrombosis upon administration of a function-blocking antibody to A3 (25) as well as identification of patients with a moderate bleeding disorder due to a point mutation that perturbs the binding of this domain to collagen (26). Although the A1 domain also possesses collagen binding activity (27), no overlap occurs between these domains in terms of the types of collagen that support such interactions. To date, no direct *in vivo* evidence exists demonstrating the importance of the A1 domain in this process.

A binding site for only two types of collagen (I and III) has been identified within the A3 domain (28). Both types are known to form fibrils composed of three helical chains, which is thought to enhance their interactions with this region of vWF (29). The multimeric structure of vWF also appears to strengthen adhesion due to the presence of numerous A3 domains, each of which can bind to exposed collagen fibrils (30). The formation of multiple A3-collagen bonds is believed to increase the overall avidity of the interaction, thus firmly anchoring vWF to the ECM.

Structurally, the A3 domain shares many common attributes with integrin I domains that also bind collagen (i.e.,  $\alpha$ -chains of integrins  $\alpha 1\beta 1$ ,  $\alpha 2\beta 1$ ,  $\alpha 10\beta 1$ , and  $\alpha 11\beta 1$ ). This includes a “dinucleotide binding” fold, composed of a central  $\beta$ -sheet flanked on both sides by amphipathic  $\alpha$ -helices, and the metal ion-dependent adhesion site (MIDAS) motif. Although present in a modified form, the MIDAS motif is not functional and, in contrast to its integrin counterparts, collagen binding is cation independent (31). Other distinctions between these two domains include unique collagen binding sites (hydrophobic and flat versus hydrophilic groove, respectively), differences in the modulation of its collagen binding affinity, and the presence of an intra-disulfide bridge linking the N- and C-termini (Cys923–Cys1109) of A3 (32,33). Although it has been speculated that the interactions of the A3 domain with collagen may regulate the binding activity of the A1 domain in terms of interactions with platelets, no direct physiological evidence exists for such a paradigm. Thus, it appears that the primary function of the A3 domain is the immobilization of vWF to components of the subendothelial matrix.

In addition to binding to components of the subendothelial matrix, vWF can also become immobilized on the surface of intact venular endothelium. Previously, it has been demonstrated that mouse mesenteric venules stimulated with the

calcium ionophore A23187 can support platelet attachment and translocation in vivo, an event reliant on endothelium-bound vWF (34). Moreover, P-selectin, an adhesion molecule expressed on the surface of inflamed venular endothelium has been implicated in anchoring ultralarge vWF multimers to these cells in vitro (35). The in vivo significance of this finding, however, remains to be determined.

Once immobilized, the role of the vWF-A1 domain (residues 497–717) is to initiate the process of platelet deposition at sites of vascular injury. The critical nature of this interaction is exemplified by the bleeding disorder, termed *type 2M vWD*, which results from the incorporation of loss-of-function mutations within this domain (36). In addition, recombinant vWF multimers lacking the A1 domain cannot support platelet adhesion in flow despite retaining the ability to interact with collagen (37). In regards to platelet receptors, it is glycoprotein Ib (GPIb)- $\alpha$  that possesses a unique binding site for this region of vWF, which is contained within its N-terminal region (residues 1–293). GPIb $\alpha$ , a member of the leucine-rich repeat (LRR) family, is constitutively expressed on the surface of platelets in an active form. It exists in a complex with at least four other polypeptide chains that include GPIb $\beta$ , to which it is disulfide linked, and GPIX and GPV that associate noncovalently with GPIb $\alpha$ . Eight LRRs found within the binding site for the A1 domain form an elongated curve, with a region proximal to the N-terminus protruding from the protein surface (referred to as the  $\beta$ -finger) and a disorder loop (referred to as the  $\beta$ -switch) found in its C-terminus of this region (Figure 102.3) (38,39).

The structure of the A1 domain is similar to that of the A3, and includes the  $\alpha/\beta$  fold, with a central  $\beta$ -sheet flanked

by  $\alpha$ -helices on each side as well as one intradisulfide bond (Cys509–Cys 695), but no MIDAS motif (see Figure 102.3) (40). Its overall shape is cuboid, with the top and bottom faces forming the major and minor binding sites that interact with the concave surface of GPIb $\alpha$ . The most extensive contact site buries approximately 1,700  $\text{\AA}^2$  of surface area, interacting with LRRs five to eight and the C-terminal flank of the GPIb $\alpha$  (39). For this to occur, the  $\beta$ -switch region of this platelet receptor undergoes a conformational change so that it aligns itself with the central  $\beta$ -sheet of the A1 domain. The smaller site ( $\sim 900 \text{\AA}^2$ ) accommodates the binding of the  $\beta$ -finger and the first LRR of GPIb $\alpha$ , an event that appears to require the displacement of the amino-terminal extension of the A1 domain. Based on these findings, as well as the preferential localization of mutations in humans within this region, which enhance GPIb $\alpha$  binding, it is speculated that the amino-terminal extension regulates the adhesive properties of this domain. Moreover, recombinant A1 proteins lacking this extension have a higher affinity for this platelet receptor (41). Despite these observations, the physiological relevance of such structural changes in this receptor–ligand pair remains to be determined, as well as the contribution of other domains to this process.

#### A1-MEDIATED ADHESION IN FLOW

Once immobilized on the EC surface or exposed subendothelial matrix, vWF faces a monumental task: engaging GPIb $\alpha$  on platelets while these cells are traveling at considerable velocities within the circulation. Moreover, hydrodynamic forces

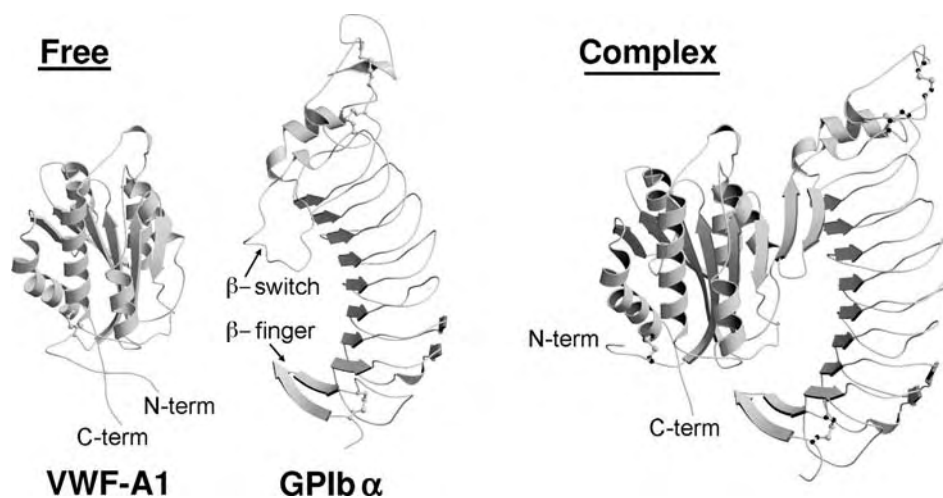

Figure 102.3. Structure of the vWF-A1 domain and the amino-terminal region of the platelet receptor GPIb $\alpha$ . In the uncomplexed form, the amino-terminal extension of the A1 domain lies across its globular core, whereas the  $\beta$ -switch region of GPIb $\alpha$  lacks defined secondary structure. In the binary complex, the concave surface of GPIb $\alpha$  formed by the LRR faces the A1 domain so that its flanking  $\beta$ -finger makes contacts at its base, an event that appears to require the displacement of the amino-terminal extension of the A1 domain. In addition, the  $\beta$ -switch region of GPIb $\alpha$  undergoes a conformational change that results in the formation of two  $\beta$ -strands that bind near the top of A1, thus facilitating interactions as well as extending the central  $\beta$ -sheet of this domain.

generated by flowing blood (termed *shear stress*), which are maximal at the vessel wall, tend to disrupt such interactions once formed. A remarkable feature of the A1 domain is its ability not only to maximize binding to GPIIb $\alpha$  under conditions of high flow, but also to limit platelet–vWF aggregate formation to sites of vascular injury. Thus, it is not unexpected that this multimeric glycoprotein functions best under the prevailing hydrodynamic conditions that exist in arterioles and arteries, where injuries can result in considerable blood loss. Interestingly, the adhesive bond formed between this receptor–ligand pair is relatively labile in that platelets captured by vWF initially translocate along the injured vessel wall in the direction of flowing blood. This interaction reduces the velocity of platelets and brings them in close apposition with the exposed ECM and other domains of vWF, permitting additional adhesion molecules on platelets (such as the integrin  $\alpha 2\beta 1$  and/or  $\alpha \text{IIb}\beta 3$ ) to engage their cognate ligands, an event that cannot precede GPIIb $\alpha$  binding at high rates of flow (42). This permits the firm adhesion and spreading of platelets, thus retaining them at the site of vessel injury. This multistep adhesive process is analogous to that reported for leukocyte recruitment to sites of inflammation, where the selectin family of adhesion molecules performs an identical role as GPIIb $\alpha$  (43). Despite the unique structures and ligand binding requirements of these two classes of adhesion receptors, their ability to support the rapid attachment and translocation of leukocytes or platelets, respectively, suggests that the bonds they form may possess similar kinetic properties. Indeed, previous studies evaluating the biophysical properties of the GPIIb $\alpha$ –A1 domain bond (44) have demonstrated that flow-dependent adhesion and rapid and force-driven kinetics are the predominant features of this interaction, characteristics shared by selectin molecules (45) (Figure 102.4). Thus, the ability of these two distinct families of adhesion molecules to perform similar biological functions relies not on structural homologies, but rather on evolutionary bias toward rapid rates of association and dissociation that are paramount for cell capture and translocation in flowing blood.

Based on the alteration in A1 structure that is required to accommodate GPIIb $\alpha$  binding, it is reasonable to speculate that certain *in vivo* conditions may favor one conformation over another, thus limiting or enhancing adhesion. This may explain the dependency on surface-immobilization and specific flow rates to promote interactions between platelets and vWF. For example, it is conceivable that surface immobilization of vWF and the hydrodynamic forces generated by flowing blood work in concert to either directly alter the structure of the A1 domain and/or increase its effective concentration by transforming this multimeric glycoprotein from a globular to an extended-chain conformation (46). In the latter case, the increased accessibility of A1 domains would permit multiple GPIIb $\alpha$  bonds to form, thus stabilizing platelet–vWF interactions. By contrast, the globular nature of vWF in the circulation would tend to limit the number of A1 domains able to interact with platelets. This, in combination with the rapid dissociation kinetics of the complex, may preclude additional

Figure 102.4. State diagram depicting the transitions in adhesion based on the kinetic properties of receptor–ligand bonds in flow. The rolling adhesion area represents the region of parameter space where rolling motion occurs over some part of shear rates range from 30 to 400  $\text{s}^{-1}$ . The x- and y-axis denote values for the intrinsic lifetime ( $k_{\text{off}}^0$ ) and reactive compliance ( $\text{\AA}$ ) of receptor–ligand bonds, respectively. The estimated  $k_{\text{off}}^0$  for the GPIIb $\alpha$ –A1 bond is  $3.5 \pm 0.4 \text{ s}^{-1}$ , with a reactive compliance (resistance of the bond to shear-induced dissociation) of  $0.16 \pm 0.002 \text{ \AA}$ , values similar to that reported for selectin–ligand interactions (45).

bonds from forming, which would prevent resting platelets from spontaneously aggregating with plasma vWF in flowing blood. Although the exact mechanism responsible for regulating adhesion between this receptor–ligand pair remains to be determined, evidence is mounting that the bond lifetime of the complex must be precisely maintained. For example, function-enhancing mutations localized to either the amino-terminus extension of the A1 domain or the  $\beta$ -switch region of GPIIb $\alpha$  not only share several clinical attributes (including a prolonged bleeding time, borderline thrombocytopenia, and a decrease in the high-molecular-weight multimers of vWF), but also result in an identical sixfold prolongation in bond lifetime of the mutant complex (47). Patients with these genetic disorders have increased bleeding tendencies that are believed to result from the spontaneous binding of plasma vWF to circulating platelets and the subsequent clearance of these hemostatic elements from blood. It has been speculated that prolongation in the lifetime of the mutant complex would favor multiple bond formation, thus stabilizing random interactions between platelets and vWF in the circulation. More recently, it has been demonstrated that botrocetin, a snake venom protein that promotes vWF–platelet aggregation in low-flow states, also prolongs the duration of the interaction between GPIIb $\alpha$  and the A1 domain. By contrast to function-enhancing mutations, this occurs in the absence of any structural changes induced by botrocetin in either molecule, but rather relies on the formation of a new interface between this snake venom protein and GPIIb $\alpha$  (48). Thus, maintaining a rapid rate of dissociation between the A1 domain and GPIIb $\alpha$  appears to be critical for preventing inadvertent aggregation between these two hemostatic elements while in the circulation.

## KEY POINTS

- ECs are the major source of vWF, a multimeric plasma glycoprotein essential for maintaining hemostasis.
- The largest vWF multimers, which are stored in Weibel-Palade bodies of endothelium and  $\alpha$ -granules of platelets, are required for effective platelet deposition at sites of vascular injury.
- A reduction in vWF multimer size in plasma through proteolytic processing by ADAMTS13 appears to play a role in preventing inappropriate thrombus formation.
- The A1 domain of vWF is the major binding site for the platelet receptor GPIIb/IIIa, and the rapid and force-driven kinetics of this interaction is well suited to promote platelet deposition at sites of vascular injury under arterial flow rates.

## Future Goals

- To decipher key structural elements critical for vWF interactions with platelets, endothelium, and components of the ECM, as well as understand the biophysical properties of such interactions, as essential to designing therapies aimed at the prevention and/or amelioration of thrombotic disorders

## Tissue Factor Pathway Inhibitor

Alan E. Mast

*Blood Research Institute, The Blood Center of Southeastern Wisconsin, Milwaukee*

Tissue factor pathway inhibitor (TFPI) is a factor Xa-dependent inhibitor of the factor VIIa/tissue factor (TF) catalytic complex that initiates blood coagulation. TFPI is expressed by, and found on the surface of, endothelial cells (ECs), where it inhibits intravascular TF activity and thereby helps to prevent the development of intravascular thrombosis (1). The identification, cloning, and characterization of TFPI in the mid-1980s represented the culmination of many studies performed in the early and mid-1900s (2). These early studies demonstrated that serum contains a calcium-dependent factor that inhibits the procoagulant activity of tissue extracts and whose preincubation with serum prevents the toxicity of TF infused into mice (3). Studies by P. F. Hjort in the 1950s demonstrated that the serum factor inhibited the TF/factor VIIa/calcium complex, but not TF or factor VIIa individually, indicating that factor VIIa and TF function as a catalytic complex. In 1985, Sanders and coworkers described a factor Xa-dependent inhibitor of the factor VIIa/TF catalytic complex present in the lipoprotein fraction of plasma (4). This finding led to the purification and identification of TFPI from conditioned medium of HepG2 cells by Broze and coworkers in 1987 (5). Subsequent cloning and cDNA sequence analysis revealed TFPI to be a trivalent Kunitz-type serine protease inhibitor that inhibits factor Xa via the second Kunitz domain and factor VIIa/TF via the first Kunitz domain (6,7). Initially, TFPI was referred to as either lipoprotein-associated coagulation inhibitor (LACI) or extrinsic pathway inhibitor (EPI). For purposes of standardization, a group of interested investigators at the International Society for Thrombosis and Haemostasis, meeting in 1991, recommended the name *TF pathway inhibitor*. Since that time, two novel proteins have been identified, which has served only to renew confusion around the nomenclature. The first protein is a trivalent Kunitz-type inhibitor with structural homology to TFPI, termed TFPI-2. The name is somewhat of a misnomer in that TFPI-2 is primarily an inhibitor of plasmin within the extracellular matrix and is a poor inhibitor of factor VIIa/TF. Nevertheless, the use of this term has led some to designate TFPI as TFPI-1. The second protein is an alternatively spliced form of TFPI that is truncated prior to the third

Kunitz domain. This protein has been called TFPI $\beta$ , leading some to designate TFPI as TFPI $\alpha$ . In this chapter, TFPI will be used to refer to the full-length form of the protein, as was originally agreed upon in 1991.

### EVOLUTIONARY CONSIDERATIONS

TFPI contains three tandem Kunitz-type serine protease inhibitor domains. The prototypical Kunitz-type inhibitor is bovine pancreatic trypsin inhibitor (BPTI), also called aprotinin, an antifibrinolytic agent used clinically to prevent bleeding after heart bypass surgery. The Kunitz/BPTI protease inhibitor family is found in a wide variety of animal species but not in plants. It appears that the ancestral Kunitz-type inhibitor arose about 500 million years ago (8). Its core structure is a conserved fold of about 60 amino acids stabilized by three disulfide bridges (9). The three tandem Kunitz domains most likely assembled by gene duplication and exon shuffling (10). In addition to gene duplication, Kunitz domains also have propagated through insertion into new genes, as appears to have occurred with the Kunitz domain of the amyloid  $\beta$ -precursor protein that accumulates within the neuritic plaques of patients with Alzheimer disease (11,12). In addition to duplication, Kunitz domains have undergone extensive evolutionary diversification of target protease specificity. This has been accomplished by alteration of the active-site amino acids with relative conservation of the core structure of the Kunitz domain. Evolutionary selection of Kunitz domains has produced a diverse family of inhibitors with a wide variety of protease specificities (9). These include the human plasma proteins inter- $\alpha$ -trypsin inhibitor and pre- $\alpha$ -trypsin inhibitor (13), as well as other interesting proteins such as penthalaris (14), a protein found in tick saliva that contains five tandem Kunitz domains. Interestingly, diversification of the Kunitz domain in nonactive site regions has produced a homologous group of proteins that function as potassium and calcium channel blockers. These proteins have lost protease inhibitory activity and act as neurotoxins in snake venoms (15).

## DEVELOPMENTAL CONSIDERATIONS

TFPI deficiency has not been described in humans, suggesting that it may be essential for development. Indeed, targeted deletion of *TFPI* in mice results in intrauterine lethality, demonstrating that TFPI is required for live birth (16). Approximately 60% of TFPI-deficient animals die between embryonic day (E)9.5 and E11.5 from apparent yolk sac hemorrhage. The 40% of mice surviving beyond E11.5 have normal organ development but have short tails and other signs of coagulopathy including diffuse fibrin(ogen) deposition in the liver and rare intravascular thrombi in the brain (16). These findings are consistent with unregulated factor VIIa/TF activity, causing a consumptive coagulopathy with subsequent bleeding. TFPI also inhibits TF activity in adult animals. This was first shown by demonstrating that wild-type mice are sensitized to TF-induced disseminated intravascular coagulation following depletion of TFPI through infusion of a polyclonal antibody directed against TFPI (17). Heterozygous mice (*TFPI*<sup>+/-</sup>) have 50% of the normal plasma TFPI activity (16). These mice develop normally, without evidence of spontaneous thrombosis or consumptive coagulopathy and have the same average time to occlusive thrombosis as wild-type mice following photochemical injury of the carotid artery (18). However, in a study of responses to vascular injury, *TFPI*<sup>+/-</sup> mice produced significantly greater neointimal proliferation than wild-type littermates (19).

Similar to the TFPI-deficient mice, mice deficient in the hemostatic proteins TF (20–22), factor V (23), factor X (24), and prothrombin (25,26) also die with variable frequency between days E9.5 and E11.5. A common finding among these mice is severe hemorrhage that is possibly associated with a defect in vascular integrity. One explanation for the similar phenotype of the TFPI-deficient mice and the mice deficient in factors that TFPI regulates is the development of a consumptive coagulopathy that causes these animals to become functionally deficient in clotting factors and die from hemorrhage. However, hemorrhage cannot be the sole cause of death, because mice with a complete loss of fibrinogen- and platelet-dependent hemostatic capacity suffer from severe hemorrhage yet they survive embryogenesis (27). Alternatively, the death of TFPI-deficient embryos may result from dysregulation of coagulation factor-mediated signaling through protease-activated receptors (PARs) that are necessary for the maintenance of vascular integrity within the developing embryo. This notion is supported by the observation that 50% of PAR-1-deficient mice also die at midgestation with apparent defects in vascular integrity similar to those found in the TFPI-deficient mice (28).

## GENE REGULATION AND GENE/PROTEIN STRUCTURE

### Gene Structure

The *TFPI* gene is located on chromosome 2. It contains 10 exons and encodes a 276-amino acid protein containing an

acidic N-terminal region followed by three tandem Kunitz-type serine protease inhibitor domains and a highly basic C-terminal region. The first two exons are not translated. Exon 3 encodes the signal sequence that is removed during post-translational processing and the acidic N-terminal region of the mature protein. Exons 4, 6, and 9 encode the three Kunitz domains. Exons 5 and 7 encode the connecting regions between the Kunitz domains. Exon 10 encodes the highly basic C-terminal region of TFPI. Exon 8 encodes the C-terminal region of TFPI $\beta$ , the alternatively spliced form of TFPI that is truncated immediately prior to the third Kunitz domain (29,30). In TFPI, exon 8 is removed as an intron. When exon 8 is expressed, a totally new C-terminal region that contains a glycosylphosphatidylinositol (GPI) anchor attachment signal replaces the third Kunitz domain and basic C-terminal region of TFPI, thereby producing so-called TFPI $\beta$ .

### Gene Regulation

TFPI is constitutively expressed by cultured ECs, and its expression is either not altered or only slightly upregulated by endotoxin, tumor necrosis factor (TNF)- $\alpha$ , or interleukin (IL)-1 (1). In contrast, these inflammatory stimuli greatly increase TF expression (1). The inability of TFPI expression to “keep pace” with TF expression in ECs may contribute to the coagulation disorders associated with severe inflammation. In contrast to the lack of response to inflammatory stimuli, exposing cultured ECs to fluid flow progressively increases the amount of TFPI made by two- to threefold as the shear stress increases from minimal flow, to venous flow, to arterial flow rates (31). In cultured vascular smooth muscle cells (VSMCs), TFPI expression is increased two- to fivefold by basic fibroblast growth factor/heparin (32), epidermal growth factor, and platelet-derived growth factor B (33). Plasma levels of TFPI in normal individuals vary by threefold (34). A study examining the association of microsatellite markers throughout the genome with plasma TFPI levels in 397 individuals from 21 families found that polymorphisms in and around the *TFPI* structural gene on chromosome 2 were the major genetic determinants of variation in plasma TFPI levels (35).

### Protein Structure and Function

Mature TFPI is an approximately 43-kDa protein (Figure 103.1). The second Kunitz domain of TFPI directly inhibits factor Xa, a process that is accelerated by heparin binding to the basic C-terminal region (36,37). The first Kunitz domain inhibits factor VIIa/TF in a factor Xa-dependent manner (7). The third Kunitz domain does not appear to function as a protease inhibitor, but is required for the full anticoagulant activity of TFPI in TF-initiated plasma clotting assays (38). Because rapid inhibition of factor VIIa by the first Kunitz domain depends on the presence of factor Xa, TFPI often has been described as a two-stage inhibitor of blood coagulation, first inhibiting factor Xa via the second Kunitz domain with

## Human TFPI

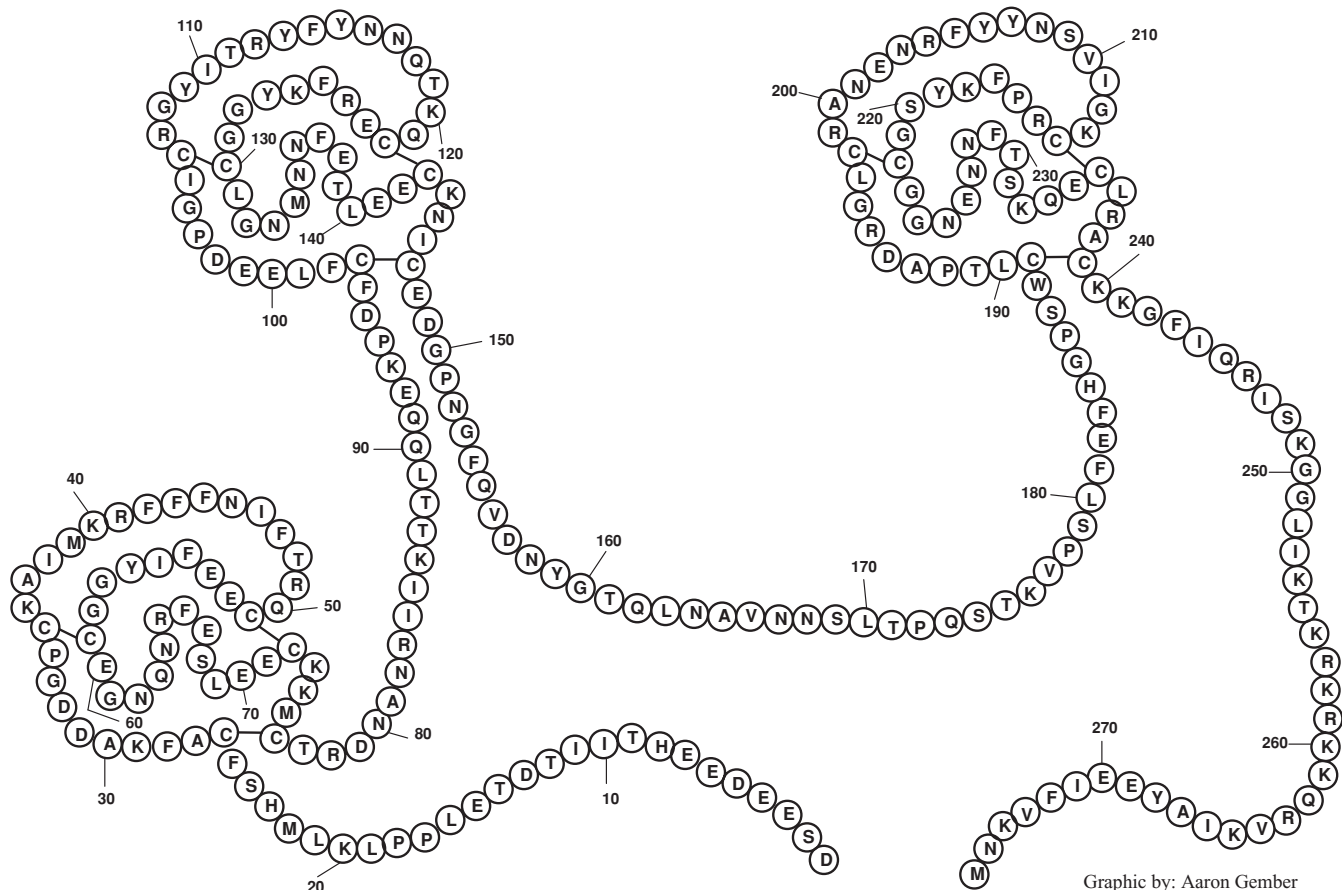

Figure 103.1. Human TFPI.

subsequent inhibition of factor VIIa/TF by the TFPI/factor Xa complex. However, recent data support a revised model of inhibition. During the initiation of blood clotting, the factor VIIa/TF complex activates factor X to factor Xa by limited proteolysis. Following activation of factor X, extended binding interactions between factor Xa and the factor VIIa/TF complex allow for factor Xa to remain transiently associated with factor VIIa/TF. Enzyme kinetic studies examining the inhibitory properties of TFPI demonstrated that the rate-limiting step for the inhibition of factor VIIa/TF by TFPI is the inhibition of the *newly* formed factor Xa (39). Therefore, it appears that it is the transient factor VIIa/TF/factor Xa ternary complex that is most efficiently inhibited by TFPI through a mechanism in which the first two Kunitz domains simultaneously bind to the active sites of factor VIIa and factor Xa. This same ternary complex has been shown to be a highly efficient activator of endothelial PARs, providing a key link between inflammation and the coagulation cascade (40–42). Blockage of endogenous TFPI activity in TNF- $\alpha$ -stimulated ECs increases TF-dependent PAR signaling (41). Thus, TFPI appears to play a central role in regulating this type of cellular signaling. Because factor VIIa/TF-mediated activation of

both blood coagulation and inflammation occurs upon phospholipid/cellular surfaces, effective inhibition will require TFPI to be optimally localized and oriented on the cell surface.

### Tissue Factor Pathway Inhibitor Location and Endothelial Association

TFPI is preferentially produced by vascular ECs regardless of the type of vessel (43,44), and it also is produced in smaller amounts by VSMCs (33,43), monocytes (45,46), megakaryocytes (44), and astrocytes (47). Its expression appears to be enhanced within arterial plaques (43,48). Approximately 85% of the intravascular TFPI is localized on the surface of the endothelium (1,49). The plasma concentration is only approximately 2.5 nM. About 50% of this plasma pool has undergone variable amounts of proteolytic degradation within its C-terminal region and is bound to lipoproteins. As a result, plasma TFPI has reduced anticoagulant activity and is unlikely to play an important role as an *in vivo* inhibitor of blood coagulation (50). Circulating platelets represent a third pool of TFPI, accounting for approximately 8% of the total

protein in whole blood (51). Both the plasma and platelet forms of TFPI inhibit factor VIIa/TF activity when tested using *in vitro* assays; however, their relative activities, when compared to endothelial-bound TFPI, for inhibition of TF *in vivo* has not been deciphered. Most studies performed to date have focused on endothelial-associated TFPI.

The preferential location of TFPI on the endothelial surface is somewhat unexpected because, structurally, TFPI resembles a secreted protein that would be found in plasma rather than on the cell surface. The C-terminal region contains neither the membrane-spanning amino acids typical of integral membrane proteins nor the hydrophobic sequence typically found in proteins directly attached to a GPI anchor. *In vivo* studies indicate that the plasma concentration of TFPI increases two- to fourfold following infusion of heparin (52,53). Because the increase is rapid (<10 minutes), it appears that heparin-releasable TFPI is bound to the endothelium through nonspecific interactions between the basic C-terminal region and cell-surface glycosaminoglycans. Consistent with these data, *in vitro* studies have demonstrated that the binding of *Escherichia coli*-produced recombinant TFPI to cultured ECs is prevented by heparin and that C-terminally truncated forms of TFPI have very low affinity for the cell surface (54,55). However, recombinant forms of TFPI, produced either in bacteria or mammalian cells, bind to cell surfaces much differently than does endogenous TFPI produced by ECs (56). In both cultured ECs and fresh placenta, which contains endothelial and trophoblast cells not exposed to the potential artifacts of cell culture, endogenous TFPI associates with the cell surface primarily through a GPI anchor in a manner that is not altered by heparin (49,57–59). It appears that heparin-releasable TFPI represents only a small portion (between 1% and 10%) of the total TFPI on the endothelium that remains bound to the cell surface through ionic interactions between the C-terminal region and cell surface glycosaminoglycans following cleavage of the GPI anchor by endogenous enzymes on the cell surface (58). The predominance of GPI-anchored TFPI within the vasculature is important clinically because it suggests that heparin infusion does not significantly redistribute TFPI within the vasculature. Additionally, it is consistent with the wide range of plasma TFPI concentrations in normal subjects, and the general lack of correlation between the plasma concentration of TFPI and the incidence of clinically significant thrombosis (60–62).

GPI-anchored proteins have an N-terminal leader sequence that directs the polypeptide to the endoplasmic reticulum. The GPI anchor attaches near the C-terminal end of the protein and displaces a C-terminal peptide of 17 to 30 amino acids from the protein. GPI-anchored TFPI on the placental surface has an intact C-terminal polypeptide, indicating that this region was not removed within the endoplasmic reticulum (58). Therefore, it is hypothesized that TFPI is attached indirectly to the GPI anchor through binding to a GPI-anchored coreceptor. Interestingly, experiments examining the structural determinants of TFPI necessary for the association of altered recombinant forms of TFPI with the cell

surface demonstrated that the active site of the third Kunitz domain and the basic C-terminal region of TFPI are required. These compelling data suggest that TFPI may interact with the endothelial surface through binding of the third Kunitz domain to a GPI-anchored serine protease (63).

### **An Alternatively Spliced Form of Tissue Factor Pathway Inhibitor**

ECs also appear to make an alternatively spliced, truncated form of TFPI that is directly attached to a GPI anchor (29,30). This form of TFPI, called TFPI $\beta$  (Figure 103.2), contains the first two Kunitz domains present in full-length TFPI and, therefore, is theoretically able to inhibit both factor Xa and factor VIIa/TF. The alternative splice occurs following exon 7, which encodes the connecting region between the second and third Kunitz domains of full-length TFPI. In human TFPI $\beta$ , exon 8 encodes a stretch of 12 amino acids followed by a GPI anchor attachment sequence that is removed in the endoplasmic reticulum. Thus, human TFPI $\beta$  has only 12 unique amino acids that are not present in TFPI. Real-time PCR measurements of cultured ECs indicate that TFPI $\beta$  mRNA is present at about one-tenth the level of TFPI mRNA (30). Purified recombinant mouse TFPI $\beta$  is a slow-binding inhibitor of factor Xa (29). In addition, enzyme kinetic studies comparing the inhibitory activity of recombinant TFPI to that of a recombinant truncated form of TFPI that contains only the first two Kunitz domains, and therefore is similar to TFPI $\beta$ , have demonstrated that loss of the third Kunitz domain and C-terminal region significantly decreases TFPI inhibitory activity in both amidolytic assays measuring antifactor Xa activity and in clot-based assays measuring anti-TF activity. Together, these data suggest that TFPI $\beta$  may be a less potent anticoagulant than TFPI (38,64). However, these assays were performed using soluble rather than cell-associated forms of TFPI and do not necessarily represent the activity of surface-associated forms of TFPI. Recently, it has been shown that when the first two Kunitz domains of TFPI are linked to annexin V to create a chimeric protein with affinity for phosphatidylserine-containing membranes, its relative potency in a TF-induced clotting assay increases 250-fold (65). Thus, TFPI $\beta$  theoretically may have significantly more anticoagulant activity when associated with the cell surface through a GPI anchor than when in solution.

### **Localization of Tissue Factor Pathway Inhibitor within Lipid Rafts**

One consequence of the attachment of TFPI to endothelium through a GPI-anchored coreceptor is that it becomes concentrated within caveolae or lipid-raft microdomains on the cell surface along with other GPI-anchored proteins (57,59). Caveolae are 50- to 100-nm invaginations of the plasma membrane that are coated with caveolin and enriched in cholesterol and sphingomyelin. Noninvaginated domains that are biochemically similar to caveolae are referred to as lipid rafts.

## Human TFPI $\beta$

Figure 103.2. Human TFPI $\beta$ .

Caveolae and lipid rafts have been implicated as mediators of endocytosis (66), vesicular transport (67), pathogen invasion (68), and signal transduction pathways (69). Downregulation of TF procoagulant activity by TFPI coincides with the translocation of the factor VIIa/TF complex from the bulk-phase membrane into caveolae and lipid-raft microdomains (57). Because these domains inefficiently support factor VIIa/TF catalytic activity (57), the translocation of TF may act to further downregulate its procoagulant activity. However, recombinant TFPI chimeras that are directly attached to the cell surface either through a GPI anchor, which localizes the recombinant TFPI to caveolae and lipid-raft microdomains, or a hydrophobic membrane spanning domain that localizes TFPI within the bulk phase membrane, demonstrate equal ability to inhibit factor VIIa/TF (70). Thus, the physiological

advantages for localization of TFPI to these domains and the role of the GPI-anchored binding protein in TFPI anticoagulant activity are not yet clear.

### INTERACTIONS WITH OTHER OUTPUTS

#### Tissue Factor Pathway Inhibitor Directly Counterbalances Tissue Factor Activity

Inactivation of the mouse *TF* gene results in lethality of most embryos between E9.5 and E11.5 (20,21). A small percentage of *TF*-null embryos survive this period but die later during gestation. One *TF*-null mouse, delivered by cesarean section, developed normally until 4 weeks of age, before succumbing to a brain hemorrhage (71). The

embryonic lethality can be rescued by expression of a human transgene that produces TF in amounts of about 1% of that found in wild-type mice (72). These TF(low) mice survive birth but develop hemostatic defects in the lung, heart, uterus, and placenta. Many of the animals die from lung hemorrhage at approximately 3 months of age. Mice living beyond 3 months suffer from cardiac fibrosis and fatal postpartum hemorrhages (73). When the TF(low) mice are bred with TFPI-deficient mice, homozygous *TFPI*<sup>(-/-)</sup> mice are viable and reproduce (74). Moreover, the TF(low)/*TFPI*<sup>(-/-)</sup> mice actually are healthier and live longer than the TF(low) mice containing normal amounts of TFPI. The decrease in TFPI activity increases the functional amount of TF activity in the lungs and prevents the mice from succumbing to pulmonary hemorrhage. These data provide clear in vivo evidence that TFPI directly counterbalances TF activity. The TF(low)/*TFPI*<sup>(-/-)</sup> mice continue to develop cardiac fibrosis and postpartum hemorrhage, suggesting that the heart and placenta/uterus require higher amounts of TF activity to prevent bleeding than is provided by expression of the transgene even in the absence of TFPI (74). The variable rescue of the hemostatic abnormalities in different organs of the TF(low) mice demonstrate that an organ-specific balance of TF and TFPI is required for proper hemostasis during both embryonic development and in adult mice. In a manner similar to the TF(low) mice, factor VII deficiency also rescues *TFPI*<sup>(-/-)</sup> mice from embryonic lethality. However, the *factor VII*<sup>(-/-)</sup>/*TFPI*<sup>(-/-)</sup> mice suffer from fatal perinatal bleeding due to the lack of factor VII (75).

#### **Tissue Factor Pathway Inhibitor Deficiency Exacerbates Thrombosis in Mice with Factor V Leiden**

Factor V Leiden is an altered form of factor V containing a prothrombotic mutation that makes it resistant to proteolytic cleavage and inactivation by activated protein C. Mice genetically altered to produce the Factor V Leiden mutation (FVQ/Q) have a mild prothrombotic phenotype, exhibiting only variable degrees of spontaneous thrombosis depending on the genetic background of the mice (76). However, when they are bred with TFPI-deficient mice to produce a *FV(Q/Q)/TFPI*<sup>(+/-)</sup> genotype, the mice suffer from nearly complete perinatal mortality. The mortality is associated with fibrin deposition in multiple organs, suggesting that they succumb to disseminated thrombosis (77). The thrombotic phenotype of the *FV(Q/Q)/TFPI*<sup>(+/-)</sup> mice is rescued by breeding into a heterozygous *TF*<sup>(+/-)</sup> background, again providing evidence that TF and TFPI directly counterbalance each other in vivo (78).

### **DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS**

#### **Tissue Factor Pathway Inhibitor as a Risk Factor for Thrombosis**

Although heterozygous *TFPI*<sup>(+/-)</sup> deficiency is a strong risk factor for thrombosis in mice with factor V Leiden, low plasma

levels of TFPI have been only weakly linked to thrombotic disease in humans. Two studies have suggested the presence of a "threshold effect" whereby patients with free (non-lipoprotein bound) plasma TFPI concentration less than 10% of the normal mean value are at increased risk (approximately twofold) for deep venous thrombosis (61) and myocardial infarction (62). However, in both studies, no difference was found in the mean free plasma TFPI level in the disease and control groups. Other published studies have reported conflicting results regarding the contribution of plasma TFPI levels and TFPI polymorphisms to the development of thrombosis. This is likely a result of the wide normal range for plasma TFPI, the various methods for measurement of plasma TFPI, and the probable poor correlation between the plasma TFPI concentration and the amount of endothelial-associated TFPI. The potential discordance between plasma and cell-associated TFPI is best illustrated in patients with abetalipoproteinemia. These individuals have greatly decreased plasma TFPI with normal amounts of endothelial-associated TFPI, yet they do not have an increased risk for thrombosis (34).

#### **Tissue Factor Pathway Inhibitor as a Therapeutic Agent for Sepsis**

The coagulation cascade is intimately connected with inflammation. As described earlier, TFPI likely inhibits blood clotting by simultaneously binding the active sites of factor VIIa and newly activated factor X within the ternary factor VIIa/TF/factor Xa complex (39). In the absence of the inhibitory effects of TFPI, factor Xa within this complex is an efficient activator of PAR-1 and -2 (42). Activation of these receptors can lead to the expression of adhesion molecules on the endothelium, with subsequent leukocyte activation and generation of an inflammatory response. In addition, TF expression is enhanced by inflammatory cytokines whereas cellular TFPI expression is largely unaffected, further contributing to the procoagulant environment associated with inflammation (1,32,33). Because of the hypothesized role for TF in propagating the inflammatory response, recombinant TFPI produced in *Escherichia coli* has been tested for use as a therapeutic agent in several animal models as well as in human trials for the treatment of sepsis and other inflammatory conditions. It improves survival in rabbit models of septic shock and lethal *Escherichia coli* peritonitis (78,79) as well as in mouse models of cecal ligation and puncture and polymicrobial gram-positive sepsis (80). In baboons infused with lethal doses of *Escherichia coli*, 70% to 100% rescue can be obtained by the infusion of recombinant TFPI beginning 30 minutes after the lethal challenge (81). The baboons receiving recombinant TFPI showed decreased activation of coagulation as evidenced by a lack of thrombosis, hemorrhage, and infarction in adrenal and renal tissues when compared with untreated controls. Increases in IL-6 and IL-8 were attenuated compared with controls, indicating that recombinant TFPI also produces a decrease in the inflammatory response within the baboons. In a subsequent study in which recombinant

TFPI was infused beginning 120 minutes after the lethal challenge, 11 of 12 treated baboons died (82). Interestingly, even though the baboons died, they again did not have evidence of thrombosis or hemorrhage in the adrenal and renal tissues. These data indicate that thrombosis and hemorrhage in these tissues is not the cause of death in this sepsis model. Additionally, they suggest that the recombinant TFPI infused at 30 minutes prevents death by altering the very early procoagulant events of sepsis, thereby preventing the development of disseminated intravascular coagulation and/or the actions of inflammatory mediators. In contrast to these data from baboons, a study of humans infused with nonlethal doses of endotoxin demonstrated that, although recombinant TFPI completely blocked the endotoxin-induced activation of coagulation, it had no effect on leukocyte activation, chemokine release, EC activation, or the acute-phase response (83). The differences between the results of these studies may reflect differences between the response of humans and baboons to inflammatory stimuli and/or differences in the response to lethal versus nonlethal challenges.

The success of recombinant TFPI infusion in preventing death from sepsis in animal models led to the initiation of clinical trials using recombinant TFPI for the treatment of sepsis. A Phase II trial demonstrated a trend toward a reduction in 28-day all-cause mortality even though the study was not powered to show efficacy (84). However, in a Phase III trial of approximately 2,000 patients with sepsis and septic shock, recombinant TFPI failed to reduce 28-day all-cause mortality (85). One potential problem with the use of recombinant TFPI as a therapeutic agent is that it appears that recombinant TFPI is much more effective at inhibiting blood coagulation than inhibiting inflammation by blocking PAR signaling when tested in an *in vitro* cellular model (86). This discrepancy of inhibitory action suggests that effective inhibition of inflammation by recombinant TFPI may produce excessive bleeding, and emphasizes the importance of the mechanisms through which endogenously produced TFPI associates with the endothelial surface.

#### KEY POINTS

- TFPI is a critical endothelial-associated anticoagulant protein that directly counterbalances TF activity *in vivo*.
- TFPI is a trivalent Kunitz-type serine protease inhibitor that inhibits both factor Xa and factor VIIa/TF. As such, it inhibits both TF-initiated blood coagulation and the inflammation initiated by blood coagulation protease-mediated cellular signaling.
- Although TFPI structurally resembles a soluble protein, it associates with endothelium through tight binding to a GPI-anchored coreceptor. An alter-

natively spliced, truncated form of TFPI, TFPI $\beta$ , directly associates with endothelium via a GPI anchor. The localization of TFPI to cellular surfaces greatly enhances its activity. The lack of, or nonphysiological, cell surface association of recombinant TFPI may limit its efficacy as a therapeutic agent.

- Low amounts of TFPI have been clearly linked to thrombotic disease in mouse models, but it has not been indisputably linked to thrombosis in humans. The poor correlation of low TFPI with thrombosis in humans may be due to a poor correlation between the plasma TFPI concentration and the amount of TFPI on the endothelial surface.

#### Future Goals

- To identify and characterize the GPI-anchored coreceptor that binds TFPI to the endothelial surface, to greatly enhance our understanding of how TFPI regulates TF activity
- To develop a peripheral blood assay that accurately measures the amount of TFPI associated with the endothelial surface, which will be a diagnostic advance that will allow for more accurate prediction of the contribution of low TFPI to the development of thrombotic and vascular disease in humans

## Tissue Factor Expression by the Endothelium

Gernot Schabbauer and Nigel Mackman

*The Scripps Research Institute, Department of Immunology, La Jolla, California*

Tissue factor (TF) is the primary cellular initiator of blood coagulation (1). It is constitutively expressed around blood vessels and plays an essential role in hemostasis. Under normal conditions, the surface of the endothelium is antithrombotic due to the binding of the anticoagulant protein tissue factor pathway inhibitor (TFPI) and the absence of TF. In addition, “resting” endothelium expresses the receptors thrombomodulin and endothelial protein C receptor, which permits the generation of the anticoagulant protein, activated protein C. However, under pathological conditions, the surface of the endothelium becomes prothrombotic due to the induction of TF and the downregulation of anticoagulants.

Numerous studies have documented the induction of TF in cultured vascular endothelial cells (ECs) in response to a variety of agonists. Other studies have described TF expression on the endothelium *in vivo*, although some controversy exists about whether or not ECs express TF *in vivo*. This chapter reviews our current understanding of the intracellular regulatory pathways that control *TF* gene expression in cultured ECs. We also evaluate the data on TF expression by ECs *in vivo*.

### TISSUE FACTOR EXPRESSION BY ENDOTHELIAL CELLS IN VITRO

#### Induction of Tissue Factor Expression in Cultured Endothelial Cells

The majority of the studies on TF expression in cultured ECs have been performed using human umbilical vein ECs (HUVECs). Quiescent cultured ECs express very low or undetectable levels of TF. The first description of TF expression by ECs was in 1977, by a group that showed a transient induction of TF activity in ECs after subculture (2). Since this time, a variety of agents have been shown to induce TF expression in ECs (Table 104-1). These agents can be broadly divided into the following classes: inflammatory mediators, growth factors, proatherogenic agents, hypertensive agents, infectious agents, and physical stimuli.

Early studies showed that the inflammatory mediators lipopolysaccharide (LPS), tumor necrosis factor (TNF)- $\alpha$ , and

interleukin (IL)-1 $\beta$  induced TF expression in ECs (3–5). In addition, TF expression was upregulated by other agents, such as vascular endothelial growth factor (VEGF), CD40 ligand, thrombin, and oxygen free radicals (6–10). The proatherogenic agents, minimally modified low-density lipoprotein (MM-LDL) and homocysteine, were also shown to induce TF expression in ECs (11,12), raising the possibility that TF contributes to the development of early atherosclerotic lesions. Several infectious agents have been shown to increase TF expression in ECs (13–15), which may represent an attempt by the host to limit the spread of the infection. Finally, angiotensin II (Ang-II) was shown to induce TF expression in cultured rat aortic ECs without affecting TFPI expression (16).

We and others have elucidated the transcriptional mechanisms by which different agents induce *TF* gene expression in ECs. In the human *TF* promoter, multiple binding sites for the transcription factors AP-1, nuclear factor (NF)- $\kappa$ B and Egr-1 are required for maximal induction of the *TF* gene in human ECs exposed to either LPS, TNF- $\alpha$ , or IL-1 $\beta$  (17) (Figure 104.1). Mutation of the NF- $\kappa$ B binding site (at -179 bp relative to the start site of transcription) significantly reduces the level of induction, indicating that this binding site plays a major role in the induction of *TF* gene expression in response to inflammatory mediators. Interestingly, the NF- $\kappa$ B motif in the *TF* promoter differs from the consensus binding site for NF- $\kappa$ B because of the presence of a cytosine instead of a guanine at position 1. We found that this one nucleotide change altered the binding specificity from the classic p50/p65 heterodimer to a c-Rel/p65 heterodimer (18). Similar results were found with the porcine *TF* promoter (19). This may explain why the pattern of *TF* gene expression sometimes differs from that of genes regulated by p50/p65 heterodimers. For example, in contrast to p50/p65-regulated genes, such as *E-selectin*, TF expression is rarely detected in activated endothelium despite evidence for nuclear translocation of p65.

An early study by Clauss and colleagues (6) showed that VEGF signaling results in increased TF expression in ECs. The mechanism of induction was analyzed by two groups who found that NF- $\kappa$ B was not involved. One group showed that nuclear factor of activated T cells (NFAT) mediated the

**Table 104-1: Induction of TF Expression in Cultured ECs**

Oxygen free radicals	7

effect of VEGF, whereas the second group concluded that Egr-1 was required for the induction (20,21). It appears that VEGF induction of TF expression in ECs is mediated by both NFAT and Egr-1 (see Figure 104.1). It is possible that VEGF induction of TF in ECs may contribute to tumor angiogenesis, because levels of VEGF in tumors often correlate with levels of TF.

MM-LDL was shown to induce TF expression in ECs (11). One of the oxidized lipids present on MM-LDL is oxidized 1-palmitoyl-2-arachidonoyl-sn-glycerol-3-phosphorylcholine (oxPAPC). Bochkov and colleagues (22) showed that oxPAPC

also induces TF expression in ECs in an NF- $\kappa$ B-independent manner via activation of NFAT and Egr-1.

TF gene expression in ECs also is induced by shear stress. ECs exposed to moderate flow (15 dynes/cm<sup>2</sup>) expressed little TF, whereas ECs exposed to low flow (0.5 dynes/cm<sup>2</sup>) expressed significant levels of TF (23). More recently, oscillating shear stress was shown to induce TF expression in cultured ECs (24). Oscillating shear stress occurs at sites within the vasculature that are prone to the development of atherosclerotic lesions. Lin and colleagues (25) proposed that induction of TF by laminar shear stress was mediated by phosphorylation and activation of Sp1. In contrast, a later study demonstrated that shear stress induction of the TF gene was mediated by Egr-1 (26). It seems likely that Egr-1 is the key regulator of shear stress induction of TF in ECs.

These studies demonstrate that induction of the TF gene in ECs in response to different agents is mediated by different combinations of transcription factors.

**Inhibition of Tissue Factor Expression in Cultured Endothelial Cells**

Other studies have shown that various agents inhibit inducible TF expression (Table 104-2). For example, the anti-inflammatory cytokines IL-4 and IL-13 have been reported to suppress TF expression in ECs stimulated either with TNF- $\alpha$  or IL-1 $\beta$  (27). These studies may lead to the development of therapeutic strategies to reduce TF expression under pathological conditions, such as sepsis and atherosclerosis.

The antioxidant pyrrolidine dithiocarbamate (PDTTC) has been shown to reduce LPS induction of TF expression in ECs by inhibiting NF- $\kappa$ B (28). A second study showed

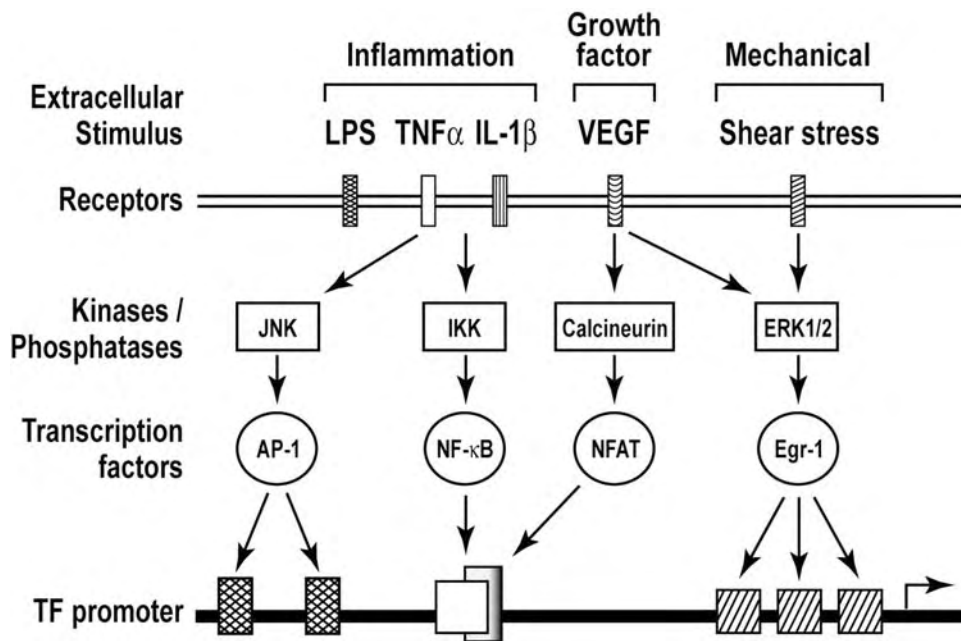

Figure 104.1. The induction of the human TF promoter in ECs by various agonists is mediated by a variety of intracellular signaling pathways and transcription factors.

**Table 104-2: Inhibition of TF Expression in Cultured ECs**

<i>Inhibitor</i>	<i>Target</i>	<i>References</i>
PDTC	NF- $\kappa$ B	28
Simvastatin	NF- $\kappa$ B	33
Adrenomedullin	cAMP	31
HDL	PI3K	36
Angiopoetin 1	PI3K	35

that inhibition of NF- $\kappa$ B by overexpression of the endogenous inhibitor, I $\kappa$ B $\alpha$ , also reduced LPS-induced TF expression in ECs (29). Surprisingly, the immunosuppressor cyclosporin inhibited TF gene expression in monocytes but enhanced it in ECs (30). We and others have shown that elevation of intracellular levels of cyclic adenosine monophosphate (cAMP) and activation of protein kinase A (PKA) inhibits both TNF- $\alpha$  and Ang-II induction of TF in ECs (31,32). The mechanism of inhibition appears to be via squelching of coactivators, such as cAMP binding protein (CBP), which are required for NF- $\kappa$ B-dependent transcription (32). These data indicate that the NF- $\kappa$ B site in the TF promoter is a key regulator of TF expression in ECs exposed to inflammatory mediators.

Statins, such as simvastatin, inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase and reduce the generation of geranylgeranyl pyrophosphate (GGPP). This molecule is required for efficient activation of Rho GTPase, Rho kinase, and NF- $\kappa$ B in ECs. Simvastatin reduced Ang-II induction of TF in ECs by inhibiting NF- $\kappa$ B activation (33). Therefore, statins may reduce the frequency of thrombosis by inhibiting TF expression in ECs and other cell types expressing TF within atherosclerotic plaques.

Several studies have shown that the phosphoinositide 3-kinase (PI3K)/Akt pathway suppresses TF expression in ECs. First, it was shown that inhibition of PI3K enhanced VEGF-induced TF expression in ECs (34). This enhancement appeared to be mediated by increased activation of the extracellular-signal-regulated kinase (ERK)1/2-mitogen-activated protein kinase (MAPK) pathway and expression of Egr-1. Second, Kim and colleagues (35) found that activation of the PI3K/Akt pathway by angiopoetin 1 inhibited the induction of TF in ECs exposed to VEGF or TNF- $\alpha$ . Third, reconstituted high-density lipoprotein (HDL) inhibited thrombin induction of TF expression in a PI3K-dependent, Akt-independent manner (36). Taken together, these studies indicated that activators of PI3K inhibit inducible TF expression in ECs.

## TISSUE FACTOR EXPRESSION BY ENDOTHELIAL CELLS IN VIVO

### General Considerations

Despite extensive studies showing that a variety of agents induce TF expression in cultured cells, the expression of TF in

the endothelium in vivo is controversial (Table 104-3). Several issues should be addressed before discussing individual studies. First, many immunohistochemical studies conclude that TF is expressed on ECs. This can be problematic for several reasons: The quality of the anti-TF antibodies can be quite variable; a positive control tissue, such as the skin, and control antibodies often are not shown; and a strong positive signal in the vessel wall makes it difficult to distinguish between TF expression by vascular smooth muscle cells versus ECs. Second, few studies show colocalization with EC markers, such as platelet-endothelial cell adhesion molecule (PECAM)-1/CD31 and von Willebrand factor (vWF). Third, some studies measure functional TF activity in intact vessels and organs and conclude that this is due to EC TF expression because no detectable damage occurs to the endothelial barrier. Finally, the level of TF expression in stimulated cultured ECs is very low compared with other cells, such as fibroblasts. However, low levels of TF expression in the endothelium in vivo have the potential to significantly contribute to intravascular clotting due to the large number of ECs in the body and the enormous amplification of the coagulation protease cascade. Therefore, it is possible that ECs may express functional TF on their surface at levels that are below the detectable threshold of in situ hybridization and immunohistochemical techniques. Thus, researchers must be cautious in concluding that TF is not expressed by ECs. Indeed, TF expression by the endothelium may contribute to different disease processes, such as thrombosis, inflammation, and tumor angiogenesis (Figure 104.2).

### Tissue Expression by Endothelial Cells in Endotoxemia and Sepsis

An early study showed that the infusion of IL-1 $\beta$  into rabbits induced TF expression in the aorta (37). The authors concluded that factor VIIa-dependent factor Xa formation was due to EC TF expression because scanning electron microscopy demonstrated the presence of a continuous layer of endothelium without exposure of the internal elastic lamina. No immunohistochemical studies for TF were performed to directly reveal expression of TF on the endothelium. A second study showed that LPS-treated rabbits exhibited increased levels of functional TF in the thoracic aorta (38). An alternative explanation for these results is that IL-1 $\beta$  and LPS disrupt the integrity of the EC barrier in the aorta, which would permit plasma clotting factors to contact the subendothelium and be activated by extravascular TF. In contrast to these in vivo studies, stimulation of human saphenous vein segments ex vivo with either LPS or thrombin failed to induce TF activity (39).

The most widely quoted paper reporting that ECs can express TF in vivo is by Drake and colleagues (40). This group analyzed TF expression in a baboon model of lethal *Escherichia coli* sepsis using a highly sensitive immunohistochemical procedure employing anti-human TF monoclonal antibodies. In septic baboons, TF was detected in ECs of the microvasculature of the marginal zone of the spleen. TF colocalized with thrombomodulin and vWF, demonstrating that the cells were

ECs. A less robust TF expression in ECs was observed in the renal glomerular and lung alveolar capillaries. Importantly, EC TF expression was not observed in larger vessels in the spleen, kidney, and lung or in the microvasculature of other tissues. We analyzed EC TF expression in a rabbit endotoxemia model but failed to detect TF expression by ECs in the splenic microvasculature or in blood vessels of any other organ (41). In a rat model of LPS-induced disseminated intravascular coagulation, TF antigen was observed in monocytes but not the ECs of the microvasculature of the lung (42). These differences may be due to the different sensitivities of the immunohistochemical techniques or the use of different models and species. Interestingly, the selective expression of TF in the ECs of some tissues in septic baboons suggests the presence of different regulatory pathways in different ECs.

### Tissue Factor Expression by Endothelial Cells in Sickle Cell Disease

Solovey and colleagues (43) examined TF expression in circulating ECs (CECs) from healthy human controls and patients

Figure 104.2. Exposure of resting ECs to inflammatory mediators or growth factors. Exposure to agonists, such as VEGF, induces TF expression and decreases the expression of the anticoagulants TFPI, thrombomodulin (TM), and endothelial protein C receptor (EPCR). TF expression by ECs in vivo may contribute to thrombosis, inflammation, and tumor angiogenesis.

with sickle cell disease as a surrogate for vessel wall endothelium. CECs from patients expressed higher levels of TF than CECs from controls. A subsequent study using a mouse model of sickle cell disease showed that TF immunostaining was significantly increased in ECs of the pulmonary veins in moderate and severe sickle cell disease (44). Hypoxia and reoxygenation also induced EC TF expression in the lung of sickle cell mice. These studies suggest that TF expression by ECs may contribute to the activation of coagulation in sickle cell disease.

### Tissue Factor Expression by Tumor Endothelium

In 1996, Contrino and colleagues described TF expression by ECs in tumors of patients with invasive breast cancer but not in ECs of benign tumors (45). The authors proposed that TF may be a useful marker of the switch to the angiogenic phenotype. A subsequent study by Rickles and colleagues (46) reported TF expression by ECs in adenocarcinoma of the lung and four out of five large-cell carcinomas. In the latter study, TF expression was colocalized with CD31. In contrast, Luther and colleagues (47) failed to detect TF expression in the ECs of breast tumors. In view of the variable expression and controversy, it seems unlikely that TF can be used as a reliable marker of angiogenic ECs.

### Tissue Factor Expression by Endothelial Cells in Atherosclerosis

In human atherosclerotic plaques, TF mRNA and protein was observed in macrophages present as foam cells and in monocytes adjacent to the cholesterol cleft, but not in the endothelium (48). In a later study, digoxigenin-labeled factor VIIa bound to vWF-positive endothelium overlying atherosclerotic plaques (49). These results suggest that TF is variably expressed

by ECs overlying atherosclerotic plaques and may contribute to thrombosis in plaque erosion.

### Tissue Factor Expression by Endothelial Cells in Cardiac Ischemia–Reperfusion Injury

A recent study analyzed the effect of oxygen free radicals in TF expression in coronary ECs in vitro and in vivo (7). Oxygen free radicals strongly induced TF expression in cultured rabbit coronary ECs. Similarly, TF activity was induced in the hearts of rabbits subjected to cardiac ischemia–reperfusion (I/R) injury. TF activity in the hearts was measured by perfusing them ex vivo with factor VII and factor X, and measuring factor Xa levels. The authors argued that the TF was expressed by ECs because the injury was not associated with ultrastructural vascular damage. In contrast, we failed to detect TF expression by ECs but did observe robust TF expression on cardiomyocytes in hearts of rabbits subjected to a similar I/R procedure (50). These differences indicate that researchers must be cautious in concluding that ECs express TF without direct immunohistochemical evidence.

### Tissue Factor Expression by Endothelial Cells in Other Diseases

TF expression by ECs has been reported in human patients with tuberculosis and idiopathic inflammatory bowel disease (51,52). In addition, TF is expressed by ECs of cardiac vessels in rat models of Ang-II-induced cardiac vasculopathy and cardiac allograft vasculopathy (53,54). TF expression in ECs in these diseases and disease models may contribute to both coagulation and inflammation.

## STUDIES USING TRANSGENIC MOUSE MODELS

We and others have used mouse models and bone marrow transplantation to determine the relative contribution of TF expression by hematopoietic and nonhematopoietic cells to LPS-induced coagulation. In these studies, we hypothesize that ECs are the major source of TF in nonhematopoietic cells, although we cannot exclude the possibility that other nonhematopoietic cells also contribute to LPS-induced coagulation. We found that mice genetically engineered to express very low levels of TF, so called low-TF mice (Table 104-4) (55), exhibited low levels of LPS-induced coagulation as measured by plasma thrombin-antithrombin (TAT) levels (56). In contrast, LPS stimulation of wild-type mice transplanted with bone marrow from low-TF mice for 6 weeks had levels of TAT that were intermediate between those of low-TF and wild-type mice. This result suggested that nonhematopoietic cells, possibly ECs, were expressing TF, and that this expression significantly contributed to LPS-induced coagulation.

In a separate study, transgenic mice were generated that expressed chimeric anticoagulant proteins under the control

**Table 104-4: Mouse Models with Altered TF Gene Expression**

<i>Model</i>	<i>Reference</i>
Low-TF mice	55
Floxed TF mice	Unpublished

of the *CD31* promoter, which directed expression in ECs, platelets, and monocytes (57). LPS-induced coagulation was substantially reduced in the transgenic mice compared with wild-type mice. Bone marrow transplantation experiments showed that expression of the anticoagulants on ECs produced a greater reduction in LPS-induced coagulation than expression on platelets and monocytes. This study provides indirect evidence that TF expression by ECs contributes to LPS-induced coagulation.

Recently, we generated mice containing a *TF* gene flanked by Lox P sites. These mice will be used to determine the effect of EC-specific deletion of the *TF* gene on LPS-induced coagulation.<sup>1</sup>

### KEY POINTS

- EC TF expression plays an important role in intravascular thrombosis and may contribute to inflammation and tumor angiogenesis.
- Induction of *TF* gene expression in ECs is primarily mediated by the transcription factors AP-1, NF- $\kappa$ B, and Egr-1.
- Inhibition of NF- $\kappa$ B and activation of PI3K reduces TF expression in ECs.
- TF is expressed by a subset of ECs in vivo in animal models of sepsis and sickle cell disease.

### Future Goals

- To elucidate the contribution of EC TF in intravascular thrombosis, inflammation, and tumor angiogenesis
- To selectively target anticoagulants to the vascular endothelium to limit the pathological effects of EC TF expression

1 A recent study showed that overexpression of the Kruppel-like factor KLF2 inhibited cytokine-mediated induction of TF expression in ECs (58). This suggests that KLF2 may act as a negative regulator of TF expression in the endothelium in vivo. A second study described a detailed analysis of TF expression in various cell types in septic baboons (59). TF was found to colocalize with TFPI and CD31, indicating that it was located on the surface of EC at arterial branching areas. However, these studies cannot distinguish between TF expression by the ECs themselves versus deposition of TF positive microparticles that are generated by monocytes and other cell types.

# Thrombomodulin

Marlies Van de Wouwer and Edward M. Conway

*Department for Transgene Technology and Gene Therapy, VIB, and the Center for Transgene Technology and Gene Therapy (CTG), K.U. Leuven, Belgium*

Thrombin has far-reaching effects in a variety of biological systems, including coagulation, inflammation, cell survival, and cell proliferation. Modulation of the dynamic production of this key protease is essential to maintain homeostasis during development and, in adults, under a variety of pathophysiological conditions. The crucial importance of thrombin has prompted intense studies over the past few decades to characterize the molecular pathways that regulate its functional expression. The remarkable insight of several scientists led to the discovery of thrombomodulin (TM) (1), a key regulator of thrombin's activities, a predominantly vascular endothelial cell (EC) cofactor in a physiologically relevant natural anti-coagulant system, and a modulator of inflammation and cell proliferation, with links to innate immunity.

## **THROMBOMODULIN IS A MASTER SWITCH THAT PREVENTS BLOOD CLOTTING**

The discovery of TM (1,2), elegantly recounted by Esmon and Owen (1), emanated from evidence in the 1960s of the existence of a circulating thrombin-activated protein – now referred to as activated protein C (APC) – and the identification and isolation of its precursor, protein C (PC) (3). PC is a vitamin-K-dependent plasma protein, synthesized in the liver and circulating as a biologically inactive species. Activation of PC by thrombin requires TM as a cofactor (4) (Figure 105.1), which accelerates the reaction over 1,000-fold. APC, in turn, suppresses further thrombin generation through the proteolysis of coagulation factors Va and VIIIa, facilitated by the cofactor, protein S (PS). Not only does TM affect the generation of APC but, when complexed with TM, thrombin's entire substrate specificity is changed such that it no longer functions as a procoagulant molecule. For example, thrombin-TM is not able to activate platelets or factor V, or to cleave fibrinogen. Thus, TM is a biological switch for thrombin, maintaining the hemostatic balance to prevent disease and/or to respond to injury. The relevance of this pathway is supported in the clinic: Individuals with functional deficiencies of PC or PS, or

with resistance to cleavage of factor V by APC (factor V Leiden polymorphism) are more prone to develop thromboembolic disease. Notably, defects in TM expression or function in humans have been difficult to document, and no reports exist of patients entirely lacking TM. This likely underlines its critical importance for survival, although it also may reflect difficulties in diagnosing TM deficiency.

## **THROMBOMODULIN MODULATES INFLAMMATION VIA ACTIVATED PROTEIN C GENERATION**

Through activation of PC and alteration of thrombin's substrate specificity, the function of TM extends well beyond coagulation. APC has potent anti-inflammatory and vasculo-protective properties (5). This is confirmed by clinical studies showing that the administration of APC to patients with severe sepsis significantly reduces mortality (6). Several mechanisms exist by which APC suppresses inflammation. For example, APC downregulates thrombin generation, which thus yields less thrombin-induced activation of platelets, leukocytes, and ECs (7,8). Additionally, APC has direct cellular effects – mostly mediated via the cleavage of protease-activated receptor (PAR)-1 (9) – interfering with endothelial apoptosis, suppressing monocyte and macrophage cytokine signaling, preventing tumor necrosis factor (TNF)- $\alpha$ -induced upregulation of leukocyte adhesion molecules, and promoting endothelial barrier protection (10).

## **THROMBOMODULIN INTERFERES WITH FIBRINOLYSIS AND COMPLEMENT ACTIVATION VIA THROMBIN-ACTIVATABLE FIBRINOLYSIS INHIBITOR ACTIVATION**

The thrombin-TM complex also modulates inflammation and fibrinolysis by activating thrombin-activatable fibrinolysis inhibitor (TAFI), a plasma procarboxypeptidase B (11).

Figure 105.1. Structure of thrombomodulin and activation of protein C (PC) and thrombin activatable fibrinolysis inhibitor (TAFI). (A) TM is represented with its five structural domains, including the N-terminal C-type lectin-like domain (CTLD) attached via a hydrophobic region to six EGF-like repeats, the serine-threonine rich region with the attached chondroitin sulfate (CS) moiety, a transmembrane domain, and the short cytoplasmic tail. Sites of potential attachment of O-linked (O) and N-linked ( $\sigma$ ) sugars are shown. (B) EGF-like repeats four through six of TM provide minimum cofactor function for thrombin (IIa)-mediated activation of PC, a step that is further enhanced by the EC protein C receptor (EPCR). Activated protein C (APC) cleaves coagulation cofactors Va and VIIIa (not shown), thereby downregulating thrombin generation; it also interferes with inflammation via several mechanisms. The CTLD of TM also directly suppresses inflammation. (C) EGF-like repeats three through six of TM provide cofactor function for thrombin-mediated activation of TAFI. The procarboxypeptidase TAFIa cleaves basic C-terminal amino acid residues of its substrates, including fibrin/ogen, and thus interferes with efficient generation of plasmin from plasminogen. TAFIa also inactivates the anaphylotoxin C3a and C5a, and the proinflammatory mediators, bradykinin and osteopontin.

Activated TAFI (TAFIa) catalyzes the removal of C-terminal basic amino acid residues from target proteins, thereby altering their functional properties. The first-described effect of TAFIa was its suppression of fibrinolysis achieved through removal of lysine residues from modified fibrinogen, which results in inefficient tissue-type plasminogen activator (t-PA)-induced conversion of plasminogen to plasmin (see Figure 105.1). Conversely, TM also may be considered profibrinolytic, because, via APC, it suppresses thrombin generation, which in turn downregulates further TAFIa production. Indeed, this may contribute to the bleeding tendency in patients with factor XI deficiency (12). TAFIa also targets and inactivates the anaphylotoxin C3a and C5a (13), and the proinflammatory mediators bradykinin and osteopontin. The physiological relevance of these biochemical pathways in health and disease remains to be resolved (14,15).

### THE *TM* GENE AND ITS PRODUCT – STRUCTURE AND FUNCTIONS

Early recognition of the importance of TM in the field of coagulation led quickly, during the 1980s, to analyses of its gene structure, regulation, and expression (16–20). The single *TM* mRNA species is transcribed from an intronless gene located on chromosome 20p in humans (21). The protein is organized as a type I transmembrane glycoprotein receptor, although soluble forms exist that are generated by proteolytic cleavage of the extracellular domains (see the following section). Human TM is 557 amino acids long, organized into

five structurally distinct domains (see Figure 105.1). After a short N-terminal signal peptide, it comprises a globular C-type lectin-like domain attached via a hydrophobic region to a series of six epidermal growth factor (EGF)-like repeats, a serine-threonine-rich region with sites of O-linked glycosylation that support a chondroitin sulfate moiety, a highly conserved transmembrane domain, and a short cytoplasmic tail. Interestingly, endosialin, a tumor EC marker without a known function, but with strikingly similar structural features to TM (including an N-terminal C-type lectin-like domain) also is encoded by an intronless gene (22). The potential relevance of this intriguing observation is discussed in the section, Evolutionary Considerations.

In vivo and in vitro studies have revealed the functions of several of the structural domains of TM (Table 105-1). The stretch of protein containing the EGF-like repeats is the best characterized, this being the site of interaction of TM with thrombin, PC, and TAFI (23). Thrombin binds to EGF5 and -6 via its anion binding exosite I, but activation of PC requires EGF4, -5, and -6, and activation of TAFI requires EGF3 through EGF6 (24,25). Nothing is known about the function of EGF1 and -2, although isolated EGF1 through -6 have mitogenic activity in vitro on cultured fibroblasts and vascular smooth muscle cells, implying a potential role in cellular proliferation and atherogenesis. An aspartic acid residue (Asp349) within EGF4 is required for  $\text{Ca}^{2+}$ -mediated binding of TM to the  $\gamma$ -carboxyglutamic acid (gla)-containing domain of PC, and thus for thrombin-mediated activation of PC. Elucidated by a combination of in vitro biochemical studies and NMR structural analyses (26), oxidation of methionine

**Table 105-1: Structure–Function Correlates of TM**

Structure	Residues	Function
C-type lectin-like domain (CTLD)	1–154	Anti-inflammatory (inhibits neutrophil adhesion) Mediates cell–cell interactions Antiapoptotic
Hydrophobic region	155–222	?
EGF1–2	223–304	?
EGF3–6	305–462	Activation of TAFI
EGF4–6	346–462	Activation of PC Thrombin neutralization by PCI
EGF5–6	387–462	Site for thrombin attachment Inactivation of scu-PA (+CS)
EGF1–6	223–462	Mitogenic
Chondroitin sulfate (CS) in serine-threonine rich region	463–495	Site for thrombin attachment (low affinity) Enhances neutralization of scu-PA Enhances neutralization of thrombin by PCI and heparin-AT PF4 binding, which enhances activation of PC
Transmembrane	496–521	Anchor for TM and site of cleavage by rhomboid
Cytoplasmic tail	522–557	Recognition site for rhomboid

388 in the linker between EGF4 and EGF5 abrogates thrombin's ability to activate PC, an event that likely occurs with neutrophil activation during inflammation. We can speculate that, at the onset of an inflammatory stimulus, leukocyte release of reactive oxygen species causes oxidation of methionine 388, suppressing the generation of APC and promoting local fibrin deposition. TAFI activation, which would still be able to be generated under these conditions (because it is unaffected by the oxidation of methionine 388), would interfere with fibrinolysis, enabling the clot to propagate and/or consolidate. The EGF-like repeats of TM also impede fibrinolysis by accelerating the thrombin-mediated conversion of single-chain urokinase-type plasminogen activator (scu-PA) to thrombin-cleaved two-chain urokinase-type plasminogen activator (tcu-PA), thus diminishing the generation of plasmin (27).

Adjacent to the EGF-like repeats, the chondroitin sulfate moiety of TM – in vitro – enhances thrombin-mediated activation of PC, accelerates neutralization of thrombin by the protein C inhibitor (PCI) and heparin-antithrombin, and promotes platelet factor 4 (PF4) binding to PC (28). This in turn

facilitates the generation of APC by altering the conformation of PC to favor its interaction with thrombin-TM.

At the N-terminus of TM, situated furthest from the membrane, the C-type lectin-like domain is physically positioned so that it may interact with other molecules. This structure lacks anticoagulant activity, but plays a direct role in inflammation and cell survival. Transgenic mice that lack the lectin-like domain of TM respond to inflammatory stimuli with augmented neutrophil extravasation, elevated cytokines, and greater tissue destruction in murine models of myocardial ischemia–reperfusion, arthritis, and endotoxin inhalation lung injury (29). In vivo studies revealed that the lectin-like domain of TM has direct anti-inflammatory properties, protecting the vasculature by interfering with neutrophil adhesion, mediated by activation of well-conserved mitogen-activated protein kinase (MAPK) pathways. Recent evidence suggests that the lectin-like domain of TM sequesters the circulating cytokine high-mobility group box 1 (HMGB1), thereby preventing it from transmitting intracellular proinflammatory signals (30). Maintenance of the integrity of cell–cell interactions also may be mediated by the lectin-like domain via homotypic and/or heterotypic interactions (31). Overall, the lectin-like domain of TM dampens the response of the vascular endothelium to proinflammatory stimuli, interestingly via mechanisms that appear to overlap with those of APC, thus highlighting their close coordination and integration.

## EVOLUTIONARY CONSIDERATIONS

As mentioned earlier, *TM* is encoded by an intronless gene (21). This is not particularly unusual, since 5% to 12% of human genes are intronless (32), including, for example, those for most heat-shock proteins, many G-protein-coupled receptors, the  $\beta_2$ -adrenergic receptor, type I interferons, and complement proteases C1r and C1s (33). The question of whether a lack of introns confers special properties to the gene is unclear. Because single exon genes, such as *TM*, are not susceptible to splice defects, it is reasonable to assume that they might be transcribed with greater fidelity. This does not necessarily imply that transcription rates are higher or more efficient, because introns actually may increase gene expression levels (34). Moreover, single exon genes may be disadvantaged in terms of flexibility in regulating expression levels in different tissues and under varying conditions. From an evolutionary standpoint, evidence suggests that intronless mammalian genes are more rapidly evolving (32), although this has not been evaluated for *TM*; nor has the relevance of this observation been elucidated.

*TM* belongs to the family of C-type lectin-like domains, which bind to protein ligands rather than to carbohydrates, do not bind calcium, and are primarily involved in immune surveillance. The domain organization of *Drosophila* proteins that contain C-type lectin-like domains is strikingly different when compared with the organization of those in mammalian

or in *C. elegans* proteins. The C-type lectin-like domain of TM is unique in its composition. Whereas most C-type lectins have a calcium-binding motif, this is lacking in TM. Furthermore, the lectin-like domain of TM contains eight, rather than the usual four cysteines. Only endosialin (35), a tumor-specific endothelial marker, and C1qRp, a molecule involved in leukocyte adhesion and complement activation (36), have structurally similar N-terminal C-type lectin-like domains. Murine C1qRp and TM may be derived from a common ancestor, because their genes colocalize to the same region of chromosome 2, and because they share similar domain composition and organization.

Lectins are commonly involved in the complement system and, indeed, the mannan-binding lectin (MBL), also containing a C-type lectin, provides an alternative activation pathway. Channel-forming proteins of the complement pathway also have a cysteine-rich N-terminal region typical of the C-type lectins, and C6 shows structural similarity (31%–38%) with TM. Notably, both C6 and TM may bind thrombin, although the relevance of the C6–thrombin interaction is unknown. Preliminary data from our group suggest that the C-type lectin-like domain of TM also might be involved in the modulation of complement (unpublished observations), consistent with a report that immobilized TM interferes with complement activation.

In contrast to many key components of the coagulation cascade (e.g., factors II, V, VII, VIII, FIX, X, tissue factor, PC, and PS), little is otherwise known about TM in terms of its evolution. Biochemical studies and comparative sequence analyses support the existence of the major coagulation factors and cofactors, including TM, in all jawed vertebrates, suggesting that they evolved before the divergence of teleosts over 430 million years ago. However, no confirmatory evidence exists of the existence of TM in nonmammalian vertebrates. Although PC has been identified in *Fugu*, the closest *Fugu* orthologue for TM is an intronless gene with 29% identity and 46% similarity to human TM, but functional studies to confirm a relationship have not yet been performed.

## ROLE OF THROMBOMODULIN IN DEVELOPMENT

During murine embryogenesis, TM first appears in the parietal endoderm at embryonic day (E)7.5, and is present in nonvascular structures at E10.5. Gene inactivation studies in mice confirmed a critical role for TM in development, unrelated to coagulation, because TM-deficient embryos die at E8.5, without clear evidence of thrombosis (37) (Table 105-2). In elegant studies, Isermann and colleagues revealed that placental trophoblasts normally express TM, which is required for their growth and survival (38,39). Embryonic lethality of TM-deficient embryos could thus be attributed to loss of TM-dependent survival of placental trophoblast cells, mediated by unregulated coagulation and/or fibrinolysis, possibly via PAR-2 or PAR-4 (39). Neither the cytoplasmic tail nor the

**Table 105-2: Transgenic Mice**

<i>Genotype</i>	<i>Phenotype (Refs.)</i>
<i>TM</i> <sup>-/-</sup>	<i>TM</i> gene inactivation results in embryonic lethality that occurs at ~E8.5 without evidence of thrombosis (37) but embryos die secondary to growth arrest of trophoblasts (38,39).
<i>TM</i> <sup>pro/pro</sup>	Mice with single amino acid substitution in TM (Glu404 to Pro) causes two- to threefold decrease in TM expression and minimal PC activation. Mice are viable, but are sensitive to prothrombotic and proinflammatory stimuli (56–58).
<i>TM</i> <sup>cyt/cyt</sup>	Mice lack the cytoplasmic tail of TM, are viable, and without significant defects in coagulation or inflammation (40).
<i>TM</i> <sup>LeD/LeD</sup>	Mice lack the C-type lectin-like domain of TM. They have normal PC cofactor activity, without coagulation defects, but are proinflammatory and more sensitive to endotoxin and ischemia–reperfusion injury (29).
<i>TMLox-</i>	Endothelial-specific loss of TM causes juvenile onset of thrombosis (38).
<i>TAFI</i> <sup>-/-</sup>	<i>TAFI</i> gene inactivation has no obvious thrombotic phenotype, but exhibits evidence of enhanced endogenous fibrinolysis (14,15).
<i>EPCR</i> <sup>-/-</sup>	<i>EPCR</i> gene inactivation results in embryonic lethality by E10.5. This is caused by lack of trophoblast expression of EPCR, because embryos with normal expression of trophoblast EPCR, but lacking endothelial EPCR survive. As adults, however, they are prone to thrombosis in response to procoagulant stimuli (42,44).
<i>Low EPCR</i> mice	Mice with low EPCR (<10%) are fertile and appear normal, and are not more prone to arterial thrombosis (43).

N-terminal lectin-like domains of TM are required for normal fetal development (29,40).

## ENDOTHELIAL PROTEIN C RECEPTOR: A PARTNER FOR THROMBOMODULIN

It is evident from the preceding sections that several proteins interact with TM to enhance and regulate the thrombin-induced activation of PC. The endothelial protein C receptor (EPCR), constitutively expressed by ECs, and similar structurally to the major histocompatibility complex class I/CDI family of proteins (41), accelerates thrombin-mediated activation of PC 10- to 20-fold in vivo. Once generated, APC first binds to EPCR, prior to proteolyzing factors Va/VIIIa. Once bound to EPCR, APC can cleave PAR-1, initiating antiapoptotic signaling pathways (9).

The expression pattern of EPCR is distinct from that of TM, with greater prominence in the endothelium of large vessels. Similar to TM, however, trophoblast expression of EPCR of at least 1% to 10% is both sufficient and necessary for survival of the embryo (42–44). In contrast to the situation with TM, lack of EC expression of EPCR does not cause profound, spontaneous juvenile onset thrombosis (38,39) (see Table 105-2). Rather, mice lacking endothelial EPCR survive to adulthood, but suffer from thromboses only in response to procoagulant stimuli (44). These data from transgenic mouse studies support major roles for both TM and EPCR in maintaining vascular thromboresistance, although TM is clearly the more prominent player.

### REGULATION OF THROMBOMODULIN EXPRESSION

In view of the central importance of TM in determining the substrate specificity of thrombin, a protease with wide biological importance, it is not surprising that expression of TM is tightly regulated via several mechanisms. Not only is TM expressed by blood ECs lining vessels of all caliber and in all organs, including the brain (45), but it also has been detected in lymphatic endothelium, astrocytes, keratinocytes, mesothelial cells, neutrophils, monocytes, platelets, VSMCs, osteoblasts, trophoblasts, and several tumor cells, in which a role in modulating thrombin might be important. The 5'-regulatory region of the human *TM* gene has been characterized – mostly through in vitro studies – dissection of which has revealed several elements that act positively or negatively. The promoter has a typical TATA box and CAAT box, with a strong transcription start signal 32 bases from the TATA box. Various potential 5' *cis*-acting elements are present, including four Sp1 sites, a region responsive to heat shock, a series of Ets motifs, four thyroid hormone/retinoic acid response elements, a silencer element, and a shear-responsive element. The approximately 3.7-kb *TM* mRNA has a half-life of approximately 9 hours, and the 3'-untranslated region contains an A+T-rich motif that might be a site for regulation of its stability. Regions that endow tissue or cell specificity have not yet been identified. Suppression of *TM* gene transcription has been documented in response to shear stress, hypoxia, oxidized low-density lipoprotein, hyperhomocysteinemia, prostaglandins, and transforming growth factor (TGF)- $\beta$  and, in vivo, to cytokines and sepsis, conditions that may be linked with endothelial damage, atherogenesis, and/or fibrin deposition (46,47). Transcriptional upregulation of TM is reported to occur with thrombin, vascular endothelial growth factor (VEGF), histamine, and statins, and in vivo in rodents after heat shock (48–51). Interestingly, inflammatory cytokines such as TNF- $\alpha$  or interleukin (IL)-1 $\beta$  that suppress TM in ECs, upregulate TM in macrophages, highlighting the complexity of its regulation.

Similar to TM, transcription of the *EPCR* gene also is suppressed by endotoxin and inflammatory cytokines. Furthermore, a soluble form of EPCR (sEPCR) is generated –

particularly during sepsis – by matrix metalloproteinase-mediated cleavage of the protein from the cell surface. The function of sEPCR is not yet resolved. It may bind to PC and APC, interfering with APC anticoagulant function by altering its active site. However, sEPCR also may complex with the neutrophil elastase-like protein, proteinase 3 (PR3), whereupon the complex interferes with neutrophil integrin function, thereby diminishing neutrophil–endothelial interactions and neutrophil extravasation (5,52).

### DIAGNOSTICS – IS SOLUBLE THROMBOMODULIN USEFUL?

Generated by enzymatic cleavage of the integral membrane endothelial protein, TM exists in a soluble form in the plasma and, depending on the assay system, normal levels range from 3 to 50 ng/mL. Soluble TM is comprised of multiple fragments from the extracellular portion of the molecule, some of which – those containing the intact EGF-like repeats – retain anticoagulant function (53). Soluble TM increases with vascular endothelial damage from infections, vasculitis, sepsis, and inflammation, probably due to cleavage by proteases released from activated neutrophils, and/or by an endothelial intramembranous protease, known as a rhomboid, which identifies a recognition sequence in the cytoplasmic domain of TM and cleaves it within the transmembrane domain (54). Indeed, soluble plasma TM may be a marker for disease activity in vasculitides such as systemic lupus erythematosus or arthritis, and in diabetic nephropathy. But much debate surrounds the relevance and utility of plasma TM levels, with some groups claiming that high levels are predictive for development of coronary heart disease, whereas others believe that soluble TM is vasculoprotective (55). This discordance may reflect the current lack of tools to identify which soluble fragment of TM is being measured, and which is biologically relevant for measuring. Data from our lab support the view that the lectin-like domain of TM, which is one of the circulating soluble fragments of TM, is vasculoprotective (29), although confirmation in humans is lacking.

### THROMBOMODULIN MUTATIONS AND HUMAN DISEASE

Increased fibrin deposition occurs in the lungs of mice that carry a TM mutation that dramatically suppresses its capacity as a cofactor in the thrombin-mediated activation of PC (56–58). There are, however, conflicting reports as to the clinical significance of TM mutations in venous and arterial thrombotic disease in humans. Since the first report of familial thrombophilia associated with a *TM* gene mutation (59), several additional mutations and polymorphisms in the coding region and the promoter region have been described (archived in <http://archive.uwcm.ac.uk/uwcm/mg/search/119613.html>). Some have been evaluated in vitro to

characterize effects on the functional expression of TM, but results often do not correlate with clinical findings (60). However, several studies do suggest a link. For example, in a large prospective analysis of men, the A455V and -1208-1209TTdelTT variants exhibit a small, but nonsignificant increase in risk for coronary heart disease (61). A natural mutation encoding an elongated TM protein with reduced expression was detected in a pedigree associated with myocardial ischemia. And in some segments of the population, the Ala25Thr substitution is a risk factor for ischemic heart disease (62). Overall, further large-scale studies are required to better characterize the potential association. Notably, there have been no surveys designed to evaluate the incidence of TM mutations in other diseases, such as cancer or inflammation, but these are warranted.

### THERAPEUTIC CONSIDERATIONS

Preclinical trials using recombinant forms of TM that encompass EGF1 through EGF6 are effective in protecting against tissue factor- or endotoxin-induced disseminated intravascular coagulation or lung injury, and in rat models, local nonviral TM gene transfer prevents thrombosis of vein grafts. Phase I clinical trials suggest that recombinant soluble TM is safe (63), but its efficacy in the prevention or treatment of hypercoagulable disorders, sepsis, or inflammatory disorders remains to be proven, and at least a theoretical risk exists of bleeding complications. Support for using TM specifically to prevent inflammation comes first from studies in rabbit restenosis models, where administration of TM via adenovirus prevented restenosis and dampened the inflammatory response. Furthermore, complement activation was diminished by TM either when immobilized in a medical device, or when systemically administered in a rat model of glomerulonephritis. The *in vivo* anti-inflammatory effects of administering recombinant forms of the lectin-like domain of TM in mouse models of human disease (e.g., myocardial ischemia–reperfusion, arthritis) are promising, but require further confirmation. Lastly, in limited studies, recombinant TM also has antitumor effects, the mechanisms of which are under investigation.

### KEY POINTS

- TM is a crucial cofactor in a major natural anticoagulant pathway, facilitating effective thrombin-induced activation of PC, switching the substrate specificity of thrombin from procoagulant and proinflammatory, to anticoagulant and anti-inflammatory.
- Critical structural domains of TM play distinct roles in inflammation, coagulation, fibrinolysis, and cell proliferation, and these are integrated to protect

the organism during development and in adults in response to a variety of stresses. Delineating the structure–function correlates of TM is leading to new diagnostics, and safer, more effective disease- and organ-specific therapies.

### Future Goals

- To elucidate the pathophysiological role of soluble fragments of TM that circulate in the plasma and determine if they reflect vascular disease
- To characterize genetic defects in TM (and/or its partner proteins), which may be useful in identifying individuals with a predisposition to develop hemostatic/thrombotic, proliferative, or inflammatory disorders
- To characterize TM within the context of a complex of multiple proteins – membrane-associated, soluble, and intracellular – differentially expressed in many cells and tissues, and to assess their contribution to human health and disease

### ACKNOWLEDGMENTS

## Heparan Sulfate

Nicholas W. Shworak

*Angiogenesis Research Center, Dartmouth Medical School, Hanover, New Hampshire*

A multitude of biological processes are regulated by heparan sulfate proteoglycans (HSPGs), which are produced by virtually all cell types. These hybrid molecules are composed of protein cores to which are attached one or more long chains of heparan sulfate (HS). Functional diversity is engendered in part from a multiplicity of core proteins and in part from the structural complexity of the HS chain. This polysaccharide is a type of glycosaminoglycan (GAG) – a long unbranched copolymer comprised of alternating amino and acid sugars. The HS sugar residues are decorated at various positions with sulfate groups, which creates a large array of short sequence motifs that bind and thereby modulate the functional properties of numerous regulatory molecules, including signaling ligands/receptors, proteases, enzymes, and lipoproteins (Table 106-1) (1,2). HS–protein interactions control cellular processes such as signaling, adhesion, migration, and vesicular trafficking. Through these cellular actions, HSPGs regulate many biological events including angiogenesis, lipoprotein metabolism, inflammation, hemostasis, developmental inductions, and axonal guidance.

This chapter focuses on only one aspect of HSPG biology – the input role of the HS chain in regulating endothelial cell (EC) signaling by “heparin-binding growth factors.” For purposes of discussion, this term is defined as any signaling ligand that exhibits high affinity to heparin, a particular type of highly sulfated HS. This definition encompasses classic growth factors such as fibroblast growth factors (FGFs); vascular endothelial growth factors (VEGFs); heparin-binding epidermal growth factor (Wnts); cytokines like interleukin-3, granulocyte monocyte colony stimulating factor (GM-CSF), and interferon- $\gamma$ ; most chemokines; and even growth inhibitors such as endostatin. Thus, this term includes the majority of HS binding ligands (see Table 106-1). The reference to “heparin-binding” reflects the historical use of heparin chromatography to purify many of these factors. By definition, heparin is found only within mast cell granules, so it is unlikely to contribute to the *in vivo* roles of most of these ligands. Instead, the physiological activities of

heparin-binding growth factors predominantly involve their interaction with the HS chains of cell surface and extracellular matrix (ECM) HSPGs, which are produced by virtually all cell types.

### HISTORY

Although heparin is a low-abundance form of HS, it was the first form of HS discovered, and thus dominated the early history of the field. In 1916, a second-year medical student, Jay McLean, found that an extract from dog liver exhibited strong anticoagulant activity (3). This activity was designated as *heparin* to denote its isolation from liver. By 1935, clinical trials were started, heralding the longstanding use of heparin as an efficacious anticoagulant (4). The acceptance of heparin as a therapeutic agent motivated studies to discover its structure and mechanism of action.

The elucidation of heparin’s mechanism of action provides a paradigm for how HS motifs convey biological activity. In 1925, William Henry Howell, McLean’s mentor, determined that heparin was some form of polysaccharide and proposed that its anticoagulant activity required a plasma cofactor (5). However, almost six decades of research would be required to unravel its intricate structure and mechanism of action (4). The hypothetical plasma cofactor was ultimately identified as antithrombin (AT) in 1968, by Abildgaard (6). Soon after, Damus, Hicks, and Rosenberg found that heparin mediates its effects by binding to AT (7). Such binding was initially considered to occur through nonspecific ionic interactions; however, this notion was soon discounted. In 1976, the three independent groups of Lindahl, Rosenberg, and Sims showed that only one third of heparin molecules could bind AT, and only this population of molecules exhibited anticoagulant activity (8–10). This landmark observation suggested structural specificity. Indeed, in the early 1980s, the groups of Choay, Lindahl, and Rosenberg demonstrated that the active component of heparin was a pentasaccharide with a specific motif of

sulfate groups (4). It is now appreciated that distinct activities of HS are conveyed by specific motifs, with each motif binding to a distinct effector protein.

Although heparin dominated the initial HS landscape, as early as 1937, it was appreciated that heparin played only a limited role in the body, being present only in the basophilic granules of mast cells (11). (The liver capsule contains high levels of mast cells, which accounts for its high heparin content.) The ubiquitous nature of HS was not realized until the early 1970s, when it was found that virtually all cell types produce HS as a proteoglycan (4). Various core proteins were identified during the 1980s, and HS biosynthetic enzymes were cloned in the 1990s. The ubiquitous form of HS and heparin were found to be synthesized by the same family of enzymes, which led to the appreciation that heparin is simply one type of HS (1,2,12). Indeed, certain non-mast cell types produce a subpopulation of HS chains that exhibit high sulfate content indistinguishable from that of mast-cell heparin. The multifaceted nature of HS function began to emerge during the 1970s, when the first of numerous heparin/HS-binding proteins were discovered. During the early 1980s, the groups of Klagsbrun and Folkman championed the use of heparin affinity chromatography to purify EC mitogens (13). This application helped trigger investigations into HS-mediated signaling by heparin-binding growth factors, which continue to this day.

## HEPARAN SULFATE PROTEOGLYCAN STRUCTURE, SYNTHESIS, AND POSTSYNTHETIC MODIFICATION

### Core Proteins

The broad functional repertoire of HSPGs in part stems from a multiplicity of core proteins (Figure 106.1A). Some core proteins exclusively bear HS chains, whereas others can carry two types of GAG chains – HS and chondroitin sulfate (CS) (Table 106-2). In vertebrates, most cell-surface HS is carried by syndecans (four related transmembrane proteins extensively described in Chapter 44 and glypicans (a family of at least six homologous glycoposphatidyl-inositol [GPI]-anchored proteins). However, a variety of additional integral membrane proteins, such as betaglycan and splice variants of CD44, can occasionally bear HS chains and are thus considered “part-time” proteoglycans. The major carriers of non-surface bound HS in the ECM appear to be perlecan, agrin, and collagen XVIII (1,14). At present, 11 core proteins are known to be expressed by ECs (Table 106-2). Such complexity does not merely reflect redundancy, because specialized features of a given HSPG core protein can: (a) define localization to extracellular or intracellular compartments; (b) allow for cellular internalization, recycling, or transcellular transport; and (c) provide direct interactions with signaling and/or cytoskeletal components (1,15,16). The importance of the core protein is exemplified

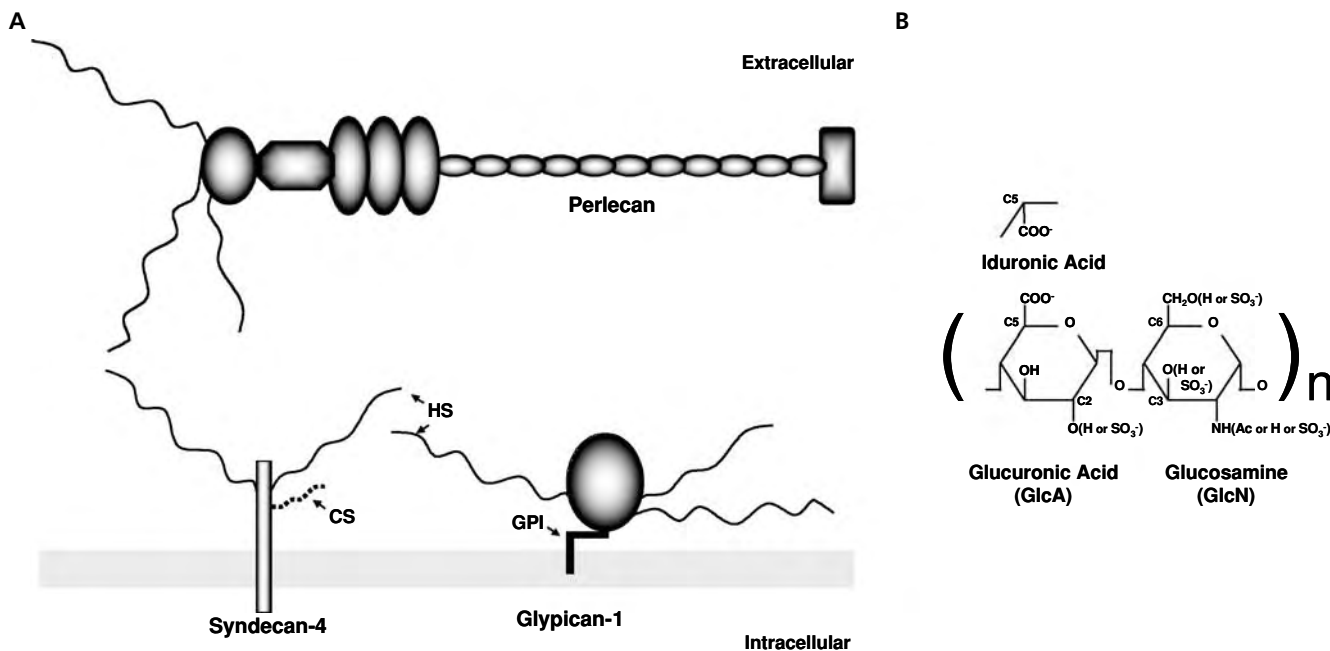

Figure 106.1. HSPG structure. (A) Representative HSPGs of ECs. Schematic presentation of the EC surface/basement membrane showing representative types of integral membrane (syndecan-4), GPI-linked (glypican-1), and extracellular (perlecan) HSPGs. Syndecan-4 is shown as carrying one CS (dotted line) and two HS (unbroken line) chains, but can bear multiple permutations of these GAGs. (B) Structure of the HS disaccharide repeat. Both HS and heparin are comprised of the same repeated disaccharide. The uronic acid can be remodeled by epimerization at C<sub>5</sub>, which converts glucuronic acid to iduronic acid (only C<sub>5</sub> region shown), or by adding a sulfate at C<sub>2</sub>. Remodeling of the glucosamine can involve replacement of the *N*-acetyl group with either a sulfate group or a proton (creating a free amino group). Sulfates can also be added at the C<sub>3</sub> or C<sub>6</sub> positions.

by Chapter 44, which elaborates on how syndecan-4 regulates EC phenotype through cell signaling events. Together, the core protein and associated machinery circumscribe a platform of such immense utility that virtually all higher eukaryotic tissues and cells employ HSPGs in multiple roles.

### Heparan Sulfate Chain Structure

In addition to the multiplicity of core proteins, the complexity and functional diversity of HSPGs is further amplified by the HS component. HS is a heterogeneous linear polysaccharide consisting of a repeated disaccharide unit, hexuronic acid  $\beta_{1\rightarrow4}$ -*N*-acetylglucosamine (GlcNAc)  $\alpha_{1\rightarrow4}$  (glucuronic/iduronic acid alternating with glucosamine, that is partially decorated with *N*- and various *O*-sulfate groups (see Figure 106.1B). In large part, the specific arrangement of the sulfate moieties gives rise to distinct binding motifs that interact with an increasingly expansive list of protein effectors (2,17,18). The HS chains are quite long, ranging from 100 to 200 disaccharide units, which span approximately 40 to 80 nm, respectively. Each chain is internally repetitive, containing short blocks of highly sulfated motifs alternating with blocks containing minimal sulfation (1,15,16). Because a single HS chain can contain multiple copies of different ligand binding motifs (19), HS is ideally suited to act as a template

for assembling multimolecular complexes, such as signaling complexes.

### Heparan Sulfate Biosynthesis

HS synthesis involves an extensive process of post-translational modification that occurs in the Golgi apparatus (Figure 106.2). The process first employs UDP-linked sugars as substrates for polymerizing the HS chain. This backbone is then remodeled largely by sulfotransferases that employ the universal sulfate donor 3' phosphoadenosine-5'-phosphosulfate (PAPS) to decorate the chain with sulfate groups, thereby creating distinct HS motifs (14). Although core proteins convey many functions, they do not play a substantial role in defining the types of HS motifs that occur along their HS chains (20). Instead, production of specific motifs is dictated by the sequence-specific properties of the various modification enzymes.

Synthesis initiates at certain serine residues of various core proteins by the assembly of a short-linkage tetrasaccharide (see Figure 106.2). This step is common to HS and CS synthesis, which explains why many HSPGs can also carry CS chains. Compared to HS, CS sugar chains are shorter, contain galactosamine instead of GlcNAc, and are sulfated in some distinct positions. As a result, CS exhibits biological activities different

**Table 106-2: HSPG Core Proteins**

<i>Core Proteins</i>	<i>Endothelial Expression Known</i>	<i>GAG Type (Number of Chains)</i>	<i>Key Features</i>
<b>Cell Surface</b>			
Syndecan family			Type I integral membrane proteins
Syndecan-1	+	HS/CS (3–5)	
Syndecan-2	+	HS/CS (3)	
Syndecan-3		HS/CS (3–5)	
Syndecan-4	+	HS/CS (3)	
Glypican family			GPI linked
Glypican-1	+	HS (3)	
Glypican-2		HS	
Glypican-3		HS	
Glypican-4		HS	
Glypican-5		HS	
Glypican-6		HS	
Betaglycan	+	HS/CS	Part-time proteoglycan
CD44	+	HS/CS	Part-time proteoglycan
FGFR2	+	HS/CS (1)	Splice variants containing the “acid box”
<b>Extracellular matrix</b>			
Perlecan	+	HS/CS (3)	Large multidomain protein
Agrin	+	HS (3)	
Type XVIII collagen	+	HS/CS (3)	Cleavage product is endostatin
Testican	+	HS/CS (2)	

(Using data from Bernfield M, Gotte M, Park PW, et al. Functions of cell surface heparan sulfate proteoglycans. *Annu Rev Biochem.* 1999;68:729–777; and Silbert JE, Sugumaran G. A starting place for the road to function. *Glycoconj J.* 2002; 19:227–237.)

from those of HS. Commitment of the primed structure to HS synthesis is determined by the addition of a GlcNAc residue by either EXTL2 or EXTL3, which are distinct isoforms of GlcNAc transferase I. Elongation of the HS backbone then requires the simultaneous action of enzymes from the genes *EXT1* and *EXT2* (2,12).

Distinct structures next arise through remodeling of the copolymer backbone by a semiordered series of reactions. Initially, subsets of *N*-acetylglucosamine residues are deacetylated and *N*-sulfated by HS *N*-deacetylase/*N*-sulfotransferase (NDST) (21,22). Occasional residues escape sulfation, which leaves a free amino group. Regions with a high density of *N*-sulfated glucosamine are then preferentially modified by less frequent reactions. Occasional glucuronic acid residues are converted to iduronic acid by the HS C<sub>5</sub> epimerase (23,24). The HS 2-sulfotransferase (HS2ST) next produces 2-*O*-sulfated iduronic acid or 2-*O*-sulfated glucuronic acid (25,26). HS 6-*O*-sulfotransferase (HS6ST) converts occasional glucosamine residues to 6-*O*-sulfated glucosamine (27). “Late” modification also includes 3-*O*-sulfation of glucosamine, which is added by HS 3-*O*-sulfotransferase (HS3ST) (20,28–30).

Multiple isozymes have been identified for NDST, HS6ST, and HS3ST. Such multiplicity serves two purposes. First, individual isoforms can exhibit distinct sequence specificities, which expands the structural diversity of HS (30–32). Second,

multiple isoforms enable cell type-specific production of distinct HS motifs (2,12). These concepts are best illustrated by the seven distinct isoforms of 3-*O*-sulfotransferases (HS3ST), which comprise the largest multigene family of HS modification enzymes. Despite the large family size, 3-*O*-sulfates are the rarest HS modification (typically comprising <0.5% of total sulfate moieties) but do serve key regulatory roles (20,33). The enzymes fall into two classes (AT-type versus gD-type) based on enzymatic specificities (34). HS3ST1 is an AT-type enzyme, which preferentially modifies a specific pentasaccharide precursor structure to create HS with high-affinity binding motifs for AT (HS<sup>AT+</sup>). In ECs, the level of HS3ST1 serves to regulate the level of HS<sup>AT+</sup> synthesis (28). The interaction of this motif with AT is thought to convey anticoagulant and anti-inflammatory properties to the endothelium. In contrast, HS3ST2, HS3ST3<sub>A</sub>, HS3ST3<sub>B</sub>, HS3ST4, and HS3ST6 are gD-type enzymes, which preferentially recognize a distinct precursor structure to create a different 3-*O*-sulfated motif (HS<sup>gD+</sup>), known to bind glycoprotein gD of herpes simplex virus 1. Cellular expression of gD-type enzymes enables the cellular entry of this herpes virus (35). HS<sup>gD+</sup> has recently been implicated in Notch signaling (described in the following section). However, its endogenous ligand is not yet known. HS3ST5 falls into both classes because it is able to generate both motifs with equal efficiency (36). Although this system

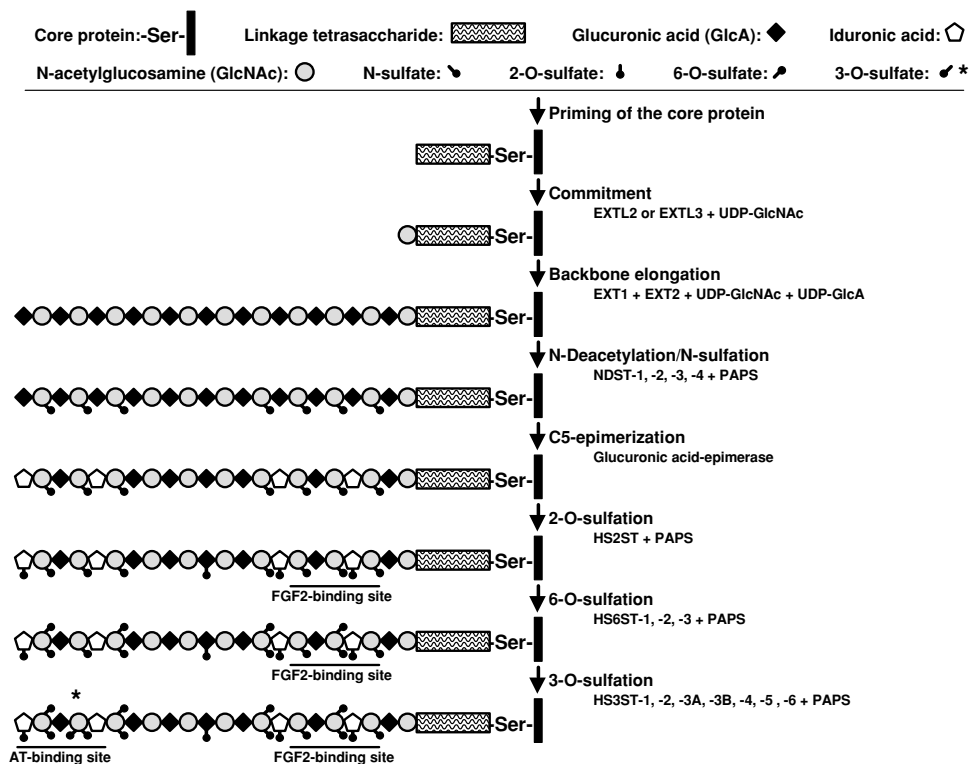

Figure 106.2. Steps of HS synthesis. This schematic indicates the major steps of HS synthesis and the involved enzymes and cofactors. This relatively ordered process creates distinct sequence motifs. Shown is the minimal sequence required to bind an FGF2 monomer. This binding site has only a few modifications, so is generated early; whereas, antithrombin (AT)-binding sites have multiple modifications and are completed later. The \* indicates a residue modified by the very rare 3-O-sulfate moiety. Structures generated by gD-type HS3ST enzymes are not shown.

appears to show redundancy, each isoform exhibits unique cell type- and tissue-specific expression patterns. The isoforms of NDST (NDST1 to NDST4) and HS6ST (HS6ST1 to HS6ST3) also exhibit sequence specificity and cell type-specific expression (2,12). Thus, the expression of distinct combinations of HS sulfotransferases enables individual cell types to produce distinct arrays of HS motifs.

### Postsynthetic Heparan Sulfate Proteoglycans Processing

The properties of HSPGs can be further modified by post-biosynthetic processing. First, cell membrane-bound proteoglycans can be shed from the cell surface. Shedding of integral membrane HSPGs involves protease clipping of the extracellular domain near the transmembrane domain, whereas a phospholipase activity liberates GPI-linked HSPGs (1). Second, HS motifs can be modified by extracellular sulfatases, which remove specific sulfate moieties. Presently known are the Sulf enzymes, which can remove 6-O-sulfate groups (37). Third, HS chains can be degraded by extracellular heparanases derived from leukocytes, tumor cells, or the endothelium (38). Fourth, HS chains can sustain damage by nitric oxide. Such HSPGs can undergo cellular internalization, removal of the damaged chain regions, resynthesis of

fresh HS chains, and transport back to the pericellular milieu (39). Thus, multiple extracellular factors can alter HSPG chain structure. Such factors may potentially influence HS-mediated cell signaling (discussed later).

### EVOLUTIONARY CONSIDERATIONS

Bona fide HS polysaccharide is not found in prokaryotes, unicellular organisms, or plants. Rigorous structural studies have found that, among multicellular animals, HS is absent only in the most primitive metazoans, the sponges. Vertebrate HS structures are clearly present, however, in the two more complex phyla *Ctenophora* and *Cnidaria*, whose ancestors represent the earliest forms of true metazoans (Eumetazoa) (40,41). The split between sponges and Eumetazoans is estimated to have occurred approximately 940 million years ago, testifying to the extreme antiquity of HS. On one hand, the evolution of HS may have conferred a selection advantage by optimizing pre-existent processes. Potential candidates include cell signaling and adhesion, which were firmly established in single-cell organisms. Additional candidates include chemokine production, innate immunity, apoptosis, and totipotent stem cells, which all occur in sponges. On the other hand, selection for the emergence of the complex HS biosynthetic pathway may

have involved a unique process appearing at the divergence of Eumetazoans. In particular, this evolutionary split was enabled by the emergence of an integrated mechanism for whole-organ homeostasis (42). Sponges are not Eumetazoans because they function almost like a colony of animals. They are comprised of semiautonomous groups of cells, with each group having an independent inlet to obtain seawater that contains food and oxygen and an independent outlet for the removal of waste and carbon dioxide. In contrast, the earliest Eumetazoans have a single inlet to a common gastrovascular cavity, which is drained by a single outlet. The gastrovascular cavity is a specialized sealed compartment surrounded by a novel sheet of cells. This sheet is the original “epithelium sensu stricto,” a cell layer that serves to separate and regulate the fluids in distinct extracellular compartments. Thus, all Eumetazoans are characterized by a single circulatory system that enables whole-body homeostasis (42).

This change in body plan was accompanied by an increase in cellular diversity beginning in embryogenesis. Sponges arise from a single germ layer; however, early Eumetazoans had two germ layers (endoderm and ectoderm), which enabled the formation of the new epithelium sensu stricto. Early Eumetazoans also developed neurons, which allowed for further coordination of whole-body homeostasis. Thus, the emergence of Eumetazoans featured the simultaneous development of a single “circulatory system” and a primitive nervous system. This common emergence might explain why both systems frequently employ similar signaling components – such as FGFs, ephrins, neuropilins, and Notch receptors – as elaborated later. From such distant evolutionary roots, it is not surprising that HSPGs are involved in homeostatic mechanisms, occur in multiple organ systems, serve to modulate cell type specific phenotypes, and regulate embryonic development.

The extent of the lower metazoan HS biosynthetic machinery is known for the roundworm (*Caenorhabditis elegans*) and the fruit fly (*Drosophila melanogaster*), both of which have completely sequenced genomes. These organisms possess genes encoding all the required components for HSPG production, including multiple core proteins and all the various HS biosynthetic enzymes. Numerous studies show that the gene products are functionally equivalent to their corresponding mammalian proteins (2). However, in contrast to vertebrates, these invertebrates largely lack multigene families. Thus, they exhibit only single genes for syndecan, glypican, NDST, and HS6ST. The notable exception is that *Drosophila* shows two forms of HS3ST, which appear to be the predecessors of the two major functional groupings of the large mammalian 3-O-sulfotransferase multigene family (34).

## DEVELOPMENTAL CONSIDERATIONS

The roles for HS in vertebrate development are just beginning to be unraveled. In contrast, significant advances have been made in studies of *C. elegans* and *Drosophila*. Unfortunately, these invertebrates have a rudimentary open circu-

latory system, and thus are not useful for directly studying vascular development. Nevertheless, genetic investigations of these animals do reveal fundamental features of the roles of HS in development. Moreover, these studies demonstrate a role for HSPGs in several signaling pathways that are known to be operable in vertebrate ECs. Thus, the genetic analyses of such lower organisms bring to light potential ways in which HSPGs may function in mammalian ECs.

Studies of invertebrate mutants lacking various core proteins show that HSPGs are required for the development of multiple organ systems, and each core is required for signaling events that are specific in time, place, cell type, and tissue (2,43). Given that each protein conveys discrete functions, the multitude of core proteins expressed in mammalian ECs may well serve to expand endothelial functional diversity. Because lower organisms have multiple core proteins, deletion of a single core protein is not necessarily lethal. However, *Drosophila* and *C. elegans* having core proteins but completely lacking HS (due to mutations in EXT enzymes that prevent polymerization of the HS backbone) die in early embryogenesis. The lethal phenotype provides evidence for a critical role of the HS component of HSPGs during development. In *Drosophila*, such mutants show defects in pathways mediated by three HS-binding signaling ligands: hedgehog, wingless, and decapentaplegic (a form of transforming growth factor [TGF]- $\beta$ ) (2,43). Vertebrates have comparable ligands that are known to be involved in vasculogenesis and angiogenesis, so it is likely that mammalian ECs employ HS to regulate these pathways.

The roles of HS modification enzymes also have been revealed. In contrast to the lethality of a global HS deficiency, *C. elegans* mutants lacking C<sub>5</sub>-epimerase, HS2ST, or HS6ST are viable. All these mutants show abnormal guidance in specific neuronal types; however, each enzyme mutation affects a specific assortment of neurons. Thus, different HS modifications convey unique properties to HS in a cell type-specific fashion. Each mutation interferes with developmental processes involving three receptors (Robo, integrin, and ephrin) (2,43). In vertebrates, signaling through all these receptors is known to involve HSPGs, with integrins and ephrin receptors controlling key endothelial functions.

*Drosophila* deficiencies of specific HS modification enzymes are lethal, due to the malformation of key organ systems. *Drosophila* mutants lacking a gD-type HS3ST isoform have multiple developmental defects stemming from the disruption of signaling through the Notch receptor. Because the vertebrate Notch pathway conveys an arterial cell phenotype to noncommitted ECs (44), a mammalian gD-type HS3ST isoform might control this form of EC differentiation. *Drosophila* mutants lacking HS6ST are lethal because of a malformation of the tracheal airway system (34,45). The development of the *Drosophila* trachea is analogous to vertebrate angiogenesis, because both processes employ comparable signaling components (including FGFs) to control branching morphogenesis of tubular structures. Tracheal cells coexpress the HS6ST and breathless (the *Drosophila* FGF

receptor); whereas, adjacent inducing cells express branchless (the *Drosophila* FGF). Mutants lacking HS6ST activity or breathless or branchless have stunted branching of the tracheal system that is phenotypically equivalent. Moreover, HS6ST-deficient mutants have impaired FGF-dependent activation of mitogen-activated protein kinase (MAPK) (45). Thus, 6-O-sulfates of HS are essential for FGF-induced branching morphogenesis in *Drosophila*. These moieties also are required for mammalian FGF signaling, as elaborated later. Clearly, the identification and delineation of HS-mediated signaling mechanisms that are operable in vertebrate ECs should be facilitated by such genetic investigations into the developmental roles of HS in lower organisms.

Indeed, the roles of HS in vertebrate vessel development are beginning to come to light. HS is critical for the signaling activity of VEGF-A splice variants that contain HS-binding domains (VEGF-A<sub>164</sub>, VEGF-A<sub>188</sub>). Mice that exclusively express the non-HS-binding VEGF-A<sub>120</sub> exhibit abnormal angiogenesis with defective vessel branching (46,47). Although individual VEGF isoforms have distinct receptor specificities, it is likely that vessel branching requires HS-binding activity, because angiogenic sprouting in zebrafish has recently been shown to require the syndecan-2 core protein (48). Moreover, FGF-stimulated angiogenesis is defective in knockin mice that express a perlecan core protein lacking HS chains (49). Mice lacking various HS modification enzymes have recently been generated. *Hs3st1*<sup>-/-</sup> mice are described in Chapter 107. Deficiencies in C5-epimerase, NDST1, and HS2ST greatly alter HS structure and result in multiple developmental defects that produce postnatal lethality (50–54). Given the multiple roles of HS, an evaluation of adult functions will require mice with cell type-specific deficiencies. Indeed mice selectively lacking NDST1 in ECs recently have been generated. They have reduced neutrophil infiltration into tissues, which involves reduced (a) L-selectin-mediated binding of leukocytes to ECs, (b) EC transcytosis of chemokines, and (c) EC presentation of luminal surface chemokines to leukocytes (55). Thus, future analyses of mice with global or cell type-specific deficiencies in HS modification enzymes should reveal the involvement of specific HS structures in multiple aspects of vascular development and function.

## LIGAND-RECEPTOR INTERACTIONS

### The Coreceptor Model of Heparan Sulfate Proteoglycan Action

HSPGs play multiple roles in signaling and can act as either positive or negative regulators (15,56). The involved mechanisms have been most extensively established for FGF signaling, which we review as a paradigm of the many ways in which the HS component of HSPGs can modulate signaling of heparin-binding growth factors.

The FGF family is comprised of more than 20 members of ligands that mediate signaling through five different receptors containing tyrosine kinase domains (FGFRs). Multiple splice

variants of each FGFR exist, further expanding the complexity of this system. HSPGs modulate this system by acting as low-affinity “coreceptors” that facilitate the formation of a ternary complex in which two FGFs bind and thereby dimerize two FGFRs (57–59) (Figure 106.3A). Ligand-driven dimerization of the receptors is essential for cytoplasmic domain cross-phosphorylation, which initiates cell signaling (56).

A variety of HSPGs can act as endothelial coreceptors (including perlecan, glypican-1, and syndecans-1, -2, and -4) (60–62), which indicates a critical role for the HS chain. Solution phase studies suggest that one role of HS is to facilitate FGF dimerization into a configuration that is essential for receptor activation (63). However, the precise mechanism of ternary complex formation is disputed because two distinct HS-FGF-FGFR ternary complexes have been crystallized (56) (Figure 106.3A). One complex is asymmetric, with a single HS decasaccharide bridging two FGF1-FGFR2 dimers (64). The other complex is symmetric, with the ends of two HS fragments each stabilizing a single FGF2-FGFR1 dimer (65). One possible explanation for the structural differences is that each complex was formed with different isoforms of ligand and receptor. Given the large number of combinations of FGF receptors and ligands, perhaps multiple ways exist to generate ternary complexes. Regardless, both models show that the HS fragment(s) make similar contacts to the HS-binding residues of both the ligand and receptor. Thus, both models confirm that a major role of HS is to crosslink FGF to the FGFR (56).

### Regulatory Properties of Coreceptor-Modulated Signaling

The deployment of an HSPG coreceptor engenders growth factor signaling with several novel properties and influences signaling kinetics, strength, and specificity. In part, this reflects fundamental differences between HSPGs and growth factors. For example, HSPGs are long-lived, exhibiting half-lives in the range of hours to days, compared to the rapid turnover of growth factors (15). Consequently, HSPGs can serve to stabilize growth factors and can drive sustained signaling events. Indeed, in the absence of HS, low concentrations of FGF2 can bind FGFRs and stimulate phosphorylation of MAPK (66). However, the effect is transient and does not lead to cell proliferation, whereas in the presence of HS, signaling events are sustained and mitogenesis occurs (67,68). An additional difference is that pericellular HSPGs can occur in micromolar concentrations, which greatly exceeds the nanomolar levels of growth factors (15). The influence of HSPG concentration on signaling is best addressed by considering the stoichiometry of the ligand-receptor-HS ternary complex.

### Stoichiometric Considerations of Coreceptor Signaling

Because HS interacts with both FGFs and FGFRs, the successful formation of a functional HS-FGF-FGFR ternary complex is extremely dependent on the levels of HSPG present on the

Figure 106.3. Multiple mechanisms of HSPG regulated signaling. Schematically depicted are FGFs (as indicated) and the cell membrane with FGFRs (as indicated) and usually a syndecan-4 type HSPG, which can bear variable ratios of HS (solid lines) and CS (dotted lines) chains. Formation of an HS-FGF-FGFR ternary complex results in cell signaling (lightning bolt). For simplicity, this figure predominantly shows asymmetric signaling complexes. (A) Potential ternary complexes. The asymmetric complex requires only a single HS chain, whereas the symmetric complex requires the free ends of two HS chains. (B) Extremely high HS levels can potentially inhibit signaling by partitioning ligands and receptors onto separate HS chains and thereby prevent ternary complex formation. (C) Extracellular matrix (ECM)-regulated signaling. High levels of ECM HSPGs, such as perlecan (partially shown) can sequester growth factors away from the cell membrane and inhibit signaling. Matrix-bound growth factors are liberated in conditions such as tissue injury, in which proteases and heparanase release HS-growth factor complexes that diffuse to the cell surface to initiate signaling. (D) Cellular responsiveness to FGF can be enhanced by hypoxia, which increases the HS content of heteroglycan-type HSPGs. (E) Certain FGFR splice variants can be nonglycanated or glycanated with either a CS or HS chain. The latter receptor can form a ternary complex in the absence of other HSPGs. (F) HS can regulate isoform-specific signaling. Presented are two cells expressing two FGFR isoforms and exposed to two FGF isoforms. HS sequence motifs (triangles versus circles) can determine which FGF:FGFR isoform combinations are functionally operable.

cell surface. This feature is readily evident for developmental morphogen gradients, in which the strength of growth factor signaling is regionally defined by the level of HSPG expression (69). Extreme concentration effects are demonstrated in HSPG-deficient cells, in which FGF signaling is restored by the addition of exogenous HS/heparin. Low concentrations of GAG stimulate FGF signaling, but high concentrations are inhibitory (60,70,71). It has been proposed that low HS/heparin concentrations promote ternary complex formation at the cell surface, whereas high GAG concentrations that exceed levels of receptors and ligands will partition each component onto separate HS chains and thereby prevent ternary-complex formation (see Figure 106.3B). Indeed at high HS/heparin concentrations, mitogenic signaling can be re-established by simply increasing the concentration of FGF (72).

The prevention of ternary complex formation by high HS levels is clearly operable *in vivo*, and can involve spatial segregation (see Figure 106.3C). The endothelial basement membrane contains high levels of growth factors bound to HSPGs; however, signaling does not occur because the ligands are physically separated from their cell surface-bound receptors. Thus, the basement membrane contains sequestered growth factors. However, this reservoir of growth factors can be recruited during vessel injury or remodeling. The actions of proteases or heparinase can release growth factor–HS complexes that diffuse to activate their cell surface receptors (2,15,56).

### Glycanation Effects

One means of regulating HS levels is by altering the number and type of GAG chains synthesized on a core protein (glycanation). Glycanation control is germane to “heteroglycans” – in which the core proteins can be glycanated with multiple GAG types. Table 106-2 shows that ECs express several heteroglycans. Syndecan-4, for example, exhibits three GAG attachment sites that are always occupied, and each site can bear either HS or CS chains. Consequently, a single cell type can produce a variety of isoforms: pure HS-syndecan-4, pure CS-syndecan-4, and all possible permutations of heteroglycans (73). The ratio of these forms is biosynthetically controlled in response to external stimuli. For example, the exposure of ECs to hypoxia increases the cell surface HS-to-CS ratio and enhances cell responsiveness to FGF2 (74). Hypoxia does not increase core protein expression but instead enhances the expression of EXTL2, which commits GAG attachment sites to synthesis of HS chains (see Figure 106.2). Such biosynthetic control should increase the HS content on all heteroglycans expressed by a cell, and thus dramatically elevate cell surface levels of HS (see Figure 106.3D).

Glycanation also can lead to novel signaling mechanisms by placing GAG chains on certain receptors (see Figure 106.3E). An FGFR2 splice variant has recently been identified that contains a single GAG chain (75). The variant contains an alternate exon that encodes a GAG attachment site, which can bear either HS or CS chains. Compared to nonmodi-

fied or CS-modified receptors, the HS-bearing FGFR2 exhibits high affinity for FGF1. Moreover, in the absence of exogenous HS/heparin, only the HS-modified receptor responds to FGF1 stimulation with enhanced and sustained signaling events that result in mitogenesis (75). Similar forms of FGFR3 also may be possible, because this receptor also shows a similarly positioned potential GAG attachment site. Thus, the presence of an HS chain on select FGFRs appears to abrogate the need for an HSPG coreceptor. It follows that such receptors might play a dominant role in FGF signaling when cell surface levels of HSPGs are low.

### Regulation of Signaling by Heparan Sulfate Sequence Motifs

Most importantly, the existence of distinct HS motifs provides a means of regulating signaling specificity. Specific HS motifs are critical for FGF signaling. For example, the HS sequence for FGF2 binding requires 2-*O*-sulfated iduronic acids (76–78). This necessity is confirmed by a cell mutant deficient in HS2ST activity, which produces HS lacking 2-*O*-sulfated iduronic acids. Consequently, the mutant cells can neither bind to nor respond to the growth factor (79). Successful signaling also requires 6-*O*-sulfates that form direct contacts with the HS binding site of the FGFR (64,65,80). This requirement is further revealed by the defective FGF-driven tracheal morphogenesis found in a HS6ST-deficient *Drosophila* mutant, as described earlier.

The dependence of FGF signaling on HS motifs allows for cell type and temporal control of ligand–receptor signaling specificity. For both FGFs and FGFRs, residues of the HS-binding regions are nonconserved across the respective families (56). Consequently, distinct FGF and FGFR isoforms recognize distinct HS motifs (81). It follows that the structural composition of cellular HS will dictate which ligand–receptor combinations are functionally operable and how efficiently they will signal (82). Because HS structure varies between cell types, two distinct cell types bearing the same FGFRs, but different HS motifs, could exhibit differential responsiveness to a given FGF isoform (see Figure 106.3F). Indeed, HS isolated from different EC phenotypes can even activate distinct FGF-FGFR combinations (83). Physiological cues also can alter the cellular expression of various HS sulfotransferases and thereby change the array of HS motifs on the cell surface (74). Such regulated HS synthesis enables the growth factor responsiveness of a single cell type to be modulated in a temporal fashion.

Apart from altering sulfotransferase expression, the array of HS motifs expressed by a cell can be modulated subsequent to HS synthesis. For example, cells can secrete endosulfatases (Sulf1 and Sulf2), which can function in the extracellular environment to remove 6-*O*-sulfates from intact HS chains. Because 6-*O*-sulfates are required for HS interaction with certain FGFRs, these enzymes could influence FGF signaling. Indeed, forced Sulf1 expression can inhibit the formation of HS-FGF-FGFR ternary complexes and thereby prevent FGF-stimulated mesoderm induction and angiogenesis (37).

Thus, the modulation of HS structure superimposes specificity control onto the myriad of FGFs and FGFRs.

### DOWNSTREAM SIGNALING EFFECTS AND EFFECTS ON ENDOTHELIAL-CELL PHENOTYPE

At the cellular level, the downstream signaling events and effects on EC phenotype mediated by HS largely depend on the particular growth factor that initiates the signaling event. In large part, these effects are mediated by specific cell surface receptors; the ensuing effects are covered under individual chapters dealing with specific growth factors. However, growth factors also can induce oligomerization of HSPGs, some of which can directly function as signaling receptors. This process is best understood for the syndecan family of core proteins (see Chapter 44). At the whole-organism level, it is likely that the ability of HS to interact with a vast number of growth factors serves to coordinate certain global phenotypes or processes. Such global trends are beginning to come to light.

In the adult, the endothelium normally is comprised of highly differentiated nonproliferating cells. The endothelial basement membrane contains high levels of HS, which sequesters growth factors and thereby likely limits their function (see Figure 106.3C). Genetically engineered mice have recently revealed the importance of HS-bound growth factors stored in the basement membrane. First, knockin mice have been generated that express a form of perlecan, the major basement membrane HSPG that lacks HS chains. HS-deficient perlecan mice are viable but exhibit delayed wound healing and retarded FGF2-induced tumor growth due to defective angiogenesis (49). These phenotypes are observed in the context of tissue damage, in which basement membrane degradation normally releases HS–growth factor complexes that stimulate EC proliferation. Thus, the low levels of basement membrane HS in these mice limits the reservoir of HS-bound growth factor that can be mobilized in response to injury. Conversely, enhanced release of HS–growth factor complexes should occur in transgenic mice that overexpress the heparan cleaving enzyme, heparanase. Indeed, such mice show increased vascularization (84). Combined, these results indicate that at least one function of HS of the endothelial basement membrane is to stimulate EC proliferation in response to tissue damage.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

At present, HS-based therapeutics are only used to inhibit coagulation. This application has evolved from the use of unfractionated heparin, which is a very diverse mixture of molecules, to the recent deployment of a pure synthetic pentasaccharide binding site for AT, which is the active HS motif that conveys anticoagulant activity. The chemical synthesis of

HS motifs is exceedingly complex and difficult to scale up for industrial production. However, the recent cloning of HS biosynthetic and degradation enzymes should enable much more facile approaches that combine enzymatic and chemical methodologies. Thus, it is likely that additional synthetic HS motifs can be exploited as therapeutics in the near future. Further studies of the sequence-specific nature of signaling by heparin-binding growth factors should identify potentially important HS motifs.

Angiogenesis is a major arena amenable to potential HS-based therapeutics. Angiogenesis is induced by the concerted action of a number of heparin-binding growth factors. Thus, HS-based therapeutics could serve to inhibit or activate this process. Inhibition is desirable in the treatment of solid tumors, which secrete heparanase and heparin-binding growth factors that stimulate tumor vascularization and hence tumor growth. Optimal treatment would involve a mixture of HS motifs capable of binding specific growth factors but incapable of activating the corresponding receptors (85,86). Such treatment could also include an HS motif that inhibits tumor-secreted heparanase (87), thereby preventing the release of HS–growth factor complexes from the endothelial basement membrane.

The activation of angiogenesis is a potential means of treating ischemic disease by generating new blood vessels to bypass obstructed vessels. Those ECs downstream of an obstruction that experience hypoxia should exhibit enhanced HS levels and therefore have enhanced sensitivity to growth factors. However, bypass vessels must originate upstream of the obstruction; these ECs are not hypoxic, so likely will show low responsiveness to growth factors. One means of circumventing the need for endogenous cell surface HS may be to treat with a growth factor containing a covalently coupled HS fragment (88). The sequence of the attached HS motifs could dictate specificity for a particular receptor isoform. Thus, HS–growth factor hybrids could exhibit far greater specificity than nonconjugated growth factors. Such specificity may be capable of exploiting endothelial phenotypic diversity. For example, HS–growth factor hybrids could potentially allow for the targeted activation of coronary versus peripheral vessels.

#### KEY POINTS

- HS superimposes multiple levels of control over signaling by heparin-binding growth factors.
- Changes in cell surface HS levels should influence multiple heparin-binding growth factors and thus provide a means of globally regulating multiple signaling pathways.
- Conversely, changes in HS sequence motifs provide a means of regulating the signaling capacity of individual ligand–receptor combinations.

### Future Goals

- To use studies of mice deficient in various HS-sulfotransferases to clarify the aspects of EC biology regulated by specific HS-motifs; such studies may reveal novel therapeutic applications for synthetic HS motifs

# Antithrombin

Nicholas W. Shworak

*Angiogenesis Research Center, Dartmouth Medical School, Hanover, New Hampshire*

Antithrombin (AT) is considered to be the most important natural anticoagulant found in plasma. AT irreversibly neutralizes thrombin, factor Xa, and other activated proteases of the coagulation cascade. This neutralization reaction is dramatically enhanced by a longstanding therapeutic anticoagulant, heparin. Endothelial cells (ECs) produce HS<sup>AT+</sup> – a specific form of heparan sulfate (HS) that is biochemically related to heparin. In vitro, this EC glycosaminoglycan (GAG) also can catalyze AT neutralization of coagulation proteases; consequently, HS<sup>AT+</sup> has been designated as anticoagulant HS. Based on heparin's pharmacological mechanism of action, it has long been proposed that, in vivo, HS<sup>AT+</sup> produced by the endothelium would activate AT and thereby regulate the antithrombotic tone of the blood vessel wall. The objective of this chapter is to evaluate whether the endothelium deploys HS<sup>AT+</sup> as an output component to regulate coagulation. It is readily apparent that this issue has yet to be conclusively resolved. However, HS<sup>AT+</sup> might participate in an alternative or additional function: the anti-inflammatory signaling activity of AT. Consequently, this chapter also evaluates whether the endothelium deploys HS<sup>AT+</sup> as an input component that mediates cell signaling.

## HISTORY

AT also has been referred to as AT-II/heparin cofactor and AT-III. Various names were proposed because AT initially was identified as a biochemical activity. At one point, four distinct antithrombin activities of plasma were described. AT-I and AT-IV reflected the thrombin inhibitory activities of fibrin and a cleavage fragment of prothrombin, respectively. AT-II/heparin cofactor and AT-III respectively reflected the heparin-dependent and -independent anticoagulant activities of AT (1). Fortunately this arcane nomenclature has been abandoned (2).

At the end of the 19th century, thrombin was known to lose activity when incubated with defibrinated plasma, thereby

suggesting that blood must contain a specific inhibitor of thrombin (i.e., antithrombin activity) (3). In 1916, McLean found that extracts from ox heart and liver exhibited a distinct anticoagulant activity (4). McLean's mentor, Howell, purified a potent form of this anticoagulant from dog liver, which was designated as heparin to denote its source of isolation (5). In the early 1930s, Connaught Laboratories ushered in a new era by generating industrial quantities of heparin (6). The initial tissue source was beef liver, soon followed by beef lung; however, during the 1950s, a shift to using pig intestinal mucus/mucosa occurred (7). Industrialization enabled the therapeutic deployment of heparin in the mid 1930s, and provided the material necessary to characterize its mechanism of action (7). In 1939, Brinkhous and colleagues showed that heparin's anticoagulant action required a plasma component termed *heparin cofactor* (8). During the 1950s, several groups conducted kinetic studies indicating that plasma AT and plasma heparin cofactor activities were intimately related (7). In 1968, Abildgaard purified AT and demonstrated that it embodied both activities (9). Shortly thereafter, in 1973, Rosenberg and coworkers demonstrated that heparin catalyzed the inherent ability of AT to form covalent 1:1 inhibitory complexes with coagulation proteases (10).

The importance of AT as a natural anticoagulant was highlighted by Egeberg, who showed that a heritable deficiency was associated with thrombophilia (11). The characterization of AT deficiency was facilitated by Bock, who isolated the AT cDNA in 1982 (12). The next year Prochownik isolated the gene and demonstrated that multiple mutations can lead to AT deficiency (13). Today it is appreciated that more than 120 distinct mutations of this gene exist that reduce AT levels or activity and thereby convey an increased risk of thrombosis (14).

The elucidation of heparin's molecular interactions required an understanding of heparin's structure. In 1925, Howell determined that heparin was a polysaccharide (15). Shortly thereafter, it was determined that heparin was a

sulfated GAG – a linear polymer of alternating acid and amino sugars. However, heparin is a complex mixture of structures; consequently, almost 60 years of research were required to determine the critical structural features that conveyed anticoagulant activity (7). The prevailing view during this period was that heparin's effects were mediated by nonspecific ionic interactions. However, structural specificity was implicated in 1976, when three separate investigations from the groups of Lindahl, Rosenberg, and Sims showed that only one third of heparin molecules could bind AT, and only this population of molecules exhibited anticoagulant activity (16–18). In the early 1980s, the groups of Casu, Choay, Lindahl, and Rosenberg demonstrated that the active component of heparin was a specific pentasaccharide motif (reviewed in 7). This motif contained a very rare substituent, a 3-O-sulfate group, that was essential for both high-affinity AT-binding and the enhancement of AT activity (7).

The relevance of heparin's pharmacological action to endogenous physiology was initially unclear, because heparin is not a normal constituent of blood. Since 1937, it was known that heparin was a minor body component, being present only in the basophilic granules of mast cells. (It has subsequently been shown that the liver and other sources of commercial heparin are indeed rich in mast cells [7].) In 1948, it became apparent that the body also produces HS, a structurally related compound with a lower sulfate content (19). Since the late 1960s, accumulating data have revealed that heparin is simply a minor form of HS. HS is produced by virtually all cell types as HS proteoglycans (HSPGs). Proteoglycans are hybrid molecules, comprised of a protein core to which are attached one or more GAG chains. The structure and synthesis of HSPGs are detailed in Chapter 106. During the 1970s and 1980s, it was found that ECs produce HSPGs as components of the cell surface and extracellular matrix (ECM). Moreover, a subpopulation of endothelial HSPGs were found that bear HS<sup>AT+</sup>, heparin-like chains exhibiting the pentasaccharide motif that binds and enhances AT activity. Thus, it was proposed that endothelial HS<sup>AT+</sup> may be an endogenous activator of AT, thereby regulating the anticoagulant tone of the blood vessel wall (7). During the 1990s, Rosenberg, Shworak, and coworkers showed that EC synthesis of HS<sup>AT+</sup> was regulated by the rate-limiting action of the HS biosynthetic enzyme that adds the very rare 3-O-sulfate group, HS 3-O-sulfotransferase (OST)-1 or Hs3st1 (Figure 107.1) (20–23). They additionally cloned the mouse gene (*Hs3st1*) and generated *Hs3st1*<sup>-/-</sup> mice, which provided a means of evaluating the influence of endogenous HS<sup>AT+</sup> on the activities of AT (24).

Since 1989, it has become apparent that AT exhibits an anti-inflammatory activity that is discrete from its anticoagulant action. The anti-inflammatory activity stems from AT-stimulated EC signaling and appears to depend on HSPGs (25,26). Thus, HS<sup>AT+</sup> might regulate the anticoagulant and/or anti-inflammatory activities of AT.

Figure 107.1. Hs3st1 regulates HS<sup>AT+</sup> production. Hs3st1 acts late in HS/heparin synthesis and recognizes chain regions that conform to a specific pentasaccharide structure (*top*). AT has low affinity for this precursor structure. Hs3st1 transfers a sulfate group from the sulfate donor, PAPS, to the 3-O-position of the central glucosamine residue (ring positions underlined), thereby creating the high-affinity AT-binding pentasaccharide motif of HS<sup>AT+</sup>/heparin (*bottom*). The sulfate donor is converted from PAPS to PAP. Boxes indicate the altered atoms.

## THE AT PROTEIN AND GENE

### Antithrombin Protein Structure and Function

To appreciate the importance of AT in regulating coagulation, one must understand the present view of the major pathways that control thrombin production (27). This process is initiated predominantly by the “extrinsic pathway.” Limiting amounts tissue factor (TF) trigger a series of proteolytic activation reactions that occur on cell and platelet membranes, as detailed in Figure 107.2. Two phases of thrombin production occur. The initiation phase generates low levels of thrombin, which in turn sustains this phase through the activation of platelets and the generation of activated cofactors Va and VIIIa. These positive feedback loops also support a transition to the propagation phase, characterized by massive thrombin production. In both phases, thrombin levels are controlled by factor Xa, the limiting component of the prothrombinase complex. The predominant Xa source of the initiation phase is the *extrinsic Xase* complex (TF-VIIa). The *extrinsic Xase* complex also drives production of factor IXa and the *intrinsic Xase* complex (IXa-VIIIa), which is the major source of Xa during the propagation phase. The *intrinsic Xase* complex can also result from the factor XIa activation of factor IXa. Although a relatively minor reaction, thrombin stimulation of this portion of the intrinsic pathway can help to sustain the initiation phase when TF levels, and hence *extrinsic Xase* complex levels,

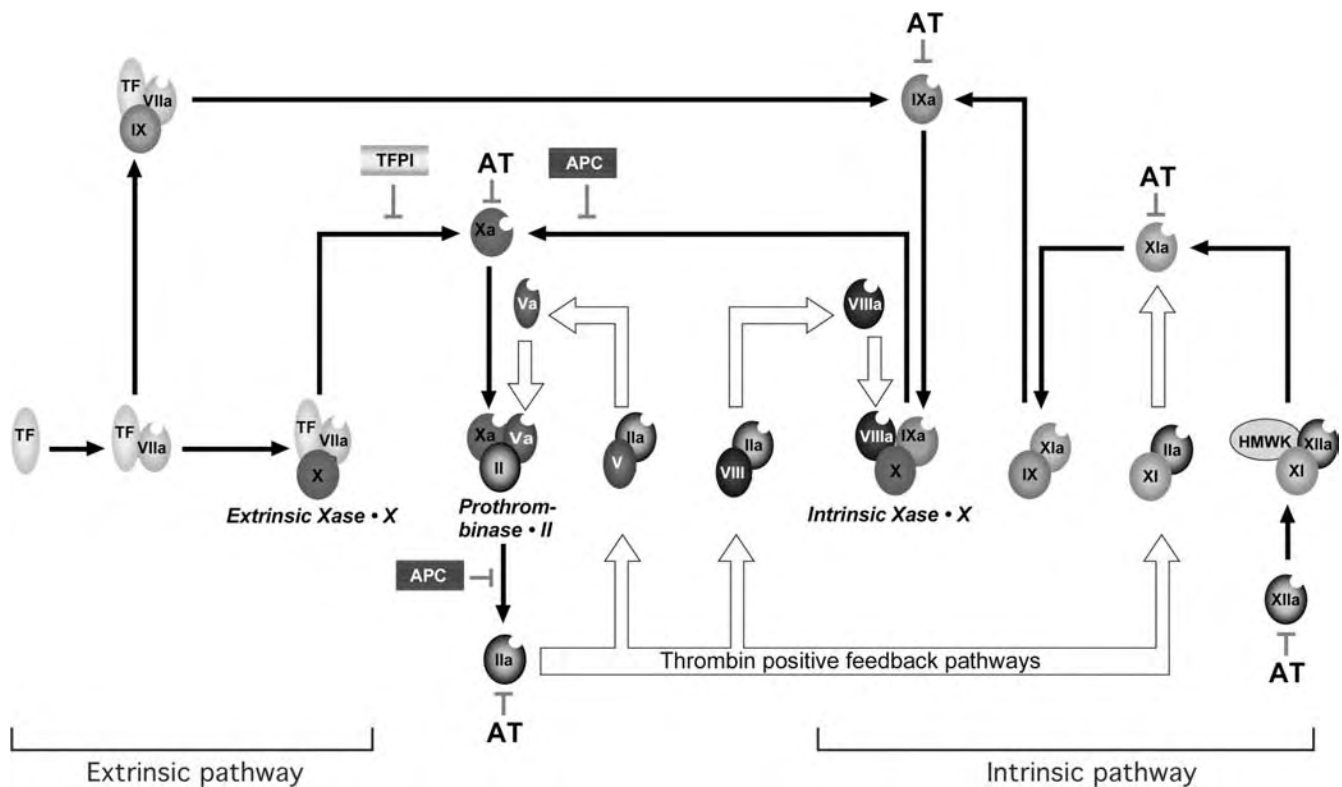

Figure 107.2. Major activators and inhibitors of thrombin generation. Thrombin generation initially is triggered (*black arrows*) by tissue factor (TF) expressed by activated ECs or revealed by endothelial denudation. TF binds and activates circulating factor VIIa. The resulting *extrinsic Xase* complex generates factor Xa. The *extrinsic Xase* complex additionally generates factor IXa, which forms the *intrinsic Xase* complex that also produces factor Xa. Factor Xa is the limiting component of the *prothrombinase* complex that cleaves prothrombin (II) to create thrombin (IIa). Thrombin then triggers positive feedback pathways (*gray arrows*) that increase levels of activated factors required for the above initiation steps. The *intrinsic Xase* complex also can result from the less understood intrinsic pathway, which starts with surface activation of factor XII. For simplicity, kallikrein/high-molecular-weight kininogen activation of Factor XII, and thrombin activation of APC are not shown. *Dark arrows* indicate components inhibited by AT, TFPI, and APC, as elaborated in the text.

are low. Activation of factor XIa by factor XII/kallikrein/high-molecular-weight kininogen has largely been thought to have dubious biologic relevance (27,28). However, recent studies of factor XIIa-deficient mice suggest this portion of the intrinsic pathway may be essential for the propagation phase of arterial thrombosis induced by major trauma (29).

The ability of AT to inhibit coagulation in the absence of GAGs has been revealed by *in vitro* and kinetic modeling studies. The importance of AT is highlighted by its ability to inhibit all the coagulation proteases. AT inhibits factors IIa (thrombin), IXa, Xa, XIa, XIIa, and kallikrein in their noncomplexed forms (30). Conversely, AT only inhibits factor VIIa when it is complexed with (and activated by) TF. However, AT is only a minor inhibitor of this *extrinsic Xase* complex. As predicted from the above specificities, *in vitro* studies show AT is only a minor regular of the initiation phase but is a major inhibitor of the propagation phase of coagulation (31). Thus, in the absence of GAGs, AT is primarily operable when there are high levels of noncomplexed factors IIa, IXa, and Xa.

The contribution of additional inhibitors of coagulation has been studied similarly. Tissue factor pathway inhibitor

(TFPI) is the predominant inhibitor of the *extrinsic Xase* complex and is the major inhibitor of the initiation phase (31). The remaining *prothrombinase* and *intrinsic Xase* complexes are inhibited by activated protein C (APC), which primarily inhibits the propagation phase (27). APC is a protease that degrades factors Va and VIIIa. These molecules are cofactors, not proteases, so APC controls those components that cannot be regulated by AT. The generation of APC by thrombomodulin-bound thrombin, and the ability of protein S to enhance APC activity are covered in Chapter 108. Finally, heparin cofactor II (HCII) lacks significant anticoagulant activity in the absence of GAGs (31). However, analyses of knockout mice indicate HCII can limit arterial coagulation initiated by endothelial denudation (32). This injury exposes GAGs of the subendothelial ECM, which presumably bind HCII and activate its neutralization of thrombin. In summary, AT blocks numerous coagulation components, whereas the remaining inhibitors have more restricted and largely complementary roles.

The broad specificity and mechanism of action of AT are derived from its structure. AT is a 58,000-Da protein

Figure 107.3. Distinct mechanisms of heparin-catalyzed protease neutralization. The speed of neutralization is limited by the rate of protease–AT binding. Heparin accelerates the protease–AT interaction by protease-specific mechanisms, as illustrated for factor Xa and thrombin (*T*). The top figure shows the minimal pentasaccharide motif (*Penta*) allosterically enhancing AT neutralization of factor Xa. Pentasaccharide binding to AT alters the conformation at one end of the reactive center loop (RCL), thereby exposing an exosite (*triangle*). Interaction of this exosite with an Xa exosite enhances the rate of Xa binding to the RCL. Cleavage of the RCL triggers a major AT conformational change that releases the pentasaccharide while simultaneously trapping and distorting the tethered protease. The bottom figure shows how a minimal 16-mer enhances thrombin binding through bridging. The 16-mer pentasaccharide motif (*black*) binds AT and produces the above conformational change; however, thrombin does not interact with the exosite for Xa (*triangle*), so that allosteric enhancement is minimal. Instead, thrombin binding is expedited by contact with the white saccharide residues. Once thrombin is bound, cleavage and entrapment occur as for Xa.

that belongs to the superfamily of serine protease inhibitors (serpins), which encompasses members such as HCII,  $\alpha$ 1-antitrypsin, angiotensinogen, and the plasminogen activator inhibitors (PAIs) 1 and 2. Serpins are “suicidal inhibitors.” They have an exposed reactive center loop that serves as bait for a target protease. When a serine protease cleaves a peptide backbone, a covalent acyl–enzyme bond is created between the protease and the substrate peptide. For normal substrates, this transient bond is broken to release the protease. However, a serpin’s reactive center loop functions like a mouse trap. Upon cleavage of this loop, the mousetrap springs from an open to a closed conformation. The serpin undergoes a rapid conformational change that buries the acyl–enzyme bond into the hydrophobic body of the serpin, thereby preventing bond cleavage and release of the tethered protease. This movement additionally disrupts the architecture of the protease’s active site (Figure 107.3). Thus, serpins trap the protease into an inactive 1:1 complex (33,34). All serpins exhibit a similar three-dimensional structure, which reflects the common “mouse trap mechanism” of inhibition. However, AT exhibits minimal primary sequence identity to other serpins and has a very unique attribute: It is the only serpin that normally exists in a “low-activity” conformation (35). The pharmacological action of heparin exploits this unique feature.

In the absence of heparin, AT slowly neutralizes activated coagulation proteases. This heparin-independent activity is designated as the “progressive reaction.” In contrast, heparin functions as a catalyst to increase the rate of protease neutralization. The precise mechanism depends on the nature of the target protease (see Figure 107.3). Neutralization of factors such as IXa and Xa require just the pentasaccharide motif of heparin/ $\text{HS}^{\text{AT}+}$ . The binding of the pentasaccharide to AT induces a conformational change that accelerates the docking of factors IXa and Xa and thereby enhances the neutralization rate by approximately 300-fold. This allosteric activation creates or exposes exosites on AT that interact with exosites of factor IXa or Xa, respectively. (Exosites are protein interaction regions that are distinct from the active site/reactive center loop.) In contrast, the pentasaccharide-induced conformational change only enhances AT neutralization of thrombin by approximately 1.6-fold. The efficient neutralization of thrombin instead requires a minimal 16-mer fragment of heparin/ $\text{HS}^{\text{AT}+}$  that functions as a bridge between AT and thrombin. One end of the fragment must contain the pentasaccharide for binding to AT, and the other end must have a highly sulfated trisaccharide for binding to thrombin. Compared to the pentasaccharide, a bridging 16-mer enhances the AT neutralization of thrombin by approximately 2,000-fold (36,37).

Although AT recognizes multiple proteases, it is not a major inhibitor of APC, an anticoagulant serine protease. Specificity against APC in large part results from the structure of AT’s reactive center loop, which is poorly recognized by APC. Indeed, it appears that AT’s reactive center loop has evolved residues that maximally select against recognition by APC (38). In addition, it is likely that APC also lacks exosites for AT (39). In contrast, factors IXa, Xa, and thrombin clearly have exosites that interact with AT (36,37). Thus, AT’s action is selectively anticoagulant because evolution has generated multiple interactions between AT and coagulation proteases, but largely prevented interactions between AT and the anticoagulant protease, APC.

AT has different conformational and glycosylation isoforms that exhibit distinct properties. The predominant conformational isoform is latent AT (L-AT), which is a senescent form. L-AT arises when a portion of the reactive center loop spontaneously embeds into a hydrophobic region of AT, similar to the “closed mouse trap” conformation. This conformational change is irreversible and prevents L-AT from inhibiting proteases. However, L-AT may serve an alternative physiological role, because it exhibits antiangiogenic properties (40).

The glycosylation isoforms are  $\alpha$ -AT and  $\beta$ -AT.  $\alpha$ -AT is fully glycosylated, bearing four *N*-linked glycans, and it is the major form of native AT in plasma.  $\beta$ -AT lacks glycosylation at N135, which results in enhanced affinity for heparin (41). Given this higher affinity, and given that most  $\text{HS}^{\text{AT}+}$  is localized on the abluminal surface,  $\beta$ -AT preferentially accumulates in the blood vessel wall. Consequently,  $\beta$ -AT may preferentially confer antithrombotic or anti-inflammatory tone to the blood vessel wall (42).

**Table 107-1: Relevant Knockout and Knockin Mice**

<i>Gene</i>	<i>Phenotype (Refs.)</i>
<i>Serpinc1</i> (AT-knockout)	Homozygous knockout embryos die at embryonic day (E)15.5–16.5 of a consumptive coagulopathy characterized by extensive subcutaneous hemorrhages and fibrin(ogen) deposition in heart and liver but not in hemorrhagic regions (49). Heterozygotes are viable and, when challenged with lipopolysaccharide, show enhanced fibrin deposition in glomeruli, myocardium, and liver sinusoids (81).
<i>Serpinc1</i> (type IIHBS knockin)	Homozygous knockin mice are viable but develop spontaneous life-threatening thrombosis in neonates and adults. Thrombosis in adults predominantly occurs in heart, liver, and vessels of eye, placenta, or penis. These mice show normal levels of T·AT complexes and normal venous stasis-induced thrombosis but enhanced levels of activated coagulation factors of the intrinsic pathway (67). Treatment with factor VIII blocking-antibodies can prevent thrombosis (82).
<i>Hs3st1</i>	Homozygous knockout mice are viable on a hybrid genetic background and show large reductions in HS <sup>AT+</sup> . Knockouts show wild-type levels of fibrin accumulation and T·AT complexes, and a normal thrombotic response to arterial injury. On a pure genetic background, knockouts show intrauterine growth retardation and die ~3 days after birth. Knockout embryos and placentae do not show thrombosis or hemorrhage (24,52).
<i>Serpind1</i> (HCII)	Homozygous knockout mice are viable and have normal longevity. They show a more rapid thrombotic response to arterial injury (32).

## SERPINC1, THE ANTITHROMBIN GENE

### SERPINC1 Structure and Function

The official designation of the *AT* gene is *SERPINC1*, which denotes AT as member 1 of serpin structural homology class C. The *SERPINC1* gene contains seven exons spanning 13.4 kbp on human chromosome 1. SERPINC1 expression is highly specific to liver hepatocytes, with only minor expression in some other organs, such as the kidneys. Consequently, plasma AT levels are predominantly controlled by the liver levels of *AT* mRNA (43).

AT behaves as a negative acute phase reactant, with plasma levels dropping after acute sepsis or surgery (44). This effect may be partially mediated by the retinoid X receptor  $\alpha$  (RXR $\alpha$ ) transcription factor. RXR $\alpha$  normally stimulates transcription of *AT* (45) and other negative acute phase reactants; however, hepatic nuclear levels of RXR $\alpha$  decline in acute sepsis (46). Proinflammatory cytokines can additionally reduce *AT* mRNA levels (47). Conversely, glucocorticoid (which is anti-inflammatory) stimulates SERPINC1 transcription (48). These alterations in gene expression are consistent with the anti-inflammatory properties of AT, as elaborated on in the next section.

### SERPINC1 MUTATIONS

Numerous mutations of the human *SERPINC1* gene have been identified; these highlight the importance of AT as a natural

anticoagulant. AT deficiency occurs at a frequency of about 1:3000 and is usually inherited as an autosomal dominant. Mutations are classified by the following scheme, which predicts clinical presentation:

**Type I:** Low functional and immunological levels of AT

**Type II:** AT structural variants

Subtypes:

RS, altered reactive site function

HBS, dysfunctional heparin binding site

PE, pleiotropic effect

In general, type I and type II<sub>RS</sub> have the most severe impact on plasma AT activity and convey the highest general risk of venous thrombosis. Afflicted individuals are virtually always heterozygotes, because complete AT deficiency is likely incompatible with human life (14). Indeed, complete AT deficiency in mice (see Table 107-1) causes intrauterine death from an extreme hypercoagulable state (49).

Increasing evidence suggests that the type II<sub>PE</sub> group may exhibit the unique clinical features of severe fever-induced thrombosis (50). Several members of this group exhibit conformational instability, and have a greater tendency to convert to the inactive L-AT form. Slight increases in body temperature can dramatically accelerate this transition, so sudden-onset thrombosis can occur in response to a minor incidental fever of 39°C to 40°C (102°F to 104°F). It is important to note that L-AT can inactivate normal AT by forming inactive dimers. Such inactivation may account for the

extreme severity of thrombosis in certain type II<sub>PE</sub> individuals (50).

Conversely, mutations that reduce heparin binding (type II<sub>HBS</sub>) have the “mildest” gene dosage effect. In contrast to the lethality of complete AT deficiency, individuals homozygous for type II<sub>HBS</sub> mutations are readily found. Indeed, this category of mutations typically behaves in a recessive fashion, with thrombosis predominantly occurring in homozygotes but not heterozygotes. The exclusive viability of homozygous type II<sub>HBS</sub> mutations suggests that the majority of AT’s anticoagulant activity does not require a functional heparin binding site. Type II<sub>HBS</sub> individuals also show an additional unique feature. Whereas other AT mutations lead to venous thrombosis, type II<sub>HBS</sub> patients frequently present with arterial thrombosis (14). Thus, AT binding to endothelial HS<sup>AT+</sup> may convey unique properties to the arterial wall.

## THE Hs3st1 PROTEIN AND GENE

### Hs3st1 Protein Structure and Function

HS biosynthesis occurs in the Golgi apparatus and is mediated predominantly by type-II integral membrane proteins. An interesting exception is Hs3st1, which exhibits the unusual structure of an intraluminal resident protein. The precursor protein gains entry into the endoplasmic reticulum via a leader sequence of 20 amino acids. Removal of these N-terminal residues by signal peptidase activity leaves an approximately 36,000-Da protein that lacks direct membrane attachment. The mature protein is modified by four N-linked glycans and is comprised of an approximately 30-amino acid N-terminal SPLAG-domain (rich in Ser, Pro, Leu, Ala, and Gly) and a 259-amino acid C-terminal sulfotransferase domain. It is presumed that a hypothetical membrane-bound retention partner binds to the SPLAG domain to localize Hs3st1 to a *trans*-Golgi compartment, where HS synthesis occurs. The retention mechanism is somewhat leaky. Consequently, substantial levels of Hs3st1 are secreted into the plasma. However, it is unclear if plasma Hs3st1 serves any function (22,51).

In ECs, the level of HS<sup>AT+</sup> production is dictated by the rate-limiting action of Hs3st1 (see Figure 107.1). About 25% of HS chains in the Golgi contain motifs that correspond to the AT-binding site devoid of the essential 3-*O*-sulfate residue (HS<sup>preAT+</sup>). Hs3st1 preferentially binds these precursors and adds the critical 3-*O*-sulfate group to create HS<sup>AT+</sup> with functional AT-binding sites. This reaction employs the universal sulfate donor adenosine 3'-phosphate 5'-phosphosulphate (PAPS), which is converted into adenosine 3'-phosphate 5'-phosphate (PAP). The sulfotransferase domain contains those residues that mediate catalysis and those residues that define sequence specificity (i.e., recognizing HS<sup>preAT+</sup>). HS<sup>preAT+</sup> occurs in excess, and the level of Hs3st1 determines the extent of this precursor that is converted into HS<sup>AT+</sup> (21). Thus, the rate-limiting action of Hs3st1 allows HS<sup>AT+</sup> production to be regulated independently of total HS synthesis.

### Hs3st1 Gene Structure and Function

The human gene is designated as *HS3ST1* and the mouse gene is *Hs3st1*. The gene is remarkable in that it spans more than 140 kb, but the entire coding region occurs in a single exon at the 3' end of the gene. Thus, the vast majority of the gene encodes exons and introns of the 5' untranslated region (UTR). This region of the mouse gene has seven exons that undergo variable splicing, to make at least 10 distinct splice variants of the 5' UTR. Presumably, these variants enable distinct forms of translational control; however, it is not yet known if the human transcripts are equally complex (52).

*Hs3st1* expression is not limited to ECs. Hs3st1 is also produced by certain neurons and by a variety of epithelial cell types such as alveolar type II cells, ovarian granulosa cells, and glomerular epithelial cells, which largely deposit HS<sup>AT+</sup> in their respective basement membranes (53–55; N. Shworak, unpublished observations). Such a diversity of cell types suggests that HS<sup>AT+</sup> may function in processes discrete from the coagulation cascade.

*Hs3st1* expression appears to be altered in vascular inflammation, because intimal levels of both total HS and HS<sup>AT+</sup> decrease with the progression of vessel inflammation and atherosclerosis (56). In particular, HS<sup>AT+</sup> levels are selectively reduced by certain proinflammatory molecules such as homocysteine (57) and are selectively enhanced by the antiatherogenic apolipoprotein E (58). These alterations in HS expression are consistent with the possibility of HS<sup>AT+</sup> mediating the anti-inflammatory properties of AT. In this regard, it is intriguing that type II<sub>HBS</sub> AT mutants, which lack heparin binding, are the only mutant category that exhibits arterial thrombosis. As described later, the anti-inflammatory activity of AT requires direct engagement of AT with EC HSPGs. Thus, type II<sub>HBS</sub> individuals may exhibit atherosclerotic lesions with an enhanced inflammatory state. Because inflammation can trigger coagulation, it is possible that type II<sub>HBS</sub> arterial thrombosis is secondary to the loss of an AT/HSPG anti-inflammatory pathway.

## EVOLUTIONARY CONSIDERATIONS

Evolutionary studies suggest that AT arose long after HS<sup>AT+</sup>. AT is potentially very ancient, because serpins have been identified in prokaryotes, plants, animals, and viruses. However, serpins have undergone rapid evolution to fulfill highly specialized functions. Consequently, considerable primary sequence diversity exists between major phylogenetic groupings. For example, plant serpins are very distinct from animal serpins, suggesting that both lineages began with a single primordial gene that underwent extensive duplication and structural/functional divergence. Among invertebrates as well, serpin structure varies widely even between species. In contrast, orthologues of human serpins are present throughout vertebrate species, which indicates that they arose after

the vertebrate-cephalochordate or the chordate-invertebrate divergence (35,59).

AT bears little resemblance to other vertebrate serpins. Its unique structure likely reflects its necessity to interact with a large number of activated coagulation proteases. Indeed, AT and most components of the coagulation cascade appear to have coevolved with the divergence of vertebrates from cephalochordates, about 450 million years ago. It is important to note that some invertebrates (e.g., the horseshoe crab, *Limulus polyphemus*) do exhibit a coagulation cascade that is driven by serine proteases and is regulated by serpins; however, the components are extremely primitive. The invertebrate coagulation proteases lack  $\gamma$ -carboxy glutamic acid domains, epidermal growth factor-like domains, and kringle domains. These elements enable essential interactions that are unique to the vertebrate coagulation cascade. For example, they allow the proteases to interact with lipid membranes, with other coagulation proteases, and with the protease inhibitors (60). Moreover, AT and the entire family of vertebrate serpins appear to have arisen from a common invertebrate serpin that was intracellular rather than extracellular (35). Thus, AT and a human-like coagulation cascade are unique to vertebrates.

In striking contrast, the pentasaccharide AT-binding site of HS<sup>AT+</sup>/heparin has been detected in several invertebrates (61). Indeed, the entire molecular machinery for generating HSPGs arose with the emergence of Eumetazoans. In particular, *Drosophila* exhibits a gene that is clearly orthologous to human *HS3ST1* (62). Thus, HS<sup>AT+</sup> emerged some 250 million years before AT, making it unlikely that HS<sup>AT+</sup> initially served as an anticoagulant. It seems more likely that invertebrate HS<sup>AT+</sup> plays a role in cell signaling, because this is a major primordial function of HSPGs. Moreover, *Drosophila* has a gene, paralogous to human HS3ST1, which has recently been found to regulate the Notch signaling pathway (62). This discrepancy in evolutionary appearance evokes an important unresolved question: Did AT recruit HS<sup>AT+</sup> to regulate vertebrate coagulation, and/or did HS<sup>AT+</sup> recruit AT to function in cell signaling?

## DEVELOPMENTAL CONSIDERATIONS

The developmental expression of AT suggests that it may be multifunctional. The anticoagulant activity is highlighted by AT-knockout mice that die of an extreme hypercoagulable state late in gestation (49). This timing reflects the unique state of hemostatic balance during embryonic development. Levels of procoagulant and anticoagulant proteins tend to be initially low and then gradually rise to near-adult levels at term (48,63). Thus, AT-deficient embryos lack protection against the late gestational rise in procoagulant activity. However, the expression profile of AT in the embryonic mouse is dramatically different from that of the major procoagulant factors. Embryonic expression of fibrinogen and most coagulation proteases typically begins sometime after implantation and peaks in mid to

late gestation, corresponding with the development of the liver, which is the major source of these plasma proteins. Although AT expression also increases in mid to late gestation, it is also highly expressed in the unfertilized egg and in preimplantation embryos (N. Shworak, unpublished observations). The expression of AT in the absence of the coagulation machinery suggests it may play an additional role that is functionally discrete from anticoagulation. HS<sup>AT+</sup> also is produced by oocytes (N. Shworak, unpublished observations), raising the possibility that HS<sup>AT+</sup> may be involved in very early developmental roles of AT.

## ROLES IN HOMEOSTASIS

### Anticoagulant Roles of Antithrombin and HS<sup>AT+</sup>

The dramatic degree to which heparin enhances AT's anticoagulant activity has led some to propose that the progressive (HS-independent) activity of AT is biologically irrelevant, and that endogenous AT requires activation by endothelial HS<sup>AT+</sup>. However, multiple lines of evidence suggest that AT's anticoagulant effects are mediated, at least in large part, by this progressive activity, whereas the role of endothelial HS<sup>AT+</sup> is unresolved.

The vast majority of plasma AT must exist independently of HS<sup>AT+</sup>, because blood normally does not contain free HS<sup>AT+</sup>/heparin (64). Given the slow rate of the progressive reaction, this bulk of HS<sup>AT+</sup>-free AT could potentially be relatively inert. However, in vitro analyses and kinetic modeling show that the normal plasma concentration of AT is high enough to compensate for the slow heparin-independent rate. As elaborated earlier, the rate of the HS<sup>AT+</sup>-free progressive reaction is sufficient to account for AT inhibition of the propagation phase of thrombin production (31,65). This phase occurs almost exclusively on platelet membranes (28,66), which lack HS<sup>AT+</sup> (N. Shworak, unpublished observations). Thus, AT's predominant anticoagulant activity does not appear to involve HS<sup>AT+</sup>. This conclusion also is supported by clinical observations. Mutations affecting total AT activity cause increased risk for thrombosis in the heterozygous state, whereas hypercoagulability from mutations that specifically target heparin-dependent activity (type II<sub>HBS</sub>) requires two affected AT alleles (14). Similarly, mice completely lacking AT die embryonically of a severe hypercoagulable state, whereas mice expressing a type II<sub>HBS</sub> AT form are viable (although they eventually succumb to sudden-onset thrombosis) (49,67). For both of these mouse models, it is presently unclear whether thrombosis is due predominantly to the loss of AT's anticoagulant activity or its anti-inflammatory activity. However, the type II<sub>HBS</sub> mice exhibited wild-type levels of thrombin-antithrombin (T·AT) complexes and also exhibit wild-type levels of thrombus induced by venous stasis (67). Combined, these results clearly indicate that the majority of AT's anticoagulant activity occurs through the progressive reaction and is independent of HS<sup>AT+</sup>.

Yet the hypercoagulable state of mice and humans with type II<sub>HBS</sub> mutations suggests that HS<sup>AT+</sup> may contribute to the regulation of AT anticoagulant activity. To evaluate the potential contribution of HS<sup>AT+</sup>, one must first consider the likely mechanism. Possibly, HS<sup>AT+</sup> conveys anticoagulant tone just to the vascular EC surface, because it is “tethered” to this site by various core proteins. Such a role might initially seem unlikely, as >95% of HS<sup>AT+</sup> exists in the subendothelial matrix and is not in direct contact with blood. However, a surface effect may be possible, because the perfusion of purified thrombin and AT into the hind limbs of rodents leads to an elevated rate of T·AT complex formation. HS<sup>AT+</sup> and not endogenous heparin was implicated in T·AT formation, because complex levels were reduced by enzymatic degradation of HS, but were normal in mast cell (heparin)-deficient animals (52). A surface effect also is implicated by type II<sub>HBS</sub> mice, which do show slight elevations in activated factors VIII, IX, XI, and XII (67). This observation suggests that HS<sup>AT+</sup> might play a role in enhancing AT inhibition of the poorly understood intrinsic pathway.

Two lines of evidence suggest that the level of endothelial HS<sup>AT+</sup> may define the extent of AT activation. First, the plasma AT concentration (~3.5 μM) appears saturating; that is, this level greatly exceeds the dissociation constant of AT for HS<sup>AT+</sup> (~15 nM). Saturation of HS<sup>AT+</sup> by AT implies a continuously acting anticoagulant system, which is consistent with the dynamic nature of hemostasis. Hemostatic tone is established actively as the net balance between ongoing antagonistic processes (procoagulant versus anticoagulant and fibrinolytic). Second, ECs have been shown to regulate HS<sup>AT+</sup> levels. Only a small subpopulation of HSPGs actually bears HS<sup>AT+</sup>, and this level varies between ECs isolated from different vascular beds. Moreover, analyses of mutant cell lines show that HS<sup>AT+</sup> levels can be selectively altered without influencing the bulk of HS (52). Thus, the endothelium may modulate the production of HS<sup>AT+</sup> as a means of fine-tuning AT activation, and hence local hemostatic balance.

This hypothesis has been tested in *Hs3st1*<sup>-/-</sup> mice (52). Compared with wild-types, *Hs3st1*<sup>-/-</sup> mice have normal tissue levels of total HS, but HS<sup>AT+</sup> levels are reduced by 75% to 98%. The residual levels of HS<sup>AT+</sup> were expected, because other Hs3st isoforms can contribute to HS<sup>AT+</sup> production. Such large reductions in HS<sup>AT+</sup> should generate a basal procoagulant state only if HS<sup>AT+</sup> contributes to ongoing hemostatic tone. However, unchallenged *Hs3st1*<sup>-/-</sup> mice exhibit wild-type levels of tissue fibrin, arguing against a basal procoagulant state. When given a procoagulant challenge – hypoxia, which enhances lung TF expression – *Hs3st1*<sup>-/-</sup> and *Hs3st1*<sup>+/+</sup> mice both undergo comparable elevations in lung fibrin levels. Thus, a strong thrombotic challenge failed to reveal a latent procoagulant state in these animals (52). Because most of HS<sup>AT+</sup> is found in the subendothelial matrix, an anticoagulant role might only occur following endothelial denudation, which would allow direct contact of the blood and subendothelial matrix. Subendothelial HS<sup>AT+</sup> is almost unde-

tectable in *Hs3st1*<sup>-/-</sup> mice. However, in response to chemical endothelial denudation, *Hs3st1*<sup>-/-</sup> and *Hs3st1*<sup>+/+</sup> mice have indistinguishable kinetics of occlusive thrombosis and show comparable postinjury levels of T·AT complexes (52). Hence, subendothelial HS<sup>AT+</sup> influences neither occlusive thrombosis nor formation of T·AT complexes. Combined, these data suggest that hemostatic tone is not tightly linked to HS<sup>AT+</sup> levels.

This conclusion is at odds with the procoagulant phenotype observed in humans and mice with type II<sub>HBS</sub> (14,67). Four potential explanations exist for this discrepancy. First, low HS<sup>AT+</sup> levels might be sufficient for an anticoagulant effect. Because the low residual levels of HS<sup>AT+</sup> in *Hs3st1*<sup>-/-</sup> mice are derived from other Hs3st isoforms, multiple genes may need to be eliminated to influence hemostasis. Second, other anticoagulant mechanisms may compensate for the reduced HS<sup>AT+</sup> levels. In this case, combined deficiencies in two anticoagulants may be required to detect an HS<sup>AT+</sup> effect. Third, the heparin-binding site of AT may mediate its effects through GAGs other than HS<sup>AT+</sup>. For example, AT neutralization of factor Xa also can be stimulated by HS that lacks an AT-binding site (HS<sup>AT-</sup>). Compared to HS<sup>AT+</sup>, AT has a much lower affinity for HS<sup>AT-</sup>; however, substantial binding should occur under physiologic concentrations of AT (68). Because HS<sup>AT-</sup> is 20 to 200 times more abundant than HS<sup>AT+</sup> (23), HS<sup>AT-</sup> may be predominantly responsible for AT activation. Additionally, AT neutralization of thrombin can be enhanced by a form of thrombomodulin bearing a chondroitin sulfate chain (69). In the context of these other GAGs, AT anticoagulant activity may be independent of HS<sup>AT+</sup>. Indeed, overexpression of Hs3st1 in primary ECs increases HS<sup>AT+</sup> levels, but fails to enhance AT activation by the cell surface (52). Fourth, the arterial thrombosis of type II<sub>HBS</sub> may be secondary to an enhanced inflammatory state, as discussed earlier. Thus, it is presently unclear whether HS<sup>AT+</sup> is a physiological enhancer of AT anticoagulant activity.

Although *Hs3st1*<sup>-/-</sup> mice do not show an obvious procoagulant state, they do exhibit other phenotypes. When generated on an inbred mouse strain, *Hs3st1*<sup>-/-</sup> embryos exhibit intrauterine growth retardation, and *Hs3st1*<sup>-/-</sup> pups die within 3 days of birth (52). The reasons for these consequences are unclear. However, the existence of these phenotypes in the absence of a procoagulant state suggests that a major role of HS<sup>AT+</sup> is to regulate some process apart from coagulation. This alternate function may involve the anti-inflammatory activity of AT.

### Anti-Inflammatory Activity of Antithrombin

AT exhibits an anti-inflammatory activity that can protect against the deleterious effects of systemic inflammatory response syndromes (SIRS). This acute process can lead to multiple organ dysfunction, acute respiratory distress syndrome (ARDS), and shock. SIRS can result from many clinical conditions, including trauma, disseminated intravascular

Figure 107.4. Anti-inflammatory action of AT in SIRS. Initiation of SIRS involves TNF- $\alpha$  activation of the transcription factor NF- $\kappa$ B. NF- $\kappa$ B normally resides in the cytoplasm in an inactive complex with its inhibitor I $\kappa$ B $\alpha$ . TNF- $\alpha$  induces phosphorylation of I $\kappa$ B $\alpha$ , which dissociates from the inhibitory complex and is degraded by the proteasome. The released NF- $\kappa$ B translocates to the nucleus to initiate the transcription of several genes, including TNF- $\alpha$ , which further drives EC activation. AT binding to HS<sup>AT+</sup> and/or HS<sup>AT-</sup> of endothelial HSPGs initiates anti-inflammatory signaling that in part enhances PGI<sub>2</sub> production. PGI<sub>2</sub>, or some other factor, blocks the TNF- $\alpha$ -induced phosphorylation and degradation of I $\kappa$ B $\alpha$ . Consequently, AT prevents activation of NF- $\kappa$ B and upregulation of NF- $\kappa$ B-dependent genes that initiate the deleterious aspects of SIRS. Heparin blocks the pathway by competitively inhibiting AT binding to HSPGs. The pentasaccharide motif of HS<sup>AT+</sup> is represented as a triangle and square.

coagulation, severe burns, acute pancreatitis, hemorrhagic shock, and sepsis. The syndrome involves a systemic over-activation of leukocytes and ECs that leads to overwhelming inflammation and coagulation. A major initiator of SIRS is tumor necrosis factor (TNF)- $\alpha$  (Figure 107.4). TNF- $\alpha$  activates the transcription factor nuclear factor (NF)- $\kappa$ B and thereby induces the expression of proinflammatory and pro-coagulant mediators such as interleukins and TF, respectively. NF- $\kappa$ B also induces the expression of inducible nitric oxide synthase (iNOS). In turn, iNOS causes a massive increase in levels of nitric oxide (NO) that can lead to shock. Expression of TNF- $\alpha$  itself is NF- $\kappa$ B-dependent; thus positive feedback can drive the onset of SIRS (25,26).

A large volume of data from animal and clinical trials show that intravenous therapy with AT can reduce morbidity and/or mortality in SIRS associated with sepsis, organ failure, and ischemia–reperfusion injury (25,26). A minor contribution may derive from AT-mediated neutralization of thrombin and factor Xa, which should limit further thrombin and fibrin generation, as well as proinflammatory signaling through protease-activated receptors. However, increasing evidence suggests that AT exerts its beneficial effects through direct effects on cell signaling. For example, in cultured ECs and in animals, AT stimulates the synthesis of prostacyclin (PGI<sub>2</sub>)

(70,71), a potent inhibitor of leukocyte activation, leukocyte–endothelial interactions, platelet aggregation, and NF- $\kappa$ B activation (Figure 107.4). AT treatment of cultured ECs also abrogates TNF- $\alpha$ -mediated activation of NF- $\kappa$ B (72), possibly through PGI<sub>2</sub> induction. Consequently, AT treatment prevents downstream expression of interleukin (IL)-6, IL-8, TNF- $\alpha$ , TF, and iNOS (25,26). Indeed, in a rat sepsis model, AT blockade of NF- $\kappa$ B prevented iNOS-dependent shock (73). AT also exerts signaling activities in leukocytes, which serve to inhibit leukocyte–endothelial interactions. These anti-inflammatory properties should not be surprising, because many molecular interconnections exist between coagulation and inflammation. Moreover, it is increasingly apparent that several natural anticoagulants also have anti-inflammatory activity (25,26).

In vitro and in vivo experiments show that the anti-inflammatory effects of AT (SIRS amelioration, PGI<sub>2</sub> production, and NF- $\kappa$ B inhibition) are clearly separate from its anticoagulant action. First, agents that only exhibit a pure anticoagulant activity do not induce these effects. Conversely, these effects require an AT concentration far in excess of that sufficient to resolve coagulation abnormalities. Finally, these effects are abolished by heparin, in striking contrast to heparin's enhancement of AT's anticoagulant activity (25,26). However, these experiments cannot rule out that AT anticoagulant activity at the cell surface might partially contribute to the anti-inflammatory effect.

Inhibition by heparin suggests the anti-inflammatory activity requires the binding of AT to cell surface HSPGs (see Figure 107.4). In support of this mechanism, these effects are not induced by a chemically modified form of AT that lacks heparin binding, but retains thrombin-neutralizing activity. Moreover, AT-induced PGI<sub>2</sub> synthesis by cultured ECs is prevented when cell surface HS chains are eliminated by enzymatic degradation or biosynthetic blockade. Additionally, the  $\beta$ -AT glycosylation variant exhibits enhanced affinity for HS and enhanced anti-inflammatory signaling strength. Thus, it appears that AT employs HSPGs to mediate a cell signaling event (25,26).

It is presently unclear how HSPGs mediate AT anti-inflammatory signaling. On one hand, the HS chains might facilitate the formation of a ternary complex between AT and a putative AT receptor. This mechanism would be analogous to HS-mediated signaling of growth factors. On the other hand, AT binding to the HS chain might induce proteoglycan clustering, which can directly initiate cell signaling or could influence the signaling of HS-dependent growth factors (74). It also is unclear whether AT anti-inflammatory signaling involves high-affinity interactions with HS<sup>AT+</sup> and/or low-affinity interactions with HS<sup>AT-</sup>. AT's anti-inflammatory effects occur only when plasma AT levels are augmented by 1.5- to threefold. Such high AT levels indicate that a low-affinity receptor is essential. Thus, HS<sup>AT+</sup> cannot be the signaling "receptor," but still could play an essential role in facilitating the signaling process. The recent availability of *Hs3st1*<sup>-/-</sup> mice, which exhibit large reductions in vascular HS<sup>AT+</sup>, will enable the testing of this possibility.

## DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

AT has long been recognized as the therapeutic target of heparin. The elucidation of AT–heparin interactions has led to the development of novel heparin therapeutics with improved properties for treating venous thromboembolism. The knowledge that neutralization of factor Xa, compared to thrombin, requires a shorter heparin sequence (see Figure 107.3) has prompted the development of low-molecular-weight heparins (LMWHs), which contain shorter oligosaccharides than do unfractionated heparin. This design reduces the levels of longer fragments required for thrombin neutralization, so that LMWHs are more selective toward inhibiting factor Xa. The initial rationale was that reduced inhibition of thrombin might minimize bleeding complications. This assertion has not been borne out; however, LMWHs clearly exhibit superior pharmacokinetic properties. The smaller fragments have reduced interactions with the reticulo-endothelial system (and circulating proteins, such as platelet factor 4 [PF4]), and so have better bioavailability, a longer half-life, and reduced interindividual variation. As a result, LMWHs can be administered less frequently and do not require extensive monitoring of coagulation parameters (75). However, this drug is still a complex mixture of molecules, most of which are not mediating the drug's effects.

This limitation has been resolved with the recent release of a pure AT-binding site pentasaccharide, which exclusively targets proteases like factor Xa that are inhibited by allosteric activation of AT (see Figure 107.3). The reduced size and purity have further enhanced bioavailability, which appears to improve efficacy. Most importantly, the synthetic pentasaccharide may avoid a severe adverse reaction, heparin-induced thrombocytopenia (HIT). This autoimmune disease results from the development of antibodies against complexes of heparin with PF4. The pentasaccharide does not bind PF4 and does not cross-react with HIT antisera, so it should not elicit a HIT autoimmune response (76). Also under development is a synthetic hexadecasaccharide (16-mer) with an optimal structure for AT inhibition of thrombin by the bridging mechanism (see Figure 107.3). The 16-mer contains the AT-binding pentasaccharide at one end, so it can enhance the AT inhibition of virtually all coagulation proteases. Like the pentasaccharide, the 16-mer has good bioavailability and does not bind to PF4. However, compared to the pentasaccharide and unfractionated heparin, the 16-mer is an extremely efficient inhibitor of arterial thrombosis (77). Thus, an understanding of the anticoagulant action of AT has resulted in the development of improved therapeutics.

The anti-inflammatory activity of AT opens new doors for therapeutic application, because vascular inflammation is a common denominator in numerous disease processes. On the one hand, chronic vascular inflammation plays an important role in the development of atherogenic diseases, which are the leading killers in the Western world. Although AT intravenous therapy is not appropriate for a chronic disease, the elucidation

of the AT anti-inflammatory signaling pathway might lead to the development of small molecules for selectively reducing prolonged vascular inflammation. On the other hand, many clinical conditions can trigger the acute SIRS reaction and its deleterious consequences. The impact of SIRS is exemplified by sepsis, which represents the systemic host response to infection. Severe sepsis (sepsis complicated by organ failure) is associated with 30% mortality and accounts for more than 220,000 deaths per year in the United States (78). Most patients with severe sepsis have reduced circulating levels of AT, due to suppressed hepatic synthesis and enhanced consumption by coagulation and inflammatory proteases (44). Given the acute nature of sepsis, the association of sepsis with acquired AT deficiency, and the putative anti-inflammatory effects of AT, there has been tremendous interest in exploring the therapeutic potential of AT in this syndrome.

Despite promising results in animal models and phase II clinical studies, a recent phase III trial failed to achieve its primary endpoint – a survival advantage 28 days after treatment (79). However, the trial only considered AT as an anticoagulant, and so its design ignored several key features of AT's anti-inflammatory activity. First and foremost, half of the patients in the AT treatment group received concomitant heparin treatment. A benefit should not be expected for this group, because heparin inhibits AT anti-inflammatory activity (and possibly an endothelial surface anticoagulant activity) by preventing the engagement of AT with endothelial HSPGs (see Figure 107.4). Indeed, the subgroup receiving AT without heparin showed enhanced survival as a strong trend that reached significance 90 days posttreatment. Moreover, the AT subgroup receiving heparin had an enhanced risk of hemorrhage that may have contributed to their higher mortality. Enhanced bleeding should have been anticipated as supra-physiologic levels of AT were achieved, which would increase anticoagulant tone via AT's heparin-independent activity. Thus, heparin administration is both unnecessary and contraindicated when administering supra-physiologic levels of AT. Second, plasma AT levels of the treatment group were only augmented to 1.8-fold above normal values, whereas the treatment goal was to achieve a two- to 2.5-fold increase. Because AT anti-inflammatory activity is mediated by low-affinity interactions, higher AT levels should provide a greater anti-inflammatory effect. It is important to note that maximal plasma AT levels may potentially be limited by bleeding complications arising from the heparin-independent anticoagulant activity of AT. Third, the study employed purified human plasma AT, which is suboptimal. Such preparations are predominantly composed of  $\alpha$ -AT, whereas the  $\beta$ -AT form exhibits much stronger HSPG binding and anti-inflammatory activity. Deployment of a pure  $\beta$ -AT form could additionally reduce the need for extreme AT concentrations and thereby reduce the potential risk of bleeding complications. A suitable product appears to be available. Recombinant expression of human AT in the milk of transgenic goats results in an aberrantly glycosylated AT form with a high heparin affinity, similar to  $\beta$ -AT. Intriguingly, this recombinant AT has demonstrated efficacy in reducing mortality of

septic baboons (80); however, its efficacy relative to plasma-derived AT presently is unknown. In summary, limitations in this trial highlight factors that may be essential for correctly deploying AT as an anti-inflammatory agent in SIRS.

### KEY POINTS

- AT exhibits HS-dependent and HS-independent activities, and functions as both a major natural anticoagulant and a natural anti-inflammatory.
- The normal anticoagulant activity of AT is predominantly mediated by the slow progressive reaction, thus it is independent of endothelial HS<sup>AT+</sup>.
- Endothelial HSPGs are essential for mediating the anti-inflammatory activity of AT; however, it is presently unclear whether HS<sup>AT+</sup> is specifically required.
- Heparin administration enhances the anticoagulant activity but inhibits the anti-inflammatory activity.
- The elucidation of AT's anticoagulant mechanism has led to improved anticoagulants.

### Future Goals

- To further the understanding of AT's anti-inflammatory activity, which should provide novel treatments for diseases involving vascular inflammation

## Protein C

Marlies Van de Wouwer and Edward M. Conway

*Department for Transgene Technology and Gene Therapy, VIB, and the Center for Transgene Technology and Gene Therapy (CTG), K.U. Leuven, Belgium*

Protein C (PC) is a key component in a multiprotein, physiologically relevant pathway that regulates thrombin's procoagulant activity, but which also limits inflammatory responses and provides the vascular endothelium with protection against an array of insults. Delineation of the biochemistry and molecular biology underlying regulation of the PC pathway, complemented by preclinical and clinical studies, has led to major new insights bridging the gap between inflammation and coagulation and resulting in innovative approaches to treat thrombotic disease and sepsis.

### DISCOVERY OF PROTEIN C AND A NOVEL NATURAL ANTICOAGULANT PATHWAY

In 1975, Johan Stenflo reported the discovery of a novel vitamin K-dependent factor that revolutionized our view of the molecular mechanisms by which the coagulation system is regulated and provided insights into how coagulation interfaces with other biological systems, including inflammation and cell survival. In the final steps of his strategy to isolate new vitamin K-dependent plasma proteins, Stenflo identified four peaks from a chromatography column, the third of which – “pool C” – was subsequently referred to as *protein C* (1). Shortly thereafter, Esmon and colleagues (2) recognized that PC has lipid-binding properties and is a zymogen precursor for a serine protease – so-called activated PC (APC). The importance of PC in coagulation rapidly became evident when it was determined that APC is derived from the thrombin-mediated cleavage of PC, that APC proteolytically destroys procoagulant cofactors V/Va and VIII/VIIIa, and finally that familial deficiency of PC in humans results in a hypercoagulable disorder (3–5).

### STRUCTURAL FEATURES OF PROTEIN C

PC is synthesized predominantly in the liver as a 461-amino acid, long single-chain precursor, approximately 75% of which

is subsequently processed prior to and during secretion to yield a two-chain species. Thus, both single- and two-chain species circulate in the plasma at a total concentration of 3 to 5  $\mu\text{g}/\text{mL}$  (6). At least two other forms of PC, with differing glycosylation patterns, also circulate, but in much smaller amounts. The mature protein has an apparent molecular weight of approximately 62 kDa, and is composed of three well-defined structural domains including (a) the  $\gamma$ -carboxyglutamic acid (Gla) residue-containing amino-terminal domain, (b) an epidermal growth factor (EGF)-like containing domain with two EGF-like repeats, and (c) the serine protease (SP) domain (Figure 108.1). The first two domains encompass the light chain; the third makes up the heavy chain. The Gla-EGF-EGF-SP domain structure is characteristic of other serine proteases in the coagulation system, including factors VII, IX, and X.

The amino-terminus of human PC has nine Gla residues that are formed by vitamin K-dependent carboxylation of the glutamic acid residues in that region. These are crucial for calcium binding and the protein's anticoagulant function. The Gla residues mediate PC-APC interactions with negatively charged phospholipid surfaces (e.g., the surface of activated platelets and/or endothelial cells [ECs]), as well as with the endothelial PC receptor (EPCR), thereby strategically localizing the activity of PC-APC, and coordinating its interaction with thrombin and its cofactor, thrombomodulin (TM) (see the next section). The first of the two EGF-like repeats has a site for  $\beta$ -hydroxylation that is involved in calcium binding, whereas the second EGF-like repeat has a site for N-linked glycosylation that is important for the secretion of the molecule. The EGF-containing domain also may promote interactions with protein S (PS), factor Va, and factor VIIIa. Finally, the SP domain of PC is similar to that of other serine proteases, with a conserved catalytic triad of His<sup>211</sup>, Asp<sup>257</sup>, and Ser<sup>360</sup>, but which uniquely has specificity for targeting factors Va and VIIIa for degradation. Also within the SP domain is a calcium-binding site that is required for calcium-dependent activation of PC by thrombin-TM.

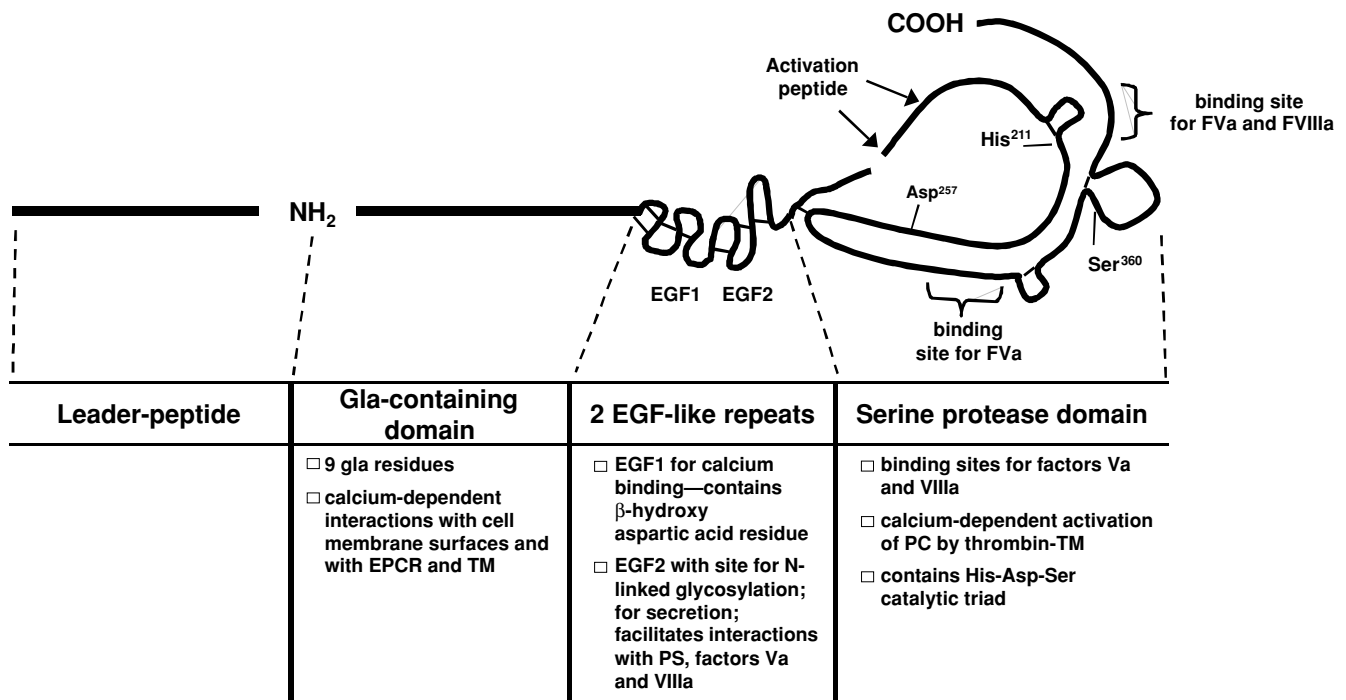

Figure 108.1. Structure of Protein C. This schematic drawing of PC shows the leader peptide, followed by three structural domains that comprise the mature protein.

### PROTEIN C – THE GENE

The human and murine *PC* genes are structurally similar, each spanning approximately 15 kb, and comprising nine exons and eight introns (7,8). In humans, the gene is located on the long arm of chromosome 2. The 53-nucleotide first exon is untranslated and is followed by a 1.3-kb intron. The sequence encoding the translation initiation methionine is located in exon 2. The 5'-untranslated region contains CCAAT sequences and GC boxes, as well as several putative recognition sequences for transcription factor interactions that are important for liver-specific expression.

### EVOLUTIONARY CONSIDERATIONS

Comparative studies support the notion that PC evolved prior to the divergence of teleosts over 430 million years ago, and that the vertebrate coagulation system arose during gene duplications prior to development of jawed vertebrates (9). Thus, evolutionary appearance of the Gla-EGF-EGF-SP domain structure common to factors VII, IX, X, and PC is evident in zebrafish (*Danio rerio*), fugu (*Takifugu* sp.), and chicken genomes, in which orthologues for the *PC* gene have been identified (9). It is not known whether *PC* appeared prior to or after the genes encoding the procoagulant factors. At least in the zebrafish, a functional coagulation system exists, with evidence that PC activation occurs and that the Gla domains are crucial for hemostatic integrity (10). Whether PC has addi-

tional properties in zebrafish or these other species has not yet been determined.

### ACTIVATION OF PC

The major components in the PC system that promote its activation – a critical step for its physiologic function – are the transmembrane glycoprotein receptor, TM, the membrane bound EPCR, thrombin, and platelet factor 4 (PF4). TM is widely expressed by ECs in all vascular beds and in vessels of all caliber, whereas EPCR is more prominently expressed by larger-vessel ECs. When complexed with TM on the cell membrane surface, thrombin catalyzes activation of PC more than 1,000-fold (compared with activation by thrombin in the absence of TM), cleaving a single bond at the amino-terminal end of the heavy chain, with release of an activation dodecapeptide. EPCR, which binds to PC and APC with equal affinity, enhances the activation event approximately 20-fold by presenting PC to the thrombin-TM complex. Activation of PC also is accelerated up to 25-fold by PF4 (also known as CXCL4), which is secreted by activated platelets and binds to the Gla domain of PC, forming a complex with thrombin-TM and thereby altering the conformation and affinity of PC for thrombin-TM (11).

The activation of PC is exquisitely regulated. Transformation of PC to APC requires renewed sources of thrombin to be present, because once thrombin binds to TM, the serine protease inhibitors (serpins) anti-thrombin (AT) and PC inhibitor

(PCI) rapidly neutralize the thrombin – more efficiently than when thrombin is free. Thus, once thrombin generation is complete, activation of PC ceases. In contrast to the rapid-on, rapid-off nature of PC activation, neutralization of existing APC proceeds much more slowly. The half-life of APC in the circulation – approximately 20 minutes – is relatively long when compared to most serine proteases, and reflects its slow inhibition by PCI,  $\alpha$ -2-macroglobulin and  $\alpha$ -1-antitrypsin, a response that may provide for a more widely distributed and prolonged functional APC in the organism.

### A CRITICAL ROLE FOR ACTIVATED PROTEIN C IN REGULATING COAGULATION

The earliest described and best characterized function of the PC pathway is centered around the natural anticoagulant properties of APC. As APC is generated, it competes with PC for binding to EPCR. When dissociated from EPCR, APC binds to the vitamin K-dependent plasma PS on the phospholipid surface of activated platelets and ECs (and probably other cell surfaces). There, it is positioned to proteolytically destroy and inhibit coagulation cofactors VIIIa and Va, thereby interfering with formation of the tenase and prothrombinase complexes, respectively, and suppressing further generation of factor Xa and thrombin. Degradation of the zymogens, factors V and VIII, occurs, but less efficiently. Inactivation of factor Va is enhanced by PS, whereas cleavage of factor VIIIa requires both PS and factor V (12) (Figure 108.2A). When bound to EPCR, APC is unable to inactivate factors Va/VIIIa but, in this form, transmits anti-inflammatory and vasculo-protective signals (Figure 108.2B and 108.2C; and see below). Thus, the PC-TM-EPCR system effectively switches the substrate specificity and functional properties of thrombin from a procoagulant/pro-inflammatory to an anticoagulant/anti-inflammatory molecule. Analogous to TM's switching of the substrate specificity of thrombin, EPCR may be considered a molecular switch for APC in determining whether the latter will function as an anticoagulant or an anti-inflammatory molecule. APC also promotes fibrinolysis by neutralizing plasminogen activator inhibitor (PAI)-1, an interaction that is enhanced by vitronectin, an abundant plasma and platelet glycoprotein (13) released at sites of injury. This results in local, uninhibited generation of plasmin, which may serve to regulate fibrin clot size and/or to promote clearing of cross-linked fibrin during and after injury.

### ACTIVATED PROTEIN C IS A NATURAL ANTI-INFLAMMATORY MOLECULE

The ability of APC to downregulate thrombin generation and to suppress inflammation was most clearly delineated in a series of elegant *in vivo* studies in baboons by Taylor, Esmon, and coworkers (14,15). Treatment of baboons with APC, PC, or PS protected against the inflammatory manifes-

tations of *Escherichia coli* endotoxin-induced sepsis; whereas blocking the activity of these proteins or EPCR exacerbated the response, promoting cytokine release, neutrophil infiltration into tissues, capillary leak syndrome, and activation of coagulation, with resulting organ failure and death (16,17). These seminal investigations were followed by many similar supportive studies. For example, heterozygous PC-deficient mice are more sensitive to polymicrobial and gram-negative bacterial sepsis, exhibiting shortened survival, higher levels of tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , and IL-6, with more prominent organ damage and vascular hypotension (18). In rodent models of endotoxemia, APC blunts TNF- $\alpha$  production and inducible nitric oxide synthase (iNOS) activity, suppresses neutrophil infiltration, and prevents hypotension and tissue damage by coagulation-independent pathways (see Figure 108.2B). Similarly, neutrophil activation and extravasation is abrogated by APC in models of ischemia-reperfusion injury, thus limiting the extent of tissue damage (19).

### MECHANISMS BY WHICH ACTIVATED PROTEIN C SUPPRESSES INFLAMMATION

The profound effects of APC on the inflammatory system appear to be mediated via several mechanisms. APC inhibits the expression of tissue factor (TF) and the release of several cytokines (e.g., TNF- $\alpha$ , IL-1 $\beta$ , IL-6, IL-8, and macrophage inflammatory protein [MIP]-1 $\alpha$ ) by monocytes/macrophages (20,21) (Table 108-1). APC may promote these anti-inflammatory responses by interfering with nuclear translocation of nuclear factor (NF)- $\kappa$ B and activation of AP-1, which moreover prevents upregulation of cell surface leukocyte adhesion molecules and leukocyte-EC interactions. Both PC and APC inhibit neutrophil chemotaxis, but interestingly, have no apparent effects on respiratory burst or bacterial phagocytosis, suggesting specificity and limits to their actions.

EPCR is believed to play a major role in mediating many of the anti-inflammatory effects of APC, although the precise molecular mechanisms and physiologic importance is still not clear. EPCR mainly is expressed on the surface of ECs, but also is found on circulating monocytes, neutrophils, and eosinophils, and on the dendritic cells of the inflamed gut (22). Thus, it is well situated to modulate inflammation and innate immune responses. A soluble form – sEPCR – is released into the circulation during inflammation, a product of matrix metalloproteinase (MMP) cleavage of the mature protein. sEPCR binds to activated neutrophils via proteinase 3 (PR3) which in turn interacts with CD11/CD18 (Mac-1), an integrin that normally mediates leukocyte-EC interactions. sEPCR likely interferes with this interaction, preventing leukocyte adhesion and extravasation (see Figure 108.2B). Binding of APC to EPCR – membrane bound or soluble – on the leukocyte surface also may reduce intracellular calcium fluxes and prevent NF- $\kappa$ B translocation and the activation of downstream pro-inflammatory events. Moreover, EPCR-APC complexes can be

Figure 108.2. Diverse functions of APC. EPCR is a natural switch that regulates the function of APC. When free of EPCR, APC is an anticoagulant; when bound to EPCR, APC exhibits anti-inflammatory and antiapoptotic properties. (A) APC is an important natural anticoagulant. After a procoagulant stimulus, APC that is generated and free from EPCR localizes with PS on platelet and EC surfaces, where it cleaves and inactivates factor VIIIa with the help of factor V (*top*) and factor Va (*bottom*) to yield the inactive species FVIIIi and FVi, respectively. Lack of the active cofactors (VIIIa and Va) results in ineffective transformation of factor X to factor Xa (FXa) (*top*), and prothrombin (II) to thrombin (IIa) (*bottom*), respectively. (B) APC is an anti-inflammatory molecule, achieving this end via several pathways described in the text. When bound to EPCR, APC activates PAR-1 and/or other cell surface receptor(s) to induce intracellular signals that interfere with NFκB and MAPK pathways, thereby preventing transcriptional upregulation of proinflammatory mediators, such as TNF-α and IL-1β; suppressing the expression of leukocyte adhesion molecules; and downregulating tissue factor (TF) expression. APC-EPCR complexes also may be internalized and localize to the nucleus, where they may further sustain transcriptional events to prevent inflammation. Finally, soluble EPCR (sEPCR) is released during inflammation, whereupon it binds to neutrophil proteinase 3 (PR3), thereby preventing leukocyte-endothelial interactions via CD11/CD18. (C) When bound to EPCR, APC also has natural vasculoprotective, antiapoptotic properties. Through PAR-1 and/or other receptor(s), APC transmits intracellular signals that augment the expression of antiapoptotic proteins, decrease p53 expression, and promote release of sphingosine 1-phosphate (S1P) that then activates S1P-receptor (S1P-R), which in turn decreases vascular EC permeability and enhances vascular integrity.

internalized and translocated to the nucleus, where they may further suppress the inflammatory response, thereby sustaining the locally protective process (Figure 108.2B). EPCR expressed by ECs also may act as a cofactor in the cleavage of protease-activated receptor (PAR)-1 by APC (23). Although PAR-1 triggers events such as the release of chemokines or the upregulation of adhesion molecules that would promote inflammation, PAR-1 also induces the expression of inhibitors

of apoptosis, such as inhibitor of apoptosis protein (IAP)-1 and A20, that would protect the vascular endothelium in the face of injury, ischemia, or inflammation (Figure 108.2C). Moreover, PAR-1 activation by APC may lead to sphingosine-1-phosphate (S1P) receptor-1 cross-activation that is selectively vasculoprotective (24). Several studies have concluded that, by this route, APC induces a transcriptional response in ECs that may explain many of its effects in sepsis.

**Table 108-1: Diverse Functions of APC and EPCR**

<i>Functions</i>	<i>Mechanism</i>
Anticoagulant	APC cleaves and inactivates procoagulant factors Va and VIIIa
Profibrinolytic	APC binds to and neutralizes PAI-1 – accelerated by vitronectin
Anti-inflammatory	APC <ul style="list-style-type: none"> <li>↓ TNF<math>\alpha</math>, IL-1<math>\beta</math>, IL-6, IL-8, MIP-1</li> <li>↓ iNOS activity</li> <li>↓ TF expression by monocytes</li> <li>↓ endothelial expression of leukocyte adhesion molecules</li> <li>↓ neutrophil infiltration</li> <li>↓ EC permeability via S1P cross-talk</li> </ul>
	sEPCR <ul style="list-style-type: none"> <li>Binds to neutrophil PR3 and prevents interaction with ECs</li> <li>APC increases Bcl2, eNOS, A20, IAP in different cell types</li> </ul>
Antiapoptotic	APC suppresses p53 APC enhances EC integrity via S1P cross-talk

Despite these reports, experimental evidence exists that challenges the *in vivo* physiologic relevance of an APC–PAR-1 interaction, and whether PAR-1 is activated at all by endogenous APC (25). This raises the possibility that other PC/APC receptors exist, consistent with an early report by Hancock and colleagues (26), and implies that alternative, non–PAR-1 mediated pathways protect the vasculature and other cells from injury. Indeed, APC induces antiapoptotic signals in ECs, renal tubular cells, and neurons, partly by inhibiting p53, but also via recruitment of Bcl-2 pathways, possibly independent of PAR-1 (27).

### FUNCTIONAL DEFICIENCIES OF PROTEIN C

The physiologic importance of the PC system is evident from the clinically significant hypercoagulable conditions associated with the impaired function of PC or PS (5,28). Over 100 mutations – mostly within exons, but also involving the 5'-untranslated region of the gene – result in quantitative defects (type I) ([http://www.xs4all.nl/~reitsma/Prot\\_C\\_home.htm](http://www.xs4all.nl/~reitsma/Prot_C_home.htm)). Over 70% of these are missense mutations. Fewer pedigrees (~20) of familial mutations yield a dysfunctional PC with normal antigen levels (type II). Deletions within the PC gene are uncommon. Compound heterozygotes, and simultaneous occurrence of PC mutations with other molecular defects involving the coagulation system (e.g., AT deficiency), have

been reported. These tend to result in a more severe thrombotic phenotype. Heterogeneity in the development of thrombosis, even within families with the same mutation, supports the notion that the clinical expression is multifactorial, modified by environmental and genetic factors (28). Patients with heterozygous PC deficiency often have few symptoms and, when they do, may only present with thrombotic episodes as adults – most commonly with deep vein thromboses and/or pulmonary emboli – spontaneously or associated with a prothrombotic stress, such as pregnancy, preeclampsia, trauma, infection, or surgery. However, thromboses also may occur in unusual locations, not infrequently involving the arterial tree (29,30). It is interesting to note that, despite the increased sensitivity of PC-deficient mice to microbial infections, little evidence indicates that humans with PC deficiency suffer a similar enhanced risk.

Homozygous PC deficiency inevitably presents during the neonatal period, uniformly associated with life-threatening spontaneous thrombosis of the large veins (e.g., deep veins of legs, pulmonary, renal, vena cava, portal, cerebral). It may however, also involve the arterial tree, thus presenting with stroke, myocardial infarction, and/or limb ischemia (31). It also may be manifest within hours of birth by *purpura fulminans*, characterized by diffuse microvascular thrombotic lesions in the skin and rapid onset of disseminated intravascular coagulation (DIC) – a syndrome that is always fatal unless treated with PC concentrates or plasma. The rarity of homozygous PC deficiency, relative to the heterozygous state in the general population, suggests that homozygosity frequently results in nonviable fetuses and spontaneous abortions.

Pathologically similar to *purpura fulminans*, but usually less extensive, is warfarin-induced skin necrosis, most frequently observed at the initiation of oral warfarin-based anticoagulation, and caused by a rapid decline in PC levels relative to the procoagulant vitamin K–dependent factors IX and X. This syndrome is more prevalent in patients with underlying heterozygous PC deficiency, but also may occur with PS deficiency. Skin necrosis also is observed in some patients with severe sepsis, in whom PC levels are suppressed due to compromised liver function and increased consumption, and where the capacity to generate APC is decreased because of suppressed endothelial expression of TM and EPCR. The striking involvement of the skin microvasculature in severe PC deficiency is not explained, but is strong evidence for the importance of APC as an anticoagulant, and possibly an anti-inflammatory factor in the dermal microcirculation.

### RESISTANCE TO ACTIVATED PROTEIN C

The steps leading to the exciting discovery of APC resistance, also known as Factor V<sub>Leiden</sub>, were superbly related by Dahlback (32). The APC resistance phenotype is overwhelming evidence for the clinical importance of the PC system

in protecting against thromboembolic disease. Factor V is a 330-kDa plasma glycoprotein that is activated through limited proteolysis at Arg306, Arg506, and Arg679 by thrombin or factor Xa, whereupon the active form – factor Va – is an essential cofactor for factor Xa mediated transformation of prothrombin to thrombin. Most factor V mutations result in quantitative factor V deficiency with abnormal bleeding. However, many patients with venous thrombosis have a missense mutation in factor V, in which Arg506 is replaced with Gln (33). This mutant factor V is resistant to APC cleavage at that site, thereby impairing not only suppression of the procoagulant activity of factor Va, but also the anticoagulant cofactor activity of factor V required for the efficient inactivation of factor VIIIa by APC-PS. The frequency of the mutation ranges from 2% to 15%, with geographical variability – more frequent in northern European latitudes – that speaks to its origin. It is thus the most common autosomally inherited hypercoagulable disorder described. Heterozygosity confers a five- to 10-fold increased risk of thrombosis, and this increases to 50- to 100-fold for homozygous patients. It is interesting to note that APC resistance may be beneficial. For example, it is associated with less bleeding in the peripartum period, as well as in hemophilia A and B. APC resistance also reduces sepsis-induced mortality, probably via the anti-inflammatory and vascular endothelial protective activities of APC, the level of which is elevated as a consequence of excess thrombin generation. Other factor V mutations have been identified that involve APC cleavage sites. For example, Arg306Thr or Arg306Gly mutations eliminate APC cleavage at Arg306, but do not apparently increase the risk of thrombosis. On the other hand, a thrombotic pedigree revealed an Ile359Thr missense mutation that resulted in diminished APC-mediated cleavage at Arg306 and lower APC cofactor-induced inactivation of factor VIIIa, similar to that seen with Factor V<sub>Leiden</sub>.

### REGULATING PROTEIN C EXPRESSION

Although the liver is the primary site of production of PC, extrahepatic sites have been identified, consistent with the wide expression pattern of other components of the PC system, including PS, EPCR, and TM (34). For example, PC is readily detected in tubular epithelial cells of the kidney, in the prostate, in spermatogenic cells of the testis, and in epithelial cells of the epididymis. PC also is expressed at low levels in bronchial epithelial cells, neurons, and Purkinje cells in the brain, and in cultured vascular ECs (34,35). Immediate availability of PC at these selected sites implies that it may have unique tissue-specific biologic functions, or alternatively, that sanctuaries such as the testis or brain require an additional supply over and above the normal liver-derived source.

Not surprisingly, the regulation of PC expression is, to a large extent, coordinated with that of TM and EPCR. In animal models of DIC and inflammation, PC levels are diminished partly due to consumption, but expression is further down-

**Table 108-2: Transgenic Mice**

<i>Genotype Identification</i>	<i>Phenotype (Refs.)</i>
<i>PC<sup>-/-</sup></i>	<i>PC</i> gene inactivation results in mice that die soon after birth from severe consumptive coagulopathy, with increased fibrin deposition as early as E12.5 (36). With decrease in maternal source of PC, total lack of PC causes embryonic lethality (37).
<i>PC<sup>+/-</sup></i>	Mice with heterozygous deficiency of PC do not exhibit spontaneous thromboses, but have enhanced sensitivity to endotoxin, responding with more severe consumptive coagulopathy, increased fibrin deposition, augmented inflammation, vascular collapse, and organ damage (18).

regulated in the liver, kidney, and testis via transcriptional mechanisms, mediated by cytokines, such TNF- $\alpha$  and IL-1 $\beta$  (34). In models of lupus nephritis or diabetic nephropathy, fibrin deposition and inflammation is exacerbated as local and systemic PC levels decrease. In patients with severe sepsis, PC levels also are reduced, and these are inversely correlated with survival.

### ROLE OF PROTEIN C IN DEVELOPMENT

Inactivation of the *PC* gene in mice resulted in a phenotype similar to that seen in humans (36), with death perinatally due to diffuse thrombosis and severe consumptive coagulopathy, particularly prominent in the brain and liver, with evidence of increased fibrin deposition in these organs evident as early as embryonic day (E)12.5 (Table 108-2). Interestingly, the *PC* “knockout” picture was strikingly different from the *TM* gene “knockout,” the latter of which caused embryonic lethality by E8.5 to E9.5. This difference has indeed recently been shown to reflect a maternal transfer of PC in the *PC* knockout embryos that provided some degree of protection (37). Using novel transgenic strategies, mice with PC levels of 1% to 18% of normal have been generated; these survive beyond birth and display prothrombotic and proinflammatory phenotypes, the severity of which depends on the level of PC (37). Mice with heterozygous deficiency of PC do not develop spontaneous thromboses. But when exposed to polymicrobial sepsis, consumption of coagulation factors was more severe in the heterozygous mice, as compared with their wild-type counterparts, and they exhibited higher serum cytokine levels, more extensive tissue damage, hypotension, and earlier mortality, highlighting the protective role of PC in coagulation, inflammation, and sepsis (18,38).

## THERAPEUTIC CONSIDERATIONS

### Activated Protein C and Protein C in Sepsis

Targeting either the coagulation system or the inflammatory system to decrease the morbidity and mortality of patients with sepsis has been uniformly unsuccessful. However, the strategy of simultaneously interfering with both systems is supported by several preclinical trials. For unclear reasons, only APC has shown benefit in phase III clinical trials. In a large, double-blind, prospective study by Bernard and colleagues (39), the administration of recombinant human APC improved survival of critically ill patients with severe sepsis, with a 6.1% reduction in 28-day all-cause mortality, that was partly sustained at 90 days and 2.5 years (40). Response to APC was linked to a more rapid resolution of cardiovascular, respiratory, and hematopoietic system failure. The only adverse effect of APC was a statistically nonsignificant increase in serious bleeding (3.5% vs 2.0%), primarily in those with low platelet counts. Notably, the most prominent effects of APC in these trials appeared to be more related to correction of systemic coagulation parameters, rather than those of inflammation. Thus, APC reduced thrombin-antithrombin TAT complexes and F1.2 levels, but had nonsignificant effects on serum levels of TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and IL-10. These markers, of course, may not reflect the local effects of APC on EC activation. Moreover, the protection by APC against sepsis-related mortality and organ dysfunction might be via antiapoptotic pathways and/or by interfering with vascular collapse, which are not directly measurable in these assays.

Can PC, rather than APC, be used to treat sepsis? This is a controversial, unresolved issue. Theoretically, administered PC may not be effectively transformed to APC during sepsis, since TM and EPCR levels are functionally and quantitatively suppressed in this setting. However, case studies indicate that even in meningococcal sepsis and purpura fulminans, in which cell-surface TM has been documented to be decreased, treatment with PC often is beneficial and associated with increased generation of APC. Overall, the efficacy of PC has not been formally tested in appropriate clinical trials and, moreover, direct comparisons with APC are lacking.

### Protein C and Activated Protein C in Other Disorders

The most obvious use of PC/APC is as an anticoagulant for thromboembolic disease. Infants with homozygous PC deficiency and purpura fulminans benefit from PC infusions. Otherwise, largely due to the availability of many other effective anticoagulants, PC/APC has not been widely applied for the treatment of thromboembolic disease, nor has it been fully evaluated.

Although not approved for these uses, preclinical data suggest that APC is safe and efficacious for a variety of common, clinically important disorders. For example, APC decreases tissue damage associated with ischemia–reperfusion injury of

the spinal cord, heart, gut, and kidneys, partly by modulating leukocyte trafficking, but also by interfering with fibrin deposition, promoting fibrinolysis, and stabilizing the vascular endothelium (19). In stroke models, APC protects the brain against ischemic injury reportedly by blocking p53-mediated apoptosis, acting directly on neuronal cells by mechanisms not yet fully elucidated (27,41) (see Figure 108.2C). The neuroprotection afforded by APC is particularly intriguing, and raises the possibility that APC might play a role in neurodegeneration. APC also suppresses lung inflammation and fibrosis by inhibiting bronchial epithelial cell and macrophage expression of inflammatory cytokines and platelet-derived growth factor, and by promoting fibrinolysis.

As the molecular mechanisms by which APC regulates coagulation, fibrinolysis, inflammation, cell survival, and innate immunity are being delineated, rapid progress is being made to develop mutant forms of APC that have highly specific functions, without undesirable side effects. For example, APC that lacks anticoagulant function, yet retains the capacity to abrogate proinflammatory cascades, will provide a safer and more effective anti-inflammatory agent, without increasing the risk of bleeding. Similarly, it is reasonable to consider that various “designer” forms of APC may in the foreseeable future enter the clinic for the treatment of a number of acute and chronic disorders, including organ transplant rejection, myocardial ischemia–reperfusion, hepatitis, asthma, chronic obstructive lung disease, atherosclerosis, arthritis, or multiorgan failure.

## KEY POINTS

- PC is a critical component in a major “natural anticoagulant” pathway. Mediated by thrombin and accelerated by TM and EPCR, the transformation of PC to APC results in cleavage of factors Va and VIIIa and downregulation of further thrombin generation.
- Turning on and turning off PC activation is tightly regulated, in terms of time and location.
- Defects in the PC system enhance the risk of developing thromboembolic disease and, at least in rodents, also increases the inflammatory response to microbial infections.
- APC has distinct anti-inflammatory, antiapoptotic, and profibrinolytic properties that protect the organism against injurious stimuli, such as occurs during sepsis or ischemia. APC modulates these biologic processes through multiple mechanisms to achieve a protective response. EPCR is recognized to play a major role in protecting against inflammatory stimuli. PAR-1 may contribute to this process, and other receptors and intracellular pathways – many yet to be defined – are likely important. Identifying these,

and clarifying the role of EPCR and the PARs, will provide new insights for developing better diagnostic and therapeutic approaches.

- Recombinant APC is currently the only approved and clearly effective drug that decreases sepsis-related mortality in humans. Immediate challenges for clinicians and scientists are to identify the critical molecular and cellular pathways by which APC functions in these settings, the best ways to safely deliver the drug (or functional derivatives with greater specificity), how to monitor therapy, who will most benefit, and what other anti-inflammatory agents should be coadministered to improve overall outcomes.
- In view of its wide spectrum of activity, APC constitutes a novel therapy of potential benefit for many disorders, including sepsis, DIC, acute and chronic inflammatory disorders, organ ischemia–reperfusion injury, stroke, and possibly neurodegeneration.

## Vitamin K–Dependent Anticoagulant Protein S

Björn Dahlbäck

*University of Lund, Malmö, Sweden*

Protein S is a vitamin K-dependent plasma glycoprotein with anticoagulant properties (1–3). It is mainly synthesized in the liver and, to a lesser degree, in several other cell types including endothelium. Protein S binds to negatively charged phospholipid membranes, where it functions as a cofactor to activated protein C (APC) in the degradation of coagulation factors Va and VIIIa, cofactors in the prothrombinase and tenase complexes, respectively. In addition, protein S has APC-independent anticoagulant activities, which directly inhibit both the prothrombinase and the tenase complexes. In vivo, endothelium presumably promotes the anticoagulant activity of protein S by providing a suitable phospholipid membrane for interaction with APC. Protein S normally circulates in human plasma at a concentration of 0.30  $\mu\text{M}$ . In human plasma, 60% to 70% of protein S is bound to the high-molecular-weight C4b-binding protein (C4BP), a regulator of the classical complement pathway (3,4). The remaining 30% to 40% of protein S circulates as free protein. Thus, protein S functions as a link between the protein C anticoagulant system and the complement system.

### PROTEIN S GENE AND SYNTHESIS

Protein S in plasma is mainly derived from synthesis in the liver. In addition, endothelial cells (ECs), testicular Leydig cells, and osteoblasts synthesize protein S (3). Platelets contain protein S, but it is not known whether this is derived from megakaryocytic synthesis or from uptake of plasma protein S. However, protein S synthesis has been demonstrated in a megakaryocytic cell line, suggesting megakaryocytes have the capacity to synthesize the protein. Two protein S genes (*PROS1* and *PROSP*) are found in the human genome, but only *PROS1* is expressed, whereas *PROSP* is a pseudogene. Both *PROS1* and *PROSP* are located on chromosome 3 close to but on different sides of the centromere: *PROS1* at q11.2 and *PROSP* at p21-cen. The two genes have a high degree of sequence identity between the exons (97%). The *PROS1* gene is approximately 80 kb long and contains 15 exons and 14 introns. Orangutan, rhesus monkey, and African green monkey have one *protein S*

gene, but chimpanzee and gorilla have two. This suggests that the gene duplication event occurred after the branching of the orangutan from the African apes (3).

### PROTEIN S STRUCTURE

Circulating human protein S is a 635-amino acid residue long, single-chain glycoprotein; the molecular weight of the apoprotein calculated from the amino acid composition is 70,690 (1–3). Protein S is extensively post-translationally modified; the mature protein contains three N-linked carbohydrate side chains and three types of modified amino acids, namely  $\gamma$ -carboxy glutamic acids (Gla),  $\beta$ -hydroxy aspartic acid (Hya), and  $\beta$ -hydroxy asparagines (Hyn) (3,5). The primary structures of protein S from many other species have been determined (e.g., monkey, bovine, porcine, rabbit, rat, and mouse protein S).

Mature protein S is composed of multiple domains (Figure 109.1): from the  $\text{NH}_2$ -terminus, a Gla-domain is followed by a small thrombin-sensitive region (TSR), four epidermal growth factor (EGF)-like domains, and the sex hormone binding globulin (SHBG)-like region comprising two laminin G (LamG)-type domains (1–3). The domain structure of protein S correlates with the intron/exon organization of the gene, suggesting that it has evolved through a combination of exon shuffling and gene duplication events.

The Gla-domain binds multiple  $\text{Ca}^{2+}$ -ions, and the domain has high affinity for negatively charged phospholipid membranes (3,6,7). It also interacts directly with APC and is important for the APC-cofactor activity (8). The thrombin-sensitive region contains two cysteines, forming a disulfide bridge. In human protein S, thrombin can cleave at Arg49 and Arg70, and FXa at Arg60. After cleavage, the Gla domain remains attached via the disulfide bridge, but the APC-cofactor function of protein S is lost. Several lines of experiments support the notion that the TSR is involved in the interaction between protein S and APC (1–3). Protein S contains four EGF-like domains, each encoded by a separate exon. EGF1 and EGF2 are important for expression of APC-cofactor activity,

Figure 109.1. Schematic model of human protein S. Protein S is a multidomain, single-chain molecule. The Gla-domain contains eleven vitamin K-dependent Gla residues (Y). The Gla domain binds  $\text{Ca}^{2+}$  and negatively charged phospholipids. It is also involved in interaction with APC. The thrombin sensitive region (TSR) is important for interaction with APC, and cleavages by thrombin or FXa result in loss of APC-cofactor activity. The four EGF-like domains contain the modified amino acids  $\beta$ -hydroxy aspartic acid (Hya) or  $\beta$ -hydroxy asparagine (Hyn), as indicated. EGF1 and EGF2 are both important for the APC-cofactor activity of protein S. The two LamG domains constitute the C-terminal half of protein S. This region also is known as the SHBG region, and it contains the binding site for C4BP. The three N-linked carbohydrate side chains are indicated ( $\nabla$ ).

with EGF1 interacting directly with APC (1–3). The first EGF-like domain contains a Hya, and the following three Hyn (5). The importance of the hydroxylation of Asp/Asn in protein S is not known, and recombinant human protein S synthesized under conditions that inhibit the hydroxylation still expresses full cofactor function and C4BP binding. The Hyn-containing EGF-like domains in protein S, in particular EGF4, contain very high-affinity  $\text{Ca}^{2+}$ -binding sites ( $K_d$  down to nM) (5). The  $\text{Ca}^{2+}$  binding is important for protein S to attain protease resistance and a native conformation. The carboxy-terminal SHBG-like region of protein S, comprising the two LamG domains, contains three N-linked carbohydrate side chains of unknown function. The second LamG domain has been shown to play a role in the degradation of both FVa and FVIIIa. The C4BP-binding site on protein S is fully contained in the LamG domains, with both LamG1 and LamG2 contributing to the binding. Several regions of the LamG domains have been suggested to be important for the binding, but the details of the binding site are still not known (1–3).

#### ACTIVATED PROTEIN C-DEPENDENT ANTICOAGULANT ACTIVITY OF PROTEIN S

Protein S functions as an APC cofactor in the degradation of both FVa and FVIIIa (3,9,10). The Gla domain of protein S plays an important role related to its ability to bind negatively charged phospholipids. Protein S and APC form a complex on this type of phospholipid membrane, with protein S increasing the affinity of APC for the membrane approximately 10-fold (Figure 109.2). However, even though the two pro-

teins form a complex on the membrane, it has not been possible to demonstrate an interaction between the two proteins in fluid phase. The interaction between APC and protein S on the phospholipid surface affects the location of the active site of APC in relation to FVa and the membrane (11). In *in vitro* experiments, the presence of protein S was found to reduce the distance of the active site of APC to the phospholipid membrane by approximately 10 Å. This change in the localization of the serine protease domain of APC may be important for the cleavages in FVa and FVIIIa. The interaction between APC and protein S has mainly been characterized in *in vitro* systems using phospholipid vesicle preparations. *In vivo*, presumably ECs, platelets, and platelet microparticles provide the phospholipid surfaces for the protein S–APC interaction (12,13).

In the degradation of FVa by APC, the cleavages at Arg506 and Arg306 demonstrate different dependencies on protein S (see Figure 109.2). Thus, although protein S provides stimulation to both cleavages, the APC-mediated cleavage at Arg506 in FVa is less dependent on the presence of protein S than is the cleavage at Arg306 (10). The Arg506 cleavage, furthermore, is more efficient than that at Arg306. This is shown to be due to a positively charged exosite on the surface of the serine protease domain of APC, which interacts specifically with a negatively charged area around Arg506 (14). The cleavage at Arg506 results in partial loss of FVa activity due to reduced binding affinity for FXa, whereas the subsequent cleavage at Arg306 results in complete inactivation of FVa. FXa, when bound to FVa in the assembled prothrombinase complex, protects the Arg506 site from degradation by APC, presumably through steric hindrance (i.e., FXa, when bound, covers the Arg506 area) (14). Protein S has been shown to abrogate the protective

Figure 109.2. Protein S in the APC-mediated degradation of FVa. APC attacks the membrane-bound FVa at three sites: Arg306, Arg506, and Arg679. The efficiency of APC is enhanced by the presence of protein S, and the two molecules form a membrane-bound complex that efficiently degrades FVa. The Arg306 cleavage site is more dependent on the presence of protein S than is the Arg506 site. The Arg679 cleavage seems to be less important than the other two, but its physiological significance is not fully understood.

effect of FXa on the Arg506 site in FVa. Thus, protein S is important to increase the efficiency of the APC-mediated cleavages at both the Arg506 and the Arg306 sites, although the mechanisms involved in the two cleavages are slightly different.

In APC-mediated degradation of FVIIIa in the tenase complex, protein S is not the only APC cofactor of importance, because FV has been found to enhance the APC-mediated FVIIIa degradation (10). The APC-cofactor activities of FV and protein S are synergistic, and result in efficient control of the activity of the tenase complex.

#### ACTIVATED PROTEIN C-INDEPENDENT ANTICOAGULANT ACTIVITY OF PROTEIN S

Protein S also expresses APC-independent anticoagulant activity. The physiological importance of this activity is unclear, and its molecular mechanism has been the topic of debate (1,2). The direct anticoagulant activity has been suggested to be due to direct interactions between protein S and FVa/FVIIIa and/or FXa. The anticoagulant activity of protein S has been demonstrated in a flow system using ECs and plasma, in which protein S-depleted plasma gave considerably higher prothrombin activation than did plasma containing protein S (15). Some reports have claimed that the APC-independent anticoagulant activity of protein S is due to competition for phospholipid (16). However, such phospholipid dependence is observed only when the protein S preparations contain multimers of protein S, which are normally not present in plasma but can form during the purification of protein S (1,2).

#### PROTEIN S INTERACTION WITH C4B-BINDING PROTEIN

The complex in human plasma between protein S and C4BP has a 1:1 stoichiometry; the interaction is noncovalent and of high affinity ( $K_d$  approximately  $10^{-10}$  M) (1,3,4,17). C4BP is important for the regulation of the C4bC2a complex (C3 convertase) of the classical complement pathway, functioning as a cofactor to the serine protease factor I in the degradation of C4b (3,4). C4BP is a high-molecular-weight (570 kDa)

glycoprotein composed of seven identical  $\alpha$ -chains (70 kDa) and a single  $\beta$ -chain (45 kDa), with the chains linked by disulfide bridges. The concentration of C4BP in plasma is approximately  $0.3 \mu\text{M}$ . High-resolution electron microscopy revealed a spider- or octopus-shape for C4BP, with the different chains radiating from a central core (Figure 109.3) (18). Each  $\alpha$ -chain contains a binding site for C4b, whereas the  $\beta$ -chain contains the single binding site for protein S, because the binding of protein S and C4b are independent. Molecular models of the  $\alpha$ - and  $\beta$ -chains have been created, and the binding sites for C4b and protein S have been elucidated in detail (4).

Under normal conditions, at least 80% of the C4BP molecules in human plasma contain the  $\beta$ -chain (C4BP $\beta^+$ ) and bind protein S. The concentration of C4BP $\beta^+$  is on a molar basis approximately 30% to 40% lower than that of total protein S, and the level of free protein S is equivalent to the molar surplus of protein S over the C4BP $\beta^+$  because the protein S-C4BP interaction is of very high affinity (1,3). C4BP is an acute-phase protein, and its concentration may increase to 400% of the normal level during inflammatory disorders. The synthesis of  $\alpha$ -chains increases more than that of the

Figure 109.3. Apoptotic cells bind protein S and the protein S-C4BP complex. During apoptosis the dying cells expose the negatively charged phosphatidylserine on their surfaces. This is an "eat me" signal to neighboring cells and professional phagocytes. Both free protein S and the protein S-C4BP complex bind to the apoptotic cells via the Gla-domain of protein S. This provides the potential for regulation of both coagulation and the complement systems on the surface of apoptotic cells. Moreover, the bound protein S stimulates phagocytosis of the apoptotic cells, whereas the protein S-C4BP complexes seem to have the opposite effects. The octopus-like shape of C4BP is illustrated, the arrows indicating the  $\alpha$ - and  $\beta$ -chains.

$\beta$ -chain during inflammation due to differential regulation of the  $\alpha$ - and  $\beta$ -chain genes by cytokines. Therefore, the C4BP molecules that are synthesized under inflammatory stress contain only  $\alpha$ -chains and are unable to bind protein S. The synthesis of protein S does not increase much during inflammation, and the differential regulation of  $\alpha$ - and  $\beta$ -chain synthesis during inflammation ensures stable levels of free protein S also during inflammatory states, even though the plasma C4BP level may be several times higher than normal.

The interaction between protein S and C4BP provides a link between the regulation of blood coagulation and the complement system. Thus, C4BP modulates the protein S anticoagulant activity, because binding of C4BP to protein S results in the loss of the APC-cofactor activity of protein S. Likewise, protein S can be involved in affecting the C4BP-mediated regulation of the classical complement pathway by localizing the complex to the surface of negatively charged phospholipid (as on apoptotic cells) (see later discussion). Because complement activation generates local inflammation due to the release of anaphylatoxins, binding of protein S-C4BP to apoptotic cells can provide local regulation of the complement system and inhibition of inflammation in the vicinity of dying cells.

#### PROTEIN S BINDING TO APOPTOTIC CELLS STIMULATES PHAGOCYTOSIS

Under normal conditions, the negatively charged phosphatidylserine is not exposed on the surface of cells but located in the inner leaflet of the cell membrane. Therefore, protein S and the other vitamin K-dependent proteins do not bind to the surfaces of normal cells. Certain situations result in the exposure of phosphatidylserine on the cell surface, such as apoptosis or platelet activation. It has been shown that protein S can bind to the negatively charged phospholipids that are exposed on the surface of apoptotic cells and on platelet microparticles (19,20). The binding is calcium-dependent and mediated by the Gla domain. When bound, protein S stimulates phagocytosis of the apoptotic cells through mechanisms yet to be defined (21). The protein S-C4BP complex also binds to the apoptotic cells but this is, in contrast, found to counteract the phagocytic process (22). In addition, protein S and the protein S-C4BP complex may have other functions on the apoptotic cell surface. Thus, protein S may contribute to controlling the coagulation system on the apoptotic cell surface, whereas the protein S-C4BP complex may take part in controlling local activation of the complement pathway. In this context, it is worth mentioning that the intravenous administration of human protein S to mice subjected to a cerebral stroke model resulted in significant neuroprotection (23). Protein S reduced fibrin deposition, neutrophil infiltration, infarction size, and edema, and improved the postischemic blood flow and the motor neurological deficit. It is not clear if these beneficial effects were mainly due to the anticoagulant or the prophagocytic properties of protein S. However, it can be concluded that the beneficial effects were not exerted by protein S in complex with C4BP, because as mouse C4BP lacks the  $\beta$ -

chain and because the mouse  $\beta$ -chain gene is a nonexpressed pseudogene (24).

Protein S has no known antiapoptotic activities, but it is noteworthy that protein S is homologous to the antiapoptotic protein Gas6 (product of the growth arrest specific gene number 6), with the two proteins sharing similar domain organization. Gas6 is a member of the vitamin K-dependent protein family and, as the name implies, Gas6 synthesis is induced by growth arrest, such as serum starvation in cultured cells (25-27). Several biological effects have been associated with Gas6, such as the inhibition of apoptosis, stimulation of mitogenesis, and growth stimulation of different cell types including ECs. Gas6 is widely expressed by ECs, fibroblasts, and smooth muscle cells but, unlike protein S, Gas6 is not expressed in the liver. The plasma concentration of Gas6 is 1,000-fold lower than that of protein S, and the function of Gas6 is unrelated to the protein C and coagulation systems (28). Gas6 binds to the tyrosine kinase receptors Axl, Sky, and c-Mer, and induces tyrosine phosphorylation and intracellular signaling (25-27). The Gla-domain of Gas6 binds negatively charged phospholipid membranes exposed on the surface of apoptotic cells and stimulates the phagocytosis of the apoptotic cells. Protein S also has been shown capable of functioning as a ligand for the Sky receptor. However, the physiological significance of this has been questioned because only protein S from certain species can stimulate the Sky receptor (29). Thus, bovine protein S stimulates the human Sky receptor, whereas human protein S has no or little such activity, with the structural difference between human and bovine protein S accounting for this species specificity located in the LamG1 domain of protein S (30). The three-dimensional structure of the two LamG domains of Gas6 has been determined (31). Based on this and other laminin G-type domains, models for the corresponding part of protein S have been created.

#### PROTEIN S DEFICIENCY AND VENOUS THROMBOSIS

Inherited protein S deficiency is a risk factor for venous thrombosis found in approximately 2% to 4% of thrombosis patients (1,3,32). The prevalence of protein S deficiency in the general population has been estimated to be between 0.03% and 0.13%. The risk of thrombosis in heterozygous carriers is about five- to 10-fold higher than in their healthy relatives. Homozygous or compound heterozygous protein S deficiency is extremely rare and incompatible with life without treatment due to extensive thrombosis. Venous thrombosis is a multifactorial disease, and the risk of thrombosis in protein S deficiency is much higher when combined with other genetic or acquired conditions predisposing for thrombosis (33). This explains the varying penetrance of thrombotic symptoms in patients with protein S deficiency.

Traditionally, inherited protein S deficiency was categorized into three different types (I-III), but convincing data have shown that there are only two types. According to the original classification, type I patients have decreased free and

total protein S, type II denotes functional deficiency with normal protein levels, and type III is characterized by low free protein S but normal concentrations of total protein S. An observed coexistence of types I and III in several pedigrees suggested the two types to be phenotypic variants of the same genetic disease, and that only two distinguishable types exist, type I having low protein S, and type II having functional defects (1,3). The concentrations of protein S and C4BP $\beta^+$  are approximately equimolar in protein S-deficient individuals, which, taken together with the high affinity of the protein S–C4BP interaction, explains the low plasma levels of free protein S that characterize type I patients. This also explains why analysis of free protein S has higher predictive value for protein S deficiency than does analysis of total protein S, and is the method of choice in evaluation of thrombosis patients (34). A majority of patients with protein S deficiency have type I, and very few have type II deficiency. Many missense and nonsense mutations have been identified in cases of protein S deficiency. However, it has been a consistent observation from many laboratories that point mutations are only found in around 50% of the protein S-deficient patients. Recently, an explanation for this was provided by genetic studies of protein S-deficient families having no identifiable point mutations. In these families, the protein S deficiency was found to be linked to the *PROS1* gene, and in many of them large deletions were identified as the genetic defect (1,35,36). Type II mutations have been found in the Gla-domain; these result in defective  $\gamma$ -carboxylation and presumably lead to folding problems and instability as well as poor Ca<sup>2+</sup> and phospholipid binding. A Thr103 to Asn mutation in EGF1 causes type II deficiency, presumably due to poor interaction with APC. In EGF2, a Lys155 to Glu mutation results in a functional defect in protein S (protein S Tokushima). Protein S Tokushima has poor APC cofactor activity, and has been shown to interact poorly with APC, consistent with the hypothesis that EGF2 is important for the APC-cofactor activity of protein S. Inherited protein S-deficient patients have similar clinical manifestations as those with other thrombophilic conditions, mainly venous thrombosis in lower extremities (1–3,33).

The concentration of protein S in plasma is influenced by several factors (e.g., pregnancy and oral contraceptives decrease the plasma protein S concentration). During normal pregnancy, the plasma levels of both total and free protein S decrease, reaching levels found in patients with inherited deficiency (1,3,34). The plasma protein S is lower in women than in men, and higher in postmenopausal women than in premenopausal women. During treatment with oral anticoagulants (e.g., warfarin), the levels of protein S decrease, because protein S is a vitamin-K dependent protein. Acquired protein S deficiency is associated with nephrotic syndrome and disseminated intravascular coagulation. The plasma concentration of C4BP is high in patients with nephrotic syndrome, because the high molecular weight of C4BP does not allow glomerular filtration. Free protein S is lost in the urine, resulting in decreased levels of functionally active protein S, which may contribute to the thrombosis risk in nephrotic syndrome. Acquired protein

S deficiency also may be the result of immunological mechanisms, as in patients with autoimmune disease or human immunodeficiency virus (HIV). Moreover, many children have been described with thrombosis and autoantibodies to protein S after varicella infections (1,3).

#### NOTE ADDED IN PROOF

Recently, novel insights into the mechanism of the APC-independent anticoagulant activity of protein S was gained by the report of Hackeng and colleagues that protein S serves as a cofactor to (TFPI) tissue factor pathway inhibitor in inhibition of tissue factor-induced coagulation (37).

#### KEY POINTS

- Vitamin K–dependent protein S binds to negatively charged phospholipid membranes and expresses both APC-dependent and APC-independent anticoagulant activities.
- In human plasma, 30% to 40% of protein S is free, whereas the rest is bound in a noncovalent high-affinity complex with the complement regulator C4b-binding protein.
- Free and C4BP-bound protein S bind to the negatively charged phospholipids exposed on the surface of apoptotic cells. Free protein S stimulates phagocytosis of apoptotic cells, whereas the protein S–C4BP complex inhibits phagocytosis.
- Inherited protein S deficiency is a risk factor for venous thrombosis, with analysis of free protein S the method of choice to diagnose the deficiency.

#### Future Goals

- To elucidate the importance of protein S in the phagocytosis of apoptotic cells. Which receptors does protein S interact with on the phagocytic cells?
- To demonstrate that free protein S and the protein S–C4BP complex, when bound on apoptotic cells, inhibit both blood coagulation and the complement system
- To create a protein S knockout mouse to elucidate the in vivo importance of protein S
- To determine the three-dimensional structure of protein S and the relationships between the protein S structure and its functions

## Nitric Oxide as an Autocrine and Paracrine Regulator of Vessel Function

William C. Sessa

*Boyer Center for Molecular Medicine, Yale University School of Medicine,  
New Haven, Connecticut*

The discovery that the paramagnetic, free radical gas nitric oxide (NO) is the chemical species responsible for endothelium-dependent relaxation of large blood vessels, neurotransmission in the central and peripheral nervous systems, and activated macrophage function of the innate immune system has forged the convergence of several disciplines to study the mechanisms of NO biosynthesis in mammals and lower organisms. The global importance of NO as a highly regulated, second-messenger gas throughout the body culminated in the focused efforts of many laboratories worldwide to understand its synthesis, spectrum of activities, and metabolism. Based on the accolades ascribed to the field of NO biology, which led to a Nobel Prize in Medicine and Physiology awarded to Ignarro, Murad, and Furchgott in 1998, it could be argued that the discovery of the NO signaling pathway was a major paradigm shift in our understanding of endothelial and blood vessel function, an attribute shared by few other discoveries in vascular biology.

### HISTORICAL PERSPECTIVES

The role of NO gas in the biological sciences has a long history, including its function as an environmental pollutant, as an active ingredient of gunpowder, and as the therapeutic antianginal nitroglycerin. In keeping with the focus of this volume, our historical perspective is considered from the vascular point of view.

Although the convergence of many disparate lines of scientific enquiry was responsible for the ground-swell of work in the field of NO biology, the defining moment for NO biology in the cardiovascular system and its vasoregulatory role of the endothelium in general hinged on the pioneering work of Robert Furchgott (1). A pharmacologist, Dr. Furchgott noticed that acetylcholine (Ach) was a very potent vasodilator *in vivo*, but was less consistent and potent in relaxing isolated blood vessels *in vitro*. He observed that with meticulous isolation of

blood vessels, Ach always had a vasodilatory effect, whereas denudation of the inner lining of blood vessels – the endothelium – converted Ach from a vasodilator to a vasoconstrictor having direct action on the underlying smooth muscle. He then performed a classic “sandwich bioassay” experiment, in which a vessel with intact endothelium was “sandwiched” into the lumen of a denuded vessel segment to determine whether the vessel with endothelium could release a transferable factor to relax the denuded segment. The experiment was successful, and he coined the biological activity endothelium-derived relaxing factor (EDRF). The remarkable simplicity of this experiment, and the ability of students and scientists all over the world to repeat this observation, is a testimony to the fundamental nature of Furchgott’s observations. This bioassay experiment also gave rise to notion that EDRF was a labile factor, inactivated by superoxide anion and oxyhemoglobin and antagonized by redox active inhibitors of soluble guanylyl cyclase (see next section).

However, a pivotal discovery from the field of tumor immunology focused researchers on finding the enzymatic mechanisms that produced EDRF. Activated mouse peritoneal macrophages inhibited tumor-cell DNA synthesis, mitochondrial respiration, and growth when L-arginine, but not D-arginine, was added to the tissue culture media (2). This cytotoxic action of activated macrophages was accompanied by the stoichiometric formation of L-citrulline and nitrite ( $\text{NO}_2^-$ ) in the media. In addition, guanidino-substituted L-arginine analogs such as  $\text{N}^G$ -monomethyl-L-arginine (L-NMMA) later shown to be an inhibitor of NO synthase (NOS), prevented the L-arginine-dependent production of L-citrulline and  $\text{NO}_2^-$  and the cytotoxic actions of activated macrophages. The ability of activated macrophages to nitrosate amines, and the lack of toxicity associated with  $\text{NO}_2^-$  or nitrate ( $\text{NO}_3^-$ ) in the culture medium, suggested that a nitrogen oxide more potent than  $\text{NO}_2^-$  or  $\text{NO}_3^-$  was responsible for macrophage cytotoxicity.

In an independent line of research studying the mechanisms of nitrate generation by activated macrophages (3), it

was shown that macrophages metabolized isotopically labeled arginine to labeled  $\text{NO}_2^-$  and  $\text{NO}_3^-$ , thus providing evidence that they were derived from one of the two chemically equivalent guanidino nitrogens of L-arginine (4). NOS activity, for the first time, was demonstrated in the cytosol of cytokine-activated macrophages, and this crude enzyme preparation was able to metabolize L-arginine to nitrogen oxides, with NO being the intermediate in this pathway and the mediator of macrophage cytotoxicity (5). These experiments defined the substrate for NO synthesis (L-arginine), identified the first inhibitors (arginine analogs), and identified the inducible nature of NOS in macrophages.

Simultaneously, NO was found to be the principal, biologically active constituent of EDRF and an endogenous activator of soluble guanylate cyclase (6–9). Effluents from isolated perfused blood vessels were directed over precontracted strips of endothelium-denuded vessels that were used to detect vasodilator substances released from the donor vessels. Under these conditions, NO mimicked the relaxing activity of EDRF released from the donor blood vessel. Both activities exhibited the same biological half-life, were attenuated by oxyhemoglobin and the generation of superoxide anions, and were potentiated by superoxide dismutase (9,10). The chemical identity of EDRF was suggested to be NO, based on the detection of nitrogen oxides by chemiluminescence and nitrosyl-hemoglobin by spectrophotometry (8,9).

However, because exogenous L-arginine did not significantly relax or potentiate the release of EDRF in freshly isolated blood vessels or cultured endothelial cells (ECs), it was very difficult to explain the mechanism of NO production in ECs. Only by culturing ECs in L-arginine-deficient media for 24 hours (at which point the intracellular L-arginine pool was depleted from approximately 100–200  $\mu\text{M}$  to less than 30  $\mu\text{M}$ ) could the exogenous administration of L-, but not D-arginine, potentiate the release of EDRF and increase the production of nitrogen oxides (11). Similar to the studies in activated macrophages, infusion of L-[guanido- $^{15}\text{N}_2$ ] labeled arginine into L-arginine-deficient ECs yielded the release of  $^{15}\text{N}$ -labeled NO. The substituted L-arginine analog, L-NMMA attenuated endothelium-dependent relaxations in various isolated vascular beds in vitro, and increased systemic blood pressure in vivo, further supporting NO as an important endogenous regulator of vascular tone (12). Soon after, L-arginine-dependent, crude NOS activity was demonstrated in cytosolic and/or membrane fractions prepared from freshly isolated or cultured ECs (13,14).

Now that L-arginine was convincingly shown to be the precursor to NO, an assay was necessary to track the enzymatic activity when isolated from cells. Work by several research teams (15–17) led to the development of two assays to track NOS activity. Bredt (15) used the conversion of radiolabeled L-arginine to L-citrulline as an assay to isolate the first NOS from brain (this method is still used as a very simple, standard assay in most laboratories). Murad's group (17) used NO activation of soluble guanylyl cyclase and cyclic guanosine monophosphate (cGMP) accumulation in a

kidney cell line to track "EDRF synthase" activity and isolated the endothelial enzyme. Stuehr isolated the macrophage enzyme (18).

Bredt then used tryptic peptide sequence information to clone the first NOS isoform, neuronal NOS from rat brain (19), followed by the cloning of macrophage NOS (inducible NOS or iNOS) by Nathan (20), and endothelial NOS (eNOS) by Bloch, Michel, Harrison, and our group (21–24). Once the cDNAs were cloned, overexpression systems led to a characterization of the enzymatic mechanisms for NO synthesis and structural biology of the NOS isoforms.

## EVOLUTIONARY CONSIDERATIONS

To date, many efforts are under way to define the origins of NO, NO synthesis, and NO binding proteins. Philosophically, it can be argued that NO is as ancient as life itself based on studies simulating the atmospheres of the Earth, Venus, and Mars. In these experiments, the formation of NO can be stimulated at 50%  $\text{CO}_2$  using a simulated lightning discharge consistent with the formation of atmospheric NO under conditions during early planetary evolution (25). More relevant to cellular production of NO in biology, NOS activity can be found in protozoa, bacteria (gram-positive, but not gram-negative), plants, *Drosophila*, and fish, leading to the conclusion that NO synthesis is one of the earliest and most widespread signaling systems in living organisms (26). A recent paper identifying NOS in the plant pathogen *Streptomyces turgidiscabies* documented a role for this NOS in generating a nitrated species of the plant toxin, thaxtomin (27). Knockout of the gene or treatment of the bacteria with NOS inhibitors reduces the synthesis of thaxtomin and the virulence of the pathogenic strain, thus defining a primitive role for NOS and NO in bacteria. In mammalian NOS, the transport of electrons through the protein occurs via the modular structure of the oxygenase and reductase domains. In many of the protozoal or bacterial species exhibiting NOS activity, conserved features exist akin to mammalian NOS in the amino terminal oxygenase domain. However, bacterial NOS lacks a carboxy terminal reductase domain, suggesting that another redox protein may serve as an electron donor.

In mammals, the three NOS isoforms (nNOS, iNOS, and eNOS) share 50% amino acid identity and are considered in the class of cytochrome P450 enzymes (28,29). All the cloned NOSs contain consensus binding sites for heme, calmodulin, and L-arginine;  $\text{BH}_4$  binding in the oxygenase domain; and an electron transport component in the carboxy half-reductase domain. All NOS enzymes work as electron transfer relay stations, transferring electrons from nicotinamide adenine dinucleotide phosphate (NADPH) through the carboxy reductase domain to the heme acceptor in the amino terminus. The activated heme binds oxygen ( $\text{O}_2$ ) to catalyze the oxygenation of guanidine nitrogen of the substrate L-arginine via complex chemistry. The carboxy-terminal half of mammalian NOS is similar (36% amino acid identity) to the electron transport

protein, cytochrome-P450 reductase, containing consensus sequence-binding domains for the flavin nucleotides (flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]) and NADPH. As with all cytochrome P450 enzymes, the inefficient coupling of electron transfer to substrate utilization results in an “uncoupled” enzyme producing superoxide anion instead of NO. This is an area of intense interest because it is possible that cardiovascular risk factors may reduce the synthesis of tetrahydrobiopterin (BH<sub>4</sub>) or interfere with hsp90 binding to eNOS, thus converting eNOS from an NO generator to a superoxide generator (30).

## GENE REGULATION

In general, the transcripts for *nNOS* and *eNOS* are thought to be “constitutively” expressed, whereas *iNOS* is clearly an “inducible” gene. However, many examples exist where nNOS and in particular eNOS are induced by physiological and pathophysiological stimuli (see reviews for control of gene expression, in Refs. 31–33). Most importantly for eNOS, shear stress – the mechanical force initiated by the flow of blood across an endothelial monolayer – induces eNOS mRNA and protein levels consistent with eNOS-derived NO and is important for flow-dependent dilation and remodeling of conduit vessels (24,34). Interestingly, in various species, increasing blood flow secondary to exercise training also induces eNOS, suggesting that eNOS upregulation is part of the “cardioprotective gene program” triggered by exercise training.

## ROLE IN HOMEOSTASIS

### Autocrine Roles of Nitric Oxide

Although NO was discovered as a diffusible gas synthesized in one cell and with actions on adjacent cells, increasing evidence suggests that NO serves as an important autocrine regulator of EC function. This discussion omits studies utilizing NO donor drugs, because these compounds do not exhibit release kinetics similar to those of enzymatic generation of NO by eNOS. Moreover, the compartmentalization of eNOS into the Golgi complex and plasma membrane is necessary for the dynamic generation of NO synthesis (35). In the context of vascular biology, treatment of ECs with inhibitors of NOS reduces the actions of several angiogenic factors in promoting NO release, proliferation, migration, tube formation, and protein secretion. In addition, blockage of endogenous NO increases mitochondrial O<sub>2</sub> consumption and sensitizes cells to apoptogens. The pathophysiological importance of eNOS in regulating angiogenesis has been explored in *eNOS*<sup>-/-</sup> mice (31,36,37). NOS inhibitors block vascular endothelial growth factor (VEGF)-induced proliferation, migration, and angiogenesis in vitro and in vivo (38,39). However, NO is not essential for the process of vasculogenesis and angiogenesis during development, because *eNOS*<sup>-/-</sup> mice survive and grow normally (40,41). This is in contrast to mice lacking VEGF

or VEGF receptors, which die early during vascular development (42,43). However, *eNOS*<sup>-/-</sup> mice exposed to hindlimb ischemia do not revascularize the circulation as well as control mice and develop critical limb ischemia. Moreover, exogenous VEGF administration or *VEGF* gene therapy failed to restore angiogenesis in *eNOS*-knockout mice, supporting the notion that NO is an essential downstream element regulating VEGF-induced angiogenesis and permeability in adult mice (44–47). Recent studies have shown that *eNOS*<sup>-/-</sup> animals are not only refractory to VEGF, but also do not improve blood flow after ischemia, when treated with statins (48) or the chemokine stromal cell-derived factor 1 (SDF1)- $\alpha$  (49), suggesting that eNOS is critical for the beneficial actions of these agents.

Mechanistically, it is not clear how NO promotes angiogenic phenotypes but there are several potential mechanisms. NO activation of soluble guanylyl cyclase (sGC) and protein kinase G (PKG) activation is responsible for some of the autocrine actions of NO in cultured cells; however, many cultured ECs lose sGC or PKG, thus suggesting other targets for NO. One exciting mechanism that may explain several autocrine functions of NO is S-nitrosylation of signaling proteins (50). NO can readily form adducts with oxidized thiols to form S-nitrosothiols in proteins, and recent evidence suggests that enzymatic denitrosylation can also regulate net NO-thiol stability (51). A recent finding of the NO regulation of von Willebrand factor (vWF) secretion is an excellent example of how S-nitrosylation may regulate EC function (52). Many agonists that mobilize intracellular calcium can promote the release of prestored vWF from Weibel-Palade bodies, a unique dense secretory granule found in ECs. Blockade of NO release augments vWF secretion, suggesting that endogenous NO negatively regulates the secretion of vWF. Lowenstein and coworkers (52) identified N-ethylmaleamide-sensitive factor (NSF) as a target for S-nitrosylation. S-nitrosylation of NSF reduces adenosine triphosphate (ATP) hydrolysis, a reaction necessary for the disassembly of the proteins required for membrane fusion and secretion. Additional side-by-side studies comparing the role of the sGC/PKG pathway versus S-nitrosylation will further define the autocrine actions of NO.

### Paracrine Actions of Nitric Oxide

As mentioned earlier, NO was initially discovered as an endothelial-derived factor that would diffuse across the basal lamina and relax the underlying vascular smooth muscle. The biological half-life of NO is 1 to 3 seconds in aqueous solution; it is rapidly inactivated by superoxide anion and its half-life is prolonged by superoxide dismutase (10). This ability of endothelial-derived NO or NO liberated by NO donors such as nitroglycerin is largely mediated by the activation of vascular smooth muscle -soluble guanylyl cyclase and PKG (53) and, to a lesser extent, via S-nitrosylation of calcium-activated potassium channels. Endothelial-derived NO also has effects on circulating cells, where it inhibits leukocyte and platelet adhesion and aggregation. *eNOS*<sup>-/-</sup> mice demonstrate increased leukocyte and platelet accumulation in certain models of

inflammation consistent with endothelium-derived NO as a paracrine regulator (54).

Another example of eNOS-derived NO controlling a paracrine function is the regulation of O<sub>2</sub> consumption by surrounding parenchyma. Indeed eNOS-derived NO is a negative regulator of O<sub>2</sub> consumption in the heart and skeletal muscle by virtue of its reversible binding to components of the respiratory chain, including cytochrome oxidase (55–57). More recently, eNOS-derived NO has been implicated as a global regulator of mitochondrial biogenesis (58,59). Skeletal muscle biopsies from *eNOS*<sup>-/-</sup> mice contain fewer mitochondria when compared with wild-type mice. In vitro, NO can regulate mitochondrial gene expression, thus exerting a profound influence on mitochondrial number and metabolism.

### THERAPEUTIC CONSIDERATIONS

Endothelial dysfunction, defined as a deficit in NO bioavailability, is a hallmark of many cardiovascular diseases. To date, data from multicenter clinical trials document that improvement in endothelium-dependent vasomotion correlates well with the beneficial actions of statin-based drugs and angiotensin-converting enzyme (ACE) inhibitors (60). This has been interpreted to suggest that maintaining a healthy eNOS/NO balance is beneficial for cardiovascular health. However, no genetic data document that mutations in the NOS/cGMP/PKG pathway cause cardiovascular disease, thus suggesting that these pathways may be genetic modifiers of polygenic disorders. In addition, other vasodilatory factors such as endothelium-derived hyperpolarizing factor (EDHF) or arachidonic acid metabolites also may be impaired and contribute to endothelial dysfunction, despite the evidence supporting impairments in NO bioactivity as the major cause of endothelial dysfunction.

Given this clinical information, what strategies are available to regulate eNOS function? Several animal studies have used *eNOS* gene transfer to improve vasomotion, blood flow, and angiogenesis; however, the clinical utility of viral approaches is still not evident. Another approach is restoration of BH<sub>4</sub> levels by administration of BH<sub>4</sub> itself or precursors that are metabolized to BH<sub>4</sub>. Indeed, BH<sub>4</sub> supplementation in humans and in animal models improves endothelial dysfunction and blood flow (61). Also, as a beneficial effect of statin-based drugs, statins exert multiple functions to improve eNOS functions. Statins stabilize *eNOS* mRNA and protein levels (62) and post-translationally activate the protein kinase, Akt. Akt in turn phosphorylates eNOS (on serine 1177 in human eNOS), increasing NO release at rest and after stimulation (63). Physiologically, these mechanisms may account for the broadly accepted beneficial actions of statins that occur in the absence of cholesterol lowering. In animal models, this seems to be correct because statins do not improve blood flow in models of limb ischemia (48) or stroke (64) performed in *eNOS*<sup>-/-</sup> mice. Finally, a more thorough molecular understanding of how eNOS is negatively regulated by its interac-

tion with the coat protein for caveolae formation, caveolin-1, may lead to caveolin-1 antagonists that should promote NO release (65).

### KEY POINTS

- NO is the first gaseous signaling molecule discovered; it can serve as an autocrine and paracrine regulator of blood vessel function.
- In mammals, three NOS isoforms produce NO. These enzymes are a highly conserved gene family that are regulated by distinct transcriptional, post-transcriptional, and post-translational control mechanisms. The endothelial NOS (eNOS) isoform plays a major role in vascular homeostasis.
- The mechanism of action of NO on vascular cells occurs either via cGMP-dependent pathways or by protein S-nitrosylation. Genetic evidence strongly supports the cGMP/PKG pathway as important for the hemodynamic actions of NO.

### Future Goals

- To determine whether maintaining a healthy eNOS/NO balance is beneficial for cardiovascular health
- To understand the transcriptional regulation and post-translational control mechanisms of eNOS, which may lead to novel modalities for enhancing eNOS function

## Heme Oxygenase and Carbon Monoxide in Endothelial Cell Biology

---

Hong Pyo Kim, Stefan W. Ryter, and Augustine M. K. Choi

*The University of Pittsburgh School of Medicine, Pennsylvania*

The realization that endogenous small gas molecules can serve critical functions in vascular biology originated in the 1980s, with the identification of the endothelial cell (EC)-derived relaxing factor as equivalent to the gas nitric oxide (NO), a potent endogenous relaxant of vascular smooth muscle (1–2). NO arises from the enzymatic conversion of L-arginine to L-citrulline, by the action of constitutive and inducible NO synthase (NOS) enzymes (3). The production of NO by endothelial NOS (eNOS) provides an essential component of EC function in the regulation of vascular processes, including vascular tone, as well as the inhibition of platelet aggregation, leukocyte adherence, and smooth muscle cell (SMC) proliferation (Reviewed in Ref. 4, 5). On the other hand, the vasoactive properties of carbon monoxide (CO) have long been recognized in the context of accidental inhalation exposure. CO binds avidly to hemoglobin, with an affinity 250 times that of oxygen, and therefore causes tissue hypoxia and ultimately death at high concentration. In the mid-twentieth century, Sjostrand and later Coburn and colleagues identified the endogenous occurrence of CO in human blood as the consequence of hemoglobin turnover (6–7). The enzymatic mechanism for the endogenous production of CO from heme degradation was identified as early as 1968, with the initial characterization of microsomal heme oxygenase (8–9), which converts heme to equimolar biliverdin-IX $\alpha$ , CO, and free iron. The reaction requires nicotinamide adenine dinucleotide phosphate (NADPH):cytochrome p450 reductase as a source of reducing equivalents, and NADPH:biliverdin reductase (BVR) to convert biliverdin-IX $\alpha$  to bilirubin-IX $\alpha$ . Until the discovery of NO, and the elucidation of its roles in vascular signaling, endogenous CO was regarded by the scientific community as a waste product of metabolism. Increasing evidence supports the notion that, in a fashion similar to the NOS/NO axis, heme oxygenase (HO)-derived CO (HO/CO) also serves a critical role in vascular function, stimulating vasorelaxation while exerting inhibitory effects of platelet aggregation, SMC proliferation, EC apoptosis, and the macrophage-dependent

release of pro-inflammatory cytokines (Figure 111.1) (5). In addition to CO generation, antioxidative or protective roles of HO activity have been proposed based on heme removal, generation of antioxidant bile pigments, and/or alteration of iron metabolism (10). This chapter reviews the functional role of the HO/CO system in the vasculature relative to the various cellular constituents, with an emphasis on the regulation of vascular tone and proliferation.

### CELLULAR EFFECTS OF CARBON MONOXIDE (GENERAL MECHANISMS)

The known vascular effects of CO involve at least three general pathways, the activation of soluble guanylyl cyclase (sGC); the modulation of mitogen-activated protein kinases (MAPK) (5,11–16), including the upregulation of p38 $\beta$  MAPK; and/or the downregulation of extracellular-signal-regulated kinase (ERK)1/2. Additional potential mechanisms of CO action, including the activation of potassium channels and the inhibition of hemoprotein targets such as inducible NOS (iNOS) or cytochrome p450, have been proposed in the context of vasomotor tone and are discussed later. The antiapoptotic effects of low-dose exogenous CO were demonstrated in ECs and shown to depend on the activation of the p38 MAPK pathway and the upregulation of nuclear factor (NF)- $\kappa$ B-dependent antiapoptotic genes (16–17). The anti-inflammatory effects of HO-derived CO, demonstrated in vivo and in vitro, resulted from the p38 MAPK-dependent inhibition of pro-inflammatory cytokine production and stimulation of anti-inflammatory interleukin (IL)-10 in macrophages (12). Additional mechanisms for the anti-inflammatory effect of HO/CO include the modulation of adhesion molecule expression in ECs (18). The antiproliferative effects of CO were originally described as dependent on stimulation of cyclic guanosine 3',5'-monophosphate (cGMP) production in vascular SMCs (19), and also as involving the upregulation of p38 MAPK,

Figure 111.1. Theoretical role of HO isozymes and CO production in vascular cells. Vascular CO arises from the action of basal (HO-2) and inducible (HO-1) heme oxygenase activity. Vascular stress (from hemolysis) or toxins may cause elevation of EC HO activity, leading to EC-derived CO. Similarly, stress conditions (e.g., hypoxia, vascular injury) can cause an elevation of HO-1 in smooth muscle cells (SMCs), leading to increased SMC-derived CO. Regardless of the cellular source, CO can cause autocrine or paracrine effects on cGMP production. CO in ECs may exert antiapoptotic (by modulation of p38 MAPK and HSP70 expression) or anti-inflammatory consequences (by modulation of cellular adhesion molecule [CAM] expression) (102). CO relaxes vascular SMCs by inducing the production of cGMP and, in part, by activating calcium-dependent potassium channels. CO targeting the SMC has antiproliferative effects, also dependent on p38 MAPK activation and increased expression of p21 and caveolin-1. CO targeting macrophages has anti-inflammatory effects dependent on the downregulation of proinflammatory cytokine production and may also inhibit iNOS activation. RBC, red blood cell; BV, biliverdin.

p21<sup>Waf1/Cip1</sup>, and the tumor suppressor protein caveolin-1 (13–15). Finally, CO may act as a neurotransmitter and modulator of the circadian clock in the central nervous system via a sGC-dependent mechanism (reviewed in 5,14).

### HEME OXYGENASE ISOZYMES, PROPERTIES, AND DISTRIBUTION IN VASCULAR TISSUE

Three genetically distinct isozymes of HO have been characterized by Maines and colleagues: an inducible form, HO-1, and two constitutively expressed forms, HO-2 and HO-3, representing the products of distinct genes (20–30). Gene transcription of the inducible form HO-1 is induced in most cells and tissues to induction by exposure to various forms of chemical and physical stress (25). HO-1 contains a conserved heme-binding catalytic domain and a C-terminal hydrophobic region that allows integration with cellular membranes (31–32). HO-2, the constitutively expressed isoform, as originally characterized in testes, brain, spleen, and liver, occurs

abundantly in most tissues, including the nervous and cardiovascular systems (20–28). HO-1 and HO-2 proteins differ in physical properties, including  $K_m$  for substrate, primary sequence, and molecular weight (36 kDa vs. 32 kDa, respectively, in the rat) (22). Furthermore, the expression of HO-2 does not respond to induction by stress agents, but may be regulated by glucocorticoids (33). HO-1 and HO-2 share less than 50% amino acid homology, yet share a conserved domain of 24 amino acid residues (34). HO-2 contains two additional heme-binding domains distinct from the catalytic site, with unclear functionality (35). The existence and functional relevance of a third putative isozyme, HO-3, remains controversial (29–30). As originally characterized, HO-3 demonstrated a high degree of sequence similarity to HO-2 (~90%), but it is devoid of heme catalytic activity (29). The occurrence of HO-1 and HO-2 in vascular tissues, including endothelium and vascular smooth muscle, is consistent with the proposed roles for endogenous HO/CO in vasoregulation (26,36–39). A comparative analysis of relative HO-2 content in different vascular beds is, however, currently lacking.

## EVOLUTIONARY CONSIDERATIONS

The HOs display high degrees of amino acid conservation between human and rodent forms (i.e., approximately 80% amino acid homology between human and rat HO-1) (40). Proteins with functional HO activity have been identified in many species from bacteria, fungi, insects, birds, and mammals, to man. Variants of HO-1 have been described in plants such as *Arabidopsis thaliana* (41), the red algae *Cyanidium caldarium* (42), cyanobacteria (43), and in various strains of gram-positive or -negative bacteria (44–48). Recently a novel variant of HO-1, apparently with two catalytic domains, has been cloned and identified in *Escherichia coli* (48).

## ENDOGENOUS PRODUCTION OF CARBON MONOXIDE

HO-dependent heme degradation accounts for at least 86% of endogenous CO production in man, with the remaining assigned to non-heme metabolic sources (e.g., cytochrome p450 reactions, lipid oxidation) (49). The non-heme-dependent CO production may increase with exposure to certain xenobiotics (e.g., methylene chloride) (50). With respect to HO activity, hemoglobin accounts for the principal source of substrate heme in tissues specialized in erythrocyte or hemoglobin turnover, such as the liver and spleen. In cell types or tissues not directly engaged in erythrocyte or hemoglobin metabolism, HO enzymes act on a heme pool derived from the turnover of endogenous cellular hemoproteins (e.g., cytochromes) (18). The ubiquitous occurrence of HO isozymes suggests that CO originates in most systemic tissue types as the product of constitutive HO-2 activity (51). This basal production of CO likely increases in parallel with the induction of HO-1 during conditions of cellular stress or injury; however, the source of additional substrate heme under stress conditions remains incompletely understood.

## REGULATION OF HEME OXYGENASE-1

The induction of HO-1 represents a general transcriptional response to oxidative cellular stress in response to stimulation from diverse chemical and physical agents (52–54). The *Ho-1* gene promoter region (mouse) contains two upstream enhancer sequences (E1, E2) that occur at –4 kb and –10 kb (relative to the transcriptional start site), respectively (55–57). These enhancers mediate the transcriptional induction of the *Ho-1* gene by a majority of inducing agents, including endotoxins, heavy metal salts, phorbol esters, oxidants, and heme. E1 and E2 contain repeated stress responsive elements (StRE) consisting of recognition sequences for several transcription factors, including Cap'n'collar/basic-leucine zipper proteins, v-maf oncoprotein, and activator protein (AP)-1 (57). The binding of the NF-E2-related factor 2 (Nrf2) to StRE sites appears to represent a major mechanism for the

transcriptional regulation of *Ho-1* by stress, including heme, heavy metals, and polyphenolic antioxidants (58–61). Additionally, heme can derepress transcriptional activation of *Ho-1* by binding to the transcriptional repressor Bach1, inhibiting its DNA binding activity and promoting its nuclear export (62–63).

HO-1 can be potentially induced specifically in the vasculature by a variety of stresses, including heme released from vascular hemolysis, oxidized lipoproteins, proinflammatory cytokines and bacterial lipopolysaccharide (LPS), hemodynamic changes, angiotensin, and NO (37,64). In various vascular cell types, HO-1 may respond to changes in oxygen tension (e.g., hyperoxia, hypoxia) (65). Hypoxia and hypoxia-reoxygenation treatments can promote strong induction of HO-1 protein/activity in animal ECs (66) and vascular SMCs (67).

## VASCULAR RESPONSES TO INJURY IN TRANSGENIC AND KNOCKOUT MODELS

Experiments with transgenic or knockout mice have revealed the respective roles of HO-1 and/or HO-2 in various models of tissue injury (Table 111-1). For example, homozygous *Ho-1*-null mice (*Ho-1*<sup>-/-</sup>) displayed increased mortality in a model of lung ischemia-reperfusion (I/R) (68), and also developed right ventricular dilation and right myocardial infarction during chronic hypoxia (10% O<sub>2</sub>), relative to wild-type mice (69). However, *Ho-1*<sup>-/-</sup> did not differ in the development of pulmonary hypertension (69). Transgenic mice with a lung-specific HO-1 overexpressing phenotype resisted the inflammatory and hypertensive effects of hypoxia (70). *Ho-2*-null mice (*Ho-2*<sup>-/-</sup>), displayed increased sensitivity to the lethal effects of hyperoxia relative to wild-type mice, despite compensatory increases in HO-1 and accumulated iron in their lungs (71). Embryo fibroblasts with the *Ho-1*<sup>-/-</sup> genotype displayed hypersensitivity to heme and H<sub>2</sub>O<sub>2</sub> treatment and generated increased intracellular reactive oxygen species (ROS) production in response to these agents (72). In direct contrast, *Ho-1*<sup>-/-</sup> rats were found to be resistant rather than sensitive to the lethal effects of hyperoxia in vivo (73). The underlying mechanisms for these apparently conflicting observations remain unclear. However, collectively these studies have indicated that HO-1 and HO-2 play critical roles in the physiological distribution of cellular and tissue iron. Aberrant accumulation of tissue iron and low serum iron content have been described in both *Ho-1*<sup>-/-</sup> and *Ho-2*<sup>-/-</sup> transgenic mice (71,73–74). The *Ho-1*<sup>-/-</sup> mice were anemic, accumulated non-heme iron in the kidney and liver, but displayed reduced total iron content in the lung; whereas *Ho-2*<sup>-/-</sup> mice accumulated total lung iron without a compensatory increase in ferritin levels (71,73).

The central importance of HO-1 in tissue protection, as well as its potential clinical significance, was recently highlighted by the discovery of a child diagnosed with HO-1 deficiency, who exhibited extensive endothelial damage. The

**Table 111-1: Functionality of HO-1/HO-2 Isozymes as Determined by Knockout and Transgenic Mouse Models**

<i>Model</i>	<i>Observation</i>	<i>References</i>
<b>Human Deficiency</b>		
<i>HO-1</i>	Growth retardation, impaired iron metabolism (anemia, iron deposition) Chronic inflammation (renal tubular injury, liver fibrosis, endothelial injury) (anemia, iron deposition)	77, 103, 104 72, 74
<b>Knockout Mouse</b>		
<i>HO-1<sup>-/-</sup></i>	Loss of defense mechanism against oxidative stress Increased vascular cell proliferation and hyperplasia after vascular injury Increased mortality after lung I/R injury Susceptibility to chronic hypoxia (increased right ventricular dilation and right myocardial infarction)	82 68 69

subject suffered from persistent hemolytic anemia characterized by marked erythrocyte fragmentation and intravascular hemolysis, with increased serum haptoglobin and low bilirubin levels. An abnormal coagulation/fibrinolysis system was described, associated with elevated circulating levels of soluble thrombomodulin and von Willebrand factor (75). Growth retardation, anemia, iron deposition, and vulnerability to stressful injury are similar characteristics, as observed in *Ho-1* gene-deleted mice (74). The underlying mechanisms for the phenotypic observations of anemia and iron deposition in animals or humans genetically altered for content of HO enzymes remain unclear. In cell culture models, Ferris and colleagues have recently described an intracellular ATP-dependent iron pump whose functioning may depend on the presence of HO-1 (76).

#### THE ROLE OF HEME-OXYGENASE DERIVED CARBON MONOXIDE IN VASOMOTOR CONTROL

The physiological signaling effects of NO and CO known to date involve relatively few defined mechanisms. With respect to vasodilation, sGC represents the principal molecular target of NO, such that the binding of NO to the heme moiety of the enzyme results in activation and the increased pro-

duction of cGMP (77–78). In a similar fashion, CO binds to the heme iron center of sGC in an interaction that stimulates enzymatic activity. In a comparative study of the vasoactive effects of NO and CO in isolated rabbit aorta, exogenous CO produced an endothelial-independent vasorelaxant response, albeit with 1,000-fold less potency than NO under the same conditions (78). The vasodilatory properties of CO in the rabbit aorta were attributed to activation of sGC and generation of cGMP by CO, also with lesser potency than that of NO (78–79).

In cell culture experiments, endothelial-derived CO was shown to regulate cGMP production in vascular SMCs (19). The treatment of vascular SMCs directly with CO stimulated an increase in cellular cGMP levels. Exposure of these cells to hypoxia also resulted in increased levels of cGMP, an effect that was dependent on HO-1-mediated production of endogenous CO, but not NO (19). CO generated by SMCs in culture could likewise affect cGMP levels in cocultured ECs (80). Thus, CO potentially arises in all vascular cell types as the product of inducible HO activity, and it can act in an autocrine fashion at the site of generation, as well as in a paracrine fashion on other cell types distinct from the cells of origin.

The role of HO isozymes and/or CO in vasoregulation is highlighted by a series of ex vivo experiments using isolated aortic rings. The exogenous application of CO reduced

contractility of isolated aortic rings in a cGMP-dependent fashion (81). Furthermore, in isolated rings, the application of metalloporphyrin inhibitors of HO activity, in the presence of NOS inhibitors, typically reduced agonist-dependent vasodilation or augmented agonist-induced vasoconstriction (26,81). Adenovirus-mediated expression of HO-1 in porcine arteries *in vivo* resulted in attenuated vasoconstriction in subsequently isolated aortic rings in a cGMP-dependent fashion, also in the presence of NOS inhibitors (82). Although many such studies support that exogenous CO causes endothelium-independent vasodilation, recent studies have also proposed that CO may cause a competing endothelium-dependent vasoconstriction based on direct inhibition of endothelial NOS activity by CO (83).

In addition to cGMP-dependent mechanisms of CO-induced vasodilation, as described in aortas, several cGMP-independent mechanisms have been described. Limited studies have implied a potential role for the modulation of cytochrome p-450-derived species in vascular effects of CO (84). Furthermore CO can dilate the peripheral vasculature, in part by activating calcium ( $\text{Ca}^{2+}$ )-dependent potassium channels ( $\text{K}_{\text{Ca}}$ ) (85–87).

For example, CO induced an endothelial-independent vasodilation in precontracted rat tail arteries dependent partially on cGMP and partially on large-conductance  $\text{K}_{\text{Ca}}$  (87). CO caused hyperpolarization of SMCs by increasing outward  $\text{K}^+$  current, which in turn inhibited voltage-gated  $\text{Ca}^{2+}$  channels and caused smooth muscle relaxation (88). Furthermore CO increased the open probability and  $\text{Ca}^{2+}$  sensitivity of single  $\text{K}^+$  channels in SMCs (88). In renal intralobar arteries, the inhibition of HO-2 expression, and consequently endogenous CO production, led to a decreased number of open  $\text{K}^+$  channels in SMCs and increased vascular contractility, in a fashion reversible by exogenous CO (86). The vasodilatory action of CO observed in porcine cerebral arterioles (89) was further attributed to an increase in the effective coupling of  $\text{Ca}^{2+}$  sparks to  $\text{K}_{\text{Ca}}$  channels (85). The  $\text{Ca}^{2+}$  release of the channel blocker ryanodine, which inhibits  $\text{Ca}^{2+}$  sparks, also inhibited the CO-induced vasodilation (85). In line with this observation, the synthetic CO releasing molecule (CORM)-3 produces aortic vasodilation *ex vivo* and reduces blood pressure *in vivo* by modulation of cGMP production and  $\text{K}^+$  channel activity (90). The relationship between the sGC/cGMP pathway and  $\text{K}^+$  channel activity remains unclear, although recent studies in the carotid body demonstrate an association of HO-2 with the  $\text{K}^+$  channel and imply a direct effect of HO/CO on channel activity (91).

#### HEME OXYGENASE-1/CARBON MONOXIDE IN VASCULAR REMODELING

Vascular remodeling, defined as changes in the size and/or structure of the adult vasculature, not only mediates physiological adaptation and healing, but also can underlie the pathogenesis of major cardiovascular diseases, such as atherosclerosis

and hypertension. HO-1 induction appears to function as an adaptive response against these injurious stimuli. In support of this hypothesis, recent studies have shown that HO-1 or CO suppresses the neointima formation associated with chronic graft rejection and vascular injury (13,82,92). These effects were attributed in part to the inhibition of vascular SMC proliferation by exogenous or HO/CO (13,82). HO/CO also may exert anti-inflammatory effects (in macrophages), and derepress the fibrinolytic pathway at sites of vascular inflammation (13,68). Additionally, SMC-derived CO has been shown to exert indirect effects on SMC proliferation by downregulating the expression of endothelial-derived myogenic factors (80).

Recent reports regarding vascular remodeling also have revealed several important genes, including caveolin-1, involved in the pathogenetic process (93). Vascular injury in caveolin-1-deficient mice promotes exaggerated neointimal proliferation. Genetic ablation of caveolin-1 in mice stimulates SMC proliferation (neointimal hyperplasia), with concomitant activation of the p42/44 MAPK cascade and upregulation of cyclin D1 (93). This study prompted the investigation of the molecular relationships between HO-1 and caveolin-1. We and others showed that the activation of the p38 $\beta$  MAPK signaling pathway by CO led to an enhanced expression of caveolin-1 in fibroblasts and SMCs, which in turn mediated the increased expression of p21<sup>Waf1/Cip1</sup> and the downregulation of cyclin A, leading to growth arrest. The inhibition of intimal hyperplasia by CO treatment in a vascular injury model involved the enhanced expression of caveolin-1 in vascular SMCs (15).

#### HEME OXYGENASE AND CAVEOLAE

In addition to showing that HO/CO increases caveolin-1 expression, we recently demonstrated a negative feedback pathway in which caveolin-1 inhibits HO activity (Figure 11.2). Like eNOS, HO-1/HO-2 localize in part to the caveolae of ECs, and the activity of all three enzymes is modulated by caveolin-1 (94). In murine pulmonary artery ECs, HO-1, BVR, and NADPH:cytochrome p450 reductase (NPR) colocalize in plasma membrane caveolae (94). The induction of HO-1 by stress conditions or adenoviral-directed gene transfer increases the relative content of this protein in a detergent-resistant fraction containing caveolin-1. Inducible HO activity appears in plasma membrane, cytosol, and isolated caveolae. In addition, caveolae contain endogenous BVR activity, supporting the co-compartmentalization of both enzymes. Caveolin-1 physically interacts with HO-1, as shown by coimmunoprecipitation studies (94). HO activity dramatically increases in cells expressing caveolin-1 antisense transcripts, suggesting a negative regulatory role for caveolin-1 toward HO. Caveolin-1 expression attenuates LPS-inducible HO activity. Thus, caveolae may act as a platform for HO activity that potentially regulates the functional consequences of HO activity in signaling processes.

Figure 111.2. Model of HO-1 interaction with caveolae. HO-1 expressed in the endothelium by stress accumulates in the endoplasmic reticulum and also, in part, to plasma membrane caveolae. The mechanisms of translocation are not known. Caveolin-1, a resident and structural protein of the caveolae, binds to and inhibits the activity of both resident eNOS and HO-1, among other proteins. Caveolin-1 knockdown experiments show deregulation of HO activity, suggesting an inhibitory role for caveolin-1 on small gas production in the caveolae. CO (and/or NO) evolving from the caveolae may have both autocrine and paracrine effects on signaling (cGMP synthesis) and gene expression.

## BILE PIGMENTS IN ENDOTHELIUM

HO-derived biliverdin is subsequently metabolized to bilirubin by the enzyme BVR. Potential protective effects of bilirubin have been determined using *in vivo* studies. In a rat model of hyperbilirubinemia, jaundiced Gunn rats displayed a diminished appearance of plasma biomarkers of oxidative stress compared to their nonjaundiced counterparts. These experiments suggested that hyperbilirubinemia may confer an antioxidant benefit to the circulation (95). Similar studies have been conducted in Eizai rats, which are hyperbilirubinemic due to mutations in the canalicular organic anion transporter gene. In this model, hyperbilirubinemia protected against neuronal I/R injury following occlusion of the middle cerebral artery relative to wild-type normobilirubinemic controls (96). A reduced expression of HO-1 and other damage markers was observed at the site of I/R injury in hyperbilirubinemic animals.

## THERAPEUTIC APPLICATIONS

### Heme Oxygenase-1 Inducers with Distinct Functions

The hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) exert cholesterol-independent, pleiotropic actions that include anti-inflammatory and antioxidant effects. Grosser and colleagues have explored the role of HO-1 as a target and mediator of statin action. In cultured human umbilical vein ECs (HUVECs), simvastatin and lovastatin increase *HO-1* mRNA levels in a concentration-

and time-dependent fashion. The results show that HO-1 is a target of statins in ECs (97). Recently, potential antioxidants (e.g., vitamin E, polyphenolics) have received much attention as potential antiatherosclerotic agents. Among the polyphenols with health beneficial properties, resveratrol, a phytoalexin of grape, can protect the vascular wall from oxidation, inflammation, platelet aggregation, and thrombus formation (98). The protective properties of resveratrol have been attributed in part to HO-1 induction (98). Recently, the antiproliferative effects of rapamycin also have been associated with HO-1 induction (99).

### Carbon Monoxide Therapy

Several approaches have been used to investigate the therapeutic potential of CO, ranging from direct administration of CO gas to the use of prodrugs that generate CO upon metabolism (90,100,101). A novel approach involves the use of specific CO-releasing molecules (CORMs), which will release measurable, controllable, and effective amounts of CO into biological systems. Transitional metal carbonyls, coordinated around iron, manganese, or ruthenium, recently have been developed as CORMs that, under appropriate conditions, will release CO. Such molecules have been shown to provide cardioprotection in both *ex vivo* and *in vivo* experiments (100). To date, CORMs have been largely incompatible with biological systems, because they are only soluble in organic solvents or require preactivation by physical or chemical stimuli. However, the recent development of water-soluble CORMs has provided new opportunities to investigate the pharmacological

and biological features of CO without such confounding influences (101). CORM-3, a novel water-soluble CORM, recently has been used to confirm the cardioprotective actions of CO (90). These findings suggest that CORM-3 may have potential for use as a modulator of vascular function and hypertension.

#### KEY POINTS

- Endogenous HO/CO, in a fashion similar to NO, appears to play an important role in maintaining EC function.
- HO-1/CO exerts vasoactive properties by activating either the sGC/cGMP pathway or enhancing  $K_{Ca}$  channel activity.
- The therapeutic potential of HO-1/CO in vascular disease originates from its antiproliferative and cytoprotective (antiapoptotic and anti-inflammatory) activity.
- CO may conceivably be delivered to humans at therapeutic concentrations by inhalation of mixed gas. Additionally, the development of safe and potent prodrugs that can act as CO donors remains an area of active investigation.

#### Future Goals

- To gain knowledge of the intracellular signaling mechanisms by which CO controls vital cellular processes in the treatment of human disease
- To develop sensitive methods for the detection of CO production in vitro and in vivo, and to develop specific HO inhibitors as well

## Endothelial Eicosanoids

Kenneth K. Wu

*Institute of Molecular Medicine, The University of Texas Health Science Center at Houston*

Eicosanoids comprise a large array of small-molecular-weight compounds that are synthesized in almost all mammalian cells from an unsaturated fatty acid, arachidonic acid (AA), chemically known as eicosatetraenoic acid. Eicosanoids are not stored in cells, but are synthesized in cells in response to stimuli. Elevated intracellular calcium and activation of protein kinase C (PKC) as the result of cell activation represent two key signaling pathways that initiate eicosanoid production. These signaling molecules activate a group of phospholipase A<sub>2</sub> (PLA<sub>2</sub>), most notably the cytosolic PLA<sub>2</sub>, that catalyze the release of AA from membrane phospholipids (1,2). AA is metabolized to form eicosanoids by many enzymes, now classified into three enzymatic pathways: (a) cyclooxygenase (COX), (b) lipoxygenase (LOX), and (c) cytochrome P450 (CYP) (Figure 112.1). The COX pathway converts AA into classic prostaglandins (PG), namely prostacyclin (also known as PGI<sub>2</sub>) and thromboxane A<sub>2</sub> (TXA<sub>2</sub>). The LOX pathway is responsible for producing leukotrienes (LT) and 5-, 12-, and 15-hydroxyeicosatetraenoic acid (HETE) (3,4). The CYP pathway generates diverse epoxy eicosatetraenoic acid (EET) and dihydroxy eicosatetraenoic acid (di-HETE) products (5).

Intracellular eicosanoids are released into extracellular milieu, where they act in an autocrine or paracrine manner. They bind a specific family of membrane eicosanoid receptors and induce diverse cellular activities via selective signaling pathways (6). Evidence is emerging that certain eicosanoids that are produced in the cell bind directly to intracellular receptors, thereby eliciting their cellular actions. Eicosanoids possess multiple, diverse biological actions that regulate and mediate the physiological functions of many organs. They play major pathophysiological roles in human diseases including cardiovascular disorders, asthma, and cancer (7–9).

The vascular endothelium occupies a pivotal position in eicosanoid biosynthesis. It is capable of synthesizing eicosanoids via all three metabolic pathways, and the eicosanoids generated are involved in mediating and regulating a variety

of important physiological functions including vascular tone, blood cell reactivity, and vascular wall integrity.

### HISTORY

Prostaglandins were discovered independently, in 1933–1934, by Goldblatt (10) and von Euler (11). They described an endogenous depressor substance in human seminal fluid and prostate glands. The substance was named prostaglandin by von Euler (12), and was subsequently isolated by Berström and Sjövall in 1960 (13). The purified substance comprised two chemically related compounds that were named PGE<sub>1</sub> and PGF<sub>1 $\alpha$</sub> . Additional stable prostaglandins were isolated and their structures determined during the next several years by Berström, Samuelsson, and coworkers (14,15). All the purified compounds contain 20 carbons with unsaturated bonds. It was subsequently demonstrated that prostaglandins are biosynthesized from polyunsaturated fatty acids such as AA (C20:4 $\omega$ 6) (16,17). Prostaglandin endoperoxides PGG<sub>2</sub> and PGH<sub>2</sub> were identified in 1973–1974 (18,19), which led to the discovery of TXA<sub>2</sub> (20). Prostacyclin was discovered by Vane's group in 1976, as an antiaggregatory and vasodilatory substance produced by aortic tissues (21); its chemical structure was solved in the same year (22). The actions of PGI<sub>2</sub> on platelets and vascular smooth muscle cells (VSMCs) via cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA) signaling pathway was delineated in the late 1970s (23).

Prostaglandin H synthase (PGHS)-1 (also known as cyclooxygenase or COX-1) was purified to homogeneity during the late 1970s, and its cDNA was cloned about 10 years later (24,25). COX-2 (PGHS-2) was cloned independently during the early 1990s by two groups (26,27). PGI synthase (PGIS) was described as an enzyme of PGI<sub>2</sub> biosynthesis in arterial tissues during the late 1970s (21). It was purified about 10 years later (28), and its cDNA was cloned during the mid-1990s by two laboratories (29,30).

Leukotrienes and CYP metabolites were discovered during the 1980s (3,5).

Figure 112.1. Eicosanoid biosynthesis via COX, CYP, and LOX pathways. Key eicosanoids are shown. PG, prostaglandin; TXA<sub>2</sub>, thromboxane A<sub>2</sub>; HETE, hydroxyeicosatetraenoic acid; EET, epoxy eicosatetraenoic acid; LT, leukotrienes.

**EICOSANOID BIOSYNTHESIS IN ENDOTHELIAL CELLS**

Like other properties of the intact endothelium, eicosanoid synthesis varies among different types of endothelial cells (ECs). However, the nature and mechanisms of spatial and temporal regulation of eicosanoid generation in vivo remain poorly defined. In contrast, there is a wealth of information on eicosanoid synthesis derived from studies on umbilical vein ECs (HUVECs) and bovine aortic ECs (BAECs).

**Endothelial Eicosanoid Biosynthesis**

Major eicosanoids produced from PLA<sub>2</sub>-initiated AA metabolism in HUVECs and BAECs include 6-keto-PGF<sub>1α</sub> (a stable

metabolite of PGI<sub>2</sub>) and PGE<sub>2</sub> derived from the COX pathway, and 15-, 11-, and 12-HETE from the LOX pathway (31,32). PGD<sub>2</sub>, PGF<sub>2α</sub>, and 5-HETE are produced in smaller quantities. 12-hydroxyheptadecatrienoic acid (12-HHT) is invariably detected, which represents a nonenzymatic breakdown product of PG endoperoxides.

The eicosanoid profile produced by microvascular ECs is different from that produced by HUVECs or BAECs. The 6-keto-PGF<sub>1α</sub> level is much lower, whereas EETs from the CYP pathway are more abundant. Major CYP metabolites produced by microvascular EC include 14,15 and 11,12-EET as well as 14,15- and 11,12-di-HETE (33).

The synthetic enzymes that have been clearly demonstrated to be expressed in ECs are shown in Figure 112.2. As described earlier, the synthetic enzymes are classified into

Figure 112.2. Eicosanoid synthetic enzymes expressed in ECs. Enzymes are shown in circles. COX, cyclooxygenase; PGIS, prostaglandin I<sub>2</sub> (PGI) synthase; PGES, PGE<sub>2</sub> synthase; PGDS, PGD<sub>2</sub> synthase; CYP2C8 and 9; cytochrome p450 family 2C8 and 2C9; 12-LOX, 12-lipoxygenase; 15-LOX-1, 15-lipoxygenase-1.

three groups according to their synthetic steps. Enzymes in the first step comprise several PLA<sub>2</sub> isoforms, including calcium-dependent cytosolic PLA<sub>2</sub> (cPLA<sub>2</sub>), calcium-independent cytosolic PLA<sub>2</sub> (iPLA<sub>2</sub>), and secretory PLA<sub>2</sub> (sPLA<sub>2</sub>) (1). cPLA<sub>2</sub> in ECs has been characterized extensively. It is localized to the cytosol in resting ECs and, upon cell activation, is translocated to intracellular membranes where it is functionally coupled to COX, LOX, and CYP. COX-1 and COX-2 are expressed in ECs (2). COX-1 is constitutively expressed and may be induced by cytokines and tissue injury by two- to threefold (34). Analysis of its promoter function reveals that it has typical housekeeping gene features (35). By contrast, COX-2 is expressed in resting ECs at a very low level that is often not detectable by Western blots but may be detectable by flow cytometry (36). Its expression is induced by diverse agonists, including cytokines, growth factors, and shear stress (37).

Of the enzymes in the final step of the COX pathway, PGIS is constitutively expressed in ECs (29,30). Its promoter region is typical of a housekeeping gene (38). PGE synthase (PGES) comprises three isoforms: a constitutively expressed cytosolic PGES (cPGES) (39,40) and two inducible membrane-bound PGES (mPGES) (40). Expression of these isoforms in ECs has not been documented extensively. cPGES is probably constitutively expressed in ECs and is responsible for the production of basal PGE<sub>2</sub>. mPGES was reported to be expressed in brain ECs, in which it was coexpressed with COX-2 (41). Two isoforms of PGD synthase (PGDS) have been identified: the lipocalin-type (L-PGDS) and the hematopoietic type (H-PGDS) (42,43). L-PGDS is expressed in ECs and is considered to play a role in coronary artery disease (44). L-PGDS is likely to be responsible for the small amount of PGD<sub>2</sub> generated from AA in ECs.

The LOX enzymes in EC are expressed in low abundance, and their regulation remains controversial. For example, a low level of 15-LOX-1 is detectable in EC, where it was reported to be induced by interleukin (IL)-4 (45), but studies from *IL-4*<sup>-/-</sup> mice failed to support the essential role of IL-4 for 15-LOX-1 expression (46). Other LOX, including leukocyte-type 12-LOX, platelet type 12-LOX, and 5-LOX, have been reported to be constitutively expressed in ECs, and their levels are generally very low, in accord with the synthesis of low levels of corresponding HETEs (47–49).

Human ECs express several CYP enzymes including CYP2C8, -2C9, -2J2, and -2B1 (33,50,51). The CYP2C8 and -2C9 family of enzymes is considered to be largely responsible for the formation of vasorelaxing EETs (50,51).

### Endothelial Eicosanoid Synthesis by Transcellular Metabolism

Eicosanoids are produced not only from AA but also from an intermediate metabolite produced by blood cells that come in contact with ECs, a process called *transcellular metabolism*. This concept originated from work showing that PGI<sub>2</sub> is produced from platelet PG endoperoxides that are translocated

from platelets to ECs via platelet–EC interactions (52,53). Transcellular metabolism enables ECs to synthesize certain metabolites that cannot be produced from AA. One example is the EC synthesis of LTC<sub>4</sub> from leukocyte-derived LTA<sub>4</sub>. Because ECs express a very low level of 5-LOX, they do not produce detectable LTC<sub>4</sub>. However, they are capable of synthesizing LTC<sub>4</sub> from LTA<sub>4</sub>, because they express LTC<sub>4</sub> synthase (54).

### ACTIONS OF ENDOTHELIAL EICOSANOIDS

Existing data indicate that endothelial PGI<sub>2</sub>, EET, and 15-LOX products are physiologically and pathophysiologically important. Their actions are described in more detail in the following sections.

#### Prostacyclin

PGI<sub>2</sub> inhibits platelet aggregation induced by diverse physiological agonists by raising the platelet cAMP level in a paracrine manner (23). PGI<sub>2</sub> binds to a specific receptor, designated I type prostaglandin (IP) receptor, which belongs to the eicosanoid receptor superfamily (6). IP receptor is a seven-transmembrane G-coupled receptor. It is coupled to G<sub>s</sub> protein, which is, in turn, coupled to adenylyl cyclase. The cAMP generated by adenylyl cyclase binds and activates PKA and exerts inhibitory action on platelet reactivity. Enhanced PGI<sub>2</sub> production in ECs in response to exogenous insults probably plays an important role in suppressing platelet aggregation and maintaining a thromboresistant state. EC-produced PGI<sub>2</sub> relaxes VSMCs and controls the reactivity of blood leukocytes such as neutrophils, Th2 lymphocytes, and macrophages via the IP-receptor and PKA signaling pathway (55–57).

In addition to its IP receptor–mediated actions on platelets, leukocytes, and vascular cells, PGI<sub>2</sub> has been shown to bind peroxisome proliferator-activated receptor (PPAR) $\delta$  and activate PPAR $\delta$  transcriptional activity (58). COX-2–derived PGI<sub>2</sub> has been shown to defend renal interstitial cells from damage by hypertonicity (59). It was suggested that the cytoprotective action of PGI<sub>2</sub> is mediated by PPAR $\delta$  activation. However, the evidence provided in these studies is indirect (58,59). Neither study has provided clear evidence for the requirement of PPAR $\delta$  for the PGI<sub>2</sub> cytoprotective action. It is also unclear how PPAR $\delta$  activation by PGI<sub>2</sub> protects cells from damage. Because ECs constantly encounter environmental stresses from circulating blood, it is of major importance to determine whether PGI<sub>2</sub> protects endothelial survival in an autocrine fashion. It has been shown that ECs express IP receptors (60). However, no studies have reported on endothelial protection by PGI<sub>2</sub>. Preliminary results from our laboratory reveal that PGI<sub>2</sub> produced by gene transfer, or synthetic PGI<sub>2</sub> analogs such as carbaprostacyclin, protects HUVECs from hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>)–induced apoptosis. PPAR $\delta$  is constitutively expressed in HUVECs. Overexpression of PPAR $\delta$  enhances the antiapoptotic action of PGI<sub>2</sub>, whereas suppression of PPAR $\delta$  by small-interference RNA (siRNA)

renders HUVECs less resistant to H<sub>2</sub>O<sub>2</sub>-induced apoptosis. These preliminary data suggest that PGI<sub>2</sub> protects ECs from oxidant-induced apoptosis in a PPAR $\delta$ -dependent manner.

A major role that PGI<sub>2</sub> plays in blood vessels is to antagonize the action of TXA<sub>2</sub>. The TXA<sub>2</sub> produced primarily by platelets and, to a lesser extent, by monocytes induces platelet aggregation and causes vasoconstriction. It plays a key role in arterial thrombosis. PGI<sub>2</sub> antagonizes the actions of TXA<sub>2</sub> on platelets and VSMCs, thereby reducing thrombosis and vasoconstriction. Recent work from IP receptor and thromboxane-type prostaglandin (TP) receptor-deficient mice supports an essential role for PGI<sub>2</sub> in controlling TXA<sub>2</sub>-induced atherosclerosis and thrombosis (61).

PGI<sub>2</sub>, thus, plays critical roles in maintaining vascular integrity, conferring thromboresistance, and inhibiting vascular inflammation. Its production is dynamically regulated to meet the challenge from frequent vascular insults.

### Epoxy Eicosatetraenoic Acids

Several EETs are produced in ECs via the actions of CYP epoxygenases. CYP2C8 and -2C9 catalyze the conversion of AA to 14,15- and 11,12-EET and, in addition, CYP2C9 converts AA to 8,9-EET (62). CYP2J2 catalyzes the formation of 5,6-, 8,9-, 11,12-, and 14,15-EET (63). 11,12- and 14,15-EET possess vasodilating properties (64). The reported data indicate that they act directly on VSMCs to reduce contractility. However, 5,6- and 8,9-EETs may be converted via COX-2 pathway to form vasodilating or vasoconstrictive compounds (65). The mechanism by which EETs reduce VSMC contraction is not entirely clear. One common view is that EETs open the K<sub>Ca</sub> channels of VSMCs to facilitate release of K<sup>+</sup> into the extracellular milieu (66,67). It remains controversial whether the actions of EETs are receptor-mediated.

Several reports show that EETs possess anti-inflammatory actions (50). EETs prevent the adhesion of activated monocytes to vascular endothelium and 11,12-EET suppresses cytokine-induced expression of adhesive molecules, such as vascular cell adhesion molecule (VCAM)-1 and E-selectin, on the endothelial surface (50). EETs have been reported to mediate the proliferation of diverse cells including VSMCs and ECs (68). EETs increase intracellular calcium concentration and activation of mitogen-activated protein kinase (MAPK) pathway in ECs and VSMCs, suggesting that the anti-inflammatory and mitogenic actions may be mediated by these pathways (69). In summary, EC-derived EETs relax VSMCs, inhibit monocyte interaction with ECs, and mediate VSMC proliferation in a paracrine manner, and they induce EC proliferation in an autocrine manner.

### Lipoxygenase Products

There is considerable information regarding the role of murine 12/15-LOX (a homolog of human 15-LOX-1) in atherosclerosis. Murine 12/15-LOX is a multifunctional enzyme that cat-

alyzes the formation of 12-HETE and 15-HETE from AA, and 13S-hydroxyoctadecatrienoic acid (13S-HODE) from linoleic acid (4). Increased 12/15-LOX eicosanoids are reported to increase monocyte-endothelial interactions in diabetic mice and accelerate atherosclerosis in *ApoE*<sup>-/-</sup> mice (70). The deletion of 12/15-LOX by gene targeting reduces atherosclerosis (71). 15-LOX-1 is a human homolog of murine 12/15-LOX that catalyzes the formation of 15-HETE from AA and 13-HODE from linoleic acid. It was reported that overexpression of 15-LOX-1 increases atherosclerosis (72). These results suggest that 15-LOX-1 and 12/15-LOX play a role in atherosclerosis. However, the metabolites that are responsible for the atherosclerotic actions are not entirely clear.

It has been reported that 12-HETE derived from 12-LOX increases monocyte adhesion to human ECs (73). It is further shown that oxidized low-density lipoprotein (LDL) induces ECs to generate 12-HETE and 11,12-EET (74). The inhibition of 12-HETE suppressed LDL-induced monocyte adhesion to vascular ECs, consistent with the involvement of 12-HETE in monocyte-endothelial interactions.

### STIMULATION OF PROSTACYCLIN SYNTHESIS

PGI<sub>2</sub> is functionally and quantitatively the most important eicosanoid produced by ECs. Resting ECs produce a basal level of PGI<sub>2</sub> that maintains vascular homeostasis under physiological conditions. When ECs are stimulated by diverse agents, an increased level of PGI<sub>2</sub> is produced. Many physiological and pathological agents have been shown to stimulate PGI<sub>2</sub> production. Based on kinetic differences, two types of stimulation are noted: (a) rapid stimulation independent of new COX mRNA or protein synthesis, and (b) robust PGI<sub>2</sub> stimulation secondary to increased COX-2 expression. The mechanisms underlying these two types of stimulation are distinct and are described separately.

#### Rapid Stimulation of Prostacyclin Production by Histamine, Bradykinin, and Thrombin

It was discovered in 1977 that ECs are capable of producing PGI<sub>2</sub> (75). Histamine was subsequently shown to stimulate the production of PGI<sub>2</sub> in ECs (76). It was noted that histamine induces a rapid synthesis of PGI<sub>2</sub>, followed by a period of refractoriness to stimulation. Bradykinin, thrombin, and ionophore A23187 were also reported to stimulate EC production of PGI<sub>2</sub> in a similar manner (77). Kinetic analysis of 6-keto-PGF<sub>1 $\alpha$</sub>  production revealed a rapid response that reached a plateau at 10 minutes after the addition of histamine or thrombin (77). These physiological agonists stimulate PGI<sub>2</sub> production by a common signaling mechanism. They activate phospholipase C, which generates inositol triphosphate (IP3) and diacylglycerol (DAG). IP3 elicits an elevation of intracellular calcium levels, which induces cPLA translocation to the outer surface of nuclear envelope (NE) and endoplasmic reticulum (ER). There, it is functionally coupled to COX-1

(78), which is localized to the luminal membrane by hydrophobic interaction (79,80). PGIS is localized to ER and NE membrane through a single transmembrane domain, and the bulk of the enzyme is located at the cytosolic side (81). PGIS is colocalized with COX-1 in ECs (82). It is widely accepted that activated cPLA<sub>2</sub> catalyzes the release of AA from membrane phospholipids, and the released AA enters COX-1, where it is converted to PGH<sub>2</sub>. PGH<sub>2</sub> enters PGIS and is converted to PGI<sub>2</sub>. Although the functional coupling of cPLA<sub>2</sub>, COX, and PGIS implies a direct transfer of substrate and intermediate metabolite from one enzyme to the next within the NE and ER membrane, the precise mechanism by which PGI<sub>2</sub> is synthesized from AA remains to be elucidated.

PGI<sub>2</sub> production declines rapidly after stimulation with histamine, thrombin, and ionophore. A plausible explanation is that COX-1 has a short half-life once it participates in the catalytic reaction. It has been estimated that COX-1 has a half-life of about 10 minutes (83). The short half-life of COX-1 catalytic activity is attributed to the inactivation and degradation of COX-1 by reactive oxygen species generated by COX-1 (84). The kinetic analysis suggests that PGIS catalytic activity also has a short lifespan (85), which is explained by autoinactivation of PGIS during catalysis (85). The so-called "suicidal" autoinactivation of COX-1 is considered to be responsible for the refractory period that ECs experience after an episode of stimulation, because it takes hours for COX-1 to be resynthesized. Thus, the extent of PGI<sub>2</sub> production by ECs under the stimulation by vasoactive agonists is limited and transient.

#### **Sustained Prostacyclin Production Induced by Proinflammatory Cytokines and Growth Factors**

Numerous reports have shown that PGI<sub>2</sub> production induced by PMA, lipopolysaccharide (LPS), cytokines (e.g., IL-1 $\beta$ , tumor necrosis factor [TNF]- $\alpha$ ), and growth factors (e.g., platelet-derived growth factor) has a different time course from that produced by histamine, thrombin, and bradykinin. PGI<sub>2</sub> production is not detected until 30 to 60 minutes after the cytokine or growth factor stimulation, with levels reaching plateau at 4 to 6 hours and declining over a 12-hour period. In response to proinflammatory cytokines, the kinetics of PGI<sub>2</sub> production parallels that of COX-2, suggesting that a majority of PGI<sub>2</sub> is derived from COX-2. COX-2 shares a high sequence homology with COX-1; the key functional motifs, including the heme ligation site and substrate binding residue, are conserved. The x-ray crystallographic structure of COX-2 is also similar to that of COX-1 (79,80). Furthermore, a majority of COX-2 also is localized to NE and ER (82). The catalytic kinetics of COX-2 is also similar to COX-1 (2). A major difference between COX-2 and COX-1 resides in the robust expression of COX-2 induced by diverse proinflammatory and mitogenic factors (37). COX-2 proteins induced by proinflammatory mediators and mitogenic factors peak at 4 to 6 hours and return to baseline at 12 to 24 hours after stimulation, mirroring the kinetics of PGI<sub>2</sub> production. Consequently, the quantity of PGI<sub>2</sub> produced via the inducible COX-2 pathway is

several orders of magnitude higher than that via COX-1 pathway. PGI<sub>2</sub> overproduction signaled by cytokines and mitogenic factors is likely to play an important role in maintaining vascular integrity, thromboresistance, and normal vascular tone.

Good evidence suggests COX-2-mediated *in vivo* PGI<sub>2</sub> production in humans. PGI<sub>2</sub> synthesis in humans has been determined by measuring the excretion rate of 2,3-dinor-6-keto PGF<sub>1 $\alpha$</sub>  (86). It has been shown that urinary 2,3-dinor-6-keto-PGF<sub>1 $\alpha$</sub>  levels in healthy human subjects are suppressed by the administration of selective COX-2 inhibitors, thus suggesting that PGI<sub>2</sub> production in healthy humans is catalyzed largely by COX-2 (86). The urinary 2,3-dinor-6-keto-PGF<sub>1 $\alpha$</sub>  levels are elevated in patients with atherosclerosis (87), suggesting a compensatory production of PGI<sub>2</sub> by ECs, although the exact cell types that generate PGI<sub>2</sub> in atherosclerosis have not been clearly defined.

A majority of PGI<sub>2</sub> produced in atherosclerotic patients is COX-2-dependent, but COX-1 appears also to play a role in contributing to PGI<sub>2</sub> production (88). Because atherosclerotic tissues are enriched with cytokines and mitogenic factors, COX-2 expression probably is induced by a multitude of proinflammatory mediators. The role of increased PGI<sub>2</sub> production in atherosclerosis is unclear. Circumstantial evidence suggests that it may play an important protective role.

#### **Transcriptional Regulation of Cyclooxygenase-2**

The molecular basis for transcriptional upregulation of COX-2 by PMA, LPS, proinflammatory mediators, and growth factors has been studied extensively. The promoters of human and murine COX-2 genes are similar and contain a canonical TATA as well as a number of functionally important enhancer elements within 500 base pairs (bp) of the 5'-untranslated region (89–91). Transfection assays and DNA binding studies have led to the identification of several transactivators essential for the basal and inducible expression of COX-2 (92). Basal promoter activity in HUVECs is mediated by a cAMP response element (CRE), and a C/EBP enhancer element located at the proximal promoter region. These have been shown to bind CRE-binding protein (CREB) and C/EBP $\delta$ , respectively (93). CRE is required for promoter activation by proinflammatory mediators, and its mutation has been shown to abrogate the inducible expression of COX-2 (93,94). In addition to CRE, full induction of the COX-2 promoter requires binding of several transcriptional activators that cooperatively recruit p300 (95–97). Interestingly, the combination of transactivators varies according to the extracellular agonist. For example, PMA stimulates binding of CREB-2, c-Jun, and C/EBP $\beta$  to their respective enhancer elements, whereas TNF- $\alpha$ -mediated induction of COX-2 involves the inducible binding of p50-p65 nuclear factor (NF)- $\kappa$ B to both  $\kappa$ B enhancer elements of the COX-2 promoter/enhancer region. The binding activity of p50/p65 is regulated by post-translational modification. Work from our laboratory reveals that p50 is acetylated by the action of p300 histone acetyltransferase (HAT) activity, and that the

acetylated p50 exhibits an increased binding activity to COX-2 promoter (97). C/EBP $\beta$  comprises several truncated forms as the result of using different start codons for translation (98). Two of the truncated forms have opposite actions: the liver-transcription activating protein (LAP) truncated form binds and activates gene transcription, whereas a shorter liver transcriptional inhibitory protein (LIP) inhibits gene transcription (99). Full-length as well as LAP- and LIP-truncated forms of C/EBP $\beta$  are detected in ECs. At resting state, C/EBP $\beta$  has weak DNA binding activities due to the presence of an intramolecular inhibitory element that blocks the binding domain. Stimulation of cells by PMA results in phosphorylation of C/EBP $\beta$  by P90 ribosomal S6 kinase (100). The importance of C/EBP $\beta$  binding is underscored by the inhibition of C/EBP $\beta$  binding by aspirin and sodium salicylate (100,101).

### Prostacyclin Synthase

PGIS is constitutively expressed in ECs. Only a single copy of the gene has been identified (38). Its promoter region is TATA-less and GC-rich. It was reported to be inducible, but this has not been supported by solid evidence. PGIS is a cytochrome P450 protein, classified under family 8 (CYP8). It anchors to the ER and NE membrane via a single transmembrane domain, and the bulk of the enzyme is located in the cytosol. Topographic analyses reveal that its substrate entrance channel is close to the membrane surface, allowing rapid transit of the PGH<sub>2</sub> produced by COX to be metabolized into PGI<sub>2</sub> by PGIS (81). PGIS activity is suppressed by peroxynitrite generated from the interaction of nitric oxide (NO) with superoxide anion (102). Subsequently, it was shown that peroxynitrite induces the nitration of tyrosine 430 of PGIS, leading to reduced PGIS catalytic activity (103). PGIS nitration has been shown to have a pathophysiological relevance in experimental animals. It causes defective vasorelaxation of atherosclerotic bovine aortic arteries (104). It remains unclear whether PGIS is inactivated by endogenous peroxynitrite in ECs. Nevertheless, the negative regulation of PGIS activity by the cross-talk between NO, superoxide, and PGIS is likely to have important pathophysiological implications.

### PROSTACYCLIN AS A THERAPEUTIC AGENT

PGI<sub>2</sub> and its analogs have proved to be efficacious in treating pulmonary hypertension. It was reported that urinary levels of 2,3-dinor-6-keto-PGF<sub>1 $\alpha$</sub>  in patients with pulmonary hypertension was reduced, consistent with defective PGI<sub>2</sub> production (105). Defective PGI<sub>2</sub> production is probably due to inactivation of PGIS (106). In a randomized clinical trial, intravenous infusion of PGI<sub>2</sub> produced symptomatic and hemodynamic improvement when compared with conventional therapy (107). A long-term trial using aerosolized iloprost, a stable analog of PGI<sub>2</sub>, in patients with primary pulmonary hypertension revealed that iloprost improved exercise capacity and pulmonary hemodynamics (108).

There are reports on the beneficial effects of PGI<sub>2</sub> analogs in relieving the symptoms of peripheral vascular diseases. For example, oral beraprost, a PGI<sub>2</sub> analog, is effective in improving intermittent claudication (109). Similarly, a PGE<sub>1</sub> analog that acts via IP and EP receptors was reported to improve intermittent claudication from peripheral arterial disease (110).

### ENGINEERING EICOSANOID BIOSYNTHESIS AND FUNCTION BY GENE TRANSFER

Eicosanoids produced by ECs are dynamically regulated. A major factor that determines the level of eicosanoid synthesis is the cellular level of the synthetic enzymes for a given eicosanoid. Because PGI<sub>2</sub> is the key eicosanoid produced by ECs, with a high degree of functional relevance, we have used its biosynthesis as a model to investigate eicosanoid augmentation by gene transfer. COX-1, PGIS, and a bicistronic COX-1/PGIS (COPI) cDNAs were constructed in an adenoviral vector. HUVECs transfected with Ad-COX-1 (50 moi) were shown to produce a twofold increase in 6-keto-PGF<sub>1 $\alpha$</sub> , and a marked increase in PGE<sub>2</sub> when compared with those transfected with control vector (111). The endoperoxide product, 12-HHT, was increased by approximately 20-fold. These results suggest that, in the presence of COX-1 overexpression, PGIS is a limiting factor in PGI<sub>2</sub> production. This notion was confirmed by Ad-PGIS transfer, which increased 6-keto-PGF<sub>1 $\alpha$</sub>  by more than fivefold without an increase in PGE<sub>2</sub>, PGF<sub>2 $\alpha$</sub> , or 12-HHT (111). Results from Ad-PGIS experiments suggest that a limited COX-1 catalytic capacity exists, probably because of COX-1 autoinactivation. All the available PGH<sub>2</sub> generated from COX-1 is shunted into the overexpressed PGIS pathway.

To analyze the relationship between COX-1 and PGIS, HUVECs were transfected with Ad-COX-1 and Ad-PGIS at different viral titers, then assayed for eicosanoids. When Ad-COX-1 was fixed at 50 moi, increasing Ad-PGIS moi caused a selective augmentation of 6-keto-PGF<sub>1 $\alpha$</sub>  and a concurrent reduction in PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub> . At an equivalent moi (50:50), 6-keto-PGF<sub>1 $\alpha$</sub>  was the predominant product, with a level approximately 40-fold higher than Ad-PGIS alone. Surprisingly, when Ad-PGIS exceeded Ad-COX-1 (50 Ad-COX-1 to 100 Ad-PGIS) the 6-keto-PGF<sub>1 $\alpha$</sub>  level was reduced to less than 50% of that produced by an equivalent moi (50:50), whereas PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub>  levels remained unchanged. The results from the Ad-COX-1 and Ad-PGIS mixing experiments suggest a delicate relationship between COX-1 and PGIS in PGI<sub>2</sub> synthesis. Optimal PGI<sub>2</sub> production appears to require an appropriate molecular level of COX-1 and PGIS (111). To ensure that COX-1 and PGIS are co-overexpressed in the same cell, we transduced HUVECs with a bicistronic Ad-COPI (COX-1 and PGIS expressions are driven by identical but separate promoters). The results confirm an equivalent COX-1 and PGIS protein overexpression and a selective augmentation of PGI<sub>2</sub> production without a concurrent overproduction of other prostanoids.

Taken together, these results indicate that the level of eicosanoid production is determined largely by the protein levels of the synthetic enzymes. It is feasible to engineer cells for the selective augmentation of a given eicosanoid by co-overexpressing enzymes catalyzing the formation of that eicosanoid. This approach should be valuable for studying enzyme coupling and eicosanoid regulation. Furthermore, it has therapeutic potential, as demonstrated in its application to control brain ischemia–reperfusion injury, described next.

### Control of Brain Ischemia–Reperfusion Injury by Cyclooxygenase-1, Prostacyclin Synthase, Cyclooxygenase/Prostacyclin Synthase Gene Transfer

It has been reported that Ad-COX-1 or Ad-COPI gene transfer directly into brain before or after ischemia reduces infarct volume (112), and that Ad-PGIS gene transfer attenuates carotid artery restenosis (113,114). Although the protective effects of these gene transfer approaches are attributed to PGI<sub>2</sub> augmentation, other factors such as alteration of the balance between protective and damaging eicosanoids may contribute to the protective actions. To identify the factors that protect tissue survival by COX-1–based gene transfer, we administered Ad-COX-1, Ad-COPI, and control vector to rat brain via cerebral ventricular infusion before and after ischemia–reperfusion injury. Key eicosanoids in brain tissues were measured and correlated with infarct volume. Ad-COX-1 overexpression in nonischemic brain tissues increased PGI<sub>2</sub>, PGE<sub>2</sub>, PGD<sub>2</sub>, and TXA<sub>2</sub>, with a reduction in LTB<sub>4</sub> and LTC<sub>4</sub>. The eicosanoid profile in Ad-COX-1–transfected ischemic brain tissues was similar, except that TXA<sub>2</sub> was no longer significantly increased, and LTB<sub>4</sub> and LTC<sub>4</sub> were more significantly suppressed (112). Ad-COX-1 was effective in reducing infarct volume when administered before and even 5 hours after a 60-minute middle cerebral artery occlusion (112). The beneficial effect of COX-1 gene transfer was attributed to: (a) augmented PGI<sub>2</sub>; (b) augmented PGD<sub>2</sub>, which is converted 15-deoxy- $\Delta^{12,14}$  PGJ<sub>2</sub> (15d-PGJ<sub>2</sub>); and (c) reduced LTs.

The administration of Ad-COPI exerted a protective action similar to that of Ad-COX-1. However, its brain eicosanoid profile differed from that of Ad-COX-1 transfection. Consistent with the *in vitro* cellular data, Ad-COPI increased PGI<sub>2</sub> and decreased PGE<sub>2</sub>, PGD<sub>2</sub>, TXA<sub>2</sub>, LTB<sub>4</sub>, and LTC<sub>4</sub> (112). Thus, the beneficial effect of Ad-COPI was mediated primarily by an augmented PGI<sub>2</sub> production accompanied by suppression of damaging eicosanoids, notably LTB<sub>4</sub> and LTC<sub>4</sub>.

Using an identical protocol, the administration of Ad-PGIS reduced infarct volume only at 72 hours before ischemia. Its infusion at 24 hours or immediately before, and at 5 or 24 hours after ischemia was no longer protective. The brain eicosanoid profile in rats infused with Ad-PGIS 72 hours before injury revealed a highly increased PGI<sub>2</sub> without a significant change in other eicosanoids.

These experimental data validate a fundamental principle of eicosanoid biochemistry. It is feasible to engineer eicosanoid productions through the transfer of a single or multiple syn-

thetic enzymes. The gene transfer approach should be valuable for experimental studies and have important therapeutic implications. At present, gene therapy is limited because vectors for efficient and safe gene transfer remain unsatisfactory. However, when the vector problems are resolved, gene transfer to enrich protective and suppress proinflammatory eicosanoids should have the potential for treating diverse diseases, including ischemia–reperfusion injury.

### CONCLUSION

ECs are capable of synthesizing eicosanoids via COX, LOX, and CYP pathways. Functionally important eicosanoids include PGI<sub>2</sub>, EETs, and probably 15- and 12-HETE. Among EC eicosanoids, PGI<sub>2</sub> has been well characterized, and is probably the most important. It exerts diverse actions that are mediated by two receptors. The classic actions of PGI<sub>2</sub> on inhibiting platelet aggregation, VSMC relaxation, and leukocyte activation are mediated by a G<sub>s</sub>-coupled IP receptor, whereas the novel actions of PGI<sub>2</sub> – notably cell survival and proliferation – are mediated by the nuclear factor PPAR $\delta$ . PGI<sub>2</sub> defends ECs from apoptosis in an autocrine fashion, and controls blood and VSMC reactivity in a paracrine manner. PGI<sub>2</sub> in ECs is derived primarily from the COX-2/PGIS pathway (Figure 112.3). The inhibition of COX-2 abolishes PGI<sub>2</sub> production and results in loss of the protective mechanism and exacerbation of vascular diseases. Selective augmentation of PGI<sub>2</sub> by combined COX-1

Figure 112.3. Production and action of PGI<sub>2</sub>. PGI<sub>2</sub> production is catalyzed by COX-2, which is induced by physical and chemical agents shown by arrows. PGI<sub>2</sub> exerts multiple biological actions via PGI<sub>2</sub> receptor (IP) pathway and peroxisome proliferator-activated receptor  $\delta$  (PPAR $\delta$ ) pathway.

and *PGIS* gene transfer protects brain tissues from ischemia-reperfusion injury. EETs derived from CYP2C and CYP2J in ECs play an important role in relaxing VSMCs. Their mechanisms of action remain poorly understood. ECs produce 15-HETE and 12-HETE via 15-LOX-1 and 12-LOX. Their quantities are generally small relative to PGI<sub>2</sub> and PGE<sub>2</sub>, and their physiological and pathophysiological roles in humans require further investigation.

**KEY POINTS**

- COX-2-derived PGI<sub>2</sub> and CYP2-derived EETs are major EC eicosanoids.
- PGI<sub>2</sub> controls blood cell reactivity, VSMC contractility, and EC apoptosis by binding to IP and PPARδ receptors. EETs relaxes VSMCs.

*Future Goals*

- To determine whether selective augmentation of PGI<sub>2</sub> and other protective eicosanoids by gene transfer will be therapeutically beneficial for vascular diseases and tissue infarction
- To elucidate the mechanisms by which PGI<sub>2</sub> exerts antiapoptotic actions and EETs inhibit vascular constriction and inflammation

## Regulation of Endothelial Barrier Responses and Permeability

---

Joe G.N. Garcia

*Pritzker School of Medicine, University of Chicago, Illinois*

The endothelial cell (EC) lining of the systemic and pulmonary vasculatures was considered for decades to exist merely as an inert and passive semipermeable cellular barrier between the blood and the interstitium of all tissues. During the early 1960s, however, Majno and Palade described the ultrastructural appearance of an actively contracted endothelium in pulmonary vessels previously exposed to the edemagenic agent histamine (1), thus igniting a controversy over whether the endothelium plays an active role in the inflammatory response. It is now well recognized that endothelial activities are critical and essential aspects of inflammation. Disruption of the integrity of the endothelial barrier results in marked increases in permeability to fluids leading to tissue edema and pain (dolor), and leukocyte infiltration into tissues (rubor and calor). When persistent and of significant intensity, this process invariably progresses to organ dysfunction. For example, in systemic inflammatory states such as sepsis, increased vascular permeability results in high morbidity and mortality via multiorgan dysfunction, including acute renal or hepatic failure, cardiac dysfunction, and respiratory insufficiency.

Despite multiple attempts to improve upon the adverse clinical outcomes associated with increased endothelial permeability, the termination of fulminant edema with restoration of endothelial integrity remains an unrealized goal. Considerable progress in the past several years, however, suggests that several barrier-enhancing agents (or their selective derivatives with greater receptor selectivity) may be on the horizon for therapeutic purposes. It also should be noted that in selective vascular cells such as the cerebral circulation, the goal may be to actually increase permeability in order to increase the access of novel therapeutics across the blood–brain barrier (Figure 113.1). Nevertheless, barrier-enhancing agents hold considerable utility not only in a variety of inflammatory disorders, in which limitation of tissue edema is a goal, but also in diverse vascular pathologies (when inflammation is not the most prominent feature) such as tumor angiogen-

esis, ischemia–reperfusion injury, and atherosclerosis – vascular processes that exhibit vascular leak as a fundamental phenotypic element (2,3). The overlapping involvement of vascular permeability in broad biologic processes such as inflammation and angiogenesis is underscored by recalling that the potent angiogenic agent, vascular endothelial growth factor (VEGF), was first characterized as a vascular permeability–increasing factor (VPF) and only later was linked to its capacity to profoundly promote blood vessel growth. Developmentally, the genesis of new blood vessels (vasculogenesis) or extensions of existing vessels (angiogenesis) concludes with a critical terminal maturation event: the restoration of an intact vascular barrier from the nascent and inherently leaky vessel.

Given that these temporal- and stage-dependent alterations in endothelial permeability are key to the angiogenic process, it is not surprising that other angiogenic growth factors such as hepatocyte growth factor (4), angiopoietin 1 (5), and sphingosine 1-phosphate (S1P) (6), are now recognized as angiogenic mediators with potent barrier-enhancing properties. For example, S1P proved to be the most potent EC chemotactic in serum (7) and a complete angiogenic factor (i.e., does not require additional angiogenic cofactors) (6), while demonstrating a robust and sustained duration of barrier enhancement (2,6). The ligation of specific members of the endothelial differentiation gene (Edg) family of S1P receptors results in strong barrier enhancement *in vitro* and *in vivo* (6), whereas targeted deletion of the gene encoding the barrier-enhancing S1P<sub>1</sub> (also known as Edg1) receptor resulted in embryonic lethality due to progressive edema formation and hemorrhage because of an inability to establish functional barrier integrity (8). S1P is generated by numerous cell types but is the major barrier-protective agent released by platelets (9), and significantly attenuates thrombin-induced barrier disruption (2) while rapidly restoring barrier integrity in the isolated perfused murine lung (3). Furthermore, a single intravenous infusion of S1P given after intratracheally

Figure 113.1. (A) A number of maintenance processes ensure that vascular integrity is maintained and responsive to alterations in barrier integrity by initiating signals that restore the integrity of the vascular monolayer. These include low levels of shear stress, the negatively charged glycocalyx, and barrier-protective molecules released by circulating platelets such as sphingosine 1-phosphate. (B) Mechanisms of increased vascular permeability via transcellular and paracellular pathways. Bioactive agonists, growth factors, cytokines, and mechanical forces (high shear stress or cyclic stretch), as well as activated leukocytes, serve to activate the vascular endothelium. This produces cellular contraction and increased passage of fluid and cells through intercellular spaces into the interstitium to initiate organ dysfunction.

administered endotoxin, produced highly significant reductions in multiple indices of inflammatory lung injury including vascular leak in both murine and canine models of inflammatory lung edema (3,10). The underlying signaling mechanisms by which S1P increases vascular integrity is discussed later in the context of G-protein–dependent signaling cascades, cytoskeletal rearrangement, and enhanced junctional integrity and focal adhesion to the extracellular matrix (ECM). The identification of novel biologically compatible agents that can restore vascular integrity offers much promise for the future management of edema formation and organ dysfunction in the critically ill.

### REGIONAL DIFFERENCES IN ENDOTHELIAL CELL PERMEABILITY

ECs from different regions in the vasculature share many common features, but also exhibit site-specific properties. EC phenotypes vary between vessels of different caliber (e.g., large arteries vs. capillaries), between different organs (e.g., blood–brain barrier versus pulmonary vascular endothelium), and even between neighboring ECs (11,12). For example, pulmonary endothelium is of the continuous type, with the majority of fluid and solute exchange occurring at the level of the capillary and postcapillary microvascular endothelium

because this layer has the largest surface area (relative to other vascular beds) available for both diffusion and filtration. The albumin permeability value in cultured pulmonary microvessel ECs is about one-half to one-fifth of the values of similarly cultured cells from the mainstem pulmonary artery, a feature also noted in vivo (12,13). Interestingly, cells from microvessels are significantly more restrictive to sucrose and inulin, indicating that transport occurring via paracellular pathways is reduced to a greater degree than in cells from large vessels. Additional routes of albumin transport (i.e., vesicular transport or transcytotic transport) also are involved in albumin flux across lung microvessel endothelium (14). In addition, microvascular ECs proliferate at a higher level than do macrovascular ECs and retain phenotypically distinct calcium ( $\text{Ca}^{2+}$ ) and cyclic nucleotide signaling responses as well as oxidant-mediated signaling transduction (12).

Studies of ECs from different sites in the vasculature also have identified organ-specific antigens on capillary endothelium that are responsible in part for the different degrees of permeability of regional vascular beds with phenotypic differences in lectin-binding domains (15), although the correlation with barrier properties is not robust. The plasmalemmal membrane, vesicles, and paracellular channel structures also contain microdomains of anionic sites consisting of distributions of glycosaminoglycans, sialoconjugates, and monosaccharide residues. Heterogeneity in these cell surface glycoproteins, collectively known as the glycocalyx, has been described across various vascular beds and relate to the permeability characteristics of these vascular ECs in situ (16). For example, flux of albumin across glomerular capillaries is critically dependent on the negative charge of the capillary ECs and the ECM proteins constituting the basement membrane (17), with disruption of cell surface negative charge sites increasing "leakage" of albumin across the capillary-matrix complex. Because the glycocalyx in general, and heparan sulfate proteoglycans in particular, are now known to be directly linked to the endothelial cytoskeleton, these proteins may not only represent sensors for mechanical stress and cytoskeletal rearrangement, but also serve as endothelial-surface binding domains for inflammatory cationic peptides (18,19). This provides potential mechanistic insight for the recent observations that polymorphonuclear neutrophil (PMN)-derived cationic peptides are responsible for the increase in vascular permeability that evolves following EC interaction with activated PMNs (20).

### VASCULAR BARRIER REGULATION: MODIFIED TENSEGRITY MODEL<sup>1</sup>

Vascular permeability is mediated by two well-accepted pathways: a transcellular pathway that involves either vesicular transport or the formation of channels through the

endothelium, and a paracellular pathway with transport of fluid and cells occurring at the opening of intercellular junctions between neighboring ECs. The transcellular pathway utilizes a tyrosine kinase-dependent, gp60-mediated transcytotic albumin route whose regulation and function are unclear, but which may serve to uncouple protein and fluid permeability (14). However, there is general consensus that the primary mode of fluid and transendothelial leukocyte trafficking during inflammation occurs via the paracellular pathway, whose essential role in endothelial permeability has been well supported by an impressive body of research, including electron microscopy studies that demonstrate the formation of paracellular gaps at sites of active inflammation within the vasculature (1,21). The role of intercellular gaps in mediating paracellular permeability also has been determined by osmotically shrinking ECs. This process results in the formation of intercellular gaps and increased paracellular permeability, and is reversed by rehydration of the cells (22).

To study paracellular permeability, we have found it particularly useful to employ a working model of vascular barrier regulation, a modified tensegrity model, which highlights the critical importance of a delicate balance between ongoing EC contractile forces (which generate centripetal tension) and adhesive forces (generated by cell-cell and cell-matrix tethering) (Figure 113.2). Together, these competing barrier-regulatory forces govern changes in cell shape and permeability, with both contractile and tethering elements intimately linked to a complex network of endothelial cytoskeletal proteins (actin microfilaments, microtubules, intermediate filaments) that combine to regulate shape change and transduce signals within and between ECs. The EC cytoskeleton, as a result, is centrally involved in multiple endothelial biologic processes including angiogenesis, mechanotransduction, apoptosis, and critical elements of the inflammatory response, including leukocyte diapedesis and permeability to proteins. The fine tuning of these responses is governed by the over 80 actin-associated proteins (actin-binding, -capping, -nucleating, -severing proteins) identified that participate in cytoskeletal rearrangement, tensile force generation, and the regulation of cell shape, adhesion, and orchestrated cell migration, as well as endothelial junctional stability (23).

### ENDOTHELIAL BARRIER REGULATION: ROLE OF THE CONTRACTILE APPARATUS

Over the past two decades, it has become increasingly clear that ECs contain an abundance of the molecular machinery necessary to generate tension via an actomyosin motor. The actin microfilament cytoskeleton, normally peripherally distributed as cortical bands in orientation to directional blood flow, is essential for the maintenance of endothelial integrity and basal barrier function. Contributing to basal barrier function and cell-cell adhesion is the presence of phosphorylated regulatory myosin light chains (MLC) within the loose subcortical actin mesh. MLC phosphorylation is catalyzed

1 The original tensegrity model was proposed by Ingber and Wang (Wang N, Butler JP, Ingber DE. *Science*. 1993;260[5111]:1080-1); also see Inger DE. Cellular tensegrity: defining new rules of biological design that govern the cytoskeleton. *J Cell Sci*. 1993;104, 613-627.

Figure 113.2. Modified model of tensegrity. In this working model of EC barrier regulation, under basal conditions, a balance exists between actomyosin contractile and cellular adhesive forces. When contractile forces predominate, as depicted in the thrombin-stimulated model in the left panel, ECs pull apart to form paracellular gaps, favoring barrier disruption. Thrombin cleavage of the labeled PAR-1 receptor on the surface of ECs, activates both heterotrimeric G-proteins ( $G_q$ ,  $G_{12/13}$ ) as well as small GTPases such as Rho. Activated Rho (Rho-GTP) induces Rho kinase, which via phosphorylation of the phosphatase regulatory subunit, inhibits MYPT. Rho kinase and MLCK activation occurs via independent pathways. Increased cytosolic  $Ca^{++}$  (via IP3 production) activates the  $Ca^{++}$ /calmodulin-dependent MLCK, with conformational changes allowing the enzyme to access the preferred substrate (MLC). Rho kinase and MLCK activation both culminate in increased MLC phosphorylation which, in turn, enables actomyosin contraction and results in increased stress fiber formation, cellular contraction, paracellular gap formation, and ultimately barrier dysfunction. In balance with these contractile forces, agents such as sphingosine 1-phosphate, a platelet-derived lipid growth factor, serve to maintain barrier function via increased cell–cell adhesion. S1P ligates  $S1P_1$ , resulting in the activation of the small GTPase Rac, a signaling cascade that results in cytoskeletal rearrangement and increased cortical actin with increased linkage to the adherens junction and focal adhesions. Rac activation initiates intracellular events dependent on specific PKC isotypes; PAK; LIM kinase; the actin severing protein, cofilin; and MLCK, which all contribute to increased cell–cell and cell–matrix tethering. These are spatially defined by recruitment to lipid rafts.

by the  $Ca^{2+}$ /calmodulin (CaM)-dependent serine/threonine MLC kinase (MLCK). Gene expression studies have demonstrated that the EC *MLCK* gene (*MYLK* is the gene name) is differentially expressed between micro- and macrovascular ECs (24), with more abundant expression in the microvascular endothelium. We have reported that several single nucleotide polymorphisms in *MYLK* confer increased susceptibility to sepsis and acute inflammatory lung injury (25). Direct activation of MLCK is sufficient to produce EC contraction via inducing actin stress fiber formation, barrier dysfunction, and EC permeability (25). This effect is significantly atten-

uated by treatment with MLCK inhibitors (26–28). In addition, MLCK inhibition prevents transforming growth factor (TGF)- $\beta$ 1-stimulated EC permeability (29), abolishes barrier dysfunction in rat lung models of ischemia–reperfusion injury (30), and attenuates ventilator-induced lung permeability (31). MLCK activities are tightly coordinated with the function of the small GTPase, Rho, in regulation of the contractile apparatus through its downstream effector, Rho kinase (32). Rho activation leads to phosphorylation of the myosin binding subunit of MLC phosphatase (PP1) by Rho kinase, thereby inhibiting phosphatase activity and

resulting in increased levels of MLC phosphorylation, actomyosin interaction, stress fiber formation, and subsequent EC barrier dysfunction. The inhibition of either MLCK activity or Rho activation attenuates thrombin-induced EC barrier dysfunction (23). Rho/Rho kinase and MLCK may also differentially regulate MLC phosphorylation according to spatial localization.

Another critical function of the EC barrier is the regulation of PMN margination and migration into sites of acute inflammation, a complex process involving specific recognition molecules and cytokine/chemokine signaling to the cytoskeleton evoked by PMN interaction with ECs. Activation of the EC contractile apparatus by PMN adherence and diapedesis also involves MLCK activity, as indicated by the increased MLC phosphorylation after PMN–EC interaction and the observation that reduction in MLCK activity significantly attenuates leukocyte migration (33,34). Furthermore, disruption of either the actin cytoskeleton with cytochalasin B or stabilization of microtubules with paclitaxel decreases transendothelial movement, whereas disassembly of microtubules increases leukocyte migration (23). Overall, this provides a mechanistic linkage between permeability to solutes, permeability to fluids, and permeability to cells.

#### MODEL OF ENDOTHELIAL BARRIER REGULATION: ROLE OF JUNCTIONAL AND MATRIX ADHESION

Under homeostatic conditions, the EC cytoskeleton is focally linked to multiple membrane adhesive proteins within two intercellular complexes – adherens junctions and tight junctions. Adherens junction assembly and stabilization is essential for the maintenance of EC barrier function, with the greater complexity of the intercellular junctions (i.e., more complex involvement of adherens junction proteins) potentially accounting for the significantly lower permeabilities to small and large proteins observed in pulmonary microvessel ECs. Adherens junction complexes in ECs consist primarily of cadherin proteins bound together in a homotypic- and  $\text{Ca}^{2+}$ -dependent fashion to link adjacent ECs. The cytoplasmic tails of the cadherins are intimately linked to the actin cytoskeleton via complexes of proteins including  $\alpha$ -,  $\beta$ -, and  $\gamma$ -catenin and p120. Together, these complexes result in decreased permeability to fluid and solute both in vitro and in vivo (35). The primary adhesive cadherin protein present in endothelial adherens junctions is vascular endothelial (VE)-cadherin, which is essential for the maintenance of EC barrier integrity, as demonstrated by increased vascular permeability induced in mice after infusion of VE-cadherin blocking antibody (35). Leukocyte binding to ECs causes a disruption of adherens junctions, with the disappearance of VE-cadherin and catenin staining in cell–cell contacts (23,35). Adherens junctions appear integral to this process because VE-cadherin blocking antibodies increase PMN diapedesis, while conversely tight junctions remain intact during this migration. Both intracellu-

lar  $\text{Ca}^{2+}$  and tyrosine phosphorylation pathways are involved, because activated PMNs increase  $\text{Ca}^{2+}$  and the phosphotyrosine content of VE-cadherin and  $\beta$ -catenin in association with adherens junction disruption and hyperpermeability (23).

Tyrosine phosphorylation may provide an additional regulatory link between actin cytoskeletal rearrangement and adherens junction function, because the antiadhesive protein, thrombospondin (TSP)-1 induces tyrosine phosphorylation of adherens junction proteins, actin rearrangement with stress fiber formation, and increased albumin flux across EC monolayers, whereas tyrosine kinase inhibition attenuates these effects. Thrombin alters the dissociation of the tyrosine phosphatase SHP2 from VE-cadherin complexes to produce increased levels of tyrosine phosphorylation of catenins and subsequent destabilization of adherens junction linkage to the cytoskeleton. Site-directed mutagenesis studies have tightly linked  $\beta$ -catenin phosphorylation on tyrosine residues with EC junctional integrity, consistent with a minimal level of basal tyrosine phosphorylation necessary for the maintenance of cell–cell contacts.

Tight junctions, consisting of a complex of proteins that include the claudins, occludin, and junctional adhesion molecule (JAM)-1, also interact with cytoskeletal actin (23). Tight junctional transmembrane proteins also include the zona occludens (ZO) family, which appear to participate in signal transduction and provide a link between occludin and the actin cytoskeleton with colocalization of polymerized actin (also referred to as F-actin) and ZO-1. Alterations in tight junctions may be signaled through the mitogen-activated protein kinase (MAPK) pathway, because both VEGF and hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) induce occludin dissociation from cell junctions and produce EC barrier dysfunction, which is partially blocked by MAPK inhibitors (23).

Although alterations in EC permeability depend largely on the function of intercellular adhesions, focal contacts that exist between the EC and the underlying matrix (focal adhesions) also provide additional adhesive forces in barrier regulation contributing approximately 20% of the resistance to transvascular permeability (36). Focal adhesions form functionally dynamic bridges for bidirectional signal transduction between the actin cytoskeleton and the cell–matrix interface; these bridges are comprised of ECM proteins (collagen, fibronectin, laminin, vitronectin, and proteoglycans), transmembrane  $\alpha$ - and  $\beta$  integrin receptors, and cytoplasmic focal adhesion plaques (containing  $\alpha$ -actinin, vinculin, paxillin, and talin). The core matrix proteins, because of their position and points of contact with ECs, may determine cell–substratum adhesion and thereby determine vascular permeability in normal conditions and in response to inflammatory mediators such as tumor necrosis factor (TNF)- $\alpha$ . Extracellular stimuli can be transmitted to the cytoskeleton through focal adhesion rearrangement linked to integrin ligation; antibodies to  $\beta_1$  integrin alter EC attachment, cell spreading, and permeability. Integrin binding to the ECM induces the attachment of integrins to intracellular actin fibers, a process that stimulates tyrosine phosphorylation of multiple focal adhesion proteins

(focal adhesion kinase [FAK], cortactin, and paxillin) as well as tyrosine phosphorylation-dependent  $\text{Ca}^{2+}$  influx.

In addition to cues derived from cytoskeletal integrin linkages, the ECM also can be remodeled by EC-released proteases, causing ECs layered upon this matrix to exhibit compromised monolayer integrity. Specific patterns of focal adhesion distribution and altered interactions between constituent focal adhesion proteins (including FAK, G-protein-coupled receptor kinase interacting [GIT]-1, GIT2, and paxillin) are associated with EC contraction and barrier dysfunction. In quiescent cells, FAK and paxillin are both distributed between the cytosol and focal adhesions. As discussed later, EC barrier function is increased by S1P, which induces partial disassembly of pre-existing focal adhesions coincident with the transient association of GIT1 with FAK, followed by translocation of FAK and paxillin from the cytosol to the cell periphery. FAK, paxillin and GIT2 are incorporated into new peripheral focal adhesions that are linked to the newly reinforced cortical actin ring (37,38). Integrin binding also targets activated extracellular-signal-regulated kinase (ERK) to newly formed focal adhesion sites. Reciprocally, intracellular signaling pathways that regulate cytoskeletal rearrangement also can modulate cell-matrix contacts. Rho inhibition dissociates stress fibers from focal adhesions, decreases the phosphotyrosine content of paxillin and FAK, and enhances EC barrier function (36). Similarly, v-Src-induced tyrosine phosphorylation of focal adhesion proteins is a well-established stimulus for the disassembly of these adhesive structures (36). Further studies to clarify the role of barrier-protective and barrier-disruptive tyrosine kinases in both focal adhesion and adherens junction complexes will increase our understanding of EC barrier regulation by tethering forces.

### THROMBIN MODEL OF INCREASED VASCULAR PERMEABILITY

A variety of bioactive agonists, cytokines, growth factors, and mechanical forces alter pulmonary vascular barrier properties through overlapping yet often distinct mechanisms and serve to increase vascular permeability. The serine protease thrombin represents an ideal model for the examination of agonist-mediated EC activation and barrier dysfunction, because this agonist evokes numerous EC responses that regulate hemostasis, thrombosis, and vessel wall pathophysiology. The effect of thrombin on permeability is mediated by the protease-activated receptor, (PAR)-1. Thrombin ligates and proteolytically cleaves the extracellular  $\text{NH}_2$ -terminal domain of PAR-1. The cleaved  $\text{NH}_2$ -terminus functions as a tethered ligand, activating the receptor and initiating a number of downstream effects, including the activation of phospholipases  $\text{A}_2$ , C, and D; increases in cytosolic  $\text{Ca}^{2+}$ ; release of von Willebrand factor (vWF), endothelin, nitric oxide (NO), and prostacyclin ( $\text{PGI}_2$ ). Thrombin binding alone, without receptor cleavage, is insufficient to elicit the complex signaling cascade that results in increased endothelial permeability. The effect of thrombin

on EC permeability is rapid (within 2 minutes) and reversible, and is critically dependent on G-protein-transduced signals that result in increases in cytosolic  $\text{Ca}^{2+}$ , activation of the contractile apparatus, and characteristic alterations in the cytoskeletal elements, such as marked increases in actin stress fibers. These effects have been confirmed using fluorescent microscopy and biophysical measurements (23). Critical to the increase in vascular EC permeability is a rise in intracellular  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_i$ ), with significant endothelial heterogeneity in the magnitude of this response (12) (i.e., differences in spatially defined  $\text{Ca}^{2+}$  response dictate site-specific differences in permeability).

Consistent with the modified tensegrity model, EC gap formation and permeability evolves via an increase in intracellular tension, with the activated actomyosin contractile apparatus leading to thrombin-induced EC permeability, disruption in the integrity of paracellular adherens junctions, and reorganization of focal adhesion plaques. In addition to  $\text{Ca}^{2+}$ -dependent MLCK and Rho kinase activation, thrombin also induces coordinate increases in protein kinase C ( $\text{PKC}\alpha$ ,  $\zeta$ ) and p38 MAPK activities. These latter pathways can be evoked by edemagenic agents or mechanical signals, which does not necessarily result in an overall increase in the levels of MLC phosphorylation. PKC-mediated signaling pathways exert a prominent effect on barrier regulation (both protection and dysfunction) in a time- and species-specific manner (39). PKC is able to increase MLC phosphorylation at sites distinct from MLCK-mediated phosphorylation (Ser<sup>19</sup>, Thr<sup>18</sup>). This does not produce an overall increase in MLC phosphorylation or an increase in the formation of actin stress fibers. PKC activation also causes increases in the myosin phosphatase known as myosin light chain phosphatase (MYPT). These phosphatase activities are directed specifically to MLC residues Ser<sup>19</sup>/Thr<sup>18</sup> (39). Therefore, PKC-mediated increases in bovine EC permeability may occur through the phosphorylation of caldesmon, an actin-, myosin-, and calmodulin-binding protein, whose phosphorylation in smooth muscle alters actomyosin cross-bridges (40). Caldesmon distributes along stress fibers in a process that reflects the actin- and CaM-binding domains in caldesmon (40), and it is phosphorylated in ECs after thrombin and PMA challenge (23). Caldesmon-mediated regulation of actomyosin adenosine triphosphatase (ATPase) in smooth muscle also is modified by the actin cross-linking proteins filamin and gelsolin (23). Although filamin participates directly in barrier regulation through CaM kinase II activation, its effects on actin cytoskeletal rearrangement are regulated through Rho family GTPases, thereby providing another link with a known modulator of EC barrier function.

Unlike thrombin,  $\text{TNF-}\alpha$  induces slow-onset barrier disruption that is independent of MLCK activity (23) but requires p38 MAPK activation; this also has been linked to contractile regulation in EC migration and lipopolysaccharide (LPS)-induced EC permeability (23,41). The mechanism through which p38 MAPK exerts these effects is unclear but may involve the actin-binding protein HSP27, a known p38 MAPK target whose actin polymerization-inhibiting activity dramatically

decreases after phosphorylation in association with stress fiber development (41,42).

In the model of thrombin-induced endothelial permeability, focal adhesions remodel to withstand increased mechanical loading from contracting actomyosin stress fibers. Thrombin induces novel focal adhesion signaling, including increased association of GIT1 and GIT2 with FAK and paxillin, prominent FAK phosphorylation (at Y<sup>397</sup>, Y<sup>576</sup>, and Y<sup>925</sup>), partial localization of GIT1 along the actin stress fibers (37,38), and rapid redistribution of focal adhesion proteins to the ends of stress fibers, with a temporal sequence similar to thrombin-induced alteration in EC permeability (37,38). As focal adhesions in adherent ECs normally undergo a constant basal rate of turnover that accelerates with cell activation, the elevated and sustained association of GIT1 with paxillin may reflect accelerated focal adhesion turnover in both barrier-promoting and barrier-disrupting models as GIT1 participates in focal adhesion disassembly. Src-kinase, which also participates in contractile regulation via phosphorylation of MLCK (43), is likely also involved in thrombin-induced focal adhesion rearrangement. Src-kinase inhibitors (PP2) blocked thrombin-induced FAK Y<sup>397</sup> phosphorylation but failed to alter phosphorylation at Y<sup>576</sup> and Y<sup>925</sup> or thrombin-induced FAK localization and stress fiber formation, implicating other tyrosine kinases in the response to thrombin (37,38). The inhibition of FAK attenuates the permeability response to VEGF in coronary venular ECs, further validating the functional role for focal adhesion complexes in EC barrier modulation.

### MECHANICAL STRESS, SIGNAL TRANSDUCTION, AND VASCULAR BARRIER REGULATION

In addition to the activation of the contractile apparatus by receptor-mediated pathways, mechanical signals also are transduced to the EC cytoskeleton and trigger complex alterations in junctional and matrix protein gene expression (36). The study of ECs in static cultures, although providing the opportunity to mechanistically evaluate the role of cytoskeletal components in physiology, has major limitations given that the endothelium in its native state is continuously exposed to mechanical forces that greatly influence cellular structure and function. Mechanical shear stress in the range of 1 to 10 dynes/cm<sup>2</sup> has been associated with increased monolayer integrity and barrier enhancement (44). Shear stress activates signaling pathways and leads to the upregulation of transcription factors and subsequent gene expression of various vasoactive substances, growth factors, and adhesion molecules (36). Active cytoskeletal rearrangement begins rapidly and continues to occur over several hours as ECs realign to reduce both peak shear stresses and shear stress gradients. The cellular mechanisms for sensing flow and transducing its signal are still unclear, but are believed to involve both apical actin stress fibers linked to cell-cell contact sites and integrin-mediated signal transduction.

When exposed to shear stress, ECs in static culture demonstrate altered signaling associated with cytoskeletal rearrangement, including Ca<sup>2+</sup> mobilization, G-protein activation, increased tyrosine phosphorylation, and MLCK and MAPK activation (44). These pathways interact downstream to produce the complex cellular effects of flow. For example, during shear stress, the GTPases Rho and Cdc42 combine to activate MAPKs, whereas individually, Rho is necessary for flow-induced stress fiber formation and cell alignment and Cdc42 activates transcription factors. The integrated effects of these shear-induced signals on EC barrier function are variable depending on the magnitude, duration, and gradient of flow. Exposure of human pulmonary ECs to laminar shear stress (15 dyn/cm<sup>2</sup>) results in a peripheral accumulation of focal adhesions, whereas cyclic stretch (18% elongation) induces randomly distributed focal adhesions attached to the ends of newly formed stress fibers (45,46). Shear stress activates small GTPase Rac without effects on Rho, whereas 18% cyclic stretch activates the Rho GTPase without affecting Rac. Shear stress-mediated increases in transendothelial electrical resistance was further elevated by challenge with S1P (46). Shear stress also induced FAK phosphorylation at Y<sup>397</sup> and Y<sup>576</sup>, whereas cyclic stretch induced FAK phosphorylation at Y<sup>576</sup> (46). This suggests that mechanical and chemical factors share the signaling and cytoskeletal mechanisms involved in EC barrier regulation with differential effects of shear stress and cyclic stretch on Rho and Rac activation, focal adhesion redistribution, and site-specific FAK phosphorylation.

Shear stress maximally increases the protein expression of integrins after 12 hours of exposure, and it significantly enhances cell-matrix attachment, suggesting that flow helps maintain the EC monolayer through the augmentation of focal adhesions. However, ECs exposed to high shear gradients, or turbulent flow, develop increased permeability relative to areas of either constant, laminar flow or no flow. The majority of these studies have been performed using ECs from the systemic circulation, and any potential differences in pulmonary EC responses to flow are not well understood. Although the mechanism for this signal transduction is not well understood, the complex array of proteins that constitute the lung endothelial glycocalyx are likely involved and behave as viscoelastic anionic polymers, undergoing shear-dependent conformational changes that may function as blood-flow sensors to transduce signals into ECs. One mechanism by which shear stress may alter barrier function is through inhibiting EC apoptosis, although recent work using a TNF- $\alpha$  model under static conditions suggests divergent processes are involved in cytokine-induced apoptosis and permeability (23).

### SPHINGOSINE 1-PHOSPHATE MODEL OF VASCULAR BARRIER RESTORATION

Despite significant progress in our understanding of the molecular and cellular events regulating increased permeability, the mechanisms of vascular barrier restoration are less

Figure 113.3. EC cytoskeletal rearrangement induced by thrombin and sphingosine 1-phosphate (S1P). These immunofluorescent images utilizing Texas red-conjugated phalloidin to identify polymerized actin filaments and focal adhesion kinase demonstrate that relative to controls, human pulmonary artery ECs stimulated with thrombin demonstrate a prominent increase in actin stress fibers associated with cell contraction and evidence of paracellular gaps (*small arrows*), with focal adhesions at the end of the actin cords. In contrast, EC stimulated with Sph-1-P reveal prominent cortical actin enhancement, a relative paucity of central stress fibers, and no paracellular gaps. Focal adhesion remodeling is associated with the cortical actin ring, as evidenced by the strong colocalization of these proteins. For color reproduction, see Color Plate 113.3.

well understood, and therapeutic agents for modulating barrier function in a clinically advantageous way remain elusive. Historically, increasing the level of cyclic nucleotides has represented the sole strategy for reducing the edema phase observed in inflammatory syndromes. Increases in intracellular cyclic adenosine monophosphate (cAMP) concentrations decrease vascular endothelial permeability and inhibit the permeability-increasing effects of thrombin and histamine in association with inhibition of F-actin reorganization (23). The reduction in paracellular permeability involves activation of 1) cAMP-dependent protein kinases that phosphorylate proteins, such as MLCK, thereby reducing MLC phosphorylation and 2) phosphatases that dephosphorylate proteins, such as MLCs, which serve to reduce stress fiber formation. Increases in cellular cAMP also prevent the increase in  $[Ca^{2+}]_i$  and isotype-specific PKC activation, important downstream signals regulating permeability (12,23).

Recently, additional barrier-promoting effectors have been identified that enhance basal vascular endothelial barrier function, and either reverse or prevent agonist-mediated barrier dysfunction (2,4,5,47–50). Of these effectors, the most extensively studied is S1P (Figure 113.3; for color reproduction, see Color Plate 113.3), which is a naturally occurring sphingolipid normally found in nanomolar quantities in

plasma. S1P binding to S1P receptor subtypes, also called Edg receptors (endothelial differentiation gene, although their expression is not restricted to endothelium). S1P mediates important biological functions including cell adhesion, barrier regulation, proliferation, differentiation, migration, and all survival. S1P binds to the plasma membrane heptahelical S1P receptors 1 (Edg1/S1P<sub>1</sub>), -2 (Edg5/S1P<sub>2</sub>), -3 (Edg3/S1P<sub>3</sub>), -4 (Edg6/S1P<sub>4</sub>), and -5 (Edg8/S1P<sub>5</sub>) expressed in a variety of cell types, including endothelium, in which expression of S1P<sub>1</sub> and S1P<sub>3</sub> is high. Ligation of cell surface S1P receptors triggers a complex signaling cascade. S1P<sub>1</sub> signaling is coupled to the G<sub>i</sub> pathway and activation of the small GTPase Rac1, whereas S1P<sub>3</sub> signaling is coupled to the G<sub>i</sub>, G<sub>q/11</sub>, and G<sub>12/13</sub> pathways, resulting in greater activation of Rho than of Rac1 (2,6,38). The importance of S1P<sub>1</sub> is demonstrated in Edg1 (S1P<sub>1</sub>) receptor knockout mice, which succumb in utero to incomplete vascular maturation with progressive vascular hemorrhage (8).

Specific Rho-family guanine nucleotide exchange factors (GEFs) catalyze the exchange of Rac1-GDP (inactive) for Rac1-GTP (active). One such GEF is T-lymphoma invasion and metastasis gene 1 (Tiam 1), which is implicated in diverse functions including regulation of cell–cell adhesion (51). Selective S1P activation of Rac/S1P<sub>1</sub> and S1P<sub>3</sub>/Rho depends on the S1P concentration (38) and possibly

S1P-induced recruitment of S1P receptors to specialized plasma membrane microdomains containing the scaffolding protein, caveolin-1 (51, discussed later). Rac GTPases are rapidly activated by physiologic concentrations of S1P (10 nM–2  $\mu$ M) to produce barrier enhancement, whereas higher concentrations of S1P (>5  $\mu$ M) activate Rho GTPases that result in active cytoskeletal rearrangement, stress fiber formation, and barrier disruption (38).

Overexpression of constitutively active Rac enhances peripheral actin polymerization in the cortical ring. Moreover, Rac activation induces lamellipodia formation, membrane ruffling, the formation of cortical actin filaments, and the spreading of ECs (2). The inhibition of Rac GTPase leads to increased EC monolayer permeability and enhances thrombin-mediated barrier dysfunction response. A variety of signaling proteins activate Rac and thus modulate molecular trafficking to and enzymatic activity at the cell periphery; this results in cortical cytoskeletal enhancement and the formation of functional adherens junction complexes. We recently reported the critical importance of Rac GTPase-dependent cortical actin rearrangement not only in the augmentation of pulmonary EC barrier function by S1P (2) but also in the barrier response to hepatocyte growth factor (HGF) (4), shear stress (44), simvastatin (52), adenosine triphosphate (ATP) (47), and oxidized phospholipids (49). Rac inactivates the actin-severing protein cofilin in the cell periphery through a signaling cascade involving p21-associated kinase (PAK)-1 and LIM kinase (2). Rac activation of the PAK family is well described and is essential for S1P-mediated cortical actin rearrangement (12).

Rac GTPase is also essential for translocation of cortactin, an F-actin binding protein that stimulates actin polymerization (but only at the cell periphery, not in transcellular actin stress fibers) and stabilizes the filamentous actin network, an event necessary for the peak barrier-enhancing response to S1P *in vitro* (53). Cortactin exhibits an amino acid structure that contains an N-terminal acidic region (NTA) and stimulates actin polymerization by binding the Arp2/3 complex (murine AA #1–90). Cortactin also contains a unique tandem repeat site for the direct binding of F-actin (AA #91–326), a proline and tyrosine-rich area containing sites for p60<sup>src</sup> phosphorylation (AA #401–495), and a C-terminal SH3 domain (#496–546), which binds junctional proteins such as ZO-1 as well as key cytoskeletal effectors such as MLCK. A blocking peptide that inhibits direct binding of EC MLCK to the SH3 domain of cortactin reduced the S1P-induced MLC phosphorylation and barrier protection (53), whereas an EC MLCK dominant-negative mutant decreased S1P-induced barrier-protective cytoskeletal rearrangement (53). A rapid increase in cortactin tyrosine phosphorylation is critical to subsequent barrier enhancement, because ECs transfected with a tyrosine-deficient mutant cortactin exhibit a blunted transepithelial electrical resistance (TER) response (53). Although cortactin has long been appreciated as a target for p60<sup>src</sup>, we were unable to link p60<sup>src</sup> to cortactin peripheral translocation after S1P, despite rapid increases in the phosphotyrosine

content of cortactin in ECs. PP2, a specific p60<sup>src</sup> inhibitor, failed to significantly attenuate S1P-induced endothelial barrier enhancement and transient overexpression of mutant tyrosine-deficient cortactin construct (site-directed mutation of three critical tyrosine residues, Y<sup>421</sup>, Y<sup>466</sup>, Y<sup>482</sup>), accounting for more than 90% of p60<sup>src</sup> cortactin phosphorylation (53). This definitively demonstrated that p60<sup>src</sup> signaling is not required for S1P-induced cortactin translocation. Tyrosine phosphorylation of cortactin appears to be necessary, however, for peak S1P-induced endothelial barrier enhancement because ECs overexpressing the tyrosine-deficient mutant cortactin exhibit a blunted TER response. Significant inhibition of the S1P response was observed after incubation with the non-specific tyrosine kinase inhibitors genistein, herbimycin A, or erbstatin, suggesting that tyrosine kinases other than p60<sup>src</sup> phosphorylate cortactin at these three critical residues during S1P-induced barrier enhancement. Dominant-negative Rac prevents the translocation of cortactin and subsequent actin polymerization in the cell periphery, and it attenuates barrier enhancement by simvastatin, S1P, ATP, and shear stress. S1P-induced barrier enhancement likely involves cortactin binding to MLCK at the site of cortical actin polymerization, thus localizing the actomyosin interaction peripherally and facilitating the stabilization of intercellular and cell–matrix adhesions. The functional role of peripheral MLC phosphorylation in promoting S1P-induced barrier enhancement remains unclear, but phosphorylating MLC at the periphery may stimulate actomyosin interactions that produce cell spreading, cell flattening, or other changes that strengthen the cortical actin ring. Alternatively, MLCK may serve as a scaffolding protein that stabilizes the cortical actin ring through multiple actin-binding sites or through other potential, yet undefined, cytoskeletal interactions. Clearly, multiple signaling proteins contribute to modulate dynamic cytoskeletal arrangements, which play a key role in the maintenance or disruption of endothelial barrier integrity.

### SPHINGOSINE 1-PHOSPHATE SIGNALING IN LIPID RAFTS

Because the exact mechanisms of S1P-mediated barrier protection remain poorly understood, we examined the role of caveolin-enriched plasma membrane lipid microdomains – termed *lipid rafts* – in S1P-mediated signaling and human EC barrier regulation. Although controversial, lipid rafts have been implicated in EC migration, proliferation, adhesion, endocytosis, cholesterol and Ca<sup>2+</sup> regulation, and signal transduction. We observed that S1P requires the existence of lipid rafts for phosphoinositide 3-kinase (PI3K) activation, Rac1 signaling, and EC barrier enhancement (51), observations in agreement with prior studies and the proposed role for lipid rafts as sites for receptor clustering and consequent EC signal transduction. We observed that S1P<sub>1</sub> (but not S1P<sub>3</sub>) is endogenously present within lipid raft fractions, with S1P recruiting additional S1P<sub>1</sub> receptors and a fraction

of cellular S1P<sub>3</sub> receptors to these EC plasma membrane microdomains. The targeted use of silent RNA (siRNA) to differentially reduce the expression of either S1P<sub>1</sub> or S1P<sub>3</sub> revealed that S1P ligation of S1P<sub>1</sub> is responsible for subsequent signaling to the EC cytoskeleton and barrier-enhancement (via PI3K activation and Rac1 signaling). Consistent with the well-appreciated barrier-disruptive role of Rho, silencing S1P<sub>3</sub> expression enhanced the initial barrier enhancement and cortical actin rearrangement induced by S1P. Although not directly tested, it is plausible that S1P<sub>3</sub> recruitment to lipid rafts after S1P challenge may serve as a negative regulator of specific S1P<sub>1</sub>-mediated functions.

Endothelial lipid rafts are enriched in the phospholipid PIP<sub>2</sub>, which serves as a substrate for the Class I PI3Ks whose activity often is modulated by regulatory subunits. S1P actively recruits to lipid rafts, PI3K catalytic subunits p110 $\alpha$  and  $\beta$ , Tiam1, and  $\alpha$ -actinin isoforms 1 and 4 in a PI3K-dependent manner. This results in cortical actin rearrangement and EC barrier enhancement (51). The catalytic PI3K subunit, p110 $\alpha$ , is the primary PI3K recruited to and activated within lipid rafts by S1P, an association that is consistent with increased PIP<sub>3</sub> production in these lipid microdomains. The exact regulatory subunit(s) that interact with p110 $\alpha$  PI3K during S1P-mediated stimulation of ECs is currently being explored. An important downstream target of PI3K signaling is the serine/threonine kinase, protein kinase B (also known as Akt), which regulates cellular functions including survival, proliferation, and migration. Akt directly phosphorylates threonine residues within S1P<sub>1</sub> (T<sup>236</sup>), an event critical for S1P-mediated EC Rac1 activation, cortical actin reorganization, and migration (6). S1P induced significant recruitment of Tiam1 into lipid rafts and increased total cellular Tiam1 activation, indicating either post-translational modifications of Tiam1 or an association between localization within lipid rafts and Tiam1 activity. Tiam1 is phosphorylated by serine/threonine kinases including Ca<sup>2+</sup>/calmodulin-dependent protein kinase II and PKC-dependent mechanisms. Interestingly, we observed clear evidence for a complex formation between Tiam1 and S1P<sub>1</sub> (but not S1P<sub>3</sub>) in lipid raft fractions following S1P. It remains unknown whether this interaction is direct or mediated through an adaptor protein. Tiam1 contains two pleckstrin homology (PH) domains; the N-terminal PH domain of Tiam1 is involved in Tiam1 translocation to the plasma membrane, binding to PIP<sub>2</sub> and/or PIP<sub>3</sub>, and interaction with various signaling molecules. Whether S1P-induced PIP<sub>3</sub> production in EC lipid rafts promotes Tiam1 recruitment to lipids, in which where direct S1P<sub>1</sub> binding may occur, is unknown.

Finally, the link between lipid raft components and the EC cytoskeleton also remains poorly understood. The  $\alpha$ -actinin family of cytoskeletal proteins regulates a variety of cellular functions including cell–cell adhesion and migration with four  $\alpha$ -actinin isoforms identified: two nonmuscle (1 and 4) and two muscle (2 and 3). Two  $\alpha$ -actinin monomers can form a functional dimer that can link certain cell surface adhesion receptors (i.e.,  $\alpha$  integrins, intercellular adhesion molecules [ICAMs], cadherins) to the actin cytoskeleton. Furthermore,

the PI3K pathway plays an important regulatory role in  $\alpha$ -actinin cellular localization and function. The  $\alpha$ -actinins bind to a host of molecules including actin, vinculin, catenin, PI3K, and PIP<sub>3</sub> (23). Our data supports a regulatory role for the PI3K pathway in  $\alpha$ -actinin translocation to lipid rafts. This suggests a potential involvement of adhesion receptors in S1P-induced S1P<sub>1</sub> receptor–mediated EC signaling and cytoskeletal reorganization via  $\alpha$ -actinin. Reductions in the expression of either S1P<sub>1</sub> receptor or Tiam1 (siRNA), but not S1P<sub>3</sub>, inhibited S1P-induced  $\alpha$ -actinin-1/4 lipid raft translocation, Rac1 activation, cortical actin reorganization, and increased EC barrier function (51). These data indicate the critical importance of the PI3K pathway and  $\alpha$ -actinin in S1P signaling to the EC cytoskeleton and barrier enhancement through the S1P<sub>1</sub> receptor.

### SPHINGOSINE 1-PHOSPHATE-MEDIATED BARRIER REGULATION: ADHERENS JUNCTIONS AND FOCAL ADHESIONS

Because increased vascular permeability and secondary tissue edema occur primarily via a paracellular pathway during inflammation, there has been intense focus on the forces that regulate the integrity of the paracellular junction. Consistent with a critical role for the endothelial cytoskeleton in vascular barrier regulation, the Rho family of small GTPases – critical regulators of the nonmuscle cytoskeleton – is intimately involved in S1P-mediated cytoskeletal rearrangement and the distribution/assembly of intercellular adherens complexes and focal adhesions. Rac rapidly redistributes to areas of cell–cell contact after S1P, and dominant-negative Rac polypeptide attenuates S1P-induced VE-cadherin and  $\beta$ -catenin localization to areas of cell–cell contact. S1P induces the peripheral enhancement of VE-cadherin, which overlaps with F-actin and the linkage of VE-cadherin,  $\beta$ -, and  $\gamma$ -catenin to actin filaments. The localization of these proteins to areas of cell–cell contact occurs within 1 hour of S1P stimulation with VE-cadherin,  $\alpha$ -catenin, and  $\beta$ -catenin partitioning into the Triton-insoluble fraction, suggesting the induction of functional adherens junction assembly with increased affinity with the endothelial cytoskeleton. The translocation of VE-cadherin to cell–cell contact regions in ECs after treatment with S1P was attenuated by microinjection of oligonucleotides designed to interrupt Edg1 and Edg3 receptor expression. Solid evidence suggests an increased linkage of the S1P-activated cortical actin cytoskeleton with newly remodeled focal adhesions (38), events that we speculate result in increased cellular tethering to adjacent cells and to the ECM. Concomitant with peripheral cytoskeletal redistribution, S1P induces p60<sup>src</sup>-mediated phosphorylation of FAK Y<sup>576</sup> and redistribution of paxillin and FAK to the cell periphery. The Src kinase inhibitor, PP2, abolished this response and the formation of the cortical actin ring, thus implicating p60<sup>src</sup> in the upstream signaling cascade and linking FA redistribution to the cytoskeletal alterations induced by S1P.

### ENDOTHELIAL BARRIER REGULATION BY ACTIVATED PROTEIN C: SIGNALING VIA S1P RECEPTORS

Sepsis is a devastating inflammatory syndrome producing life-threatening end-organ dysfunction. It is characterized by essential and defining pathophysiological features of coagulation cascade activation and marked increases in vascular permeability. The anticoagulant serine protease, recombinant activated protein C (rhAPC; drotrecogin alfa) reduced levels of the inflammatory marker IL-6 and was the first agent to improve survival in severely septic patients. Although the mechanism underlying the prosurvival effects of APC in sepsis remains enigmatic, one mechanism of APC benefit is likely related to the recent report of the inhibition of widespread

increases in vascular permeability (a characteristic of severe sepsis) and accelerated recovery from the untoward effects of edemagenic agonists. Both APC and nonactivated protein C bind to the endothelial protein C receptor (EPCR) – a crucial participant in the protein C pathway, because EPCR ligation increases the activation of protein C by approximately 20-fold. Our recent studies indicate that APC evokes human lung EC signaling paradigms that target the Rho family GTPase Rac1, with subsequent Rac1-dependent cytoskeletal rearrangement and profound EC barrier protection (Figure 113.4) (50). Finally, APC-mediated protection from the edemagenic effects of thrombin appears to occur via novel transactivation of S1P<sub>1</sub>, the potent barrier-enhancing receptor for S1P. Rac1 activation, MLC phosphorylation, and cytoskeleton rearrangement are consistent with previous data concerning S1P<sub>1</sub> signaling

Figure 113.4. Proposed schema of APC mechanism of barrier protection against thrombin via S1P<sub>1</sub> transactivation, lipid raft formation, and Rac signaling to the EC cytoskeleton. Prior investigation described S1P-mediated signaling involving phosphorylation of S1P<sub>1</sub> at Thr236 via PI3K and its downstream effector Akt, which in turn activates Rac1 and leads to cortical cytoskeletal rearrangement. This cortical redistribution results in barrier protection, which is S1P<sub>1</sub>-, Rac1-, PI3K-, and Akt-dependent. We propose a model of APC-mediated barrier protection whereby APC, via EPCR and PI3K, transactivates S1P<sub>1</sub>, thus leading to EC barrier protection, which is associated with Rac1 activation and cortical actin redistribution. Prominent is the recruitment to lipid rafts of a complex including EPCR, S1P<sub>1</sub>, AKT, cortactin, and MLCK.

(50). The elevated levels of phosphorylated MLCs are spatially localized within the enhanced cortical ring, a locale in which increased tensile strength occurs with enhanced affinity between adherens junctions and focal adhesion components and the cortical cytoskeleton (53). The peripheral distribution of actin and phosphorylated MLC evoked by APC was highly reminiscent of the pattern seen with other barrier-protective agents, such as S1P, HGF, shear stress, and simvastatin, as well as with oxidized phospholipids as described earlier. Unlike S1P, APC does not directly increase baseline electrical resistance. However, both agonists exhibit a protective effect in the presence of the barrier-disruptive agent, thrombin. Utilizing S1P<sub>1</sub> phosphorylation on threonine (Thr<sup>236</sup>) residues as the accepted read-out of S1P<sub>1</sub> activation, we convincingly demonstrated that APC-ligated EPCR transactivates S1P<sub>1</sub>, as evidenced by robust S1P<sub>1</sub> phosphorylation, which was eliminated by EPCR blocking antisera (50). Coimmunoprecipitation studies strongly suggest an interaction between EPCR and S1P<sub>1</sub>. Furthermore, use of the PI3K inhibitor LY294002 blocked APC-induced S1P<sub>1</sub> Thr<sup>236</sup> phosphorylation, demonstrating that APC phosphorylates S1P<sub>1</sub> via the PI3K/Akt pathway (50). Finally, and of critical importance, S1P<sub>1</sub> silencing abrogates the APC-mediated EC barrier protection, thus indicating that S1P<sub>1</sub> expression is essential for APC-mediated barrier protection. S1P<sub>1</sub> transactivation is not a novel observation, and has been previously described in the context of ligation of growth factor receptors such as platelet-derived growth factor (PDGF) and VEGF. S1P increases tyrosine phosphorylation of the VEGF receptor, FLK-1/KDR, and S1P-mediated phosphorylation of Akt and EC NO synthase is VEGF-dependent. The exact mechanism by which growth factor receptor–S1P<sub>1</sub> transactivation occurs is unknown but has been suggested to involve increases in sphingosine kinase activity and newly generated S1P secretion that allows S1P<sub>1</sub> ligation to occur. Nevertheless, together our data indicate that S1P<sub>1</sub> is a key target for APC/EPCR-mediated barrier protection and suggests that S1P<sub>1</sub> may in fact be central to plasma membrane signaling sequences that evolve to enhance vascular integrity. The ability of APC to ameliorate the vascular leak observed in severe sepsis provides an attractive mechanism for the survival benefit of patients treated with this agent.

## CONCLUSION

The integrity of the EC monolayer is a critical requirement for the preservation of organ function, and barrier disruption is recognized as a cardinal feature of inflammation angiogenesis and ischemia–reperfusion injury. Endothelial barrier properties are heterogeneous and not uniform throughout the vasculature, with capillary and postcapillary venular ECs exhibiting greater barrier properties than do macrovascular ECs (5). This reflects differences in the content of barrier regulatory components such as key cytoskeletal and adhesive elements (MLCK, FAK, cortactin), Ca<sup>2+</sup> signaling pathways, and cAMP-dependent barrier protective elements. A complex interplay

exists among these processes in regulating the two general pathways (transcellular and paracellular) for the movement and flow of fluid, macromolecules, and leukocytes into the interstitium. The modified tensegrity model describes paracellular gap formation as regulated by the balance of competing contractile forces. These forces generate centripetal tension and adhesive cell–cell and cell–matrix tethering forces that together regulate cell shape changes. Edemagenic agents, such as thrombin, initiate cytoskeletal rearrangement characterized by the loss of peripheral actin filaments, a concomitant increase in organized F-actin cables (stress fibers), and increased intracellular tension, via the coordinate activation of the small GTPase Rho and Ca<sup>++</sup>/CaM-dependent MLCK. The resultant increase in the formation of actin stress fibers and phospho-MLC-mediated actomyosin cellular contraction destabilizes cytoskeletal-junctional linkages, culminating in increased vascular permeability.

Although significant progress has been made in understanding the molecular and cellular events that regulate permeability, the goal of modulating the EC barrier in a clinically advantageous way remains elusive. Exciting developments in the understanding of barrier restoration have led to several barrier-protective strategies that have the capacity to activate the S1P receptor, thus inducing Rac-dependent cytoskeletal cortical rearrangement; this requires Tiam1 and a strengthening of linkages of cortical actin to adherens junctions and focal adhesions. Given that structural analogs of S1P are in phase III trials, the future of barrier-enhancing therapy appears promising. These observations further confirm the potential for S1P in the treatment of acute lung injury (ALI) and may represent a novel therapeutic strategy for vascular barrier dysfunction, a signal event during inflammatory states.

Finally, identification and analysis of single nucleotide polymorphisms in candidate cytoskeletal genes with defined barrier-regulatory properties also may take us closer to understanding issues of individual variability in disease severity and therapy responses in edemagenic states. Exciting high-throughput techniques provide an opportunity to determine the critical regulatory genes responsible for complex processes such as barrier regulation and may reveal multiple novel targets for therapeutic intervention. Further understanding of barrier-restorative or barrier-preserving mechanisms likely involved after short-acting edemagenic agents may provide valuable clues about which therapies may shorten the edemagenic phase.

## KEY POINTS

- EC barrier regulation is a dynamic process, with both barrier disruption and barrier restoration enhancement involving coordinated rearrangement of the endothelial cytoskeleton.

- Cytoskeleton rearrangement driven by receptor-regulated signaling occurs in spatially defined locales for barrier regulation.
- Adherens junctional proteins and focal adherens proteins are the key participants in signaling to and from the cytoskeleton.

#### Future Goals

- To design vascular bed-specific barrier regulatory therapies to promote the resolution of inflammatory vascular leak syndromes
- To identify key genetic variants and protein modifications that underlie the heterogeneity of susceptibility to sustained vascular permeability and result in multiorgan dysfunction

#### GLOSSARY

**$\alpha$ -Actinin** is an actin binding protein composed of two identical antiparallel peptides, with the actin binding domain close to the N-terminus, followed by four spectrin-like repeats and terminating with two EF-hands; links actin cytoskeleton to focal adhesions.

**Actin-associated proteins** regulate assembly and disassembly of actin filaments.

**Actin microfilaments** are helical protein filaments formed by the polymerization of globular actin molecules, which are major constituents of the cytoskeleton of all eucaryotic cells and a critical component of the contractile apparatus of muscles involved in cell motility, cell-substrate interactions, transport processes, cytokinesis, and the establishment and maintenance of cell morphology.

**Actin polymerization** is a dynamic process that results in formation of actin filaments that are derived from individual globular actin molecules. This process is regulated by many different actin-associated proteins.

**Actin stress fibers (or F-actin cables)** are large actin filaments that form in response to multiple signaling events and are often part of the actomyosin contractile motor.

**Actomyosin motor (actomyosin cross bridges)** is a contractile apparatus formed by the dynamic interaction of actin and myosin and resulting in contraction within the cell.

**Arp2/3** is a seven-subunit protein that nucleates actin polymerization. When activated by various proteins, the Arp2/3 complex binds to the side of an existing actin filament and nucleates assembly of a new actin filament in a branching pattern at the cell periphery.

**Caldesmon** is an actin- and myosin-binding protein, which is an essential component of the cytoskeleton in smooth muscle and nonmuscle cells, and is involved in the regulation of cell contractility, division, and assembly of actin filaments.

**Cofilin** is a family of actin-binding proteins that disassembles actin filaments. The protein is known to sever actin filaments by creating more positive ends on filament fragments.

**Cortactin** is an actin-binding protein and Src target that stimulates Arp2/3 actin polymerization and interacts with multiple other cytoskeletal proteins through its C-terminal SH3 domain.

**Cortical actin filaments (cortical actin ring)** are peripheral actin filaments that circumferentially surround the cell and provide structure for cytoskeletal linkages within the cell.

**F-actin**, or filamentous actin, consists of multiple subunits of globular actin arranged in a linear fashion and provides the basic structure of the actin cytoskeleton within the cell.

**Filamentous actin network (subcortical actin mesh)** is a branching network of actin filaments at the cell periphery, often involved in migration.

**Filamin** is a V-shaped actin cross-linking protein that induces actin filaments to associate in loose networks that give some areas of the cytosol a gel-like consistency.

**Gelsolin** is a calcium-dependent actin-binding protein that modulates actin filament length and gelation and thus influences the structure of the cytoskeleton and plays a key role in cellular motility and differentiation. Inhibition of its activity decreases actin stress fiber–dependent contraction.

**Hsp27 (heat shock protein 27)** helps regulate stress fiber formation through the mitogen-activate protein kinase (MAPK) pathway.

**Intermediate filaments** are fibrous protein filaments (about 10 nm in diameter) that form ropelike networks within cells. One of the three prominent types of cytoskeletal filaments, including actin and microtubules.

**Microtubules** are polymers of  $\alpha$ - and  $\beta$ -tubulin that form a lattice network of rigid hollow rods spanning the cell in a polarized fashion from nucleus to the periphery while undergoing frequent assembly and disassembly.

**MLCK (myosin light chain kinase)** is a  $\text{Ca}^{2+}$ /calmodulin-dependent enzyme that catalyzes the phosphorylation of regulatory myosin light chains (MLC), which is a key EC contractile event.

**Peripheral actin filaments** are structures at the periphery of the cell involved in the dynamic regulation of migration and barrier function.

**Profilin** is an actin-binding protein involved in cytoskeleton dynamics. It is responsible for the growth and stabilization of actin filaments and is important in the restructuring of microfilaments.

**VASP (vasodilator-stimulated phosphoprotein)** is a member of the Ena-VASP protein family. Ena-VASP family members contain an EHV1 N-terminal domain that binds proteins containing E/DFPPPPXD/E motifs and targets Ena-VASP proteins to focal adhesions. VASP stimulates actin nucleation and polymerization at focal adhesions.

**Vinculin** is located at the cytoplasmic side of focal contacts or adhesion plaques, where it binds actin and catenin.

## Molecular Mechanisms of Leukocyte Transendothelial Cell Migration

---

F. William Luscinckas

*Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts*

In this chapter, the focus is on three areas of interest relevant to the study of leukocyte transmigration as an output device of the vascular endothelium. The mechanisms underlying leukocyte adhesion and recruitment have been discussed in earlier chapters, and readers are referred there to obtain this information. The first section presents a brief historical perspective on the history of inflammation and, in particular, leukocyte transmigration. Second, the signaling capacity of endothelial adhesion molecules that capture leukocytes and mediate adhesion and transmigration is discussed. It is apparent that these adhesion “receptors,” in particular intercellular adhesion molecule (ICAM)-1, signal during their engagement with leukocytes. Third, the process of leukocyte diapedesis at endothelial cell (EC)–cell lateral junctions and the transient and reversible alterations that occur in junctional components (e.g., transient loss of vascular endothelial [VE]-cadherin) during transmigration is addressed. This area is clearly of interest, because prolonged and/or excessive leukocyte recruitment and the inflammatory milieu together are predicted to have negative effects on the permeability barrier function of the endothelium. Finally, a discussion is included on a somewhat controversial aspect of diapedesis, namely, do leukocytes undergo diapedesis at junctional or nonjunctional sites, and what factors dictate the location? Each of these topics can be envisioned as altering or modulating the output of the endothelium.

### HISTORICAL PERSPECTIVE

The study of inflammation began more than two thousand years ago with the Egyptians (see the excellent review chapter by Klaus Ley; Ref. 1). This culture described some of the signs and consequences of inflammation, notably descriptions of abscess and ulcer. It was many centuries later (during the late 1800s), however, that Elie Metchnikoff (2), a Russian embryologist and immunologist, described the process of phago-

cytosis by inflammatory leukocytes, and Julius Cohnheim, a German experimental histologist and pathologist, described components of the leukocyte adhesion cascade as we know it today (Figure 114.1). He articulated the process of a leukocyte “crawling” out of a blood vessel in the frog tongue and into the interstitial space, a process now termed *leukocyte transendothelial migration* (TEM), emigration, or diapedesis. In the early 20th century, Clark and Clark were among the first to describe an *in vivo* model to visualize the adhesion and transmigration of leukocytes in the microvessels of the rabbit ear at the light-microscopic level. They further found that leukocyte transmigration did not lead to loss of the EC barrier (3).

Another major milestone came during the early 1960s, when Marchesi, Florey, and Gowans described TEM at the ultrastructural level using fixation of tissues and electron microscopic techniques (4,5). This was the first detailed analysis of leukocyte TEM in animal models of inflammation, and this analysis and others have helped germinate the idea that leukocytes transmigrate out of the vessel wall by passing either between cell–cell lateral junctions (paracellular) or directly through the vascular ECs (transcellular). These modes of TEM are discussed later in the chapter.

Regarding the mechanisms by which leukocytes recognize a site of injury or inflammation, it was widely held, despite a paucity of evidence, that the blood leukocytes followed a gradient of chemoattractants released from sites of infection, damage, or injury (6). Little consideration was given to the idea that the vascular endothelium was involved in this process. This notion was dismissed during the mid 1980s, following reports that certain inflammatory cytokines and bacterial endotoxins could trigger vascular endothelial monolayers to become hyperadhesive for isolated blood leukocytes *in vitro* (7), and furthermore, that leukocytes actually transmigrated across these monolayers in the absence of exogenously added chemoattractants (8). Subsequent studies *in vivo* confirmed these findings (9) and began the remarkable wave of progress in unraveling the molecular and cellular mechanisms of

Figure 114.1. The leukocyte recruitment adhesion cascade. Model of neutrophil attachment to 6-hour TNF- $\alpha$ -activated HUVEC monolayers under defined laminar shear flow in vitro. This figure shows five sequential events (steps 1–5) that can be observed during neutrophil adhesive interactions with the endothelium at 1.8 dynes/cm<sup>2</sup>.

inflammation and the central role of the vascular endothelium in this process (10). It is now well appreciated that the endothelium becomes “activated” by many types of inflammatory stimuli to induce gene transcription; protein synthesis; surface expression of adhesion molecules (vascular cell adhesion molecule [VCAM]-1, E-selectin, P-selectin, and ICAM-1); secretion of chemotactic cytokines, known as chemokines, such as interleukin (IL)-8 (also known as CXCL8) and monocyte chemoattractant protein (MCP)-1 (also known as CCR2); and chemotactic phospholipids, such as platelet-activating factor (PAF). Moreover, it is clear that general dysfunction of the endothelium is an underlying pathophysiological factor in many chronic diseases (11).

#### ENDOTHELIAL CELL ADHESION MOLECULE SIGNALING AND ENDOTHELIAL CELL FUNCTION

The work of many investigators has shown that peripheral blood leukocytes including neutrophils, lymphocytes, monocytes, basophils, and eosinophils use multiple adhesive steps

to emigrate from the blood, with each step requiring multiple and overlapping functions of different sets of adhesion molecules. Although early studies described a two- or three-step model (12,13), the multistep adhesion cascade is conveniently divided into five steps as identified in Figure 114.1:

1. Initial attachment
2. Rolling
3. Arrest
4. Diapedesis of the endothelium
5. Migration through tissues

Figure 114.2 depicts an example of an isolated human neutrophil transmigrating across a tumor necrosis factor (TNF)- $\alpha$  activated human EC monolayer under physiological levels of laminar shear flow. In this system, initial attachment is primarily dependent on both E- and P-selectin, and L-selectin. Subsequently, the neutrophil rolls across the apical EC surface at approximately 10  $\mu$ m/sec for variable distances before arresting, presumably due to activation of its integrins by apically presented chemokines. The arrest step is mediated by leukocyte  $\beta$ 2 integrins interacting with ICAM-1. For

Figure 114.2. Neutrophil transmigration of cytokine-activated EC monolayer under shear flow in vitro. Neutrophil initial attachment, rolling, arrest, and transmigration across 6-hour TNF- $\alpha$ -treated human umbilical vein endothelium under shear flow in vitro (1.5 dynes/cm<sup>2</sup>). Sequential frames taken from left to right were digitized and manipulated using MetaMorph software and PhotoShop as previously described. (Reproduced with permission from Shaw SK, Ma S, Kim M, et al. Coordinated redistribution of leukocyte LFA-1 and endothelial cell ICAM-1 accompanies neutrophil transmigration. *J Exp Med.* 2004;200:1571–1580.)

other leukocyte types, including monocytes, lymphocytes, basophils, and eosinophils  $\beta 1$  integrins interacting with VCAM-1 also can mediate initial attachment and arrest. The majority of neutrophils (~75%) arrest at or close to cell–cell junctions (14–16) and then crawl to intercellular cellular junctions and ultimately diapedese by squeezing between intercellular junctions. Amazingly, the entire process that leads to transmigration occurs within a few minutes and, despite the relatively high frequency of leukocyte trafficking observed, rarely is there frank damage to the EC monolayer in this system (see Figure 114.2).

Several studies have shown that the cytokine-induced EC adhesion molecules VCAM-1, ICAM-1, and E-selectin can signal upon engagement in ECs (17). E-selectin ligation by leukocytes (HL-60) triggers its association with the cytoskeleton and initiates outside-in signaling (18–20). Similar findings have been reported for leukocyte binding or mAb crosslinking to E-selectin and VCAM-1 (21). Endothelial ICAM-1 is the major receptor for  $\beta 2$  integrins, and this pathway is essential for neutrophil arrest and transmigration (22). Therefore, the remainder of this discussion focuses on EC ICAM-1 as a prototype adhesion molecule that signals during leukocyte ligation.

ICAM-1 is a transmembrane glycoprotein with five extracellular IgG-like domains and a short cytoplasmic tail (28 amino acids) that appears to associate with multiple cytoskeletal linker proteins in a variety of cell types (22). Under in vitro and in vivo conditions, ECs express low levels of ICAM-1, and inflammatory stimuli can markedly increase ICAM-1 surface expression (23,24). In acute and chronic inflammatory diseases, ECs become activated and express high levels of ICAM-1, in addition to VCAM-1 and E-selectin (25–28).

The engagement of ICAM-1 in cytokine-activated ECs by adherent leukocytes or cross-linking with monoclonal antibodies triggers elevations in intracellular free calcium ( $\text{Ca}^{2+}$ ) and myosin contractility (29,30), as well as the activation of small GTPases, in particular members of the Rho family (31,32) and the tyrosine kinase  $\text{p60}^{\text{Src}}$  (33) (Figure 114.3). A prominent substrate for  $\text{p60}^{\text{Src}}$  in endothelium is the actin-binding protein, cortactin (34–37). These changes are proposed to cause cytoskeletal remodeling events that influence EC contractility and function to keep neutrophils adherent near cell–cell junctions (38). This would be a convenient mechanism to assure diapedesis occurs at a junctional location. In another study, adhesion of the leukocyte THP-1 cell line under static conditions also triggered Src kinase-dependent tyrosine phosphorylation of cortactin (39). Pharmacological inhibition of Src kinase tyrosine phosphorylation by PP2 did not prevent association of E-selectin and ICAM-1 with cortactin, but did reduce by approximately 50% THP-1 adhesion to cytokine-activated endothelial monolayers. THP-1 cells do not transmigrate in most models, so the effect of PP2 on this step is unknown. Although little is known about the function of cortactin in leukocyte transmigration, it is of interest because biochemical studies show that it binds to ICAM-1 and E-selectin (39), that it contains an actin-binding domain,

Figure 114.3. ICAM-1 engagement triggers intracellular signals in EC. ICAM-1 interacts with the adapter proteins ezrin, moesin, cortactin, and  $\alpha$ -actinin, which link ICAM-1 to the cytoskeleton. In ECs, antibody-mediated cross-linking of ICAM-1 leads to an increase in intracellular  $\text{Ca}^{2+}$  and activation of Rho A and src kinases. These upstream signals are thought to converge with other pathways to initiate cytoskeletal remodeling (17,21,38,39). In addition, ICAM-1 clusters around those leukocytes actively transmigrating across EC (15,16,44,45), presumably through its associations with these adapter proteins.

and that a separate N-terminal domain stimulates actin polymerization (in vitro) by binding and stabilizing the Arp2/3 complex in cortical actin networks (36,37). The Arp2/3 complex is composed of actin-related proteins (Arp)-2 and -3 and five unrelated proteins (40); it is a major actin nucleating factor in cells (41). Activation of Arp2/3 is the dominant mechanism for the explosive actin polymerization characteristic of platelet shape-change on activation (42,43). Finally, recent work reported that ICAM-1 and E-selectin localize in regions of the plasma membrane that have properties consistent with “lipid rafts” (39), endowing additional properties to sites of leukocyte adhesion such as the potential for downstream signaling. Future studies are needed to ascertain the extent to which such signals alter the EC phenotype at sites of immune reactions, infection, or injury.

In addition to its adhesive and signaling capabilities, recent studies report that ICAM-1-enriched microvilli-like projections in human umbilical vein ECs (HUVECs), termed *docking structures*, can be observed during leukocyte arrest and locomotion (44) and transmigration (45), and in T-lymphoblast diapedesis (46). Pharmacological inhibition showed that maintenance of the docking structure depended, in part, on phosphoinositides  $[\text{PI}(4,5)\text{P}_2]$  and the Rho p160 kinase (ROCK) and phosphoinositide 3-kinase (PI3K) pathways. Our lab also has reported that ICAM-1 clusters at the sites of neutrophil transmigration (both junctional [16] and non-junctional sites [15]) under defined shear flow, although our data differ from those of Barreiro (46) and Carman (44,45) in that we did not observe robust microvilli-like projections

containing ICAM-1 emanating from endothelium during transmigration. Rather, we observed the coordinated remodeling of both leukocyte and endothelial adhesion molecules within a narrow plane at endothelial cell–cell junctions (16). Likely explanations for these differences reside in the use of the chemoattractant PAF in the latter studies (44,45), and the use of T-lymphoblasts in the former study (46), which have a low rate of transmigration relative to neutrophils and a prolonged mobility on the apical surface that precedes transmigration. These reports, however, are consistent with the concept that leukocyte adhesion and transmigration initiates a fast assembly of specialized structures in the endothelium that contain the adhesion molecules ICAM-1, E-selectin, and VCAM-1, and actin-linking molecules that bridge these components to actin filaments. Future studies are needed to address which EC actin-binding proteins associate with ICAM-1 under resting conditions and after leukocyte ligation, and whether these associations are necessary for the observed clustering of ICAM-1 during leukocyte transmigration, both at junctional and nonjunctional sites. The *in vivo* counterpart is a logical target for future studies.

### DIAPEDESIS AT THE JUNCTIONS

Most *in vitro* experimental systems have revealed that the TEM of leukocytes occurs predominantly at endothelial junctions along a paracellular pathway (47–49) (step 4 in Figure 114.1). Because leukocytes encounter multiple EC junctional molecules and molecular complexes during paracellular transmigration, the field has focused on cell surface molecules that localize at cell–cell junctions (49,50). CD99 and platelet-endothelial cell adhesion molecule (PECAM)-1/CD31 are expressed on vascular endothelium and are enriched at cell–cell lateral junctions. These molecules are expressed on most leukocyte types (49). Both molecules interact through homophilic interactions: CD99 on one EC binds to the same molecule on adjacent ECs. PECAM-1 homophilic interactions work in an analogous fashion. PECAM-1 also can function as a signaling molecule in platelets, leukocytes, and endothelium (51). During leukocyte TEM, both PECAM-1 and CD99 engage in homophilic binding of the molecule on the endothelium with the same molecule on the migrating leukocyte. Transmigrating leukocytes must cross endothelial tight junctions (TJ) and adherens junctions (AJ), which contain numerous proteins involved in selective permeability, growth control, and cell–cell adhesion (52). Endothelial AJs contain the transmembrane protein VE-cadherin, which forms a complex with cytosolic molecules  $\alpha$ -catenin,  $\beta$ -catenin, plakoglobin (or  $\gamma$ -catenin), and p120 (53). The VE-cadherin complex then links to the actin cytoskeleton, providing stability. Recent studies have suggested the VE-cadherin complex regulates the passage of blood leukocytes (54). A recent experimental strategy directly visualized the effects of leukocyte TEM on VE-cadherin in endothelium using live-cell imaging of fluorescently tagged VE-cadherin (VE-cadherin-green fluores-

cent protein [GFP]) under defined laminar flow (55). Neutrophils and monocytes triggered transient and reversible displacement (4–6  $\mu\text{m}$  “gaps”) in VE-cadherin-GFP during transmigration. Others have reported similar alterations in VE-cadherin during neutrophil transmigration using fluorescently tagged mAb to VE-cadherin (56). The mechanism underlying displacement of VE-cadherin during leukocyte TEM is currently unknown, but may involve a localized and reversible uncoupling of the VE-cadherin from the actin cytoskeleton. These findings suggest that the transmigration of leukocytes across intercellular junctions is regulated by complex signaling events within both cell types. Burns and colleagues (57,58) also have reported that neutrophils transmigrate at tricellular or multicellular endothelial junctions that exhibit small gaps in VE-cadherin staining, although the mechanism for these small constitutive gaps is unknown.

### NONJUNCTIONAL DIAPEDESIS: NOVEL MODELS OF LEUKOCYTE TRANSCELLULAR DIAPEDESIS

*In vivo*, the inflammatory response is a complex and extremely well orchestrated series of events that leads to dramatic changes in leukocyte–EC interactions, an increase in vessel permeability, and an accumulation of leukocytes in the extravascular space and surrounding tissues. The technique used to reliably determine the location of transmigration in tissues is ultrastructural analysis using serial sectioning and electron microscopy. This approach is not a high-throughput type analysis, and therefore frequency or statistical analysis is not performed. Nonetheless, the most detailed analysis was the publication by Feng and colleagues (59), in which multiple sets of consecutive serial electron microscopic sections were obtained from skin sites injected with the chemoattractant formyl-Met-Leu-Phe (fMLP). The images representing these serial sections were reconstructed in three dimensions using software programs. Analysis of these images revealed that most (at least 10 of the 11) openings were transendothelial pores, not inter-EC gaps. Based on these data, the authors concluded that transcellular diapedesis was not a rare event. More recent studies using intravital fluorescence video-microscopy and subsequent ultrastructural analysis also have reported evidence for lymphocyte transcellular migration across the blood–brain barrier (60,61). Additional *in vivo* studies using other models of inflammation have provided further evidence for transcellular transmigration (61–63).

As discussed earlier, *in vivo* studies have found that blood leukocytes can undergo transcellular TEM in a variety of *in vivo* animal models of inflammation, which suggests that this route of leukocyte transmigration is physiologically relevant. The underlying mechanisms, however, have not been identified. Historically there were few, if any, reports of leukocyte transcellular diapedesis *in vitro*. Two papers in 2004 reported transcellular diapedesis, but the levels ranged from a few percent to approximately 10% (45,64). Our laboratory has addressed this gap in information by utilizing *in vitro*

live-cell fluorescence imaging to visualize the EC junction marker VE-cadherin and accurately determine the site of neutrophil arrest and TEM (paracellular or transcellular) under physiologically relevant shear flow (15). These findings confirm the recent paper by Carmen and Springer and Cinamon and colleagues (45,64) that leukocytes undergo transcellular diapedesis *in vitro*, and extend these findings by identifying two factors – namely high-density ICAM-1 expression and polygonal EC shape – as key mediators in neutrophil transcellular diapedesis. Elevated levels of apical ICAM-1, identical to those found on chronic (24-hour) TNF- $\alpha$  activated HUVECs, promote an increase in neutrophil arrest at nonjunctional locations, where high occupancy levels of ICAM-1 by the  $\beta$ 2 integrins lymphocyte function-associated antigen (LFA)-1 and Mac-1 trigger neutrophil-robust levels of neutrophil transcellular diapedesis. Strikingly, we found that freshly isolated peripheral blood CD3<sup>+</sup> T cells exclusively undergo paracellular diapedesis. These data indicate a clear difference in T-lymphocyte and neutrophil diapedesis behavior and indicate differential signaling downstream of ICAM-1 ligation in these two leukocyte types. Future studies are necessary to directly compare the transmigration behavior of different preparations of T cells (freshly isolated versus *in vitro*-generated IL-2 driven T lymphoblasts, CD4 and CD8 memory or naive T cells) in ICAM-1 overexpressing endothelium.

#### KEY POINTS

- The emerging picture suggests an intimate dialog between the adherent leukocyte and the underlying endothelial monolayer that culminates in a dramatic and rapid assembly of adhesion molecules of both cell types as the leukocyte “discovers” the correct site at EC junctions.
- New *in vitro* models are available to study junctional and nonjunctional leukocyte transmigration pathways (15,45,64). These allow investigators to compare and contrast the cellular mechanisms underlying each pathway and to determine whether different leukocyte types utilize one or both pathways. This information can then be used to develop similar assays using *in vivo* models.
- EC adhesion molecules are capable of generating intracellular signals that initiate alterations in several pathways. A common output after adhesion molecule ligation is an alteration of cytoskeletal components.

#### Future Goals

- To determine whether ligation of EC adhesion molecules by different leukocyte types leads to common or divergent downstream signal generation

- To determine if the transcellular and paracellular transmigration pathways elicit different downstream signals in endothelium
- To elucidate the mechanisms that regulate the reversible alterations in junctional VE-cadherin complex during leukocyte transmigration

## Functions of Platelet-Endothelial Cell Adhesion Molecule-1 in the Vascular Endothelium

Peter J. Newman and Debra K. Newman

*Blood Research Institute, Blood Center of Wisconsin, Milwaukee, Wisconsin*

Platelet-endothelial cell adhesion molecule (PECAM)-1 first appeared in the literature in 1985, in reports by two different groups. These reports described a 145-kDa glycoprotein of unknown function that was constitutively expressed on the surface of platelets and endothelial cells (ECs) (1); and the 120-kDa target antigen of two murine monoclonal antibodies (mAbs), termed TM2 and TM3, that were derived by immunizing mice with the monocytic leukemia cell line, THP-1 (2). The TM-2/TM-3 antigen was found on all normal peripheral blood monocytes, neutrophils, granulocytes, platelets, and mitogen-activated lymphoblasts, as well as on blasts from various leukemia patients, especially those with leukemia of myeloid origin. Clustering by the 1989 CD Workshop of seven different CD31 mAbs having similar reactivity (3), together with cloning of its cDNA by three different laboratories in 1990 (4–6), permitted a unification of these previously disparate observations. Thereafter, PECAM-1 was assigned to the cell adhesion molecule (CAM) subfamily of immunoglobulin (Ig) gene superfamily receptors.

Human PECAM-1 (Figure 115.1) is encoded by an approximately 70-kb gene (7) located at q23 of chromosome 17 (8). The gene is comprised of 16 exons, with exons 2 through 8 encoding the six extracellular Ig-like domains, exon 9 encoding the transmembrane domain, and exons 10 to 16 encoding a complex cytoplasmic domain that is subject to a rather large degree of alternative splicing (9). The cytoplasmic domain contains at least five serine and tyrosine phosphorylation sites, the most well-characterized of which are two consensus immunoreceptor tyrosine-based inhibitory motifs (ITIMs) centered on tyrosine residues 663 and 686 (10). These ITIMs, following phosphorylation during a variety of cellular activation events, serve to recruit cytosolic signaling molecules, in particular the protein tyrosine phosphatase, SHP-2 (11,12). Although the signaling properties of PECAM-1 (13) and its role in the biology of blood and vascular cells (14) have been reviewed, no compendia are devoted solely to the function of PECAM-1 in vascular endothelium. This chapter, therefore,

focuses on when and where PECAM-1 becomes expressed on ECs, what happens to it as a consequence of EC activation, and the role it plays in shaping EC responses to inflammatory stimuli, flow-mediated mechanical shear stress, and chemical perturbation.

### ENDOTHELIAL CELL EXPRESSION OF PLATELET-ENDOTHELIAL CELL ADHESION MOLECULE-1

PECAM-1 first appears early during mouse embryonic development in endothelial precursors within the yolk sac (9). It soon becomes detectable within the embryo itself on angioblasts (15) (mesodermally derived EC progenitors that participate in the development of blood vessels), together with other early EC markers like the basic helix-loop-helix transcription factor TAL1/SCL, the FLK-1 receptor for vascular endothelial growth factor (VEGF), and other cell adhesion and signaling molecules such as CD34 and vascular endothelial (VE)-cadherin (16). On fully mature blood vessels, PECAM-1 is a constitutively expressed, prominent component of EC junctions at all levels of the vascular tree (17,18). It also has been found on cells with significant endothelial-like properties, including trophoblasts (19), retinal pigment epithelium (20), and circulating endothelial progenitor cells (21). PECAM-1 expression on human umbilical vein ECs (HUVECs) reaches  $1 \times 10^6$  molecules/cell (22). Expression of PECAM-1 within the lung vasculature may increase even further under hyperoxic conditions (23) or following irradiation (24).

As illustrated in Figure 115.2, PECAM-1 is diffusely distributed in the plasma membrane of isolated ECs, and it becomes strongly border-localized upon cell–cell contact (25). This appears to be a dynamically regulated process, because PECAM-1 has been shown to leave the junctions at the leading edge of migrating ECs during processes like wound healing or

Figure 115.1. Schematic representation of PECAM-1. (A) PECAM-1 is a 130-kDa type I transmembrane receptor glycoprotein encoded by a 62-kb gene located on the reverse strand of the long arm of chromosome 17. The extracellular domain is comprised of six Ig Type C2 domains, with the first two mediating its homophilic binding properties. The 118-amino acid cytoplasmic domain is genetically and structurally complex, being encoded by eight different exons, some of which have been found to be alternatively spliced to yield PECAM-1 isoforms with potentially distinct signaling properties. The molecular mass of the mature protein contributed by its 711 amino acids is only approximately 80 kDa, with the remaining 50 kDa accounted for by N-linked glycosylation at nine sites, denoted by small circles. ITIMs encompassing tyrosine residues 663 and 686 contribute importantly to PECAM-1-mediated signal transduction. (B) Homophilic interactions of PECAM-1 at the cell-cell interface strategically position it to be able to respond to mechanical and chemical environmental signals.

angiogenesis (26). Somewhat surprisingly, border localization is mediated not by connections of the cytoplasmic domain with the underlying cytoskeleton, but rather by extracellular domain-mediated homophilic interactions, in a process that has been termed *diffusion trapping* (27). Border-enriched PECAM-1 is actually comprised of two distinct populations (28) – those molecules on the cell surface proper, and a continuously recycling pool of PECAM-1 molecules present on a surface-connected submembranous compartment that helps

guide leukocytes through the junction (28) and/or affects leukocyte activation (29) during the process of transendothelial migration (TEM). Unlike its cell junctional neighbor, VE-cadherin, PECAM-1 does not appear to be enriched at adherens junctions per se, but instead is found nearer the adluminal surface (30), where it has been reported to serve as a receptor that facilitates the binding and internalization of certain strains of *Plasmodium falciparum*-infected erythrocytes (31).

Figure 115.2. Cell contact-dependent localization of PECAM-1 at EC-cell junctions. PECAM-1 is found evenly distributed on the surface of the plasma membrane (*upper left panel*) until cells contact each other. When cells reach confluence (*upper right panel*), PECAM-1 becomes highly enriched at cell borders, both in vitro (*upper panels*) and in vivo (*lower panels*). (Photos reproduced with permission from Drs. Cunji Gao and Xia Tang, Blood Research Institute and Medical College of Wisconsin.)

PECAM-1 can be induced to change its EC junctional distribution by a number of physiological events, most notably those associated with the process of inflammation. Although neither treatment with ethyleneglycol-bis-( $\beta$ -aminoethyl)-N, N, N', N'-tetraacetic acid (EGTA) (30) nor neutrophil adhesion per se (32) causes gross redistribution of PECAM-1 from EC-cell junctions, mediators like interleukin (IL)-1 and tumor necrosis factor (TNF)- $\alpha$  have been found to affect both endothelial PECAM-1 expression levels as well as its subcellular distribution. For example, the treatment of intact blood vessel explants with TNF- $\alpha$  was found to increase the concentration of PECAM-1 at EC junctions (33), whereas herpes simplex virus infection of the cornea of live mice, which leads to locally elevated interferon (IFN)- $\gamma$  levels, significantly upregulated PECAM-1 expression on corneal vascular endothelium (34). These findings are in sharp contrast to four different in vitro studies using cultured ECs, in which exposure to TNF- $\alpha$  and/or IFN- $\gamma$  resulted in a decrease in PECAM-1 mRNA and protein levels (35,36) and a rapid redistribution out of cell-cell junctions (36–38). In either case, cytokine-mediated redistribution of PECAM-1 may affect several of its endothelial functions, including maintenance of a permeability barrier and support of leukocyte TEM.

#### THE ROLE OF PLATELET-ENDOTHELIAL CELL ADHESION MOLECULE-1 IN THE TRANSENDOTHELIAL MIGRATION OF LEUKOCYTES

One of the earliest described functions of EC PECAM-1 was its ability to mediate the TEM of leukocytes (39) – a property that involves homophilic interactions between the first extracellular Ig domains of leukocyte PECAM-1 and EC PECAM-1 (40). PECAM-1-deficient mice exhibit a marked defect in neutrophil and monocyte migration in response to inflammatory stimuli (41). Why this is so is not clear, but the engagement of EC PECAM-1 has been shown to initiate a number of downstream events, including: (a) tyrosine phosphorylation of its cytoplasmic ITIMs and formation of a PECAM-1/SHP-2 signaling complex (42), (b) increase in cytosolic calcium (43), (c) prostacyclin generation (43), and (d) activation of cell surface integrins (44). Of these, a recent study (29) suggests that the primary function of EC PECAM-1 in the transmigration process is to serve as a passive ligand for leukocyte PECAM-1, which, as a result of homophilic interactions with its EC counterpart, sends activation signals into the leukocyte that upregulate integrin function and facilitate the latter stages of

TEM (45). In this regard, two studies (46,47) have shown that anti-PECAM-1 mAbs inhibit leukocyte TEM by blocking their transit through the basement membrane, a collagen- and laminin-rich barrier whose transit likely requires activated leukocyte integrins. Additional evidence that PECAM-1 functions to modulate leukocyte integrin function has recently been provided by two groups who found that leukocytes became transiently delayed while traversing the perivascular basement membrane of PECAM-1-deficient mice (48,49). The nature of PECAM-1-initiated signals that activate leukocyte integrins has not been established with certainty, but may involve PECAM-1 clustering (50), activation of phosphoinositide 3-kinase (PI3K) (51), the small GTPase Rap1 (52), and/or calcium flux (53).

The ability of anti-PECAM-1 mAbs – via their ability to block leukocyte TEM – to serve as anti-inflammatory agents has been exploited numerous times. Vaporciyan and colleagues injected anti-PECAM-1 mAbs into rats, and were the first to show that such reagents *in vivo* could block neutrophil emigration into inflamed peritoneal and alveolar compartments, as well as across TNF- $\alpha$ -treated human endothelium (54). Bogen and colleagues soon thereafter observed similar effects of anti-PECAM-1 mAbs in mice (55). Beneficial effects of anti-PECAM-1 mAbs in reducing leukocyte-mediated ischemia-reperfusion injury have been demonstrated in at least six different experimental systems (56–61), providing a rationale for the eventual use of such reagents in humans.

#### **PLATELET-ENDOTHELIAL CELL ADHESION MOLECULE-1 AS A REGULATOR OF ENDOTHELIAL CELL MIGRATION AND ANGIOGENESIS**

Although individual ECs can exist for many months as stable components of the vasculature, their ability to migrate and organize into new blood vessels is important during vasculogenesis, in wound repair following vascular injury, and during the neovascularization that occurs in response to growth factors, chemokines, and solid tumor-induced angiogenesis. Many cytoskeletal elements and cell surface adhesion and signaling molecules are involved in EC migration and angiogenesis, and numerous observations suggest that PECAM-1 plays a positive role in both these processes. First, VEGF – which functions as an EC mitogen and stimulator of EC migration and new blood vessel formation – stimulates tyrosine phosphorylation of PECAM-1 (62). Second, ECs derived from PECAM-1-deficient mice show reduced migration rates *in vitro* (63) and form new blood vessels at a slower rate *in vivo* (64) – an observation similar to that found in HUVECs, in which cell migration rates were reduced by treatment with PECAM-1-specific antisense oligonucleotides (63). Third, although not universally observed (26,65,66), transfection of PECAM-1 into PECAM-1-deficient ECs (63) or PECAM-1-negative cell lines (67,68) has most often been

found to enhance the cells rate of migration, as well as their ability to organize and form networks of cords on Matrigel (69). Interestingly, the PECAM-1 cytoplasmic ITIMs and their ability to recruit SHP-2 appear to be required for both these events (67). Fourth, numerous investigations have shown that anti-PECAM-1 antibodies block EC tube formation in three-dimensional collagen or laminin gels (67,69–73), and are effective inhibitors *in vivo* of growth factor-induced neovascularization (71) and tumor-induced angiogenesis (67,73). Taken together, these data support the notion that PECAM-1 adhesion and/or signaling contribute importantly to EC migration in wound healing and a multitude of other angiogenic responses, and it provides a rationale for the future development of anti-PECAM-1-based therapeutics to inhibit solid tumor growth.

#### **PLATELET-ENDOTHELIAL CELL ADHESION MOLECULE-1 AS A BIOSENSOR**

The observation that PECAM-1 has both adhesive as well as signaling properties, together with the fact that it is expressed at high receptor density on the surface of vascular ECs, suggested that it might function as a biosensor of local environmental changes. Evidence that this is in fact the case was first provided by Fujiwara and colleagues, who found that PECAM-1 becomes phosphorylated on ITIM tyrosine<sup>686</sup> within minutes following EC exposure to changes in fluid shear stress, or to mechanical changes brought about by hyper- or hypo-osmotic shock (12,74). These findings have since been confirmed (42,75,76) and extended to PECAM-1-expressing EC-like REN cells (77) and murine endothelioma cells (78). Shear stress-induced tyrosine-phosphorylation of PECAM-1 ITIMs triggers rapid translocation of SHP-2 (11,42,75) and Gab1 (42) from their cytosolic location to the inner face of the plasma membrane. Several studies have addressed the requirements for PECAM-1 tyrosine phosphorylation in response to the application of shear stress to ECs. Calcium mobilization and the activation of trimeric G-proteins, which are early responses to shear stress, are not sufficient for PECAM-1 tyrosine phosphorylation (12,74). Rather, this event requires that ECs have an intact cytoskeleton (11) and that PECAM-1 be engaged as a consequence of either cell confluence (42,78) or the adherence of nonconfluent cells to immobilized PECAM-1-specific antibodies (42). A mutant form of PECAM-1 incapable of engaging in homophilic interactions did, however, become tyrosine phosphorylated in mechanically stimulated, confluent REN cells (77), suggesting that the requirement for PECAM-1 homophilic engagement may be somewhat lax. Members of the Src (11,12,76,79) and Fps/Fes or Fer (80) families of protein tyrosine kinases have been implicated in PECAM-1 phosphorylation in response to mechanical stimulation; however, the pathways leading to the activation of these kinases in response to shear stress, and whether PECAM-1 is downstream (11,12,76,79,80) or upstream (81) of kinase activation remain important topics of investigation.

Regardless of the order of events, tyrosine phosphorylation of PECAM-1 in response to shear stress creates a scaffold for recruitment-type signaling molecules that have the potential to modulate the responses of ECs. ECs respond to shear stress by initiating a number of processes that result in biochemical, morphological, and physiological changes in the vasculature (82). PECAM-1 recently has been implicated in several of these processes. Specifically, PECAM-1-deficient ECs, derived either from PECAM-1-deficient mice or by small-interfering RNA (siRNA)-mediated knockdown of endogenous PECAM-1 expression, exhibit defective activation of Src (81), mitogen-activated protein kinase (MAPK)/extracellular-signal-regulated kinase (ERK) (42,75), and PI3K/Akt (75,81) in response to shear, although the latter two pathways were not found to be affected by PECAM-1 deficiency in a separate study (78). The upstream mechanisms by which PECAM-1 contributes to the activation of these pathways are as yet incompletely characterized, but appear to include activation of Src and integrins (81); formation of a multimolecular complex with VE-cadherin/ $\beta$ -catenin, VEGF receptor 2 (VEGFR2), PI3K, Tie2, SHP-2, and Gab1 (42,75,81); and a requirement for both the catalytic activity (42) and adaptor function (75) of SHP-2. PECAM-1 deficiency has predicted consequences for events downstream of these pathways, such as MAPK/ERK-dependent initiation of nuclear factor (NF)- $\kappa$ B-driven gene transcription (81) and activation of endothelial nitric oxide synthase (eNOS), which depends in part on activation of the PI3K/Akt pathway (75,76) and may also be regulated by colocalization of eNOS with PECAM-1 at the cell surface (76,83,84).

Although these studies provide evidence that PECAM-1 plays a role in activation of signal transduction pathways in cultured ECs exposed to shear stress, recent studies have demonstrated that the responses of PECAM-1-dependent ECs to shear stress are both observed in, and contribute significantly to, in vivo responses within the vasculature. In vessels, fluid shear stress is accomplished by increasing perfusate flow, in response to which vessels normally dilate. Flow-mediated dilation is attributable to ECs release of vasodilatory factors, including prostacyclin, nitric oxide (NO), and endothelium-derived hyperpolarizing factor (EDHF) (85). Two recent studies have reported that flow-mediated dilation is markedly impaired in the absence of PECAM-1, although a different mechanism was found to underlie impairment in each case. Thus, one study reported that PECAM-1-deficient skeletal muscle arterioles exhibited impaired dilation in response to a high temporal gradient of increased flow, in this case due to a defect in NO production (86). A second study reported that PECAM-1-deficient coronary arteries exhibited impaired dilation in response to a steady-state increase in flow; however, in this case, the impairment was due to *overproduction* of NO, superoxide anion, and peroxynitrite, which interfered with responses of vascular smooth muscle cells to EDHF (87). The molecular mechanisms by which PECAM-1 regulates flow-mediated dilation in different vascular beds have not been determined.

The physiological relevance of PECAM-1-mediated, shear stress-induced, signal transduction in ECs is just beginning to be examined in the context of cardiovascular diseases like thrombosis and atherosclerosis. Conflicting results have been obtained in murine models of these diseases; PECAM-1 deficiency has been found to have both prothrombotic (88) and atheroprotective effects (81). Although PECAM-1 deficiency has not yet been described in humans, certain allelic polymorphisms within the *PECAM-1* gene have been associated with a higher risk for developing atherosclerosis in the human population (89). Whether the ability of PECAM-1 to influence the response of vascular ECs to hemodynamic changes is mechanically linked with its reported effects on the development of thrombotic and atherosclerotic lesions remains an intriguing avenue of future investigation.

In addition to its role as a mechanosensor, PECAM-1 also appears to modulate EC responses to peptide and lipid mediators generated during the inflammatory response. For example, when ECs are exposed to the inflammatory cytokine IL-1 $\beta$ , NF- $\kappa$ B becomes activated and translocates to the nucleus, where it upregulates the gene transcription of a number of EC surface adhesion molecules used to attract leukocytes, including intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1. If left unchecked, however, excessive invasion of leukocytes, particularly neutrophils, can lead to tissue injury, organ failure, and death. PECAM-1-positive transmigrating leukocytes appear to limit this untoward inflammatory response by engaging EC PECAM-1 during transit, which, via a poorly understood negative-feedback mechanism initiated by intercellular PECAM-1/PECAM-1 homophilic interactions, suppresses further NF- $\kappa$ B activation (90). PECAM-1 appears to exert additional anti-inflammatory effects by limiting the extent of the systemic acute phase response to bacterial lipopolysaccharide (LPS), because PECAM-1-deficient mice are highly susceptible to endotoxin-induced septic shock (91,92). This may be caused, in part, to failure of PECAM-1-deficient ECs to sustain tyrosine phosphorylation of the transcription factor, Stat3 (92), which, upon cytokine stimulation and phosphorylation by Janus kinase (Jak), dimerizes and moves to the nucleus. There, it transactivates a plethora of genes involved in controlling inflammation (93–95) and suppressing apoptosis (96). Because PECAM-1-deficient mice exhibit increased lethality following LPS challenge, it may be of future interest to determine whether people expressing low levels of EC PECAM-1 might be at greater risk for developing septicemia following bacterial infection. Finally, when lysophosphatidylcholine (Lyso PC) – a prominent phospholipid component of atherogenic lipoproteins that is also elevated in many inflammatory diseases – binds to one of its recently identified G-protein-coupled receptors on vascular endothelium, it induces tyrosine phosphorylation of PECAM-1 within minutes, and upregulates expression of ICAM-1 and VCAM-1 over a period of hours (97). The consequences of Lyso PC activation of PECAM-1 have not yet been examined.

Figure 115.3. Reactive oxygen species activate PECAM-1 ITIMs and trigger cell border localization of the protein-tyrosine phosphatase, SHP-2. Endothelial-like REN cells were transfected with a green fluorescent protein (GFP) fusion protein containing the tandem SH2 domains of SHP2 together with either wild-type PECAM-1 (*top two rows*) or an ITIM-crippled (Y<sub>663,686</sub>→F) form of PECAM-1 (*bottom row*). In resting cells (*top row*), PECAM-1 is concentrated at cell–cell borders, whereas SHP-2 is largely cytoplasmic and nuclear. Upon exposure to oxidative stress (*middle and bottom rows*), SHP-2 is recruited to the inner face of the plasma membrane of cells expressing wild-type (*middle panels*) but not ITIM-less (*lower panels*) PECAM-1. (Reproduced with permission from Maas et al. *Am J Physiol Heart Circ Physiol.* 2003;285:H2336. Photo courtesy of Cathy Paddock, Blood Research Institute.) For color reproduction, see Color Plate 115.3.

PECAM-1 also functions as a redox sensor in vascular cells. Because intracellular tyrosine phosphatases contain a reactive site cysteine that is susceptible to oxidation, exposure of cells to even mild oxidants like hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) results in their inactivation. This disrupts the carefully controlled balance of intracellular tyrosine kinases and phosphatases, resulting in a marked increase in the tyrosine phosphorylation state of a number of cellular proteins, one of the more prominent of which is PECAM-1. Maas and colleagues (98) have shown that exposure of ECs to reactive oxygen species (ROS) causes rapid, reversible phosphorylation of PECAM-1 cytoplasmic domain ITIM tyrosine residues and the resultant recruitment of SHP-2 to cell–cell borders (Figure 115.3; for color reproduction, see Color Plate 115.3). Similarly, Ji and coworkers (99) found that EC exposure to H<sub>2</sub>O<sub>2</sub>, at concentrations expected to be achieved at sites of inflammation, resulted in SFK-dependent phosphorylation of the PECAM-1 cytoplasmic domain ITIM tyrosines and subsequent activation of a calcium-permeant, nonselective cation channel. This channel gives rise to the prolonged calcium currents that are required for ECs to open their intercellular junctions during the transendothelial passage of leukocytes. Because intact ITIMs were required for PECAM-1–dependent current activation, it is tempting to speculate that PECAM-1–mediated recruitment of SHP-2 to the inner face of the plasma membrane facilitates dephosphorylation of one or more ion channel regulatory proteins, resulting in the observed opening of plasma membrane

cation channels. The identity of such proteins is unknown at present.

#### SUPPRESSION OF ENDOTHELIAL CELL APOPTOSIS

EC apoptosis is a normal physiological event that is thought to play an important role in branching morphogenesis during development (100), hypertension-induced remodeling of the peripheral vascular tree (101), and the development of tumor vasculature (102). In addition, microvascular EC apoptosis has been shown to be the primary cause of epithelial sloughing following radiation treatment of the gastrointestinal tract (103). Thus, identifying the cellular factors that control EC survival and death has implications for our understanding of angiogenesis (104), atherosclerosis (105), and tumor responses to radiotherapy (106).

Increasing evidence suggests that PECAM-1 is able to transmit antiapoptotic survival signals into ECs. Three different groups have found that the engagement of the PECAM-1 extracellular domain confers resistance in cultured ECs to serum-deprivation–induced cell death (107–109). The cytoprotective effects of PECAM-1 appear to operate *in vivo* as well. Gao and colleagues have shown that lung endothelium in PECAM-1–deficient mice is hypersensitive to radiation-induced apoptosis, compared to that derived from their

wild-type counterparts (110). PECAM-1 appears to be active in suppressing only one of two major cell death pathways. Thus, whereas PECAM-1 confers no survival benefit to cells challenged with activators of the extrinsic (TNF/death receptor) pathway, it is a potent suppressor of the mitochondrial-dependent, Bax-mediated intrinsic pathway of programmed cell death (110). Because the intrinsic pathway is activated by a range of stimuli that include many genotoxic chemotherapeutic agents, ROS, and UV- and X-irradiation, targeted modulation of PECAM-1 expression might represent a novel approach to sensitizing tumor vasculature to proapoptotic anticancer agents (111).

The nature of the prosurvival signals that PECAM-1 confers to the vascular endothelium has not been firmly established. Gao and colleagues found that mutations within the homophilic binding domain or its cytoplasmic ITIMs abolish PECAM-1's cytoprotective effects, suggesting that PECAM-1-PECAM-1 interactions lead to the transmission of still-to-be-defined ITIM-dependent signals (SHP-2 binding?) that suppress apoptosis (110). An ITIM-independent mechanism by which PECAM-1 expression may confer cytoprotective properties to ECs is suggested by the recent observation that a major isoform of sphingosine kinase (SphK) is constitutively associated with part of the PECAM-1 cytoplasmic domain (that encoded by exons 9–13) in transfected HEK 293 cells overexpressing both proteins (112). How, though, might PECAM-1-SphK interactions influence the susceptibility of ECs to proapoptotic signals?

Sphingomyelin is a ubiquitous, abundant, and naturally occurring sphingolipid component of animal cell membranes that can be enzymatically catabolized to ceramide, sphingosine, and sphingosine 1-phosphate (S1P) via the sequential actions of sphingomyelinase, ceramidase, and SphK, respectively (Figure 115.4). Cells maintain a dynamic equilibrium (sometimes termed the *ceramide/S1P rheostat*) (113) among these three sphingolipid metabolites, as each can act as second messengers that activate opposing downstream signaling pathways. In particular, ceramide and sphingosine are both potent stimulators of mitochondrial-mediated EC apoptosis (114,115), while SphK serves not only to antagonize the apoptotic effects of ceramide and sphingosine by depleting them from the cellular pool, but also generates S1P, which has potent intrinsic antiapoptotic activity of its own (116).

The potential for PECAM-1 to regulate SphK/S1P signaling may be especially relevant to radiation-induced EC apoptosis, because irradiation activates sphingomyelinase (115), which is abundantly expressed in ECs (117). At the same time, it upregulates PECAM-1 expression (24,118,119). It is therefore tempting to speculate that the prosurvival effects of PECAM-1 may be due, at least in part, to its ability to recruit and concentrate SphK near sphingosine, where it can inactivate it via conversion to S1P. Manipulating cellular PECAM-1 expression levels could, at least theoretically, affect the conversion of proapoptotic sphingosine to antiapoptotic S1P, thereby exerting some control over the ceramide/S1P rheostat. For example, overexpressing PECAM-1 would be predicted to

Figure 115.4. Schematic diagram showing the potential for PECAM-1 to regulate intracellular ratios of proapoptotic and antiapoptotic levels of sphingomyelin metabolites by influencing the subcellular distribution of sphingosine kinase.

increase S1P levels and thereby enhance cell survival, whereas lowering PECAM-1 would have the effect of tipping the rheostat such that cellular ceramide and sphingosine levels increase, thereby sensitizing cells to radiation-induced apoptosis. Further studies will be required to establish the relevance of this pathway to EC survival and the utility of manipulating it to promote radiation-induced injury of tumor vasculature.

## BARRIER FUNCTION AND REGULATION OF VASCULAR PERMEABILITY

Ferrero and colleagues reported more than 10 years ago that PECAM-1-specific F(ab')<sub>2</sub> fragments are able to augment <sup>125</sup>I-labelled albumin transit across EC junctions, both in cultured cells and in mice (120). Conversely, they also found that cultured NIH/3T3 and ECV304 cells could be made less permeable to albumin if the cells were transfected with PECAM-1 cDNA. Based on their findings, they were the first to suggest that PECAM-1 contributes to EC barrier function. It was, therefore, somewhat surprising to discover that vascular development is overtly normal in PECAM-1-deficient mice (48). However, a number of studies have since shown that the stability of EC-cell junctions is more easily compromised in the blood vessels of PECAM-1-deficient mice subjected to stress and strain. For example, despite the fact that platelets are hyperreactive in PECAM-1-deficient mice (121), Mahooti and colleagues found that tail vein bleeding times are actually prolonged compared with that of wild-type mice (122). Reassuringly, these authors were able to show, using bone marrow-transplanted radiation chimeric mice, that the bleeding abnormality segregated with the phenotype of the endothelium, and not with that of circulating platelets. These

data, therefore, suggest that PECAM-1 deficiency creates an EC junctional defect that becomes most obviously manifest during vascular responses to injury. Further support for an *in vivo* role for PECAM-1 in EC barrier function was provided by the studies of Graesser and colleagues (123), who observed that re-establishment of a vascular permeability barrier is delayed in the vessels of PECAM-1-deficient mice in skin exposed to histamine and in the brain microvasculature of mice suffering from experimental autoimmune encephalomyelitis (EAE). The most dramatic consequence of PECAM-1's absence from EC junctions, however, becomes evident during septicemia, as two different groups found that PECAM-1-deficient mice are much more susceptible to LPS-induced septic shock than are their wild-type counterparts (91,92). When challenged with LPS, the blood vessels of PECAM-1-deficient mice exhibit increased permeability and have an exaggerated loss of blood volume, with a concomitant, fatal drop in blood pressure (91). Interestingly, similar to the bleeding time phenotype, this could be corrected by expressing PECAM-1 solely on ECs. Taken together, these data support the notion that PECAM-1-mediated adhesion and/or signaling contributes appreciably to vascular integrity and the maintenance of a stable vascular permeability barrier, especially following disruptive stimuli.

The mechanism by which PECAM-1 contributes to EC barrier function is still not well understood. Several groups (70,124) found evidence for the formation of PECAM-1/ $\beta$ -catenin complexes, and suggested that the ability of PECAM-1 to recruit  $\beta$ -catenin might influence junctional stability by affecting the dynamics and assembly of VE-cadherin/ $\beta$ -catenin/F-actin complexes. In addition to this scaffolding function, PECAM-1 recently has been shown to regulate the ability of Jaks to phosphorylate Stat3 (92), which, in ECs, may play a protective role against LPS-induced septic shock (93,125). Whether this is related to the ability of PECAM-1 to bind SHP-2 and regulate the phosphorylation state of Jak/Stat complexes is not yet known.

#### KEY POINTS

- PECAM-1 is a 130-kDa member of the immunoglobulin gene superfamily, expressed at high concentrations at the intercellular junctions of confluent ECs. It contributes importantly to a variety of endothelial-specific functions, including cell migration, angiogenesis, responses to flow, and cell survival.
- The extracellular domain of PECAM-1 mediates PECAM-1/PECAM-1 homophilic interactions between cells, and is responsible for capturing PECAM-1 at cell-cell junctions. These properties are important in PECAM-1-mediated leukocyte TEM, in endothelial migration during angiogenesis, and in maintaining EC junctional integrity.

- The cytoplasmic domain of PECAM-1 contains two ITIMs that become phosphorylated and serve as a docking site for cytosolic signaling molecules, in particular the protein-tyrosine phosphatase, SHP-2. The PECAM-1/SHP-2 complex may play an important role in conferring prosurvival properties to ECs subjected to radiation injury, in the ability of PECAM-1 to mediate EC migration and blood vessel formation, and in the function of PECAM-1 as a biosensor of chemical and mechanical stress.

#### Future Goals

- To determine the molecular mechanisms by which PECAM-1 regulates EC responses to cytokines
- To determine how PECAM-1 protects ECs from Bax-mediated apoptosis
- To determine the mechanism by which PECAM-1 contributes vascular integrity and helps maintain the EC permeability barrier
- To determine the molecular mechanism by which PECAM-1 regulates flow-mediated dilation in different vascular beds

In 1984, two groups independently described monoclonal antibodies that bound to activated but not to resting platelets (1,2). The antibodies recognized a 140-kD platelet membrane glycoprotein. Immunocytochemical analysis revealed that the protein was concentrated in the membranes of  $\alpha$ -granules in resting platelets (3,4). Thrombin and other agonists that induced fusion of  $\alpha$ -granules with the plasma membrane caused the protein to redistribute to the platelet surface; this finding explained why the antibodies bound only to activated platelets. The protein was originally called granule membrane protein of 140 kDa (GMP-140) or platelet activation-dependent granule-to-external-membrane protein (PADGEM). Soon after, the same groups reported that endothelial cells (ECs) also expressed this protein (5–8). In resting endothelium, the protein was concentrated in membranes of Weibel-Palade bodies. Thrombin, histamine, and other agonists that induced fusion of Weibel-Palade bodies with the plasma membrane caused the protein to redistribute to the EC surface. Therefore, GMP-140/PADGEM was a glycoprotein that could be rapidly mobilized to the cell surface from storage granules by mediators generated during injury or infection (Figure 116.1). This suggested that the protein had important functions at vascular sites where platelets and/or ECs became activated.

In 1989, one of the groups reported the primary structure of GMP-140/PADGEM derived from protein sequencing and cDNA cloning (9). This analysis revealed a modular, type I membrane glycoprotein with an N-terminal domain similar to those in calcium ( $\text{Ca}^{2+}$ )-dependent (C-type) lectins, followed by an epidermal growth factor (EGF)-like module, nine short consensus repeats related to those in complement-regulatory and other proteins, a transmembrane domain, and a short cytoplasmic tail (Figure 116.2). At the same time, other groups reported the cloning of cDNAs encoding two other proteins with related modular structures (Figure 116.2). A homing receptor expressed on leukocytes mediated the adhesion of lymphocytes to lymph node endothelium by a mechanism that was believed to involve carbohydrate recognition

(10,11). Endothelial leukocyte adhesion molecule (ELAM)-1, which was expressed on cytokine-activated endothelium, supported the adhesion of leukocytes in vitro (12). The structural relationship of GMP-140/PADGEM to these proteins immediately suggested a functional relationship. Shortly thereafter, leukocytes were shown to adhere to the GMP-140/PADGEM expressed on the surfaces of activated platelets and ECs (13–15). The new family of proteins received the consensus name *selectins*, to indicate that they mediated selective cell–cell interactions through the interactions of their lectin domains with putative carbohydrate ligands (16). Each family member was assigned a letter prefix to represent the cell in which it was first identified. Thus, the homing receptor was named L-selectin, ELAM-1 was named E-selectin, and GMP-140/PADGEM was named P-selectin. Since then, the properties of the selectins in vitro and in vivo have been the subject of numerous papers. The selectins have attracted great attention because of their contributions to leukocyte trafficking, and because they represent one of the earliest and best-characterized examples of a biological function for lectins in mammals. P-selectin has received particular notice as an inducible cell adhesion molecule that links the hemostatic and inflammatory responses to tissue injury.

### GENE REGULATION, GENE/PROTEIN STRUCTURE, AND PROTEIN TRAFFICKING

The genes encoding all three selectins are tightly linked on syntenic regions of chromosome 1 in both humans and mice (17). They represent a classic example of the use of gene duplication and exon shuffling to generate a new gene/protein family. Almost all exons encode discrete structural domains (18). The selectin genes are located close to a group of genes encoding complement-regulatory proteins that have similar short consensus repeats. This suggests that several genes with functions during immune responses developed coordinately. The C-type lectin, EGF-like, and short consensus repeat domains are

Figure 116.1. Inducible expression of P-selectin in platelets and ECs. P-selectin is constitutively synthesized by megakaryocytes and ECs, where it is sorted into the membranes of  $\alpha$ -granules in platelets and Weibel-Palade bodies in ECs. Within seconds to minutes after cellular activation by mediators such as thrombin or histamine, P-selectin is redistributed to the plasma membrane.

derived from ancient structural modules that are also found in invertebrates. However, the specific organization of these domains in the selectin genes has been observed only in vertebrates. Expression of the selectins is restricted to hematopoietic cells and ECs, which suggests that the genes evolved to support specialized functions in the vascular system.

Expression of P-selectin is confined to megakaryocytes, from which platelets are derived, and to ECs. Recently, some macrophages, but not their parental monocytes, were also shown to express P-selectin *in vivo* (19). In both humans and mice, megakaryocytes and ECs synthesize P-selectin constitutively. Normally, only the ECs of postcapillary venules express P-selectin (5). Postcapillary venules, in which shear stresses are lowest, are the favored regions for leukocyte recruitment during inflammation. However, P-selectin also is expressed in the ECs of inflamed arterioles and of large arteries at sites of atheromas, usually at bifurcations having lower, oscillatory

shear stresses (20). The mechanisms that confer tissue-specific expression of P-selectin are not well understood.

In mice and several other mammals, the inflammatory mediators tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , and lipopolysaccharide (LPS) markedly increase the transcription of the *P-selectin* gene (21). Transcripts for P-selectin peak within 4 to 6 hours, and decline to basal levels within 12 to 24 hours. The gene encoding E-selectin responds similarly, except that there is normally no basal synthesis of E-selectin in the absence of inflammatory stimuli. The mechanisms underlying inducible expression of E-selectin have been intensively studied in both humans and mice (22). Inflammatory signals mobilize the transcription factors nuclear factor (NF)- $\kappa$ B and activating transcription factor (ATF)-2, which migrate to the nucleus and bind to an enhanceosome in the 5' flanking region of the *E-selectin* gene. These transcription factors cooperate with basal transcription machinery to drive gene expression.

Figure 116.2. Domain organization of the selectins. Each of the selectins has an N-terminal C-type lectin domain, followed by an EGF-like domain, a variable number of consensus repeats like those in complement-regulatory proteins, a transmembrane domain, and a cytoplasmic domain.

Regulatory elements in the 5'-flanking region of the murine *P-selectin* gene are organized like those in the human and murine *E-selectin* genes (23), and site-directed mutagenesis and reporter gene experiments suggest that binding sites for NF- $\kappa$ B and ATF-2 in this region contribute to transcriptional upregulation in response to TNF- $\alpha$  and IL-1 $\beta$  (24). In sharp contrast, the 5'-flanking region of the human *P-selectin* gene lacks these regulatory elements. Furthermore, TNF- $\alpha$ , IL-1 $\beta$ , and LPS fail to upregulate transcription of the *P-selectin* gene in humans or baboons (25). These results suggest a divergence in the mechanisms for inducible expression of the *P-selectin* gene, but not of the *E-selectin* gene, in humans and other primates. The biological significance of this divergence is not understood. Interestingly, IL-4, oncostatin M, and complexes of IL-6 with the soluble IL-6 receptor- $\alpha$  subunit augment transcription of the human *P-selectin* gene in cultured human ECs (26). Whether these mediators contribute to the elevated expression of P-selectin overlying human atheromas is not known.

As mentioned, basal synthesis of P-selectin occurs in megakaryocytes/platelets and in ECs. Therefore, the most critical control step is the display of the protein at the cell surface. This is achieved initially by sorting of newly synthesized P-selectin, presumably at the *trans*-Golgi network, for delivery to regulated storage granules. Determinants in the cytoplasmic domain of P-selectin are required for sorting into Weibel-Palade bodies of ECs and into regulated storage granules of transfected endocrine cells that do not normally express P-selectin (27). These determinants presumably interact with cytosolic sorting proteins in coated transport vesicles. Unexpectedly, the cytoplasmic domain is not required to deliver P-selectin into the  $\alpha$ -granules of platelets, which implicates an alternative sorting mechanism in these cells (28). A variety of physiological and pathological agonists can mobilize P-selectin from Weibel-Palade bodies to the cell surface. These include thrombin, histamine, complement components, hypoxia, and oxygen-derived radicals. After P-selectin moves to the surface of activated platelets and ECs, other mechanisms regulate the duration of its appearance. In vitro, P-selectin is stably expressed on the surface of activated platelets for many hours. In vivo, however, circulating activated platelets rapidly shed P-selectin from the surface by an uncharacterized proteolytic cleavage event (29). In some situ-

ations, P-selectin also may be cleaved from the surface of activated ECs. However, ECs and transfected heterologous cells also rapidly internalize P-selectin in clathrin-coated pits. Sorting determinants in the cytoplasmic tail are required for internalization (30). The protein may recycle from sorting endosomes to the cell surface or return to the *trans*-Golgi network for reincorporation into Weibel-Palade bodies. Other sorting determinants in the cytoplasmic domain direct the protein from late endosomes to lysosomes, where it is degraded (31). The net result of this intracellular trafficking is to shorten the time that P-selectin is displayed on the surface of activated ECs. This is likely an important mechanism for limiting the inflammatory response. Persistent surface expression of P-selectin probably requires a sufficiently large increase in synthesis of the protein to saturate the sorting pathway at the *trans*-Golgi network, bypass delivery to Weibel-Palade bodies, and transport newly synthesized protein directly to the cell surface. Interestingly, differential signaling by histamine and thrombin results in different rates of the internalization of P-selectin in clathrin-coated pits (32). More rapid endocytosis is associated with more efficient clustering of P-selectin in clathrin-coated pits, which enhances its adhesive function on the cell surface.

## ROLE IN HOMEOSTASIS

### Autocrine and Paracrine Effects

The primary function of P-selectin is to mediate the adhesion of leukocytes to activated platelets and ECs (33–35) (Figure 116.3). This can be considered both an autocrine and paracrine function in that the protein promotes adhesion of leukocytes (paracrine) to the cells that express P-selectin (autocrine). Leukocytes originally were shown to adhere to P-selectin under static conditions in vitro (13–15). During an inflammatory response in vivo, however, flowing leukocytes first tether to and roll on vascular ECs. Some of the rolling cells then decelerate until they arrest on the endothelium, and they eventually crawl between or through ECs into the underlying tissues (36). Importantly, all three selectins mediate the initial rolling adhesion of leukocytes on vascular surfaces (33–35,37). This was demonstrated in vitro by visualizing the adhesion of leukocytes to selectins in flow chambers using

Figure 116.3. Multicellular adhesive interactions mediated by P-selectin. Leukocytes roll on P-selectin that is mobilized to the surfaces of activated ECs and activated platelets. Platelets also interact with ECs by a P-selectin-dependent mechanism that has not been fully defined.

**Table 116-1: P-Selectin Knockout Mice**

Genotype	Phenotype	References
<i>P-selectin</i> <sup>-/-</sup>	Healthy, viable without challenge. Mild neutrophilia. Defective leukocyte rolling on P-selectin on activated platelets and ECs. Mild to moderate defects in leukocyte recruitment after inflammatory challenge.	38, 89, 90

videomicroscopy, and in vivo by observing the adhesion of leukocytes to the postcapillary venules of mice using intravital microscopy. Key tools have been monoclonal antibodies that block the adhesive functions of the selectins and gene-targeted mice that lack one or more selectins (Table 116-1). Although exceptions exist, selectin-mediated rolling usually is required before leukocytes can adhere more stably through integrins, another class of adhesion molecules. Because it can be rapidly translocated to the cell surface, P-selectin often mediates the earliest stages of leukocyte rolling on activated platelets and ECs at sites of injury (38).

Selectins enable adhesion by interactions of the membrane-distal C-type lectin domains with specific glycoconjugates on cell surfaces. Selectins primarily interact with fucose in and around a Ca<sup>2+</sup>-coordination site in the lectin domain, and they secondarily interact with sialic acid (39,40). Leukocytes typically present these sugars on a determinant called sialyl Lewis X, or sLe<sup>x</sup> (NeuAc $\alpha$ 2-3Gal $\beta$ 1-4[Fuc $\alpha$ 1-3]GlcNAc $\beta$ 1-), which is a terminal component of some oligosaccharides. However, P-selectin binds with very low affinity to sLe<sup>x</sup>, and cells other than leukocytes that display sLe<sup>x</sup> determinants adhere poorly to P-selectin under static or flow conditions (41). Indeed, P-selectin binds preferentially to a single glycoprotein on leukocytes called P-selectin glycoprotein ligand (PSGL-1) (Figure 116.4) (34,42-44). PSGL-1 is an extended homodimeric mucin that contains many O-glycans attached to serine and threonine residues. Most of these O-glycans are not fucosylated (45), and P-selectin binds specifically to a single branched O-glycan capped with sLe<sup>x</sup> near the

membrane-distal end of PSGL-1. The site is preferred because other regions of the lectin domain of P-selectin simultaneously interact with peptide components and sulfated tyrosine residues on PSGL-1 that are near the O-glycan (40,46,47). This cooperative binding to glycan, peptide, and sulfate moieties on PSGL-1 explains why P-selectin has much higher affinity for this glycoprotein than for other proteins that have glycans capped with sLe<sup>x</sup>. Monoclonal antibodies to the membrane-distal region of PSGL-1 block leukocyte rolling on P-selectin in vitro and in vivo (48,49), and gene-targeted mice lacking PSGL-1 exhibit little or no rolling on P-selectin in vivo (50,51). Therefore, PSGL-1 is the key physiological ligand for P-selectin on all subsets of leukocytes, including neutrophils, monocytes, lymphocytes, eosinophils, and basophils.

The flow conditions in the circulation impose significant kinetic and mechanical constraints on interactions between P-selectin and PSGL-1. To roll, cells must rapidly form and break macromolecular interactions, usually termed *bonds*, between adhesion molecules. Biochemical measurements confirm that the interaction of P-selectin with PSGL-1 involves very fast association and dissociation rates (52). Moreover, force is applied to adhesive bonds at the trailing edge of an adherent cell under flow. At the flow rates most commonly observed in postcapillary venules, the forces applied to P-selectin-PSGL-1 bonds cause them to dissociate more rapidly (53). Such bonds are called *slip bonds*. In principle, progressively higher flow rates should cause adhesive bonds to dissociate faster and faster until bond lifetimes become too short to support rolling. Yet leukocytes roll on P-selectin at nearly uniform velocities over a range of flow rates. This stabilization of rolling results from cellular alterations that dissipate force as flow rates increase (54). A major factor appears to be the dynamic extension and retraction of long membrane tethers at adhesive contacts (55,56). More tethers form at higher rates rather than at lower flow rates. At very low flow rates, a force regime paradoxically slows the dissociation of P-selectin from PSGL-1 (57). Such bonds are called *catch bonds*. Although the physiological significance of these P-selectin-PSGL-1 bonds is not clear, catch bonds may be very important for regulating L-selectin-dependent adhesion (58).

Figure 116.4. Binding of P-selectin to PSGL-1. Both P-selectin and PSGL-1 are extended homodimers that enable dimeric binding as illustrated. The lectin domain of P-selectin binds cooperatively to tyrosine sulfates, amino acids, and a specific O-glycan at the membrane-distal end of PSGL-1. Although PSGL-1 has many other O-glycans, these do not contribute significantly to the interaction with P-selectin.

Other factors control P-selectin–dependent rolling. Both P-selectin and PSGL-1 form homodimers in the membrane, which favors dimeric interactions (see Figure 116.4) (59). Dimeric interactions have longer lifetimes than monomeric interactions and distribute a given force over two bonds rather than one bond. P-selectin also clusters in the clathrin-coated pits of ECs (32,60), and PSGL-1 clusters in the tips of microvilli of leukocytes (48). These arrangements may favor bond clusters that increase the aggregate lifetime of adhesive contacts at the trailing edges of leukocytes. The extension of the binding sites of both PSGL-1 and P-selectin above the membrane increases the probability of contact (54,61). Higher molecular density on the cell surface also promotes slower and more regular rolling. In this regard, the density of P-selectin on activated platelets appears to be much higher than on activated ECs (1,7). This might allow more stable adhesion of leukocytes to platelets.

Under certain conditions, both leukocytes and platelets generate membrane fragments, or microparticles, which express PSGL-1 and P-selectin, respectively. Leukocyte microparticles can adhere to P-selectin on intact platelets, and platelet microparticles can adhere to PSGL-1 on intact leukocytes. Leukocyte microparticles also may express tissue factor, a key initiator of blood coagulation. The P-selectin–dependent accumulation of such microparticles on platelet thrombi augments thrombosis in some murine models of vascular injury (62,63). Some leukocyte microparticles can fuse with platelets (64). This suggests that leukocyte fragments, perhaps generated by the fission of long membrane tethers, might also adhere to and fuse with ECs.

Platelets have been reported to roll directly on the P-selectin of ECs (65). The platelet ligand for P-selectin has been suggested to be either PSGL-1 (66) or the glycoprotein (GP) Ib-IX complex (67), which is the major receptor for von Willebrand factor (vWF). However, it remains controversial whether platelets express PSGL-1, and the nature of the reported interaction between P-selectin and the GP Ib-IX complex requires further study. Leukocyte microparticles that adhere to ECs might also indirectly promote platelet rolling on the vessel surface. Activated ECs secrete ultralarge multimers of vWF, which may bind to P-selectin on the EC surface (68); the region of vWF that binds to P-selectin has not been identified. The ultralarge forms of vWF may enable platelets to roll on the endothelium through interactions with GP Ib-IX. In most circumstances, however, the metalloprotease ADAMTS-13 (a disintegrin and metalloprotease, with thrombospondin-1-like domains, member 13) rapidly cleaves vWF into smaller multimers, which dampens platelet adhesion to the endothelium.

In addition to its role as an adhesion receptor, P-selectin has a paracrine function as a signaling molecule when it binds to PSGL-1 on leukocytes. The cytoplasmic domain of PSGL-1 has no apparent intrinsic kinase motifs. However, engagement of PSGL-1 activates Src kinases and induces the tyrosine phosphorylation of several proteins (69–71). The enrichment of PSGL-1 in lipid rafts, where signaling molecules often cluster,

may favor these responses (64). The cytoplasmic domain of PSGL-1 binds to ezrin and moesin, which link membrane proteins to the actin cytoskeleton and which can also bind to and activate the Syk kinase (72). Effector responses from PSGL-1 signaling include integrin activation (73) and both translational and transcriptional augmentation of chemokine synthesis (74,75). Cross-linking of PSGL-1 appears to be required for optimal signaling. In contrast to paracrine signaling of leukocytes through PSGL-1, autocrine signaling of ECs or platelets through P-selectin has received little attention.

Soluble forms of P-selectin circulate in the plasma of both humans and mice. In humans, some of this material represents an alternatively spliced, secreted isoform that lacks the transmembrane domain (18,76). This form has not been found in mice. Some plasma P-selectin is derived from proteolytic cleavage of the extracellular domain of P-selectin, yielding a form with a slightly lower molecular weight than the transmembrane form (28,29). Some of the material may represent P-selectin in microparticles derived from platelets and possibly from ECs. Plasma levels of P-selectin are modestly elevated in some human inflammatory and thrombotic diseases (77). Leukocytes shed microparticles expressing PSGL-1 that can also adhere to activated platelets and ECs expressing P-selectin. Circulating P-selectin has been postulated to increase the release of prothrombotic and proinflammatory microparticles from leukocytes, representing a potential paracrine function (78). However, plasma levels of P-selectin are low even in disease states. If plasma P-selectin is monomeric, its ability to signal is questionable because it would be unable to cross-link PSGL-1. Plasma concentrations are also well below the  $K_d$  for binding of monomeric P-selectin to leukocytes (52). Nevertheless, if some plasma P-selectin were oligomeric, its avidity for leukocytes and its signaling capability would increase. P-selectin in microparticles also might form multivalent interactions with PSGL-1 on leukocytes that favor signaling.

### Interactions with Other Outputs

P-selectin interacts with many other molecules to promote cell adhesion and signaling. Often P-selectin cooperates with E-selectin and L-selectin to mediate leukocyte rolling. At many sites of inflammation, activated ECs express both P-selectin and E-selectin (33–35). E-selectin normally is expressed at higher densities, and it binds to more than one glycoprotein ligand on leukocytes. Interactions of P-selectin with PSGL-1 are particularly suited for mediating the initial tethering and rolling of leukocytes on ECs, whereas interactions of E-selectin with its ligands slow rolling velocities and prolong the transit times of leukocytes as they roll along venules (79). Interactions between L-selectin and PSGL-1 enable flowing leukocytes to roll on other leukocytes that have already adhered to ECs. These rolling cells may then “transfer” to the endothelium and continue to roll on P-selectin and E-selectin. Leukocytes also use L-selectin to roll on leukocyte-derived fragments expressing PSGL-1 that have been deposited on the endothelium (80). These additional interactions provide more

opportunities for signaling through the engagement of E-selectin ligands or L-selectin on leukocytes. Slower rolling through cooperative selectin interactions augments encounters of leukocytes with chemokines on the apical surfaces of activated ECs. These chemokines, which generally are anchored by endothelial proteoglycans, bind to G-protein-coupled receptors on particular subsets of leukocytes. Cooperative signaling through selectin ligands and chemokine receptors enhances many effector responses in leukocytes (35,79). The most important early response is the activation of  $\beta$ 2- or  $\alpha$ 4 integrins, which further slow rolling and promote firm adhesion of leukocytes to the EC surface. The display of various combinations of selectins, chemokines, and integrin ligands on the EC surface has a major impact on which leukocyte subsets ultimately migrate into a particular inflamed tissue. Because P-selectin is expressed on both activated platelets and ECs, the possibilities for cooperation with other molecules further increase. In addition to their well-documented roles in hemostasis, platelets also secrete chemokines and other proinflammatory molecules. Cooperative signaling of P-selectin and platelet-derived chemokines might favor synthesis of tissue factor and chemokines in leukocytes (75,81).

#### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Monoclonal antibodies to P-selectin have proven very useful as probes to identify platelets that have been activated *in vitro*, or more specifically, to identify platelets that have fused  $\alpha$ -granule membranes with the plasma membrane. Flow cytometry is the usual method of choice for such experiments. Initially there was great interest in using flow cytometry to identify circulating activated platelets in patients with thrombotic disorders. However, the discovery that circulating activated platelets rapidly shed P-selectin *in vivo* has dampened enthusiasm for such studies, because flow cytometry might only detect a subset of activated platelets that have not yet shed P-selectin from the cell surface. Flow cytometry also has identified circulating platelet-leukocyte conjugates that form through interactions of P-selectin with PSGL-1 (82). Such conjugates may be a more sensitive method for detecting platelet activation *in vivo*. Circulating ECs that express P-selectin have been identified in blood from patients with some inflammatory disorders. Collectively, these studies support the possibility that platelets and/or ECs are activated in thrombotic or inflammatory diseases. Whether assays that measure platelet and EC activation with antibodies to P-selectin can actually predict prognosis or response to therapy in specific diseases requires confirmation. Similarly, numerous groups have used enzyme-linked immunosorbent assays (ELISAs) to measure the levels of soluble P-selectin in plasma from patients with a variety of hematological, thrombotic, or inflammatory disorders (77). Although such levels are modestly elevated in some patients, the ability of an elevated plasma P-selectin value to predict prognosis or response to therapy has not been

demonstrated with sufficient statistical power in prospective studies.

P-selectin contributes to inflammatory and thrombotic disease in a variety of experimental models in mice and other animals. The role of P-selectin has been documented with blocking monoclonal antibodies to P-selectin or with mice that lack P-selectin. Many of the early studies focused on models of ischemia-reperfusion injury, a condition that complicates treatment of hemorrhagic shock, myocardial infarction, and stroke in humans (83,84). The blockade of P-selectin function or the genetic deficiency of P-selectin markedly reduces tissue injury in these models. Such results suggested that drugs that block the function of P-selectin or other adhesion molecules might be effective therapeutics for these diseases. However, enthusiasm has declined because of the failures of antibodies to integrins or integrin ligands to improve outcome in randomized clinical trials of myocardial infarction or stroke. Small clinical trials of low-affinity selectin inhibitors also yielded negative results. These data suggest that excessive leukocyte adhesion might not be the dominating contributor to ischemia-reperfusion injury in patients, or that the appropriate subsets of patients who might respond to antiadhesion therapy have not been identified.

Despite these setbacks, anti-P-selectin therapy remains an attractive candidate to treat thrombotic and inflammatory diseases in humans. One potential disease target is sickle cell anemia, which is now widely acknowledged to be an inflammatory disease. In models of sickle cell anemia in mice, P-selectin contributes to the adhesion of leukocytes, platelets, and sickled erythrocytes to the vascular endothelium of the microcirculation, which exacerbate vaso-occlusion (85–87). A second example is deep vein thrombosis, which is an inflammatory as well as thrombotic process. P-selectin contributes to both venous inflammation and thrombosis in mouse and baboon models (88). A third example is delayed graft function in kidney and other organ transplants, which may be an example of controlled ischemia-reperfusion injury that might be more amenable to anti-selectin therapy. Again, P-selectin makes a major contribution to the pathogenesis of this disorder in animal models. Potential anti-P-selectin therapies include monoclonal antibodies to P-selectin, a recombinant soluble form of PSGL-1 fused to the Fc portion of immunoglobulin, glycosulfopeptides modeled after the P-selectin-binding domain of PSGL-1, and small molecules tailored to inhibit P-selectin function. The success of an anti-P-selectin drug candidate in a clinical trial in one of these diseases might encourage trials in other disorders.

#### KEY POINTS

- P-selectin is an adhesion receptor that mediates interactions among leukocytes, platelets, and ECs at sites of infection and tissue injury.

- Because P-selectin is stored in the membranes of secretory storage granules in platelets and ECs, it can be rapidly mobilized to the plasma membrane during hemostatic and inflammatory responses.
- The lectin domain of P-selectin binds cooperatively to glycan, peptide, and sulfated tyrosine moieties on its major leukocyte ligand, PSGL-1.

#### Future Goals

- To compare the biochemical and biophysical parameters of the interactions of each of the three selectins with their ligands on leukocytes, platelets, and ECs
- To further define the physiological and pathological functions of the selectins and their ligands in vivo

## Intercellular Adhesion Molecule-1 and Vascular Cell Adhesion Molecule-1

---

Silvia Muro

*Institute for Environmental Medicine, University of Pennsylvania School of Medicine,  
Philadelphia*

The vascular endothelium, positioned at the interface between the components of the blood and the interstitial milieu, plays a strategic role in the control of vascular physiology and maintenance of body homeostasis. It directs transendothelial gradients of molecules, regulates vascular tone, controls thrombosis, and is a crucial regulator of vascular redox state (1–4). Additionally, one of the most intensely studied and best characterized functions of endothelial cells (ECs) is their participation in innate and adaptive immunity, key steps in response to infection and tissue injury (5).

In a complex and elegantly coordinated process, ECs orchestrate the focal adhesion of white blood cells (WBCs) to the vessel wall and their migration into damaged tissue. This normally takes place at the level of postcapillary venules, and is governed in large part by the interaction of complementary adhesion molecules on the EC and leukocyte surfaces (Table 117-1). The generation of vasoactive compounds (e.g., prostacyclin, nitric oxide [NO]) by ECs causes vascular smooth muscle cell (VSMC) relaxation and local vasodilatation, increasing the blood flow at the site of injury and facilitating local accumulation of leukocytes (6). Flowing WBCs that collide with activated endothelium may bind to ECs through low-affinity receptors – the endothelial selectins (P- and E-selectin) – that recognize carbohydrate-based ligands on the leukocyte surface (Figure 117.1). The combined effects of blood flow and leukocyte binding to selectins result in their rolling on the EC surface. Chemotactic agents produced by ECs promote further rolling and facilitate firm adhesion via the induction of integrins on the surface of leukocytes. These integrins bind to high-affinity cell adhesion molecules (CAMs), most notably vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 (7). Finally, adherent leukocytes migrate between (paracellular) or through (transcellular) ECs, a process that is mediated by a sophisticated dialogue between the two cell types, and which includes homophilic inter-

actions between platelet-endothelial cell adhesion molecule (PECAM)-1/CD31 and CD99 (8).

Meticulous spatial and temporal regulation of VCAM-1 and ICAM-1 expression in response to specific mediators represents a complex and dynamic process permitting precise control of leukocyte anchoring to the endothelium. Additionally, VCAM-1 and ICAM-1 serve as signaling platforms that facilitate the transmigration of inflammatory cells and contribute to multiple physiological and pathological processes.

Some of the most relevant findings related to the characterization and biomedical significance of VCAM-1 and ICAM-1 are reviewed in this chapter.

### HISTORICAL PERSPECTIVES

ICAM-1 was first identified in 1986, by Springer and colleagues, as a counter-receptor for the  $\beta_2$  integrin, leukocyte function-associated antigen (LFA)-1 (9,10). They postulated that LFA-1 may mediate cell adhesion through a distinct molecule, based on the finding that homotypic adhesion of stimulated lymphocytes was abolished between LFA<sup>-</sup> cells but not between LFA<sup>-</sup> and LFA<sup>+</sup> cells (11). Using immunization with cells genetically deficient in LFA-1, Springer and colleagues produced monoclonal antibodies that inhibited homotypic aggregation of LFA<sup>+</sup> lymphoblastoid cells stimulated with phorbol ester, and defined ICAM-1 as a novel surface antigen involved in cell adhesion (10). ICAM-1 was soon found to be also expressed in fibroblasts, several types of epithelial cells, and ECs, where it was upregulated by cytokines and proinflammatory factors and was involved in WBC firm adhesion and transmigration (9,12). Analysis of the ICAM-1 coding sequence by two laboratories in parallel showed that this molecule did not contain RGD motifs typical of other integrin ligands but rather, it belonged to the immunoglobulin

**Table 117-1: Cell Adhesion Molecules on ECs That Contribute to Inflammatory Leukocyte Infiltration**

Name	Family	EC Surface Expression	Ligands	Function
P-selectin	Lectin family	Rapid and temporary induction by mediators	Fucosylated, sialylated, and sulfated ligands	Tethering rolling
E-selectin	Lectin family	Rapid and temporary induction by mediators	Fucosylated, sialylated, and sulfated ligands	Tethering rolling
VCAM-1	Ig-like family	Slow and stable induction by mediators	$\beta_1$ integrins (VLA-4)	Firm adhesion
ICAM-1	Ig-like family	Low constitutive expression. Stable upregulation by mediators	$\beta_2$ integrins (LFA-1 and Mac-1)	Firm adhesion; transmigration
PECAM-1	Ig-like family	High constitutive and stable expression	PECAM-1, $\beta_1$ and $\beta_3$ integrins	Transmigration

(Ig)-like CAM protein superfamily (13,14). Soon after this finding, two groups showed that ICAM-1 also was pathogenic, by serving as a receptor for major class rhinovirus (15,16).

While the role of ICAM-1 in leukocyte adhesion was becoming established in 1989, some evidence suggested the existence of a different inducible CAM in ECs that could mediate adhesion of both lymphocytes and nonlymphoid tumor cells to ECs in a manner that was independent of ICAM-1 and the endothelial selectins (17,18). This molecule was identified to be an immunochemically distinct, 110-kDa endothelial glycoprotein that was named inducible cell adhesion molecule

(INCAM)-110 (17,18). *INCAM-110* cDNA was soon isolated from activated ECs, the molecule was renamed VCAM-1, and classified as an Ig-like CAM (19). VCAM-1 was observed to be additionally expressed by lymphoid cells, macrophages, and reactive mesothelial cells (20), where it served as a counter-receptor for the leukocyte  $\beta_1$  integrin, very long antigen 4 (VLA)-4 (18).

#### EXPRESSION PATTERN, MOLECULAR STRUCTURE, AND FUNCTIONAL DOMAINS OF VASCULAR CELL ADHESION MOLECULE-1 AND INTERCELLULAR ADHESION MOLECULE-1

The Ig superfamily<sup>1</sup> cell adhesion molecules, VCAM-1 (CD106) and ICAM-1<sup>2</sup> (CD54), are type I transmembrane glycoproteins (9,10,17) (Table 117-2). They are synthesized

Figure 117.1. VCAM-1 and ICAM-1 in inflammation. Selectins (S) mediate WBC rolling on the endothelial surface, which subsequently bind to VCAM-1 (V) and ICAM-1 (I) extracellular domain via integrins, resulting in firm adhesion of leukocytes during the inflammatory process. Engagement by integrins triggers cell signal cascades through VCAM-1 and the ICAM-1 cytosolic tail, including VCAM-1-mediated activation of NADPH oxidase (NADPHox), generation of reactive oxygen species (ROS), phosphatase (Pases)-mediated cytoskeleton remodeling, and extracellular matrix degradation by MMPs.  $\text{Ca}^{2+}$ -mediated PKC signaling and Rho activation by ICAM-1 triggers formation of actin stress fibers, which may then interact with the cytosolic tail of this molecule via  $\alpha$ -actinin and ezrin/radixin/moesin family proteins. The consequent EC retraction, together with the contribution of PECAM-1 (P), facilitates transmigration of leukocytes to the injured tissue.

- 1 The immunoglobulin (Ig)-like superfamily of proteins is characterized by the presence of at least one 90- to 100-amino acid Ig domain consisting of two antiparallel  $\beta$ -sheets stabilized by a disulfide bond at its center. This structure is sheared by immunoglobulins, T-cell receptors, major histocompatibility (MHC) molecules, several lymphocyte-associated function antigens, and CAMs, including among others ICAMs, VCAM-1, and PECAM-1 (21).
- 2 The ICAM family comprises five type-I transmembrane glycoproteins (ICAM-1 to -5) that contain two to nine immunoglobulin-like C2-type domains. ICAM genes are clustered in chromosome region 19p13.2, except for the *ICAM-2* gene, which is located on chromosome 17q23-25 (22). ICAMs present distinct expression pattern and functions. ICAM-1 is expressed at low levels primarily on ECs but also on leukocytes, fibroblasts, and other cell types; is upregulated by cytokines; and is involved in pathological processes (e.g., adhesion and signaling during leukocyte extravasation). ICAM-2 is constitutively expressed by quiescent leukocytes, ECs, and platelets, where it is believed to contribute to physiological leukocyte transmigration and recirculation by serving as a counter-receptor for WBC LFA-1 and Mac-1 (21,23). Unlike ICAM-1, ICAM-2 expression is downregulated by inflammatory factors, hence its role in inflammation is unclear (21,23). It has been shown recently that, conversely to the luminal distribution of ICAM-1 on the EC surface, ICAM-2 is concentrated at the cell-cell borders, where it is implicated in homophilic interactions and likely contributes to vascular homeostasis and angiogenesis by regulating Rac-dependent cytoskeletal reorganizations (24). ICAM-3 (25) is constitutively and highly expressed by

as large precursor proteins, and subsequently processed to their mature forms at the rough endoplasmic reticulum and the Golgi apparatus, by proteolytic cleavage of their amino-terminal signal peptide and glycosylation at multiple sites in the region that will constitute the extracellular domain (28–30). In contrast to P-selectin, which is stored intracellularly in pre-existing Weibel-Palade bodies and is exocytosed upon endothelial activation (31), VCAM-1 and ICAM-1 rapidly traffic to the plasma membrane after their synthesis and are distributed primarily on the luminal cell surface (29,32).

VCAM-1 and ICAM-1 have been found in a variety of cell types, including both vascular and nonvascular cells. For example, in human atheroma-plaque microvessels, macrophages and VSMCs express VCAM-1 (33). VCAM-1 also is expressed by myoblasts, in which it may play a role in myogenesis. It is expressed in certain populations of dendritic cells in the lymph node and skin, bone marrow stromal cells, and synovial cells in inflamed joints (5,20,34). ICAM-1 is present in leukocytes, fibroblasts, certain epithelial cells, myoblasts, and glial and Schwann cells (35–38).

Of these various cell types, activated ECs display the highest surface density of VCAM-1 and ICAM-1. Based on studies using cultured human ECs and Scatchard analysis using specific antibodies, it is estimated that activated ECs may present approximately  $10^5$  to  $10^6$  copies of ICAM-1 (about two orders of magnitude above basal levels) and approximately  $10^3$  to  $10^4$  copies of VCAM-1 (almost undetectable in quiescent cells) at the EC luminal surface (39–41). However, ICAM-1 and VCAM-1 expression (both basal and inducible) varies among different organs and blood vessel types. For example, in skin and mesentery, VCAM-1 is most readily detected in the ECs of capillaries, postcapillary venules, and arterioles at sites of inflammation (42,43). In intact and injured rat lungs, ICAM-1 expression is discernible in capillaries and venules, but not in arterioles (44,45). Both in EC cultures and in postmortem specimens obtained from patients with acute respiratory distress syndrome, ICAM-1 is expressed at much higher levels in lung venules compared with pulmonary vein macrovessels (46,47). It is unclear to what extent these sites-specific differences in expression are intrinsic to the EC (e.g., epigenetically fixed), or are governed by the extracellular environment.

Structurally, VCAM-1 and ICAM-1 are characterized by a long glycosylated extracellular region, a single transmembrane-spanning domain, and a short cytosolic tail (Figure 117.2). The predominant form of human VCAM-1 (110 kDa) (17,18) consists of an extracellular region of 674 amino acids distributed in seven Ig-like C2-type modules, a 22-residue

transmembrane region, and a 19-amino acid cytosolic domain (SwissProt P19320) (48,49). Human ICAM-1 (also a 110-kDa glycoprotein) contains a 453-residue extracellular region than comprises five Ig-like C2-type domains, a single transmembrane-spanning region of 23 amino acids, and a short cytosolic tail of 29 residues (SwissProt P05362) (14,50, 51). These distinct structural regions regulate functions attributed to VCAM-1 and ICAM-1. The Ig-like domains in the extracellular region mediate interaction with their leukocyte counter-receptors and other ligands (fibrinogen or rhinovirus, which binds to ICAM-1 Ig-domains 1 and 3, respectively), whereas the cytosolic domain mediates signal transduction events triggered by the engagement of the extracellular domains of these molecules (see Figure 117.2).

Despite similarities in the structural domains between VCAM-1 and ICAM-1, crucial conformational differences exist that dictate ligand specificity and that may influence the composition of the cellular infiltrate during inflammatory processes. In the case of VCAM-1, Ig-like domains 1 and 4 of this molecule act as ligand-binding modules for leukocyte  $\beta_1$  integrins (e.g., VLA-4) (52,53). VCAM-1 binds to monocytes and lymphocytes, but not neutrophils. In contrast, domains 1 and 3 of ICAM-1 interact with  $\beta_2$  integrins on all WBC types, including LFA-1 ( $\alpha L\beta_2$ ), and the neutrophil determinant Mac-1 ( $\alpha M\beta_2$ ) (7,32). Adhesion through Mac-1 is enhanced by binding of ICAM-1 domain 1 to fibrinogen, which acts as a bridge molecule between the EC and the leukocyte (50). Binding to fibrinogen may provide a pathway for the modulation of intercellular adhesion during inflammation and vascular injury.

Differences in ligand recognition may be explained in part by variations in the conformation of VCAM-1 and ICAM-1 Ig-like domains. Each molecule possesses an acidic residue near the c-terminus of domain 1, which has been implicated in leukocyte binding (54). However, the identity of this residue differs between receptors; ICAM-1 contains glutamic acid, which resides on a flat surface, whereas VCAM-1 contains aspartic acid, which protrudes as a loop. These structures complement the molecular surfaces of the integrins to which these CAMs bind (54). Thus, subtle conformational differences between VCAM-1 and ICAM-1 may help provide finely tuned ligand specificity.

#### VASCULAR CELL ADHESION MOLECULE-1 AND INTERCELLULAR ADHESION MOLECULE-1 AS SIGNAL TRANSDUCERS

VCAM-1 and ICAM-1 not only serve as adhesive surfaces for WBCs, but also function as molecular switches that activate intracellular signaling pathways that contribute to the regulation of multiple (patho)physiological processes (see Figure 117.1). Such outside-in signaling is triggered when the extracellular domain of VCAM-1 or ICAM-1 binds to adhesive leukocytes. An extensively used model to study VCAM-1- or ICAM-1-mediated signaling mimicking such

---

leukocytes, in which it mediates costimulatory signals for T-cell activation during the initiation of the immune response, but it is absent from normal ECs. ICAM-4 (26) is specifically expressed on erythrocytes and is responsible for the Landsteiner-Wiener blood group system. ICAM-5 or telencephalin (27) is expressed by subsets of neurons, but not by glial cells, exclusively within the telencephalon of mammalian brain. All ICAMs bind to the leukocyte adhesion protein, LFA-1. Additionally, ICAM-1, -2, and -4 bind to the neutrophil integrin Mac-1, and ICAM-3 binds the macrophage integrin CR4 (22).

**Table 117-2: VCAM-1 and ICAM: Expression, Structure, Function, Regulation, and Animal Models**

	VCAM-1	ICAM-1
Discovered	1989	1986
CD	CD106	CD54
Cell types	ECs, WBCs, mesothelial cells, myoblasts, dendritic cells, synovial cells	ECs, WBCs, fibroblasts, mesothelial cells, epithelial cells, myoblasts, glial and Schwann cells
Expression	Inducible	Constitutive with inducible up-regulation
Surface density in activated ECs	~10 <sup>3</sup> –10 <sup>4</sup>	~10 <sup>5</sup> –10 <sup>6</sup>
In vivo EC expression during inflammation	Capillaries, post-capillary venules and arterioles	Capillaries and venules
Protein	Extracellular domain: 674 aa; Transmembrane domain: 22; Cytosolic domain: 19 aa	Extracellular domain: 453 aa; Transmembrane domain: 23; Cytosolic domain: 29 aa
Ig-like domains	7	5
Molecular ligands	The WBC $\beta_1$ integrin VLA-4	Fibrinogen, rhinovirus, the WBC $\beta_2$ integrins LFA-1 and Mac-1
WBC ligands	Monocytes and lymphocytes	Monocytes, lymphocytes, and neutrophils
Signaling pathways	p42/44MAPK, ERK2, PI3K, Rho	pp60Src, p53/p56Lyn, Raf-1, ERK1, ERK2, JNK, AP1, Rho
Proliferative responses	Increased by activation of cyclin D <sub>1</sub>	Decreased by inhibition of cdc2 cyclin-dependent kinase
ROS production	NADPH oxidase activation	Xanthine oxidase activation
Cytoskeletal remodeling	Ca <sup>2+</sup> flux, Rho	Ca <sup>2+</sup> flux, Rho, p60Src, PKC, PLC, HSP27, p38 MAPK
Promoter regulatory sites	Two NF- $\kappa$ B sites, two GATA motifs, one AP-1 site	One NF- $\kappa$ B site, two SP1 sequences, two AP-1 motifs
Differences in agonists	Stimulation by IL-4 No response to TGF- $\beta$	Stimulation by TGF- $\beta$ No response to IL-4
Effects of shear stress	Stimulation by low shear stress Downregulation by high flow	Stimulation by low and high shear stress
Post-transcriptional modifications	Ig domains 1–2–3 GPI-anchored Ig domain 4 deletion	Deletion of Ig-like domains 2, 4, 2–3, 2–3–4.
Regulatory post-translational modifications	N/D	Binding to lectins by highly glycosylated isoforms Enhanced Mac-1 binding by defective glycosylation of Ig domain 3
Oligomerization	N/D	Dimerization through Ig domains 1–1, 4–4, and multimerization through Ig domains 4–4 between 1–1 dimers.
Internalization by ECs	Monovalent ligands via clathrin coated pits. Unknown for multivalent ligands	No uptake of monovalent ligands. Multivalent ligands via CAM-mediated endocytosis
Animal models	VCAM-1-deficient mice ( <i>Vcam1<sup>tm1Roml</sup></i> ; [120]) are embryonic lethal due to severe placental development and heart abnormalities.  Mice bearing a VCAM-1 hypomorphic mutation that results in the deletion of Ig domain 4 [121]) show impaired recruitment of lymphocytes to the lungs.	Mice with ICAM-1 targeted mutation ( <i>Icam1<sup>tm1Bay</sup></i> ) (115) express ICAM-1 isoforms lacking the extracellular domain. They are viable and fertile, show mild neutrophilia, lymphocytosis, impaired lymphocyte recruitment to lungs, and suppressed contact hypersensitivity.  <i>Icam1<sup>tm1Jegr</sup></i> (119) do not express ICAM-1. They are viable and fertile, and show a similar phenotype to <i>Icam1<sup>tm1Bay</sup></i> mice.

aa, amino acids; N/D, not determined.

processes consists of clustering these adhesion molecules by artificial ligands, such as cross-linking antibodies or antibody-coated beads.

Ligation of VCAM-1 or ICAM-1 activates overlapping but distinct signaling pathways (see Table 117-2). For example,

binding of endothelial VCAM-1 to adherent leukocytes or cross-linking antibodies activates nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in ECs, whereas WBC- and antibody-engaged ICAM-1 results in the activation of xanthine oxidase (NADPH oxidase activation has been suggested

Figure 117.2. Structure of VCAM-1 and ICAM-1. Molecular architecture of VCAM-1 and ICAM-1, consisting of a large extracellular region, a single membrane-spanning domain, and a short cytosolic tail. The extracellular region contains C2-type, Ig-like domains, which are numbered starting by the domain located in the amino terminus and most distant from the plasma membrane. Distinct isoforms lacking one or several Ig-like domains can be generated from alternative splicing of the primary transcripts for these molecules. Extracellular Ig modules and intracellular domains represent docking sites for leukocyte binding and signal transduction, respectively.

but remains to be determined) and increased phosphorylation of the Src family kinases and p53/p56Lyn (55–57). Different ligands elicit distinct responses. For example, in contrast to the effects of WBCs, fibrinogen-mediated ligation of ICAM-1 activates pp60Src, but not p53/p56Lyn (58). These observations suggest that each adhesion molecule is coupled to multiple downstream signaling pathways, and that the relative activity of these pathways is determined by the nature of the ligand.

Ligand binding to the extracellular domains of VCAM-1 and ICAM-1 likely triggers signaling cascades through the cytoplasmic domain of these molecules (59), yet these pathways remain to be determined. For example, the cytosolic domain of ICAM-1 lacks a consensus tyrosine-based inhibition sequence required for recognition of molecules containing Src-homology domain 2, yet recent studies suggest that ICAM-1-mediated signaling may involve tyrosine phosphorylation of SHP-2, which may involve additional adapter proteins, such as Grb2, SOS, and Shc (59,60).

VCAM-1- and ICAM-1-mediated signaling may lead to downstream changes in gene expression (see Table 117-2). For example, binding of anti-VCAM-1 antibodies to VCAM-1 in airway smooth muscle cells leads to phosphoinositide 3-kinase (PI3K)-independent activation of extracellular-signal-regulated protein kinase (ERK)-2 and PI3K-mediated activation of p42/44 MAPK (61). In tumor necrosis factor (TNF)- $\alpha$ -stimulated ECs cultured under flow conditions, VCAM-1 cross-linking by multivalent anti-VCAM-1 beads induces phosphorylation of ERK2, but not ERK1, a response observed upon eosinophil binding to these cells (62). Ligation of ICAM-1 with cross-linking antibodies, mimicking leuko-

cyte binding, also induces the activation of Raf-1, mitogen-activate protein kinases (MAPKs), ERK1 and ERK2, and/or c-jun N-terminal kinase (JNK)-dependent/AP1-mediated gene expression (59). These cascades vary according to the cell type – in brain ECs, ICAM-1 signals stimulate JNK downstream p130<sup>Cas</sup> tyrosine phosphorylation and recruitment of the adaptor Crk, but in astrocytes these signals operate via accumulation of cyclic adenosine monophosphate (cAMP) and activation of MAPK, ERK, and p38 MAPK (63).

Hence, the modulation of gene expression triggered by ligation of VCAM-1 or ICAM-1 may alter EC phenotype. As discussed later, outside-in signaling has been implicated in cell survival, cell growth, reactive oxygen species (ROS) generation, cytokine production, expression of certain surface molecules, and cytoskeleton rearrangements.

For example, in VSMCs VCAM-1 engagement increased expression of cyclin D1 and augmented the proliferative response to submitogenic concentrations of epidermal growth factor, suggesting that VCAM-1 may function to augment growth factor-induced responses (62). In the case of ICAM-1, fibrinogen was shown to induce apoptosis of TNF- $\alpha$ -activated ECs expressing the cytosolic truncated form of ICAM-1, but not wild-type ICAM-1, suggesting a protective prosurvival role for the cytosolic tail (60). In another report, ICAM-1 cross-linking by antibodies was shown to induce phosphorylation and inhibition of the cell cycle regulator, cdc2 cyclin-dependent protein kinase. This inhibition arrests or delays cell growth, because cdc2 is dephosphorylated at the G2/M interface (59).

VCAM-1 and ICAM-1 also have been demonstrated to play a role in mediating the redox state of the cell. As mentioned previously, NADPH oxidase activation and ROS generation by WBC or antibody engagement of VCAM-1 leads to changes in the redox state (56). This may in turn result in cytokine generation, upregulation of cell adhesion molecules, activation of matrix metalloproteinases (MMPs), and ultimately increased leukocyte passage. WBC- and antibody-mediated ICAM-1 cross-linking in ECs results in increased ROS production via xanthine oxidase pathway expression of the cytokines interleukin (IL)-1, IL-8, and regulated on activation, normal T-cell expressed and secreted (RANTES); the GTPase signaling molecule RhoA; surface molecules such as MHC class II (in B cells); and adhesion molecules such as VCAM-1 and ICAM-1 itself (57,59,64).

Interestingly, a number of transduction pathways mediated by VCAM-1 and ICAM-1 intersect with signaling cascades involved in cytoskeleton remodeling (see Table 117-2). For example, VCAM-1 engagement by WBCs modulates cytosolic phosphatases, stimulates calmodulin-independent calcium ( $\text{Ca}^{2+}$ ) influx in ECs, and results in the regulation of several actin-binding proteins (65,66). Cross-linking of VCAM-1 on activated ECs by 10- $\mu\text{m}$  anti-VCAM-1 coated beads generates a ROS-dependent remodeling of the actin cytoskeleton, in which actin coalesces immediately under the sites where beads bind to VCAM-1 (67). Upon WBC binding to activated ECs, actin reorganization mediated by VCAM-1 seems to occur

independently of tyrosine kinase and PI3K signaling, but requires small GTPases (e.g., Rho) (56,65). Similarly, ICAM-1 ligation also results in cytoskeletal changes. These have been observed to be mediated by activation of p38 MAPK and heat-shock protein 27 (an actin binding protein); phosphorylation of phospholipase C (PLC)- $\gamma$ 1; production of inositol phosphate and  $\text{Ca}^{2+}$  release, which is responsible for protein kinase C (PKC) and p60Src activation; and tyrosine phosphorylation of cortactin (64,68,69). PKC activation by ICAM-1 induces Rho-dependent formation of actin stress fibers and activates cortactin, focal adhesion kinase (FAK), paxillin, and p130<sup>Cas</sup> (70,71). Thus, cytoskeletal reorganization by VCAM-1 and ICAM-1 may represent an important regulatory element of vascular permeability during pathological events.

These observations are consistent with a model of VCAM-1- and ICAM-1-mediated outside-in signaling that involves the coordinated activity of multiple binding and signaling functions (see Figure 117.1). EC changes in the redox state (e.g., due to NADPH oxidase activation upon WBC binding to VCAM-1) (56) may have a dual effect: (a) reaction of ROS on the surface of ECs and leukocytes with unpaired cysteine thiol groups that maintain inactive MMP-2 and MMP-9 propeptides may result in activation of these MMPs; and (b) diffusion of certain ROS species (e.g., hydrogen peroxide [ $\text{H}_2\text{O}_2$ ]) to the cytosol and secondary activation of phosphatases that regulate actin reorganization (56). A combination of both extracellular matrix degradation and actin cytoskeleton rearrangements facilitates EC retraction at the site of leukocyte binding and, therefore, migration into the tissue. Similarly, in the case of ICAM-1, Src and PKC activation induces the Rho-dependent formation of actin stress fibers and actin-binding proteins such as cortactin, FAK, paxillin, and p130<sup>Cas</sup> (59). Spatial regulation of this process at sites of WBC binding may be explained by the interaction of the cytosolic domain of ligated ICAM-1 molecules with cytoskeleton-associated proteins, as in the case of actin-associated elements  $\alpha$ -actinin, ezrin, and moesin, or the microtubule-related protein  $\beta$ -tubulin (72–74). These combined actions regulate vascular permeability and facilitate leukocyte transmigration.

#### REGULATION OF VASCULAR CELL ADHESION MOLECULE-1 AND INTERCELLULAR ADHESION MOLECULE-1 EXPRESSION AND FUNCTION

In addition to the minor structural differences between VCAM-1 and ICAM-1, other factors contribute to the specific roles for these proteins in mediating EC signaling and WBC adhesion. These include differences in the distribution of VCAM-1 and ICAM-1 across the vascular tree, as well as differences in their transcriptional regulation, and post-transcriptional and post-translational modifications.

The various cell adhesion molecules exhibit distinct patterns of gene and protein expression. VCAM-1 and endothelial selectins (P- and E-selectins) are expressed at low or undetectable levels on the surface of quiescent (nonactivated) ECs,

whereas ICAM-1 is expressed at modest levels, and PECAM-1 (a related Ig-like cell adhesion molecule) at high levels (5,21). VCAM-1, P-selectin, E-selectin, and ICAM-1 are induced by agonists, both in vivo and in vitro, commonly associated with inflammation and EC activation. These include inflammatory cytokines, thrombin, lipopolysaccharide (LPS), abnormal shear stress, hypoxia, and ROS (75–77). In contrast, PECAM-1 expression in vivo and in cultured ECs is stable and does not change under pathologic conditions (75,78).

In nonvascular cells, VCAM-1 and ICAM-1 expression also is upregulated by extracellular mediators, which may contribute to adhesive events in certain settings (79). For example, ICAM-1 is present at low levels not only in ECs but also in astrocytes in normal adult brain. Its expression is upregulated during inflammatory conditions such as multiple sclerosis, or after certain pathological insults, including stroke, traumatic brain injury, and Alzheimer disease (63,80,81). Genetic and metabolic conditions, such as muscular dystrophies, diabetes, familial hypercholesterolemia, or lysosomal storage disorders (among others) lead to the pathological overexpression of adhesion molecules (including VCAM-1 and ICAM-1 and their soluble forms) in ECs, WBCs, and nonvascular cells (epithelial cells, skeletal muscle, synovial cells). This prompts inflammation, a secondary hallmark of these diseases (51,82–86).

The induction of VCAM-1 and ICAM-1 expression in such settings, as with other adhesion molecules (e.g., endothelial selectins), depends on the nature and intensity of the stimulus and the EC subtype (21,43,67,87,88). For example, phorbol ester was found to stimulate expression of VCAM-1 and ICAM-1 in human umbilical vein ECs (HUVECs), but not in dermal microvascular ECs (89,90). In vascular endothelium, interferon (INF)- $\gamma$  induces the expression of ICAM-1 but not E-selectin; IL-4 stimulates VCAM-1 but not E-selectin or ICAM-1; and transforming growth factor (TGF)- $\beta$ 1 itself induces ICAM-1 expression but does not affect expression of VCAM-1 (21,67,87). Although certain extracellular agonists, such as IL-1 or TNF- $\alpha$ , induce surface expression of multiple adhesion molecules (P- and E-selectin, VCAM-1 and ICAM-1), the temporal pattern varies according to the coordinated stepwise function of these adhesion molecules (see Table 117-1). For example, in cultured ECs, P- and E-selectin (which are involved in early WBC rolling) are rapidly induced by IL-1 and TNF- $\alpha$ , with maximal protein expression occurring between 4 and 6 hours, followed by a rapid decline to basal levels by 24 hours. By contrast, surface VCAM-1 and ICAM-1 (which are involved in subsequent firm adhesion) increase more slowly in response to these mediators, with expression peaking at 6 to 12 hours and, in some cases, remaining elevated for several days (12).

In addition to chemical mediators, biomechanical forces also serve to regulate expression VCAM-1 and ICAM-1 (91,92). Under in vitro conditions, acute shear stress causes rapid cytoskeletal reorganization and activates the acute release of NO, activation of nuclear factor (NF)- $\kappa$ B, c-fos, c-jun, and SP1, and the transcriptional activation of ICAM-1,

tissue factor, platelet-derived growth factor (PDGF)-B, TGF- $\beta$ 1, and endothelial NO synthase (eNOS) (93). Interestingly, low shear stress has been shown to increase ICAM-1 and VCAM-1 expression in cultured ECs (but not E-selectin), and increasing shear stress results in reduced VCAM-1 expression (see Table 117-2) (2,94,95).

Environmentally mediated upregulation of VCAM-1 and ICAM-1 occurs through the inducible binding of transcription factors to *cis*-regulatory elements present in the upstream promoter region of these genes (48,96,97) (see Table 117-2). The 5' flanking region of the *VCAM-1* gene contains two NF- $\kappa$ B sites, as well as two functional GATA motifs and an AP-1 binding site (48,96). The *ICAM-1* promoter contains one NF- $\kappa$ B, two SP1, and two AP-1 regulatory motifs (97). Inducible expression of VCAM-1 and ICAM-1 is mediated either by an individual element (e.g., NF- $\kappa$ B), or through the coordinated action of more than one regulatory element (e.g., NF- $\kappa$ B plus GATA). Hence, any given agonist may modulate the expression of VCAM-1 and ICAM-1 through different mechanisms (48,63,96,98). For example, thrombin induces ICAM-1 via a PI3K-independent, PKC $\delta$ /NF- $\kappa$ B-dependent pathway, whereas thrombin stimulation of VCAM-1 occurs via an Akt-independent, PI3K/PKC $\zeta$ /GATA-2/PKC $\delta$ /NF- $\kappa$ B-dependent pathway. Any given gene may respond to different agonists through unique transcriptional mechanisms. For example, thrombin-mediated induction of ICAM-1 involves a PKC $\delta$ /NF- $\kappa$ B-dependent pathway, whereas TNF- $\alpha$  activates ICAM-1 via PKC $\zeta$ /NF- $\kappa$ B (63,98).

Multiple isoforms exist for VCAM-1 and ICAM-1 (see Figure 117.2). For example, in mice VCAM-1 exists either as a seven-domain transmembrane protein or as an alternatively spliced protein that contains the three amino-terminal Ig-domains linked to glycosylphosphatidylinositol (GPI) (99). In humans, two distinct isoforms of VCAM-1 have been reported: a predominant form that contains seven Ig-like domains and a molecule of six Ig modules, due to elimination of the domain 4 by alternative splicing (48,49). Although murine ICAM-1 typically contains five extracellular Ig-like domains, other isoforms may arise from alternative splicing, including proteins that lack the Ig-like domain(s) 2, 4, 2-3, or 2-3-4 (100). Importantly, different isoforms of VCAM-1 and ICAM-1 demonstrate distinct adhesive properties. For example, the mouse ICAM-1 isoform lacking Ig domains 2-3 does not bind to LFA-1 (100). Perhaps the relative expression of different isoforms represents a further level of functional control. For example, it has been observed that IFN- $\beta$ 1a regulates ICAM-1 RNA splicing in cultured ECs and leukocytes, leading to overexpression of certain isoforms with a relevant immunoregulatory role in multiple sclerosis (101).

VCAM-1 and ICAM-1 proteins undergo post-translational modification. The extent to which these changes influence molecular structure and/or function remains unclear. However, increasing evidence points to the importance of this process in regulating cell adhesion molecule function (see Table 117-2). For example, ICAM-2 and -3, but not ICAM-1, bind to lectins. The differential binding may be explained by

the selective presence of N-linked, high-mannose glycans on ICAM-2 and -3. Interestingly, certain ICAM-1 mutants with additional N-linked glycosylations exhibit lectin ligand activity (28). Other mutations affecting residues located in the Ig domain 3 of ICAM-1 destroy the consensus sequence for glycosylation and enhance binding to purified Mac-1. Similarly, agents that interfere with ICAM-1 carbohydrate processing also affect binding to Mac-1, although not to LFA-1 (30). Therefore, the type and extent of glycosylation on ICAM-1 may regulate conformation and binding functions of this molecule. Whether this regulation operates in the case of VCAM-1 is unknown.

Additionally, ICAM-1 has been found to exist either as a monomer, as noncovalent dimers, or even as large multimers (102,103) (see Table 117-2). Dimerization occurs through either D1-D1 or D4-D4 interactions. Coordinated dimerization at the D4-D4 interface of D1-D1 dimers facilitates the formation of tetramers and larger structures (104). Oligomerization of ICAM-1 on the cell surface may regulate the conformation and orientation of this molecule, thereby controlling exposure of sites to which ligands bind. This may be particularly relevant considering that ICAM-1, as an elongated surface protein, experiences the force exerted by the blood flow. Indeed, the dimeric form of ICAM-1 is capable of binding ligands with greater affinity compared with the monomer form (102,103). Less is known about the existence of VCAM-1 oligomeric forms.

Induced synthesis of fully active, accessible VCAM-1 and ICAM-1 at the EC plasma membrane may be followed by downregulation of these molecules as a mechanism to help terminate the binding and signaling functions ascribed to them. The mechanisms underlying this phenomenon have not been fully characterized, but several hypotheses have been postulated. A soluble form of VCAM-1 has been observed to appear in vitro as a result of proteolytic cleavage by TNF- $\alpha$ -converting enzyme (ADAM 17) (105). In addition, ECs in culture rapidly internalize VCAM-1 upon ligation by cross-linked antibodies in an ATP-dependent manner ( $t_{1/2} = 10-15$  min), through a pathway consistent with clathrin-mediated endocytosis (106). Both membrane shedding and endocytosis may contribute to decreased VCAM-1 levels at the plasma membrane following inflammatory induction. Similarly, ECs also appear to internalize ICAM-1 in a surface density-dependent manner, but the low extent of internalization (<10% of surface ICAM-1) suggests that such a pathway plays a minor role in ICAM-1 turnover (32). Also, cleavage of ICAM-1 extracellular domain by neutrophil proteinases (e.g., elastase and cathepsin G) may account for downregulation of ICAM-1 at the EC surface (107,108). This latter process, which appears to occur independently of ICAM-1 surface density, is a potential source of soluble circulating ICAM-1. Recently, it has been shown that ECs actively internalize ICAM-1 upon ligation by anti-ICAM coated beads, which results in an acute and rapid decrease of surface ICAM-1 (80% in 30 min) (109). Internalized ICAM-1 partially (40%) recycles to the plasma membrane by 1 hour, whereas the remaining ICAM-1 fraction traffics through a

Figure 117.3. Cell adhesion molecule (CAM)-mediated endocytosis. ICAM-1 ligation by multimeric ligands (e.g., nanocarriers targeted by anti-ICAM antibodies) induces a unique endocytic pathway, CAM-mediated endocytosis, which operates through PKC, Src, and Rho-dependent kinase (ROCK) signaling. These molecules regulate activation of the large GTPase, dynamin, and plasma membrane  $\text{Na}^+/\text{H}^+$  exchangers (NHE), resulting in actin cytoskeleton remodeling and internalization of the ligand/receptor complex. After internalization, the complex traffics to early endosomes; then ligand and receptor are differentially sorted to lysosomes and recycling compartments, respectively. Thus, the adhesive and signaling properties of ICAM-1 can be taken as a platform for designing vehicles for site-specific delivery of therapeutic agents into ECs, where ICAM-1 recycling may provide the basis for sustained targeting and prolonged effects of the delivered drugs.

degradative route (e.g., lysosomes). It is tempting to speculate that this event, which was mediated by cell adhesion molecule-mediated endocytosis (110), a novel, nonclassical endocytic pathway, also may account for regulation of ICAM-1 density at the EC surface (Figure 117.3).

### VASCULAR CELL ADHESION MOLECULE-1 AND INTERCELLULAR ADHESION MOLECULE-1 AS THERAPEUTIC TARGETS IN VASCULAR PATHOLOGIES

VCAM-1 and ICAM-1 normally play an important role in homeostasis and host defense. However, under pathological conditions, dysregulation in their expression and/or function may exacerbate tissue damage and disease progression, as occurs in adult respiratory distress syndrome, acute lung injury, autoimmune disease, hypersensitivity reactions, septic shock, ischemia–reperfusion injury, host-versus-graft rejection, atherosclerosis, and diabetes, among others (39). For example, expression of VCAM-1 and ICAM-1 has been shown to be increased in ECs (and other cell types) at sites predisposed to atherosclerosis and in developing atherosclerotic lesions (111–113), suggesting a pathophysiological role for these adhesion molecules. Certain tumor cells, such as melanoma, appear to metastasize by binding to VCAM-1 on the surface of ECs (17,114). In animal models of asthma (using *ICAM-1*-null mice [115] and mice expressing a hypomorphic VCAM-1

form lacking the Ig-like domain 4 [116]), leukocyte infiltration into the lungs depended on VCAM-1 and ICAM-1 (117) (VCAM-1 and ICAM-1 animal models are shown in Table 117-2 [115,118–121]). Moreover, VCAM-1 and ICAM-1 intervene in the recruitment of T cells and lymphocytes to the central nervous system in allergic encephalomyelitis, multiple sclerosis, and meningitis (122).

Given the potential widespread importance of VCAM-1 and ICAM-1 in mediating pathology, these adhesion molecules represent valuable therapeutic targets (39,123). Blocking VCAM-1 and ICAM-1 provides protective effects in certain human disorders, such as inflammation, ischemia–reperfusion injury, acute lung injury, or arthritis (123–125). Moreover, therapeutic agents (e.g., anticancer drugs, antioxidant enzymes, thrombolytic compounds) can be coupled in a variety of formulations (e.g., liposomes, protein conjugates, targeted viruses, particulate nanocarriers, fusion proteins) with affinity carriers (e.g., full size antibodies, antibody fragments, peptides) that recognize particular endothelial adhesion molecules, thus providing site-specific delivery to the vascular areas where expression of the molecular target is prominent. For example, antibodies to VCAM-1 have been utilized as targeting ligands coupled to imaging agents or biodegradable carrier particles (immunotargeting) to provide highly selective accumulation on inflamed endothelium *in vitro* and *in vivo* (126–128). The subcellular destination of anti-VCAM-1 carriers has not been determined; therefore, the utility of this approach as a means for delivery of therapeutics either to the endothelial surface or intracellular compartments remains elusive. Nevertheless, targeted drug delivery to inflamed endothelium via anti-VCAM-1 particles may help to improve the treatment of pathologies such as cardiovascular disease, arthritis, inflammatory bowel disease, and cancer.

In the case of ICAM-1, it has been shown that monomeric antibodies to this molecule, as well as large (micron size) multimeric conjugates of biotin-streptavidin cross-linked antibodies stably bind to ICAM-1 (129,130), thus providing a useful means for site-specific drug delivery to the endothelial surface (e.g., delivery of fibrinolytics to the vascular wall) (129,131). Paradoxically, nanoscale (100–300 nm in diameter) multimeric anti-ICAM-1 conjugates and beads of similar size coated with anti-ICAM-1 antibodies are readily internalized by ECs (110). This strategy, similar to the case of a related adhesion molecule, PECAM-1, provided the basis for intracellular drug delivery of antioxidant enzymes (e.g., catalase, superoxide dismutase) for the containment of vascular oxidative stress in several pathological settings (109,132–136).

Internalization of these anti-ICAM-1 formulations occurs via a novel endocytic mechanism (see Figure 117.3), namely CAM-mediated endocytosis, which has been shown to differ from classical endothelial endocytic pathways (e.g., clathrin- and caveola-mediated endocytosis) and also from phagocytic and macropinocytic processes (137). ICAM-1 clustering by 100-nm beads coated with anti-ICAM-1 (final size = 200–250 nm diameter) signals through PKC, Src kinases, and Rho-dependent kinase. These regulate the formation of actin stress

fibers and concomitant endocytosis mediated by the activity of cytosolic dynamin and membrane sodium/proton exchangers (110,136). Subsequent trafficking of anti-ICAM-1 conjugates to early endosomes and lysosomes is relatively slow (3 hours post-internalization) (134). This, in the case of antioxidant enzyme delivery, provides a sufficient therapeutic time window to cope with settings of acute oxidative stress, and it can be prolonged by supplementary drugs that influence intracellular trafficking and lysosomal degradation (132–136). Also, the partial recycling of ICAM-1 to the plasma membrane by 1 hour after conjugate internalization provides the basis for sustained delivery to ECs and prolongation of the effects of drugs via CAM-mediated endocytosis (109). Moreover, lysosomal trafficking subsequent to CAM-mediated endocytosis can be utilized as a strategy to improve classical means of enzyme replacement therapy for lysosomal storage disorders having marked endothelial contribution (138,139).

Thus, VCAM-1 and ICAM-1 represent attractive targets for the treatment of vascular pathologies, particularly those mediated through oxidative stress, thrombosis, and inflammation. Site-specific targeting of therapeutics to VCAM-1 and ICAM-1 may provide an effective means to minimize blood clearance, maximize effective delivery to disease sites, and reduce therapeutic dose, altogether increasing the efficacy of therapeutics.

#### KEY POINTS

- VCAM-1 and ICAM-1 are fine examples of the degree of mechanical complexity by which ECs integrate input-output signals, both in physiological and disease conditions. In response to a variety of factors, ECs regulate VCAM-1 and ICAM-1 function by controlling their expression and accessibility at the cell surface. VCAM-1 and ICAM-1 can then “sense” extracellular elements and transduce the signals intracellularly to regulate appropriate responses. Thus, the biomedical relevance of VCAM-1 and ICAM-1 may be understood from the perspective of mechanisms contributing to proper EC function and endothelial capacity to respond to environmental changes.
- VCAM-1 and ICAM-1 contribute to inflammatory cell trafficking. Their extracellular Ig-like domains provide an adhesive surface for activated leukocyte integrins, and the structural conformation of these molecules provides a fine-tune control of ligand specificity and the cellular infiltrate.
- VCAM-1 and ICAM-1 engagement by extracellular ligands serves as an outside-in transducing platform regulating EC phenotype and function (e.g., activation of kinases and transcription factors that

modulate cell growth, ROS generation, cytokine production, expression of surface proteins, cytoskeletal modulation, and EC permeability).

- Regulation of VCAM-1 and ICAM-1 functions is achieved by mechanisms controlling the expression and surface accessibility of these adhesion molecules (e.g., chemical and mechanical factors affecting their transcription, and post-transcriptional and post-translational mechanisms regulating their structural conformation and oligomerization status).

#### Future Goals

- To understand the molecular mechanism involving VCAM-1- and ICAM-1-mediated pathogenesis, because of its direct clinical implications in diagnosis, given that these molecules can be utilized as markers for active inflammation under certain pathological conditions
- To elucidate the role of VCAM-1 and ICAM-1 as important targets for the therapy of endothelial dysfunction in the treatment of disease
- To determine if site-specific drug delivery to VCAM-1 and ICAM-1 may provide selectivity for diseased tissue and blockage of endothelial adhesion by interfering with VCAM-1 and ICAM-1 to inhibit tissue injury
- To further investigate therapy systems based on these highly versatile adhesion molecules that may ultimately lead to the discovery of novel approaches in the treatment and prevention of vascular diseases

#### ACKNOWLEDGMENTS

I thank Dr. Vladimir Muzykantov (Dept. Pharmacology, University of Pennsylvania School of Medicine) for his guidance on endothelial pathophysiology and vascular immunotargeting, and his enriching comments on this chapter. This work has been funded by a fellowship from Fundación Ramón Areces (Spain) and a scientist development grant from American Heart Association 0435481N to S.M.

## E-Selectin

---

David Milstone

*Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts*

The discovery of E-selectin in 1987 (1) culminated a series of experiments investigating the molecular basis of endothelial activation and interactions with leukocytes during acute inflammation. This initiated an era in which several additional endothelial structures involved in leukocyte adhesion were identified, and their roles in inflammation were investigated. Exploiting these insights to develop diagnostic and therapeutic interventions for inflammatory and other diseases remains a promising area of clinical investigation.

Bevilacqua and Gimbrone (1) identified monoclonal antibodies that blocked polymorphonuclear neutrophil (PMN) adhesion to inflammatory cytokine-activated human umbilical vein endothelial cells (HUVECs) and used them to expression-clone a cell surface glycoprotein, designated endothelial-leukocyte adhesion molecule (ELAM)-1, which mediates initial PMN adhesion to inflamed endothelium. ELAM-1 possessed a then-unique, complex mosaic structure predicting, for the first time, that inflammation involved calcium-dependent interactions between endothelial cell (EC) surface lectins and carbohydrate-bearing "counter-receptors" on circulating leukocytes. At about the same time, investigators studying seemingly unrelated cell-cell interactions during inflammation – one involving megakaryocytes and platelets, the other involving leukocytes – discovered two additional lectin-like molecules with similar but distinct mosaic structures. Thus was the selectin gene family defined (2–4), consisting of E-selectin (endothelium, CD62E, previously known as ELAM)-1, P-selectin (platelet, CD62P, previously known as platelet activation-dependent granule-to-external-membrane protein [PADGEM] and granule membrane protein of 140 kDa [GMP-140]), and L-selectin (leukocyte, CD62L, previously known as MEL-14 and leukocyte adhesion molecule [LAM]-1). A large body of work has since established E-selectin not only as a crucial adhesion structure mediating leukocyte rolling, binding, and transmigration during inflammation, but also as a participant in a dialog between endothelium and leukocytes (and potentially other circulating cells as well, such as cancer cells), in which cell-cell interactions

induce intracellular signaling events that result in changes in the endothelial adhesive and transmigratory phenotype.

More recently, E-selectin also has been identified as one determinant of the endothelium's ability to respond to endostatin, an antiangiogenic compound currently being evaluated as an anticancer agent. This illustrates an important guiding concept: E-selectin, and potentially other gene products with well-established importance in inflammation, may play additional yet-to-be-discovered roles either in inflammation or in other processes involving vascular endothelium. The endothelium may be particularly well suited to carry out such dual functions by virtue of its unique role as both an essential component of the supporting vasculature and an integral determinant of the specific properties of diverse tissues and organs.

### EVOLUTIONARY CONSIDERATIONS

C-type lectins are common in many phyla. A protein with a selectin-like mosaic structure, but lacking an epidermal growth factor (EGF) domain, functions in peripheral nervous system development in *Drosophila* (5). The *E*-, *P*-, and *L*-selectin genes are tightly linked on chromosome 1 in both humans and mice, and show significant structural homology in their extracellular domains, suggesting this gene family arose by duplication of a common ancestral sequence. However, significantly divergent cytoplasmic domains suggest different intracellular signaling consequences of ligand engagement by each selectin. In addition, species-specific differences in transcriptional regulation at the endothelial selectin locus, presumably arising from "genetic drift," have led to potentially significant interspecies differences in E-selectin's contribution to inflammation. This has important implications for extrapolating results from experimental animals to humans (see the section "Experimental models for investigating endothelial selectin function in vivo.")

## DEVELOPMENTAL CONSIDERATIONS

Fetal endothelium participates in inflammatory reactions independent of maternal endothelium and leukocytes. This occurs during chorioamnionitis (inflammation of the placenta and gestational membranes), especially with funisitis (inflammation of the umbilical cord), and during the subsequent complication of fetal pneumonia. In these cases, fetal leukocytes (including PMNs and eosinophils) transmigrate across fetal endothelium at sites of acute inflammation. However, although E-selectin is expressed and becomes cytokine-inducible during embryogenesis, the specific functional significance of this expression and its role in fetal inflammation has not been investigated. In this context, it also is worth noting that HUVECs are of fetal origin and are the cell type used *in vitro* to initially identify and subsequently investigate E-selectin and several other endothelial adhesion molecules important in inflammation.

### Embryonic Expression

*E-selectin* mRNA is initially expressed at low levels at embryonic day (E)9.5 to E11.5 of murine embryogenesis, but it is not inducible by inflammatory cytokines at this stage, as determined in primary *in vitro* cultures of embryo-derived cells (6). Inducibility develops between E12.5 and E13.5, soon after the onset of organogenesis (lung, liver, etc.), suggesting a functional role for regulated expression in leukocyte–endothelial interactions during inflammation in the embryo. Newborn mice lacking both E- and P-selectin, but not singly deficient mice, show elevated circulating leukocytes, implying that either of the endothelial selectins can interact with embryonic leukocytes (7–9). However, expression of E-selectin protein has not been demonstrated in embryos, and the contribution of individual selectins to embryo inflammation, and its relevance to humans, has not been specifically investigated.

Despite data suggesting that E-selectin might participate in angiogenesis (10) and/or antiangiogenesis (11), growth, development, fertility, and wound healing are not affected in genetically deficient mice (8,12,13). E-selectin–deficient ECs also perform normally using *in vitro* angiogenesis assays (14).

### Placental Expression

E-selectin mRNA and protein are developmentally regulated and constitutively expressed in the absence of inflammation in both human and murine trophoblasts during placental differentiation (Figure 118.1) (15,16). Expression occurs in murine secondary trophoblast giant cells, trophoblasts lining the central artery, and a subpopulation of labyrinthine trophoblasts located at the fetal–maternal interface. These cells line vascular channels but express a unique profile of gene products not displayed by the vascular endothelium.

Placentae lacking E-selectin show increased trophoblast glycogen cells and fewer labyrinthine PMNs, suggesting that

recognition of trophoblast E-selectin by counter-receptors on other cells contributes to placental development. However, functional consequences of trophoblast expression for reproduction or embryonic development have not been reported.

## GENE REGULATION

### Inducible Expression in Endothelial Cells

E-selectin is one of a very few genes, including vascular endothelial (VE)-cadherin, whose expression in nonplacental tissues appears truly endothelial-specific. Most other endothelial-restricted gene products, including platelet-endothelial cell adhesion molecule (PECAM)-1, intercellular adhesion molecule (ICAM)-1, ICAM-2, P-selectin, thrombomodulin, and others, also are present in leukocytes, megakaryocytes and platelets, or various other non-ECs. As such, understanding the molecular mechanisms specifying endothelial-specific expression of E-selectin might shed light on the developmentally regulated transcriptional programs defining this lineage. However, little is known about these mechanisms.

Although highly specific, E-selectin expression is not uniform within the endothelium, either in cells cultured *in vitro* or throughout the normal vascular system *in vivo*. Most quiescent ECs in culture do not express E-selectin unless activated by one or more of a variety of inflammatory stimuli, including tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1, CD40 ligand, and bacterial endotoxin (lipopolysaccharide [LPS]). Under *in vivo* conditions, virtually all noninflamed murine tissues containing ECs show detectable, albeit low-level, mRNA expression, although E-selectin protein is usually undetectable. Upon activation of cultured cells, protein expression, preceded by mRNA, increases markedly within 3 to 4 hours, diminishes significantly by 6 to 8 hours, and returns to near-basal levels within 24 to 48 hours (see Figure 118.1). Expression is also dramatically upregulated during inflammation *in vivo*, where it varies significantly between organ beds (17,18) (our unpublished observations) and, within a given bed, is localized to physiologically important vascular structures, such as the postcapillary venules of human skin (19,20) or rabbit mesentery (21). Although both the onset and resolution of expression occur more rapidly *in vivo* than *in vitro*, expression often can be detected several hours, or even several days, after endothelial activation, depending on the inflammatory reaction studied and the tissue examined (see “Dermal EC Protein” in Figure 118.1). In addition, selected vascular beds, such as fetal and adult bone marrow, express E-selectin constitutively *in vivo* (9).

In contrast to E-selectin, P-selectin is present constitutively in endothelial Weibel-Palade bodies, platelet  $\alpha$ -granules, and megakaryocytes, is rapidly mobilized to the cell surface by acute secretagogues, and regulated differently at the transcriptional level during acute inflammation in mice and humans. (See the discussion in a later section “Experimental models for investigating endothelial selectin function *in vivo*,” which

## Molecular Regulation of E-Selectin Expression

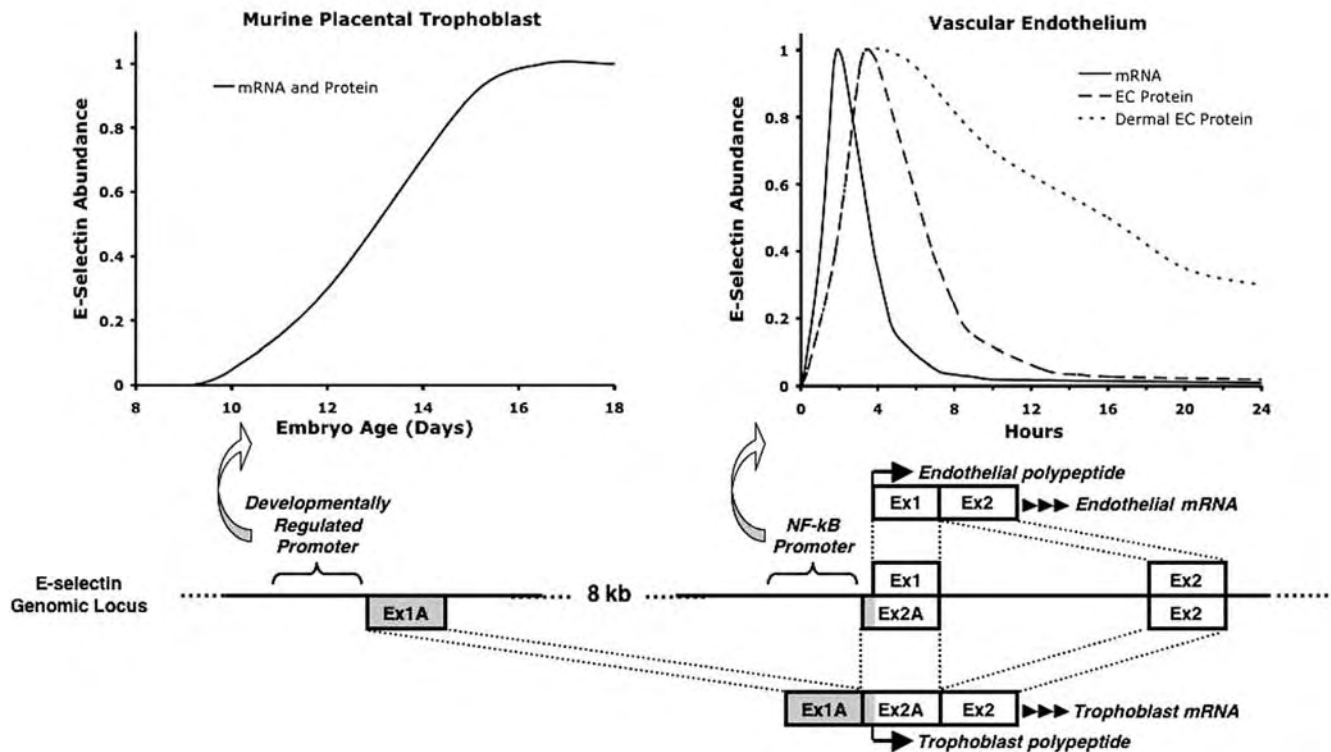

Figure 118.1. Inducible and constitutive expression of E-selectin in endothelium and trophoblast, respectively, is directed by alternative transcriptional regulatory mechanisms. *E-selectin* is transcribed in endothelium from an NF- $\kappa$ B-dependent promoter in response to diverse inflammatory stimuli. Developmentally regulated expression in trophoblasts, not further modulated during inflammation, utilizes a distinct transcriptional promoter and alternative first exon located several kb 5' in the genome. Endothelium and trophoblasts are thought to produce E-selectin protein with identical primary structure. *Upper graphs:* Kinetics of E-selectin mRNA and protein expression in murine placental trophoblast (*left*) and vascular endothelium with inflammatory activation at time 0 hours (*right*). *Lower diagram:* Structural and regulatory features of the murine *E-selectin* genomic locus. The human *E-selectin* locus is organized similarly. (*Key:* Solid line with dashed ends, DNA; open boxes, translated exons; grey boxes, untranslated exons; dotted lines, mRNA splicing events leading to mature *E-selectin* mRNA; arrows, initiation of translation; arrowheads, additional translated exons not shown.)

explores the implications of these species-specific differences for the utility of various experimental models of selectin function.)

E-selectin expression is increased in specific vascular compartments under pathophysiological settings such as sepsis, vasculitis, atherosclerosis, ischemia-reperfusion injury, rheumatoid arthritis, allograft rejection, graft versus host disease, various forms of gastrointestinal inflammation, acute hepatitis, and tumor metastasis. Expression also occurs associated with endothelial proliferation in vitro and in certain in vivo settings. It is not clear if this represents a distinct activation mechanism at the molecular level or an overlap of inflammatory and growth regulatory pathways.

This temporal, spatial and physiological heterogeneity may both reflect and contribute to the integrated complexity of the in vivo milieu, and is thought to play an important role in inflammation by focusing and restricting leukocyte recruitment to appropriate temporal stages and vascular locations (18).

A nuclear factor (NF)- $\kappa$ B-dependent promoter regulates the rapid induction of *E-selectin* mRNA at the transcriptional level (Figure 118.2) (22,23). NF- $\kappa$ B interacts with additional transcriptional activators to form an enhancer complex that transmits activation signals to coactivators and basal factors, resulting in *E-selectin* gene transcription. C-jun N-terminal kinase (JNK)/stress-activated protein kinases (SAPKs), presumably acting via the phosphorylation of c-jun and activation of the transcription factor c-jun/ATF-2, have been identified as additional critical mediators of E-selectin inducibility that may, at least in part, explain the differential responsiveness of different NF- $\kappa$ B-dependent endothelial adhesion molecule genes in different pathological, and potentially physiological, settings (24,25).

Interestingly, stimulation of E-selectin expression by TNF- $\alpha$ , IL-1, or CD40 ligand renders ECs transiently nonresponsive to restimulation by the same, but not by a different, ligand. This is not due to downregulation of receptor expression. Such so-called homologous desensitization is paralleled

### Selectins Share a Unique Complex Mosaic Domain Organization

Figure 118.2. The selectins share a unique, complex, mosaic domain organization: an N-terminal C-type lectin domain, an EGF-like domain, several complement-regulatory-like domains (CR), a transmembrane domain (TM), and a short cytoplasmic domain (Cyto). Variable numbers of CR domains position the lectin and EGF domains of E-, P-, and L-selectin differently within the cell surface glycocalyx, contributing to selectin-specific functions in endothelial–circulating cell interactions. Balls and sticks indicate the lipid bilayer of the endothelial plasma membrane.

by changes in JNK activation, suggesting that JNK also may regulate this process (26). Homologous desensitization may limit the extent of an inflammatory response mediated predominantly by a single mediator, in contrast to responses with more complicated activator profiles.

Stimulated E-selectin expression is also usually transient due to rapid degradation of *E-selectin* mRNA (27) and internalization of the mature protein from the cell surface (28), combined with inactivation of NF- $\kappa$ B (29). This downregulation is thought to contribute to the orderly resolution of inflammatory responses.

What emerges is a complex yet robust and self-limiting regulatory system that functions to place E-selectin protein at the EC surface rapidly and early during inflammation and to remove it equally rapidly. This constrains when and where leukocyte transmigration may occur.

### “Basal” Expression in Trophoblast and Hematopoietic Endothelium

Constitutive E-selectin expression in both murine and human placenta involves complex, nested first exons, and presumed transcriptional promoters physically and functionally distinct from those involved in inducible expression in the endothelium (see Figure 118.1) (15). This implies that evolutionarily conserved and lineage-restricted transcriptional mechanisms regulate expression in homologous trophoblast populations in both species. However, additional information is lacking regarding the molecular mechanisms involved, how they are regulated, and their developmental or other functional significance. Similarly, the genetic regulatory factors and the molecular mechanisms specifying constitutive E-selectin expression in fetal and adult bone marrow endothelium are not known. This expression utilizes the same transcription start site as inducible endothelial expression (see Figure 118.1), and therefore probably uses a regulatory mechanism distinct from that specifying constitutive expression in trophoblast. How such constitutive expression initiates from a site that is also immediately adjacent to an NF- $\kappa$ B–dependent promoter is not clear.

### PROTEIN STRUCTURE

E-selectin consists of an amino terminal, extracellular, calcium-dependent lectin domain followed by an EGF-like domain, six short near-replicate domains (short consensus repeats [SCRs]) homologous to those domains in proteins that bind complement, a transmembrane domain, and a 32-amino acid cytoplasmic domain with multiple potential phosphorylation sites and other residues subject to post-translational modification (Figures 118.2 and 118.3). This complex mosaic structure, shared with P- and L-selectin, is unique among the adhesion structures and imparts special properties to selectin-mediated interactions.

E-selectin’s lectin domain interacts with carbohydrate structures bearing sialyl Lewis X, or sLe<sup>x</sup> (NeuAc $\alpha$ 2–3Gal $\beta$ 1–4[Fuc $\alpha$ 1–3]GlcNAc) in a manner similar to P- and L-selectin. However, meaningful interactions occur only with specific leukocyte counter-receptors, implying that additional structural features, most likely including the EGF domain (30), determine functionally relevant ligand specificity and, in part, differentiate specific E-, P-, and L-selectin functions. Although the EGF domain does not interact extensively with the lectin domain, absence of the EGF or SCR domains decreases ligand binding, suggesting that each also contributes to overall cell adhesion. The lectin and EGF domains in combination likely dictate ligand specificity, as has been shown for P-selectin (30). The SCR domains also may position the lectin/EGF domains in a functionally significant location within the endothelial glycocalyx and/or may mediate oligomerization or overall protein structure.

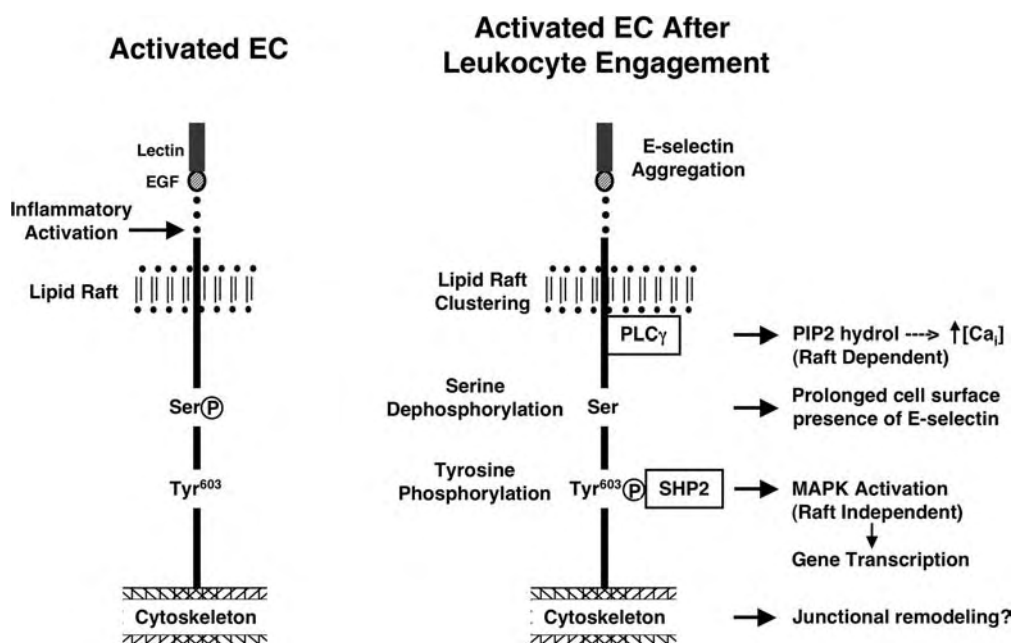

Figure 118.3. E-selectin as a signal transducing receptor. Upon leukocyte engagement with its extracellular lectin domain, E-selectin clusters in lipid rafts and its cytoplasmic domain (a) binds and activates PLC- $\gamma$  and leads to PIP<sub>2</sub> hydrolysis and increased  $[Ca]_i$ ; (b) undergoes serine dephosphorylation that may prolong cell surface expression in certain vascular beds; (c) undergoes tyrosine<sup>603</sup> phosphorylation with SHP2 recruitment, MAPK activation, and immediate-early gene transcription and; (d) interacts with the actin cytoskeleton with the potential to modulate junctional interactions with adjacent EC and influence leukocyte transmigration. Such outside-in signaling may thus modulate the phenotype of a given EC or groups of ECs during inflammation and, potentially, in other physiologic and/or pathophysiologic states as well.

More recently it has become clear that the E-selectin cytoplasmic domain, in addition to its role in endocytosis (31), interacts with intracellular components, potentially transmitting a leukocyte-dependent outside-in signaling response to the endothelium during inflammation. Upon leukocyte engagement (only PMNs have been studied to date), E-selectin, initially present in lipid rafts, associates with caveolae. This leads to phospholipase C (PLC)- $\gamma$  activation, association of E-selectin with the actin cytoskeleton, cytoskeletal remodeling, specific serine residue dephosphorylation, tyrosine residue phosphorylation with mitogen-activated protein kinase (MAPK) activation, and *c-fos* transcription (32). These leukocyte-dependent changes, all of which require the cytoplasmic domain, occurring within the EC may contribute to leukocyte slow rolling and firm adhesion (8,33,34) and to other as yet undefined endothelial phenotypic changes resulting from leukocyte-E-selectin interaction at developing inflammatory sites.

#### E-SELECTIN MUTATIONS WITH CLINICAL SIGNIFICANCE

Patients with mutations of a *GDP-fucose transporter* gene, resulting in hypofucosylated glycoconjugates, suffer from leukocyte adhesion deficiency (LAD)-2 (35). This disorder

is characterized by an inability to mount an inflammatory response, and is caused, in part, by defective counter-receptors for all three selectins. These patients also show developmental abnormalities, presumably reflecting other consequences of abnormal fucose metabolism.

The first report of specific, clinically evident E-selectin deficiency involved a patient with recurrent infections and an inability to mount purulent responses to infectious bacteria (36). This patient lacked E-selectin protein (assessed by immunohistochemistry) on the endothelium of inflamed skin obtained by clinical biopsy and on endothelium of biopsied noninflamed skin stimulated with TNF- $\alpha$  in organ culture *ex vivo*. This same patient showed only mildly elevated plasma soluble E-selectin (sE-selectin) levels, with a normal structural gene and normal levels of mRNA. Although the clinical presentation appears to reflect the consequences of isolated E-selectin functional deficiency, the underlying defect and molecular mechanism responsible for this unusual presentation remain unknown. This patient's *P-selectin* structural gene and expression pattern was found to be normal, suggesting that the clinical effects are due to specific abnormalities in E-selectin.

Point mutations of E-selectin associated with human disease have recently been described. E-selectin/Ser128Arg, involving a mutation within the EGF domain, is associated

with altered plasma levels of sE-selectin, altered ligand affinity, increased tethering by a broader than normal range of leukocytes, increased ligation-induced phosphorylation of endothelial extracellular-signal-regulated kinase (ERK)-1/2 and p38 MAPK, and increased risk of atherosclerosis, myocardial infarction, and restenosis after angioplasty (37). E-selectin/Leu554Phe also is associated with high blood pressure (38) and atherosclerosis (39), whereas circulating concentrations of sE-selectin are associated with hypertension and obesity (40).

## ROLE IN HOMEOSTASIS

E-selectin has been implicated in developmental, physiological, and pathological processes such as inflammation, hematopoiesis, tumor invasion and metastasis, and blood vessel morphogenesis.

### Experimental Models for Investigating Endothelial Selectin Function In Vivo

Although genetically engineered mice have been invaluable for determining the mechanisms regulating gene expression during inflammation, their use to investigate endothelial selectin function in vivo is compromised by differences in transcriptional regulation at the human and murine selectin loci. Specifically, murine P-selectin shares with E-selectin an endotoxin- and inflammatory cytokine-inducible pattern of gene expression that is restricted to E-selectin in humans (41,42). This suggests that studies in mice may underestimate the contribution of human E-selectin to responses regulated by NF- $\kappa$ B, and may explain why E-selectin plays a lesser role in murine inflammation than initially anticipated. However, IL-4, oncostatin M, and IL-6/IL-6 receptor complexes can activate P-selectin expression in both species (43), suggesting that species-specific differences in inflammatory expression are complex. In fact, mice lacking both P- and E-selectin show dramatic leukocytosis, elevation of circulating cytokines, and hematopoietic abnormalities (9) that may more accurately predict the phenotype of isolated human E-selectin deficiency (although some properties may reflect lack of P-selectin-specific and/or overlapping functions). The phenotypes of mice with genetically engineered endothelial selectin alleles are summarized in the Table 118-1.

Alternative approaches involve other animals, such as rabbits or pigs, and studying the vasculature of transplanted human tissues, such as skin, in immunodeficient mice. The latter strategy, which has been accomplished by several investigators, can be combined with human bone marrow transplantation into mice to also reconstitute human leukocytes in vivo. This may most accurately represent human endothelial selectin expression and function, with cells bearing authentic counter-receptors in vivo.

**Table 118-1: Mice with Genetically Engineered Endothelial Selectin Alleles**

<i>Knockout</i>	<i>Phenotype In Vivo</i>
<i>E-selectin</i> (8,11,12)	Normal viability and fertility Absent slow rolling and diminished firm adhesion of WBCs on inflamed ECs Normal WBC extravasation into inflamed tissue Insensitive to antiangiogenic effects of endostatin
<i>P-selectin</i> (58,59)	Normal viability and fertility Nearly absent WBC rolling on inflamed ECs Delayed WBC extravasation into inflamed tissue
Combined <i>E-selectin</i> and <i>P-selectin</i> (9,13)	Opportunistic bacterial infections, including ulcerative dermatitis, leading to sepsis with death beginning at 3 months of age Absent WBC rolling on inflamed ECs Absent WBC extravasation into inflamed tissue Elevated circulating levels of hematopoietic cytokines with altered hematopoiesis

WBC, white blood cell

### Cell–Cell Interactions in Inflammation

E-selectin interacts with PMNs in acute inflammation, monocytes in chronically inflamed tissues, and certain lymphocyte subtypes in immune responses. In these contexts, E-selectin is a candidate for functional importance in a vast array of human diseases and reparative processes. Studies in genetically deficient mice reveal that, in the context of inflammation, E-selectin is uniquely important in vivo for leukocyte slow rolling and subsequent firm adhesion to acutely cytokine-activated microvascular endothelium (see Table 118-1) (8,33,34). This has been demonstrated for PMN recruitment. Whether E-selectin mediates a similar specific function in monocyte and lymphocyte interactions in vivo is not known.

In general, leukocyte expression of glycosyltransferase VII is required for the production of E-selectin counter-receptors. The human disease LAD-2 described previously, in which deficient fucosylation of selectin counter-receptors leads to severe inflammatory disease, illustrates the importance of such structures.

### Hematopoiesis

E-selectin expressed by the endothelium of hematopoietic organs mediates homing of hematopoietic progenitor cells from peripheral blood (44). However, E-selectin also increases apoptosis and enhances rapid differentiation of such cells,

suggesting its overall effect may be to decrease long-term hematopoietic potential. In contrast, P-selectin also mediates homing but shows largely opposite effects on progenitor cell survival and differentiation. The overall effect in mice genetically deficient in both E- and P-selectin simultaneously is enhanced hematopoiesis with increased progenitor cell numbers in bone marrow and spleen (see Table 118-1), as is seen in mice genetically deficient in all selectin counter-receptors (45).

### Tumor Metastasis

Studies of tumor metastasis using either specific adhesion-blocking reagents, genetically deficient mice, or mice genetically engineered to express cell surface E-selectin at ectopic sites or soluble E-selectin in the systemic circulation (see Table 118-1) (46) suggest that E-selectin can act as a recognition structure for counter-receptors on several types of circulating tumor cells, thus directly mediating transendothelial migration (TEM) during the metastatic process and providing a target for therapeutic intervention (47). Such interactions also may induce bidirectional outside-in signaling in both the tumor and the endothelium, altering cellular phenotypes in ways that further modulate the metastatic process. Circulating levels of sE-selectin also correlate with hepatic metastases, of breast and colorectal carcinoma. These levels correlate inversely with prognosis (48–50), although the mechanism and functional significance of these observations is not clear.

### Blood Vessel Formation and Regression

As mentioned, genetic loss-of-function experiments show that E-selectin is not required for developmental or reproductive angiogenesis in mice. In addition, corneal angiogenesis in response to basic fibroblast growth factor (bFGF) and TNF- $\alpha$  is not impaired (51). However, early studies *in vivo* using animal models and *in vitro* using human cells suggested that either soluble or cell-associated E-selectin might be involved in endothelial proliferation or blood vessel formation (see Table 118-1) (10,52,53).

Recent evidence suggests E-selectin is required for the antiangiogenic action of endostatin, *in vitro* as well as *in vivo*, via a mechanism that involves the cytoplasmic domain. This implicates E-selectin-dependent intraendothelial signaling events in the molecular mechanism of endostatin action (see Table 118-1) (11). Interfering with E-selectin expression and/or signaling by recruited tumor blood vessels may thus be one mechanism by which tumor cells specify resistance to the antiangiogenic, antitumor action of endostatin.

### AUTOCRINE AND PARACRINE EFFECTS

E-selectin transmits adhesion-dependent intracellular signals to ECs that must interact intimately with their neighbors to initially establish, transiently relinquish, and ultimately

re-establish, in a very selective manner, a barrier to leukocyte transmigration. Newly synthesized E-selectin is localized to cholesterol-rich plasma membrane microdomains lacking caveolin. Leukocyte engagement results in the following changes:

- Larger membrane microdomains form that may contain caveolin-1 and in which PLC- $\gamma$  associates with the E-selectin cytoplasmic domain, leading to phosphatidylinositol bisphosphate (PIP<sub>2</sub>) hydrolysis and increased intracellular calcium concentrations.
- The E-selectin cytoplasmic domain also becomes physically associated with the actin cytoskeleton, leading to cytoskeletal changes that may include junctional remodeling (6).
- Constitutively phosphorylated serine in the cytoplasmic domain becomes dephosphorylated (7), which can extend the life of E-selectin at the cell surface (8).
- Tyrosine<sup>603</sup> becomes phosphorylated, initiating SHP2 recruitment, activation of the MAPK signaling pathway, and transcriptional activation of the immediate early response gene, c-Fos (9,10).

Interestingly, only PLC- $\gamma$  hydrolysis of PIP<sub>2</sub>, but not MAPK activation, requires E-selectin localization to lipid rafts, suggesting that different signaling pathways or combinations of pathways might be recruited by activating stimuli that differentially affect the plasma membrane distribution of E-selectin.

Although the ultimate functional significance of these signaling events is not clear, they may alter the “phenotype” of the EC in which they occur. This, in turn, may influence this cell’s interaction not only with the leukocyte (or potentially the hematopoietic precursor or tumor cell) initially engaging E-selectin, but also with adjacent endothelium. This presents the intriguing possibility that E-selectin may act in a cell-autonomous fashion to modulate the phenotype of the endothelium, actively supporting TEM during inflammation, hematopoiesis, or tumor cell metastasis. By comparison, the P-selectin cytoplasmic domain interacts with clathrin-coated pits (54) and is involved in intracellular trafficking, localization to EC Weibel-Palade bodies (but not platelet  $\alpha$ -granules), turnover of the mature protein product (55), and intracellular phosphorylation events (56).

Combined with the highly regulated pattern of E-selectin expression, such “phenotypic modulation” of specific ECs also is positioned to function as part of an autocrine/paracrine regulatory system “marking” or revealing, on an integrated tissue and organ scale, exactly when and where leukocyte transmigration occurs and inflammation (or hematopoiesis or metastasis) develops. Experiments using animal models mimicking the expression and function of human endothelial selectins will help define the contribution of such effects to physiological and pathophysiological transmigration.

E-selectin-counter-receptor interactions also trigger paracrine consequences of leukocyte-endothelial interactions.

Specifically, adhesion via E-selectin can lead to activation and affinity maturation of the Mac-1 integrin receptor on leukocytes (57). This may be the mechanism underlying E-selectin's role in the transition from leukocyte rolling to firm adhesion during inflammation, as described earlier.

### INTERACTIONS WITH OTHER OUTPUTS

Substantial evidence indicates that endothelial adhesion structures cooperate to orchestrate leukocyte transmigration during acute and chronic inflammation. E-selectin's importance in slow rolling and firm adhesion suggests that it interfaces, functionally if not physically, with Mac1, ICAM-1, and/or vascular cell adhesion molecule (VCAM)-1, each also implicated in these processes in various contexts, to mediate inflammatory adhesion cascades. It seems likely that different combinations of adhesion activities contributed by various adhesion structures may underlie, in part, the different leukocyte types, vascular locations, and kinetics that characterize different inflammatory states, and that perturbations of these interactions, perhaps subtle, may underlie the devastating consequences of inflammatory disease.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

E-selectin's unique specificity for the endothelium and strong association with cellular activation suggest it may be a useful "surrogate marker" for assessing the overall activation state of an individual's endothelium in clinical settings. This might be especially useful in patients at risk for or experiencing inflammatory or malignant/metastatic insults or disease. Therefore, the occurrence of circulating, soluble forms of E-selectin and their relation to a variety of diseases has been extensively investigated. Although E-selectin lacking the cytoplasmic domain circulates in plasma of humans and experimental animals, neither alternatively spliced isoforms lacking the transmembrane domain nor a regulated or unregulated secretion mechanism have been reported. Thus, sE-selectin probably derives from proteolytic cleavage of the mature EC surface protein, followed by release of a shortened form into the circulation.

In general, circulating levels of sE-selectin correlate well with clinical severity of sepsis and other systemic inflammatory states (37–40). Elevated sE-selectin has been observed in patients with hypertension, diabetes, and hyperlipidemia but not in patients with more localized diseases, such as atherosclerosis, in which endothelial activation also plays a prominent role. However, it is not clear that this parameter provides significant diagnostic advantages over traditional clinical assessment. It also seems unlikely that the levels of sE-selectin are adequate to block functional interactions between circulating leukocytes or tumor cells and activated endothelium, as appears possible for L-selectin. The prognostic implications of sE-selectin in malignancy were addressed earlier.

### KEY POINTS

- E-selectin, a cytokine-inducible, EC surface transmembrane glycoprotein lectin, is important for leukocyte and tumor cell transmigration. It participates in adhesion-dependent outside-in signaling that may modulate the EC phenotype during inflammation and metastasis, and it may be involved in certain antiangiogenic responses.
- NF- $\kappa$ B-dependent E-selectin expression in inflamed vascular endothelium, in cooperation with P-selectin, leads to lectin-counter-receptor interactions, slow rolling, and firm adhesion of circulating cells, all necessary for leukocyte and tumor cell transmigration into tissues.
- When circulating cells bind E-selectin, its cytoplasmic domain interacts with the cytoskeleton and other signal transduction components in ways that may modulate the EC phenotype during inflammation.
- E-selectin's properties suggest it may play other as yet undiscovered roles in inflammation and vasculature physiology and pathophysiology, such as its recently demonstrated role in the antiangiogenic action of endostatin.

### Future Goals

- To elucidate the specific contributions of E-selectin and P-selectin to leukocyte recruitment during inflammation, to tumor metastasis, to hematopoiesis, and to physiologic and pathophysiologic blood vessel formation and regression in human patients
- To determine E-selectin's prognostic and/or therapeutic utility in human patients

## Endothelial Cell Apoptosis

Elizabeth O. Harrington, Qing Lu, and Sharon Rounds

*Providence VA Medical Center, Brown Medical School, Providence, Rhode Island*

In an article published by Kerr and colleagues in 1972, the term *apoptosis*, defined as “dropping off or falling off of . . . leaves from trees,” was used to describe energy-dependent cellular suicide with distinct morphologic characteristics, such as chromatin condensation, plasma membrane blebbing, and apoptotic body formation (1). The term *apoptosis*, however was first used in medicine by Hippocrates (460–370 B.C.) to describe the “falling off of the bones” in a book discussing bone fractures (2). The term was also reportedly utilized by Galen (129–201 A.D.) to describe the “dropping of the scabs” (2). Since the re-introduction of *apoptosis* to scientific and medical literature 33 years ago, close to 95,000 articles published and listed in National Library of Medicine’s PubMed make use of the term.

Apoptosis or programmed cell death describes a genetically determined elimination of cells that are in excess, injured, infected, or aged. Once committed to programmed suicide, cells undergo well-ordered morphologic and molecular alterations, including cytoskeletal rearrangement, nuclear membrane collapse, chromatin condensation, cell shrinkage, plasma membrane blebbing, and the formation of disassembled membrane-enclosed vesicles, referred to as apoptotic bodies (1). DNA fragmentation also occurs by activated endonucleases, resulting in the cleavage of genomic DNA into 180- to 200-base pair fragments (1). Additionally, phosphatidylserine exposure at the cell surface acts as a chemoattractant for macrophages, thus promoting the engulfment of these apoptotic bodies and the prevention of inflammation due to limited release of intracellular contents (3,4). In contrast, cells undergoing necrosis swell and lyse, thereby releasing intracellular contents into the interstitium, leading to an inflammatory response (5). Apoptosis plays a fundamental role in normal development and tissue homeostasis, as well as in the progression of pathophysiologic diseases.

In this chapter we discuss, in general terms, the process of apoptosis, the stimuli for endothelial cell (EC) apoptosis, and evidence for EC apoptosis in normal and abnormal vasculature.

### CELLULAR AND MOLECULAR BASIS OF APOPTOSIS

Various factors, such as Fas ligand (FasL), tumor necrosis factor (TNF)- $\alpha$ , metabolite deprivation, DNA damage, inhibition of transcription and translation, hypoxia, or interferon (IFN)- $\gamma$ , can trigger programmed cell death. Although cells differentially respond to apoptotic stimuli, there are two fundamental signaling pathways by which apoptosis is mediated: the extrinsic and intrinsic pathways. The extrinsic pathway is activated when the apoptotic stimulus acts through a death receptor. Conversely, the intrinsic pathway is triggered by internal apoptotic signals involving the mitochondria. Although each apoptotic signaling pathway is activated via specific signaling mechanisms, both pathways merge and share some final common death machinery utilizing the aspartate-specific cysteinyl protease (caspase) cascades. These apoptotic pathways and their intermediate signaling molecules are delineated in Figure 119.1.

#### The Extrinsic Pathway

Death receptors, a family of transmembranous proteins belonging to the TNF receptor superfamily, directly bind to extracellular death ligands and transmit the signal to apoptotic-inducing intracellular machinery, ultimately leading to cell death. Death receptors have a cysteine-rich extracellular domain and a cytoplasmic death domain (DD). Through its death domain, death receptors transmit the death signals to caspases by associating with additional death domain-containing adapters. The best characterized death receptors are Fas (CD95, Apo1), TNF receptor (TNFR)-1, and death receptors 3, 4, and 5 (DR3, DR4, and DR5) (6,7).

FasL is primarily expressed in activated T cells, natural killer cells, and hepatocytes (6). FasL and Fas also are expressed in ECs (8). Upon FasL binding, Fas forms a homotrimeric complex. Additional binding of FasL promotes the formation of a hexameric Fas protein complex and the recruitment of the adapter protein, Fas-associated DD (FADD), forming

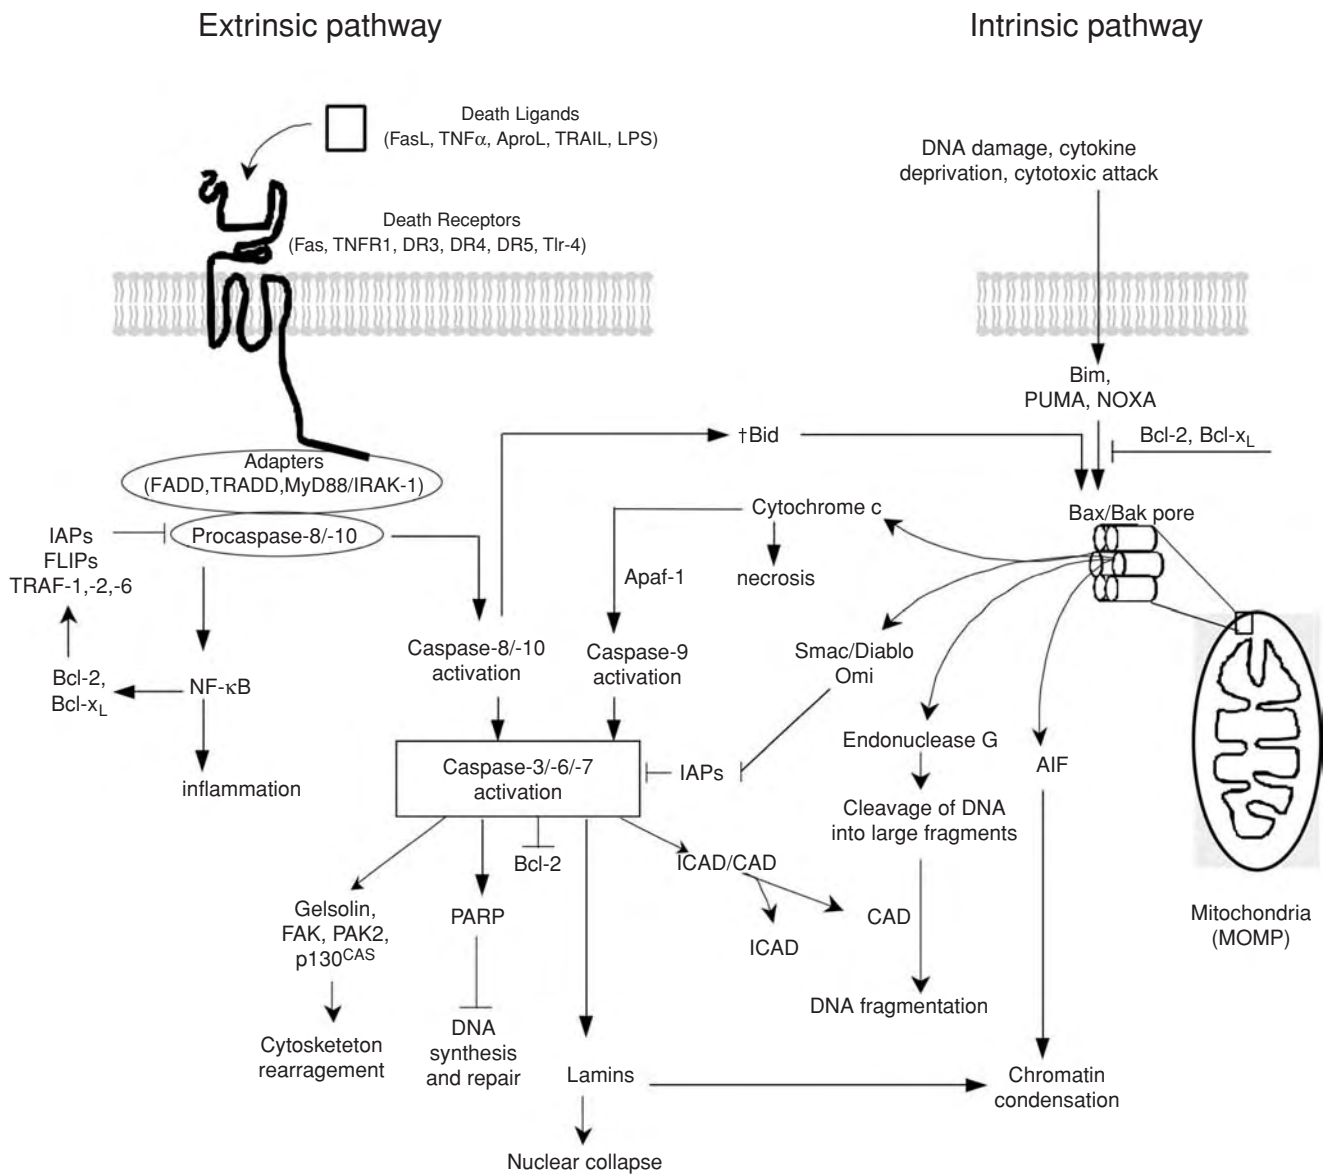

Figure 119.1. Pathways mediating the extrinsic and intrinsic apoptosis signaling response.

the death-inducing signaling complex (DISC) (see Figure 119.1). The interactions between the death domains of Fas and FADD promote recruitment of procaspase-8 via its death effector domain (DED). These protein-protein interactions cause autoproteolysis of procaspase-8, resulting in activation of caspase-8. Caspase-8 subsequently cleaves the propeptide of caspase-3, thus activating it, or it activates Bid-dependent mitochondrial pathway (9,10) and apoptosis ensues. Fas/FasL-mediated apoptosis signaling has been implicated in physiological apoptosis, such as removal of peripheral activated T cells at the end of immune response and killing of inflammatory cells at immune-privileged sites (6) and an-oikis (11).

TNF- $\alpha$  is an inflammatory cytokine produced predominantly by activated macrophages and T cells in response to infection. TNFR1 is expressed in many tissues, including

the endothelium. Similar to the Fas/FasL-mediated apoptotic pathway, ligation of TNF- $\alpha$  to TNFR1 causes DISC formation via its adapter molecule TNFR1-associated DD (TRADD). These protein complexes then recruit and stimulate the activation of caspase-8 and/or -10, which can ultimately induce cell death by activation of caspase-3 or by Bid-dependent mitochondrial dysfunction (9,10). The truncated form of Bid (tBid) triggers mitochondrial activation of caspase-9 by inducing Bax/Bak pore formation (9,10). However, unlike FasL, TNF- $\alpha$  rarely induces apoptosis. TNF- $\alpha$  concomitantly activates transcription factors, nuclear factor (NF)- $\kappa$ B and AP-1, resulting in the induction of expression of various genes that encode antiapoptotic proteins (12,13).

ApoL is expressed in many tissues, yet its receptor, DR3, expressed predominantly in T cells, is upregulated during T-cell activation. Similar to TNFR1/TNF- $\alpha$ -induced apoptosis,

DR3/ApoL also causes activation of NF- $\kappa$ B and AP-1 through TRADD (6). Apo2 ligand (Apo2L), also referred to as TRAIL, and its receptors, DR4 and DR5, are constitutively expressed in various tissues, as well as tumor cell lines. Apo2L binds to DR4 or DR5 and induces apoptosis through caspase-8 activation, which leads to cleavage and activation of Bid and subsequent Bid-dependent mitochondrial dysfunction. Although tumor cells are sensitive to Apo2L-triggered apoptosis, nontumorigenic cells are resistant, suggesting that a protective mechanism exists in these cells. Indeed, DcR1 and DcR2 (receptors similar to DR4 and DR5) that either lack the cytoplasmic tail or contain a truncated cytoplasmic death domain, respectively, are expressed in multiple nontumorigenic cells. These receptors act as decoys by competitively inhibiting the binding of Apo2L to DR4 or DR5, thus inhibiting apoptosis induced by this agonist (14).

### The Intrinsic Pathway

Death receptor-mediated caspase activation is critical for the progression of apoptosis; however, caspase activity is not necessary to cause cell death (15). For example, the activation of Bak, a proapoptotic protein, by caspase-8-dependent Bid activation causes mitochondrial damage and cell death in the absence of caspase-3 activity (15), suggesting caspase-3-independent pathways are involved in mediating apoptosis. In fact, the mitochondria can act as stress sensors, as well as executioners of cell death. Many stress-inducing stimuli, such as cytotoxic drugs, oxidants, radiation, DNA damage, elevated intracellular calcium ( $\text{Ca}^{2+}$ ), and growth factor deprivation promote mitochondrial outer membrane permeabilization (MOMP), resulting in apoptosis. This mitochondrial-dependent mechanism is referred to as an intrinsic apoptotic signaling pathway (see Figure 119.1). MOMP is regulated by the balance of the activities of antiapoptotic (such as Bcl-2, Bcl-x<sub>L</sub>, Bfl-1, Bcl-w, Boo, Mcl-1) and proapoptotic (such as Bax, Bak, Bad, Bim, Bid, PUMA, NOXA) Bcl-2 family members (16,17). Normally, proapoptotic Bcl-2 proteins, such as Bax and Bak, are sequestered through heterodimerization in the cytoplasm by antiapoptotic Bcl-2 proteins, such as Bcl-2 and Bcl-x<sub>L</sub>. During cellular stress, increased expression and/or activation of proapoptotic members of the Bcl-2 family causes their translocation to the mitochondrial outer membrane to form pores. These pores in turn allow some mitochondrial constituents located within the internal membrane space to escape into the cell cytoplasm; these include cytochrome-*c*, second mitochondrial-derived activator of caspase (Smac)/direct inhibitors of apoptosis protein (IAP) binding protein with low pI (Diablo), apoptosis-inducing factor (AIF), endonuclease G, and a serine protease referred to as Omi (16). The consequence of cytochrome-*c* release depends on cell type. If cells have an abundant amount of cytochrome-*c*, then the release of cytochrome-*c* does not significantly affect electron transport. The released cytochrome-*c* may rapidly bind to apoptosis protease-activating factor-1 (Apaf-1), in an adenosine triphosphate (ATP)-dependent manner. This inter-

action subsequently leads to the recruitment and activation of procaspase-9, with downstream activation of caspase-3, -6, or -7, culminating in apoptosis (Figure 119.1) (18,19). In contrast, in cells with high endogenous levels of caspase inhibitors, such as IAPs, the release of cytochrome-*c* is unable to effectively activate caspase-9, thus fails to induce apoptosis. Instead, the large loss of cytochrome-*c* from the mitochondrial membrane eventually disrupts the electron transport chain, driving the cells to undergo necrosis due to an increased generation of reactive oxygen species (ROS) and decreased ATP production (20). Upon release from the mitochondrial membrane, Smac/Diablo activate caspases by directly displacing IAPs from caspases, thus making the IAPs susceptible to cleavage by Omi (21,22). In addition, the release of AIF from the mitochondrial membrane allows translocation of this protein to the cell nucleus and the initiation of chromatin condensation (23). Finally, endonuclease-G contributes to DNA fragmentation by cleavage of high-molecular-weight genomic DNA, independent of caspase activity (24).

T cell receptor (TCR) ligation or cytokine deprivation has been shown to induce apoptosis by promoting mitochondrial pore formation and MOMP through the upregulation of Bim and subsequent activation of Bax/Bak (25). DNA damage also causes apoptosis through activation of p53, which in turn upregulates PUMA and NOXA expression leading to Bax activation and MOMP (26). In addition to these stimuli, in some cells, FasL-induced caspase-8 activation can promote apoptosis via a mitochondrial-dependent mechanism. In this apoptosis-inducing pathway, activated caspase-8 causes Bid truncation and activation (9). Activated Bid subsequently promotes Bax mitochondrial membrane pore formation and MOMP by displacing Bax from its heterodimeric, inactive protein complex with Bcl-2 or Bcl-x<sub>L</sub>, thus promoting apoptosis (27).

In summary, a variety of signaling cascades may initiate apoptosis via either the extrinsic or intrinsic pathways.

### Caspase Cascades

Caspases are a family of highly conserved aspartate-specific cysteinyl proteases. The caspase cascade is central to the progression of apoptosis and is utilized by both extrinsic and intrinsic pathways. All caspases have conserved amino acids and protein structure. To date, 13 mammalian caspases have been identified with distinct roles in apoptosis and inflammation. These are referred to as caspase-1 through caspase-13. All caspases are synthesized and accumulate in cells as inactive propeptides. Some caspases are activated by autoproteolysis upon the binding of adapter proteins, in response to signals initiating apoptosis. These caspases – caspase-8, -9, and -10 – are referred to as initiator caspases (28,29). Other caspases that cleave substrate proteins, culminating in cell death, are activated by the removal of bound inhibitors or by the cleavage by initiator caspases or proteases. These caspases – caspase-3, -6, and -7 – are referred to as effector caspases. Each caspase recognizes specific substrates, containing peptide motifs AXXX

(A: aspartic acid; X: any amino acid) within the N-terminus (28,29).

Caspases are executors of apoptosis (Figure 119.1). Upon receipt of the appropriate signals, the initiator caspases are activated, resulting in the immediate amplification and transmission of the signals to the effector caspases by proteolysis and activation. The activated effector caspases, in turn, cleave a select set of proteins at a single site, resulting in loss or gain of function. Over 100 proteins possessing caspase recognition motifs have been identified; these include inhibitor of caspase-activated DNase (ICAD), poly ADP-ribose polymerase (PARP), Bcl-2, lamin, and several cytoskeleton-binding proteins. In nonapoptotic cells, caspase-activated DNase (CAD) exists as an inactive complex with ICAD. Upon stimulation of a death signal, ICAD is cleaved by caspase-3, and the liberated CAD functions as an internuclease, destroying genomic DNA (28). PARP was the first substrate identified for caspase-3. Cleavage of PARP by caspase-3 inhibits DNA synthesis and repair (30). Bcl-2 prevents Bax/Bak-mediated mitochondrial pore formation by heterodimerizing with Bax or Bak, thus blocking the release of cytochrome *c* from the mitochondria. Caspase-mediated Bcl-2 cleavage not only inactivates Bcl-2, but also produces an apoptotic-promoting proteolytic fragment (31). Lamina are cytoskeletal structures composed of lamins that underlie the nuclear envelope, with roles in chromatin organization, gene regulation, and signal transduction. Caspase cleavage of lamins disrupts the nuclear membrane and contributes to chromatin condensation (32). In addition, caspases promote the reorganization of the cytoskeleton during the progression of apoptosis by cleaving several proteins important in the formation and stabilization of the cytoskeleton, including gelsolin, focal adhesion kinase (FAK), p130cas, and p21-activated kinase 2 (PAK) (31,33–36).

## REGULATORS OF APOPTOSIS

Nonpathological development and tissue homeostasis require a proper balance between survival and apoptotic signals. As expected, apoptosis is a highly regulated process, with various factors important to this control.

Bcl-2 was initially found to be overexpressed in B-cell lymphoma. This upregulation correlated with the loss of response to death signals and resistance to apoptosis (37). There are more than 15 members of the Bcl-2 family in mammalian cells. They are classified into two groups: the prosurvival or antiapoptotic subfamily, including Bcl-2 and Bcl-x<sub>L</sub>, and the proapoptotic subfamily, including Bid, Bim, Bax, and Bak. Bcl-2 proteins, which block apoptosis, heterodimerize nonspecifically with proapoptotic proteins and sequester them in an inactive state in cytoplasm. This sequestration is protective against apoptosis by preventing MOMP. Although Bcl-2/Bcl-x<sub>L</sub> protect against diverse cytotoxic stresses, such as irradiation and cytokine withdrawal, they are ineffective against FasL/

caspase-8/caspase-3-mediated apoptosis (see Figure 119.1) (14).

As mentioned previously, upon binding of FADD with the DED domain of procaspase-8, in response to FasL ligation, procaspase-8 is activated via autoproteolytic cleavage (see Figure 119.1). FADD-like inhibitory proteins have similar DEDs, mimicking the procaspase-8 domains, but lacking caspase proteolytic activity. FLIPs regulate the progression of apoptosis by competing with procaspase-8 for binding with FADD, thus inhibiting apoptosis (38). In ECs, downregulation of c-FLIP is implicated in extracellular matrix (ECM) detachment-induced anoikis (11).

IAPs normally bind to active caspases, rendering them inactive (39). Upon stimulation of death signals, inhibitors of IAPs, such as Smac/Diablo and Omi are released from mitochondria (see Figure 119.1). Smac/Diablo displace IAPs from caspases, resulting in the activation of caspases and the promotion of apoptosis. Concomitantly, the liberated IAP is degraded by Omi, thus further enhancing apoptosis (21,22).

NF- $\kappa$ B is an important antiapoptotic transcription factor. NF- $\kappa$ B is activated by TNF- $\alpha$  and ApoL, as described previously (6–10,12,13). NF- $\kappa$ B promotes the expression of various antiapoptotic proteins, including Bcl-2, Bcl-x<sub>L</sub>, FLIPs, IAP-1 and -2, and TNFR-associated factor-1 and -2 (12,13).

## IDENTIFICATION OF APOPTOSIS

Many approaches have been developed to identify apoptotic cells based on specific morphological and biochemical cellular alterations. Frequently used assays to assess cellular apoptosis in the laboratory are listed in Table 119-1.

## IMPORTANCE OF APOPTOSIS IN ENDOTHELIUM

ECs form a monolayer lining the vasculature. The functions of the endothelium are to selectively restrict the passage of solutes and macromolecules into the surrounding tissue, to maintain a nonthrombogenic surface over which the blood flows, and to regulate vascular tone. Due to the positioning of the endothelium at the interface between the blood and surrounding tissue, the endothelium is exposed to multiple stresses, mechanical and nonmechanical, which regulate vascular processes both physiologically and pathologically. One pathological consequence of these stresses in the blood vessel is the induction of apoptosis of the endothelium, which occurs in various diseases. However, EC apoptosis is also crucial in normal vascular development to regulate vasculogenesis, angiogenesis, vessel regression, and turnover of senescent EC in pre-existing vessels. Thus, a careful balance of signals regulating EC survival and apoptosis is important for the maintenance of the vascular integrity.

**Table 119-1: Methodologies for Detecting Apoptosis**

<i>Categories</i>	<i>Features</i>	<i>Methodology</i>	<i>References</i>
Cell morphology	Diminished cell size and membrane blebbing	View cell morphology by electron microscopy	1
Plasma membrane integrity assay	Live cells exclude dye	Trypan blue or fluorescently labeled propidium iodide and YO-PRO-1 staining followed by light or fluorescence microscopy, respectively	11
Chromatin characterization	Chromatin condensation and DNA fragmentation	Staining with Hoechst or propidium iodide followed by fluorescence microscopy	144
DNA laddering	Endonuclease cleavage of DNA into 180–200 bp fragments	Analysis of DNA by agarose gel electrophoresis	145
Nucleosome ELISA	Endonuclease-mediated excision produces mono- and oligo-nucleosomes	DNA-affinity mediated capture of nucleosomes followed by immunodetection and quantitation of histone proteins	145
TUNEL staining	DNA strand breaks	Fluorescence labeling of DNA strand breaks using terminal deoxynucleotidyl transferase (TdT) in situ and quantitated using fluorescence microscopy or flow cytometry	144, 146
Phosphatidylserine exposure	Cell surface exposure of phosphatidylserine	Binding of fluorescently conjugated Annexin V with plasma membrane exposed phosphatidylserine and analyzed using fluorescence microscopy or flow cytometry	147
Caspase activity assay	Activation of caspases	In vitro activity assays quantitate substrate cleavage via fluorescence, colorimetric, or spectrophotometric changes in live or fixed cells and by SDS-PAGE and immunoblot analysis. In situ assays assess the ability of fluorescently labeled caspase inhibitors or antibodies directed against the mature caspase protein to bind to the caspase and quantitate via fluorescence microscopy or flow cytometry.	33, 148
Apoptotic protein translocation	Subcellular relocalization of pro- and antiapoptotic proteins	Subcellular fractionation of mitochondrial and cytoplasmic proteins and immunoblot analysis or immunofluorescent staining of cytochrome- <i>c</i> , AIF, and members of Bcl-2 family	16, 17
Mitochondrial permeabilization assay	Mitochondrial membrane depolarization	Fluorochromes sensitive to changes in the mitochondrial transmembrane potential, such as 5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide (JC-1) and 1,1',3,3,3',3'-hexamethylindodicarbocyanine iodide (DiIC <sub>1</sub> ), are assessed using fluorescence microscopy or flow cytometry.	149

EC apoptosis has been shown to occur in vitro and in vivo by both a receptor-mediated, extrinsic pathway, as well as through the intrinsic pathway that results from alterations in mitochondrial function. Interestingly, just as there is a heterogeneous response to vasoactive or edematogenic stimulants by ECs derived from distinct vascular beds, it is also recognized that ECs respond differentially to apoptotic signals. For example, proliferative or angiogenic ECs express a greater number of death receptors when compared with quiescent, nonproliferating ECs; thus, they are more responsive to apoptosis-inducing agents (40). Additionally, several in vivo studies suggest that ECs undergo phenotypic changes with

age, resulting in diminished vasodilatory responsiveness and exposure to increased oxidative stresses (41) that result in the ECs becoming more susceptible to apoptotic stimuli and less responsive to the apoptotic-protective effects of shear stress, as compared with younger ECs. Thus, the susceptibility of ECs to apoptosis depends on many factors, including genotypic and phenotypic characteristics of the endothelium, as well as the environmental exposures in the vascular bed from which they are derived. We will review biochemical and biomechanical stresses that regulate apoptosis of the endothelium and describe the role(s) that these pathways play in vasculopathy (summarized in Table 119-2).

## BIOMECHANICAL STIMULI INVOLVED IN ENDOTHELIAL CELL PRO- OR ANTIAPOPTOTIC SIGNALING

### Shear Stress and Cyclic Strain

Mechanical, hemodynamic forces to which the endothelium is exposed include fluid shear stress from the frictional force of the blood flow and cyclic strain resulting from the rhythmic deformation of the vessels due to cardiac output forces. In addition to influencing EC protein and gene expression, proliferation, migration, and cell-cycle progression, these hemodynamic forces are important in regulating EC survival and apoptotic signaling. Early studies demonstrated that the addition of high laminar shear stress ( $>15$  dynes/cm<sup>2</sup>) protected ECs normally grown under static conditions from growth-factor deprivation-, TNF- $\alpha$ -, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>-

induced apoptosis (42,43). Disruption of, or alterations in, high laminar blood flow are proapoptotic in the endothelium both in vitro (44) and in vivo, and have been shown to be important in the progression of atherosclerotic plaques (45) and vessel narrowing upon blood flow reduction (46) (Figure 119.2). Similar to shear stress, physiologic levels of cyclic strain (6%–10%), but not excessive (20%) strain, are protective against apoptotic-inducing agents (47). Not surprisingly, the two biomechanical forces promote EC survival by utilizing both overlapping and distinct signaling pathways (48).

### Integrin and Extracellular Matrix Interactions

Integrins are a family of ubiquitous cell surface receptors that mediate the interactions between the cell and the ECM, thus anchoring the cells. Integrins are transmembranous proteins

Figure 119.2. Mediators of endothelial apoptosis in atherosclerosis.

composed of  $\alpha$ - and  $\beta$ - heterodimeric subunits (see Chapter 77). Currently, 18  $\alpha$ - and eight  $\beta$ -subunits have been identified, giving rise to 24 possible integrin pairs (49). Integrins interact with ECM proteins, such as fibronectin, vitronectin, collagen, heparin-sulfate proteoglycans, and laminin, to form focal adhesion complexes by organizing multiple intracellular signaling proteins with cytoskeletal structures at these focal points. These cell-ECM structures convey changes in extracellular biomechanical and biochemical environmental cues and result in various cellular responses important in EC adhesion, migration, proliferation, barrier function, and survival (50).

Loss of these cell-ECM interactions promotes apoptosis or anoikis in numerous cells, including the endothelium. ECs grown in suspension undergo apoptosis within 18 hours (51). In vitro studies demonstrate that ECs grown on ECM proteins are protected from apoptosis induced by serum deprivation or Fas-mediated cell death (11,52). Also, soluble ligands for  $\alpha v \beta 3$ ,  $\alpha 5 \beta 1$ , or  $\alpha 2 \beta 1$ , which act as antagonists that disrupt the cell-ECM interactions, induce apoptosis in proliferating endothelium (53,54). Further data demonstrates that laminar shear stress upregulates the expression of EC integrins and integrin-associated proteins (55,56), suggesting that antiapoptotic signaling pathways induced by these biomechanical forces are mediated, in part, at the level of cell-ECM interactions. Finally, exposure of ECs to proangiogenic agonists promotes upregulation of  $\alpha v \beta 3$  integrins (57), further sug-

gesting a role for the integrins in survival and antiapoptotic pathways.

Angiogenesis involves EC proliferation, migration, adhesion, and tube formation. The creation of these new blood vessels, during tumor growth, requires degradation of existing ECM proteins by metalloproteinases to permit the expansion of new blood vessels. Interestingly, the proteolytic fragments of several ECM proteins, naturally found in the region of neovascularization, promote EC apoptosis (58). Endothelial apoptotic bioactive functions have been attributed to endostatin, canstatin, tumstatin, and arrestin, proteolytic fragments of collagen XVIII, and collagen IV, respectively. One point of action of these soluble matrix proteolytic products is to block integrin receptors,  $\alpha v \beta 3$ ,  $\alpha 5 \beta 1$ , or  $\alpha 1 \beta 1$ , resulting in antiangiogenic signaling, in part, by promoting EC apoptosis (58). Thus, the integrity of the surrounding ECM is critically important in maintaining blood vessel survival and in regulating angiogenesis.

The roles of integrins as receptors and the ECM proteins as transmitters of biomechanical stimuli and signaling through cell survival-dependent pathways has begun to be elucidated. However, whether the function of distinct integrin molecules or ECM proteins in promoting EC survival depends on the apoptotic inducing agent and/or on cell biomechanical and biochemical cell environment remains to be determined. Moreover, if any antiapoptotic signaling pathways activated by

the integrin–ECM interactions are unique to the endothelium, this would suggest the potential for vascular-specific therapies. This is an area of great research potential.

## THE ROLE OF BIOCHEMICAL STIMULI IN ENDOTHELIAL CELL APOPTOTIC SIGNALING

### Lipopolysaccharide

Lipopolysaccharide (LPS) or endotoxin resides in the outer membrane of gram-negative bacteria and is a potent inducer of bacterial sepsis by promoting EC activation, dysfunction, and apoptosis. Both in vitro and in vivo studies have demonstrated LPS-induced apoptosis in ECs derived from various vascular beds (59). Additionally, neutralization of the lipid A moiety of LPS attenuated EC activation by LPS (60). LPS activates the extrinsic apoptotic signaling pathway through the Toll-like receptor (TLR)-4 by forming a protein complex with LPS-binding protein (LBP) and soluble CD14 (59). This ligand/receptor interacts with the adaptor protein myeloid differentiation factor 88 (MyD88) resulting in its interaction with and activation of interleukin (IL)-1 receptor associated kinase (IRAK)-1 (59). IRAK-1 subsequently activates TNF receptor-associated (TRAF)-6, which in turn activates of NF- $\kappa$ B, as well as C-jun N-terminal kinase (JNK)-1 by means of a caspase cascade (59–61). The role of FADD in LPS induction of EC apoptosis is controversial (59). While it has been speculated that the purpose of NF- $\kappa$ B activation is to counteract apoptosis by transcriptionally upregulating several antiapoptotic genes, including IAP-1, IAP-2, and X-chromosome-linked inhibitor of apoptosis protein (XIAP) (62), suppression of NF- $\kappa$ B expression exacerbated TNF- $\alpha$ -induced apoptosis, but had no significant effect on LPS-induced EC apoptosis (63). Additionally, recent studies elucidated a role for FLICE-like inhibitory protein (FLIP) as being activated by LPS and protecting against EC apoptosis and in suppressing NF- $\kappa$ B activation (64), further suggesting that this transcription factor is not protective in the LPS-induced apoptotic signaling pathway.

### Anticoagulant Pathway

Activated protein C (APC) is a component of the coagulation pathway with potent anticoagulant, anti-inflammatory, and antiapoptotic activities. The anticoagulation effects of APC work at the post-translational level by regulating thrombin formation, whereas the inhibitory effects of APC on inflammation and apoptosis are thought to occur at the transcriptional level. Indeed, APC enhanced the expression of prosurvival proteins including the homologue of Bcl-1, IAP-1, and endothelial nitric oxide synthase (eNOS) in human umbilical vein ECs (HUVECs) (65). Additionally, TNF- $\alpha$ -induced expression of NF- $\kappa$ B was attenuated by APC (65). These transcriptional effects by APC correlated with protection of ECs from staurosporine-induced apoptosis (65). In ECs derived from the human brain, hypoxia-induced apoptosis was blunted by

pretreatment with APC; these changes correlated with modifications in signaling through p53, Bax, Bcl-2, and caspase-3 (66). Thus, while APC is protective against various apoptosis-inducing agents and proving clinically efficacious in treating sepsis, the mechanism by which APC modulates EC apoptosis remains to be more clearly defined.

### Cytokines and Growth Factors

Angiotensin II is a potent vasoconstrictor implicated in various cardiac, vascular, and renal diseases. In addition to its role as a vasoconstrictor, angiotensin II has been recognized as a potent regulator of protein and gene expression and intracellular signaling pathways in various cell types, including cardiomyocytes, fibroblasts, and vascular smooth muscle cells (VSMCs) and ECs. Angiotensin II demonstrated both a proliferative and an antiproliferative effect on coronary artery ECs, depending on the angiotensin II receptor subtype stimulated, with the AT<sub>1</sub>R stimulating and AT<sub>2</sub>R inhibiting EC proliferation (66,67). The antiproliferative effect of angiotensin II activation through AT<sub>2</sub>R was further shown to be proapoptotic in ECs through the activation of caspase-3 and the possible downregulation of nitric oxide (NO) production (68). Additional studies have demonstrated that angiotensin II potentiated human coronary artery EC apoptosis induced by anoxia–reoxygenation and TNF- $\alpha$  injury through AT<sub>1</sub>R (69). Angiotensin II also may promote EC apoptosis through the modulation of gene expression. Indeed, angiotensin II was demonstrated to upregulate the receptor mediating oxidized low-density lipoprotein (oxLDL) uptake, lectin-like oxLDL receptor (LOX)-1, in ECs, thus potentially enhancing the uptake and subsequent injurious intracellular signaling effects of this oxidized lipoprotein (69,70). Furthermore, cytochrome-*c* release and Bcl-2 proteolysis correlated with EC apoptosis upon exposure to angiotensin II (71). Finally, the modulation of ROS levels has been suggested to be intimately involved in the progression of EC apoptosis in response to angiotensin II stimulation (71).

TNF- $\alpha$ , a proinflammatory cytokine produced by macrophages, has direct effects on EC secretion and surface expression of cytokines, chemokines, and growth factors important for vasoregulation and leukocyte adhesion and activation. TNF- $\alpha$  also promotes EC dysfunction, in part, by causing apoptosis. The varied cellular responses stem from the initial binding of TNF- $\alpha$  to two receptors: TNFR1 and TNFR2. This ligand–receptor interaction promotes a conformational change in the receptor that results in the recruitment of various stimulus-specific proteins. For example, in terms of the apoptotic-stimulated pathway, upon TNF- $\alpha$  binding to TNFR1, TRADD binds the cytosolic portion of TNFR1 and subsequently recruits FADD and procaspase-8. This complex then initiates the caspase cascade leading to EC apoptosis (72,73). TNF- $\alpha$  also promotes EC apoptosis by enhancing Bcl-2 proteolysis through the inactivation of mitogen-activated protein kinase (MAPK) (74). The authors speculated that the diminished levels of Bcl-2 may augment the proapoptotic

signaling pathways in ECs in response to selective stimuli (74). TNF- $\alpha$  also upregulates various antiapoptotic proteins through NF- $\kappa$ B in ECs (72), thus suggesting that the sensitivity of ECs to TNF- $\alpha$ -induced apoptosis is regulated by the balance between proapoptotic and antiapoptotic signals.

Vascular endothelial growth factor (VEGF) is essential for angiogenesis in both physiological (e.g., pregnancy and wound healing) and pathological (e.g., tumor metastasis, diabetic retinopathy, atherosclerosis) processes. In addition, VEGF has been shown to be important in mediating "vascular protective" effects by mitigating VSMC proliferation, inflammation, and thrombosis, and by promoting EC survival (75). Hyperoxia-induced downregulation of VEGF correlated with apoptosis in ECs isolated from retinal capillaries (76). The exogenous addition of VEGF prevented experimental hyperoxia-induced EC apoptosis *in vitro* and *in vivo* (76). Additionally, VEGF rescued ECs from apoptosis induced by serum deprivation, which was dependent upon activation of phosphoinositide 3-kinase (PI3K) and Akt and inhibition of the forkhead transcription factors (77,78). Additional mechanisms by which VEGF may promote EC survival is by signaling through pathways modulated by the upregulation or stabilization of Bcl-2, NO, and prostacyclin (PGI<sub>2</sub>) production; FAK phosphorylation and activation; and interaction with integrin receptors (75).

### Endogenous Metabolites

Elevated levels of ATP or adenosine may occur in blood vessels upon the exocytotic release of nucleotides from stimulated platelet granules, during cytolitic release from necrotic cells, or from EC membrane transporters (79). Exposure of ECs to elevated levels of ATP or adenosine promotes apoptosis *in vitro* (80–82). EC apoptosis had been shown to be induced both by activation of type-2X purinergic (P2X) receptors and by ectonucleotidase-mediated hydrolysis of ATP (80,81). Furthermore, adenosine-induced EC apoptosis was potentiated by homocysteine and was mimicked by inhibitors of S-adenosyl-L-homocysteine hydrolase (83). Adenosine- and adenosine/homocysteine-induced apoptosis were mediated, in part, by a protein tyrosine phosphatase-dependent inhibition of p38 MAPK (84) and degradation of FAK, paxillin, and p130CAS proteins, with subsequent disruption of focal adhesion complexes (33). Additional studies have demonstrated that increased adenosine/homocysteine also causes Ras GTPase inactivation, possibly by blunting carboxymethylation of this small GTPase through the inhibition of isoprenylcysteine carboxyl methyltransferase activity (83). Thus, it is speculated that increased levels of adenosine and homocysteine may promote EC apoptosis through multiple signaling pathways, resulting in disruption of cell–ECM interactions and anoikis.

The sphingolipid metabolites, ceramide and sphingosine 1-phosphate (S1P), have been shown to have opposing effects on EC apoptosis (see Chapter 45). Increased ceramide production in response to ionizing radiation, sep-

tic shock, and oxLDL promotes EC apoptosis (85,86). Conversely, the induction of S1P blunted EC apoptosis induced by TNF- $\alpha$ . Ceramide is a ubiquitous precursor synthesized *de novo* by the cell and utilized in the biosynthesis of sphingomyelin, a crucial component of the plasma membrane. Additional by-products of ceramide synthesis include glucosylceramide, ceramide 1-phosphate (C1P), and S1P; however, only ceramide is capable of inducing cell apoptosis (85,86). Rapid increases in ceramide production (within minutes) in response to apoptosis-inducing agents are thought to occur primarily through the degradation of sphingomyelin through the action of various sphingomyelinases, including neutral or acid sphingomyelinase (85). However, ceramide also may be increased in ECs hours later through the activation of the *de novo* synthetic pathway utilizing ceramide synthase (85). Ceramide is believed to ultimately produce apoptosis through the induction of the caspases, possibly through the modulation of gene expression through the stress activation pathway, JNK (85,86). Interestingly, increased production of VEGF or S1P, or the overexpression of Bcl-2, blunted ceramide-mediated EC apoptosis (86). S1P produced exogenously is thought to be protective against apoptosis in ECs by signaling through endothelial differentiation gene (EDG)-1 receptor via cell survival pathways involving Ras GTPase and extracellular-signal-regulated kinase (ERK)-1 (86).

### Oxidative Stresses

Oxidative stress producing ROS is another biological mediator important in promoting EC apoptosis, occurring when the level of ROS exceeds that of cellular antioxidants. Superoxide (O<sub>2</sub><sup>•-</sup>), H<sub>2</sub>O<sub>2</sub>, NO, peroxynitrite (ONOO<sup>•-</sup>), and hydroxide radicals (•OH) are some of the ROS produced in the endothelium. The levels of ROS may increase in the blood vessel by release from inflammatory cells or by elevated production by the endothelium or VSMCs. Intracellularly, ROS may be produced in the mitochondria or by multiple cytosolic enzymes, including nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, xanthine oxidase, NOS, or myeloperoxidase. Exposure of ECs to enhanced ROS promoted apoptosis, an effect suppressed by antioxidative enzymes, such as superoxide dismutase (SOD) (87). Additionally, anoikis-induced ECs demonstrated elevated levels of ROS with subsequent caspase-3 activation (88). Incubation of the cells with antioxidants partially blunted the activation of caspase-3 resulting from anoikis, suggesting a role for the ROS in the progression of EC apoptosis (88). Additionally, increased ROS production and apoptosis occurred in ECs exposed to oxLDL (71), LPS (59), angiotensin II (71), or high glucose concentrations (89), suggesting a role for ROS in the progression of atherosclerosis, sepsis, hypertension, and diabetes. The mechanism by which ROS mediates apoptosis is believed to occur at multiple points, including caspase activation, mitochondrial dysfunction, DNA damage, and activation of other proapoptotic downstream signaling molecules (71).

NO is a vasoactive product of the pulmonary and systemic vasculature that regulates many cellular functions, including vasodilation, VSMC proliferation and migration, platelet adhesion and aggregation, and EC proliferation and apoptosis. NO and L-citrulline are produced from L-arginine and oxygen by NOS. Three isoforms of NOS have been isolated: neuronal NOS (nNOS), inducible NOS (iNOS), and eNOS, which contain significant sequence homology and share cofactor requirements for NADPH, heme, flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), tetrahydrobiopterin, and calmodulin. NO has been shown to be both protective against and an inducer of apoptosis in ECs. EC survival depends on low levels of NO when grown in the presence of angiotensin II, TNF- $\alpha$ , or high glucose concentrations (68,90,91). Yet, high levels of NO were itself apoptotic for ECs (91). The modes by which NO is protective against EC apoptosis are many fold, including antioxidative effects against ROS, S-nitrosylation of and inactivation of caspases, inhibition of mitochondrial cytochrome-*c* release, and upregulation of Bcl-2 expression (92). Enhanced levels of NO may promote EC apoptosis by the combining with O<sub>2</sub><sup>•-</sup> and forming ONOO<sup>-</sup>, causing DNA damage directly or indirectly by the S-nitrosylation of various proteins or lipids and resulting in the modulation of the intrinsic apoptosis signaling pathway (92).

Enhanced oxidation of LDL creates a more reactive species of the lipoprotein, which has been shown to directly correlate with the progression of atherosclerosis (93). OxLDL has numerous effects on the endothelium, including promoting apoptosis. Recent studies have demonstrated that expression of the oxLDL receptor LOX-1 was required for the apoptosis-inducing effects of oxLDL in coronary artery ECs (94). OxLDL-induced EC apoptosis correlated with enhanced FasL expression and increased caspase-3 activation (8). Additional analyses suggested that Fas-mediated apoptosis upon oxLDL exposure occurs, in part, by downregulation of the caspase inhibitor, FLIP (95). The authors speculated that this downregulation sensitizes the ECs to Fas-mediated apoptosis signaling pathway (95). Interestingly, although other proapoptotic cytokines, such as TNF- $\alpha$  and IFN- $\gamma$ , are associated with promoting FasL expression in ECs, the signaling pathways by which these cytokines induce apoptosis in endothelium is not via the Fas-mediated pathway (8). It also has been reported that oxLDL may exert its apoptotic effects by modulating the bioavailability of NO in the endothelium (96).

## ENDOTHELIAL APOPTOSIS AND VASCULAR PATHOPHYSIOLOGY

In this section, we review the evidence for endothelial apoptosis in the pathophysiology of representative disease states and the role of endothelial apoptosis in normal vascular function. In normal blood vessels, there is little evidence for EC apoptosis. Apoptosis of endothelium occurs in pathological states and appears to limit vasculogenesis and angiogenesis.

## Endothelial Cell Apoptosis and Atherosclerosis

The most extensive literature regarding EC apoptosis in vivo relates to atherosclerosis. Atherosclerosis is a complex pathological process characterized by early EC activation and/or injury, accumulation of lipid-laden monocytes and inflammatory cells, VSMC proliferation, and eventual plaque rupture and vascular occlusion by thrombosis. A number of recent reviews have summarized the potential role of apoptosis in atherosclerosis (97–101).

Apoptosis in atherosclerotic plaques removed at atherectomy was demonstrated by TUNEL staining; among apoptotic cells identified included VSMCs, macrophages, and ECs (102,103). An important, and as yet unresolved, question is whether apoptosis is a cause of early EC injury and an initiating event in the process of atherosclerosis. Accumulating evidence suggests that EC apoptosis does contribute to the pathogenesis of atherosclerosis. For example, multiple risk factors associated with atherosclerosis also promote apoptosis of cultured ECs, as outlined in Table 119-2. These risk factors include oxLDL (104), hyperglycemia (105), elevated levels of homocysteine (106), and aging (107). In contrast, factors protective against vascular injury, such as laminar flow, also blunt EC apoptosis. In vivo atherosclerotic lesions are most common at sites of low or turbulent blood flow where shear stress is reduced (45), suggesting that EC apoptosis may be an important factor in the genesis of the lesion. Furthermore, in atherectomy specimens, EC apoptosis was most commonly observed downstream of stenotic areas, where shear stress is lowest (102); thus, reduced shear stress appears to predispose ECs to apoptosis in human atherosclerosis.

Interestingly, in atherosclerotic plaques and the serum of patients with heart disease, molecules that mediate cell survival and apoptosis signaling have been identified. Human atherosclerotic plaques (101) contain proapoptotic substances such as oxLDL, matrix metalloproteinases (MMPs), proinflammatory mediators (TNF- $\alpha$ , IFN- $\gamma$ , IL-1), vasoactive substances (angiotensin II), Fas and FasL, proapoptotic Bcl-2 family members (Bax), and executioners of apoptosis (caspases). Substances protective against apoptosis also have been localized in plaques (101); these include antioxidants (heme oxygenase-1,  $\alpha$ -tocopherol), anti-inflammatory cytokines (IL-10), growth factors (platelet-derived growth factor [PDGF], insulin-like growth factor [IGF]-1, fibroblast growth factor [FGF]-2, VEGF), and antiapoptotic Bcl family members (Bcl-x<sub>L</sub>). In addition, serum from patients with acute coronary syndromes promoted apoptosis in cultured HUVECs, an effect that was diminished in blood drawn from the same patient a year after the clinical event (108). Proapoptotic factors Fas and Bcl-2 were increased in serum from patients with acute coronary syndromes, and the ratio of Bax/Bcl-2 was decreased 1 year later (108). In another study, proapoptotic activity in serum from patients with heart failure was an independent predictor of mortality (109). These data suggest that the balance of factors

that regulate cell survival and apoptosis may determine the degree of endothelial apoptosis in patients with vascular disease.

#### ***Mediators of Endothelial Apoptosis in Atherosclerosis***

Numerous causes and modulators of endothelial apoptosis have been described using cultured cells. However, the relative importance of each has not yet been clearly determined in human disease. It is possible that pro- and antiapoptotic factors vary with the temporal stage of the disease.

Significant changes in biomechanical stresses and the promotion of EC apoptosis are thought to play an important role in the initiation and progression of atherosclerosis. For example, as noted earlier, low or turbulent blood flow resulting in diminished laminar shear stress appears to predispose the endothelium to apoptosis in atherosclerotic lesions. EC anoikis is believed to occur in atherosclerosis due to the action of proteases that disrupt EC-ECM interactions (110). Indeed, activation of the inflammatory cells in atherosclerotic plaques, such as macrophages, T-lymphocytes, mast cells, and neutrophils, results in the release of enzymes capable of proteolytic degradation of ECM proteins surrounding the ECs (111). Thus, the lack of shear stress and/or increased anoikis and elevated apoptosis may be early factors in the development of EC injury in atherosclerosis.

Other mediators that promote atherosclerosis by causing apoptosis of the endothelium include multiple biochemical stimuli. OxLDL, which is known to cause apoptosis of cultured ECs, has been implicated in the pathogenesis of atherosclerosis. Indeed, its receptor, LOX-1, has been localized on ECs in atherosclerotic lesions (112). Atheromas also contain abundant glycosphingolipids and ceramide, generated by the action of sphingomyelinase (86). Ceramide, an apoptosis-inducing agent *in vitro*, may be an important cause of endothelial apoptosis in atherosclerosis (86).

Fas and FasL are additional proapoptotic mediators expressed in cells within atherosclerotic plaques (113). Fas-FasL interaction causes the apoptosis of monocytes; thus, it could attenuate the infiltration of these inflammatory cells into atherosclerotic lesions. Vascular ECs express FasL (8). The role of EC expression of FasL in atherosclerosis is controversial, with evidence for both exacerbation of and protection from atherosclerosis (114). Recent studies using animal models indicate that overexpression of FasL by ECs decreases atherosclerosis in apolipoprotein E-deficient mice (114). In addition, EC expression of soluble Fas attenuated transplant-induced arteriosclerosis in rats (115). Thus, EC expression of soluble Fas or FasL may serve to blunt, rather than exacerbate, atherosclerosis.

#### ***Mechanisms by which Endothelial Apoptosis Contributes to the Pathogenesis of Atherosclerosis***

There are a number of ways in which EC apoptosis may contribute to the pathogenesis of atherosclerosis. First, studies

in monkeys indicate that endothelial apoptosis is associated with impaired endothelium-dependent vasodilator function (107). Thus, endothelial apoptosis causes vascular dysfunction *in vivo*.

Another means by which endothelial apoptosis may contribute to the development of atherosclerosis is by stimulating the regeneration of abnormal ECs (116). Phenotypic and functional changes have been observed in ECs repopulating porcine coronary arteries after balloon denudation (117). Increased uptake of LDL and decreased cyclic guanosine monophosphate (cGMP) production were observed in ECs harvested from regenerating vascular endothelium, suggesting that regenerating endothelium may be more susceptible to atherosclerosis (117).

Thrombus formation is important in the development of acute ischemic events after plaque rupture. Apoptosis increases the expression of phosphatidylserine on cell membrane, as described earlier. Phosphatidylserine enhances tissue factor activity and thereby enhances endothelial thrombogenicity (101). Thus, apoptotic ECs are procoagulant (118). Increased tissue factor activity has been found in human atherosclerotic lesions (119). In addition, endothelial apoptosis increases platelet activation and adhesion (118), also contributing to plaque formation. *In vivo* evidence for the importance of endothelial apoptosis in stimulating thrombosis was reported by Durand and colleagues, using an animal model in which staurosporine was used to induce EC apoptosis and vascular thrombosis (120). Caspase inhibitors markedly decreased both endothelial apoptosis and thrombus formation, suggesting that endothelial apoptosis is important in acute ischemic events (120).

During apoptosis, cell membrane blebbing occurs, and microparticles are formed from the shed blebs (121). These microparticles strongly express procoagulant phosphatidylserine, which is redistributed to the membrane upon apoptosis. Increased circulating microparticles of endothelial origin have been described in patients with acute coronary syndromes, as compared to stable angina and noncoronary heart disease (122). Thus, both *in situ* and circulating fragments of apoptotic EC may contribute to thrombosis complicating plaque rupture.

In summary, good evidence suggests EC apoptosis in atherosclerotic plaques. Causes include decreased laminar shear stress, the production of oxLDL and ceramide, and the induction of anoikis. Endothelial apoptosis may contribute to the pathogenesis of atherosclerosis via decreased endothelial-dependent vasodilation and by enhancing platelet adhesion and thrombosis. It is possible that therapies to reduce EC apoptosis may ameliorate atherosclerosis. Indeed, it is possible that the beneficial effects of therapies, such as angiotensin converting enzyme (ACE) inhibitors or statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors), may at least partially be due to inhibition of EC apoptosis (98). However, inhibition of apoptosis in other plaque cells, such as macrophages and VSMCs, could exacerbate the

atherosclerotic process. Thus, any treatments aimed at inhibiting apoptosis in atherosclerosis should be specific for ECs of conductance vessels.

### **Endothelial Cell Apoptosis and Sepsis**

Sepsis caused by gram-negative bacteremia is a cause of multisystem organ failure or sepsis syndrome, a disorder of high mortality characterized by diffuse microvascular injury and resulting in increased permeability, edema formation, and shock. A critical mediator of sepsis syndrome is LPS, a component of gram-negative bacterial cell walls. LPS stimulates the production of cytokines from inflammatory cells, including TNF- $\alpha$ . As noted in Table 119-2, both LPS and TNF- $\alpha$  cause the apoptosis of cultured ECs via the extrinsic pathway. Haimovitz-Friedman and colleagues reported that injection of LPS or TNF- $\alpha$  into mice caused early, diffuse EC apoptosis in intestine, lung, fat, and thymus, and this was preceded by increased tissue concentrations of ceramide (123), another inducer of apoptosis (86). Mice deficient in acid sphingomyelinase were protected against apoptosis (124), suggesting an important role for ceramide-induced endothelial apoptosis in sepsis-induced microvascular injury.

### **Endothelial Cell Apoptosis and Ischemia-Reperfusion Injury**

Ischemia-reperfusion can cause organ injury in circumstances in which blood flow is interrupted and then restored, such as with the relief of vascular occlusion and after organ transplantation. Ischemia-reperfusion is characterized by increased ROS, inflammatory cell accumulation, and activation of neutral sphingomyelinase and ceramide accumulation (86).

Apoptosis has been demonstrated in myocardial ischemia-reperfusion injury (125,126). Using an isolated perfused rat heart model, Scarabelli and colleagues demonstrated that microvascular EC apoptosis preceded myocardial apoptosis, with radial spread from microvessels of myocyte apoptosis (127). These data suggest that apoptotic ECs release proapoptotic substances into the surrounding myocardium and cause myocyte apoptosis in a paracrine fashion. Furthermore, inhibition of apoptosis attenuated myocardial ischemia-reperfusion injury (126).

Ischemia-reperfusion injury is an early complication of organ transplantation and is related to the duration of cold storage prior to transplantation (128). Apoptosis has been reported in ischemia-reperfusion injury accompanying transplantation of lung, heart, liver, and kidney (128). Using a rat model of lung transplantation, Quadri and colleagues found that EC apoptosis was proportional to the duration of cold storage, and that caspase inhibition decreased apoptosis and enhanced the function of transplanted lungs (128). In transplanted livers, sinusoidal EC apoptosis occurred early in the course of preservation and reperfusion injury (129).

### **Endothelial Cell Apoptosis and Radiation-Induced Organ Injury**

ECs are sensitive to radiation-induced cell injury (85). The role of radiation-induced EC apoptosis has been studied in the mechanism of radiation-induced gastrointestinal injury. Gastrointestinal injury is a key side effect of radiation, and limits the dose of treatment in cancer therapy. Using a mouse model of whole-body irradiation, Paris and colleagues demonstrated that animals deficient in acid sphingomyelinase, a protein abundantly expressed in the endothelium, did not have extensive microvascular EC apoptosis, suggesting that radiation-induced apoptosis is a result of acid sphingomyelinase-induced ceramide production (130).

Studies of tumor sensitivity to low-dose radiation also indicate a role for microvascular EC apoptosis. Tumor growth is thought to depend on angiogenesis to ensure blood supply. Because radiation commonly is used to treat cancer, the question arises as to whether the effects of radiation on tumor size are due, at least in part, to EC injury. Garcia-Barros and colleagues have reported that microvascular endothelial apoptosis occurs with low-dose radiation directed at fibrosarcomas and melanomas in mice (131). Furthermore, tumors in acid sphingomyelinase-deficient and Bax-deficient mice were resistant to radiation and displayed less radiation-induced EC apoptosis (132). Thus, both complications of and response to radiation therapy appear to be due to radiation-induced EC apoptosis.

### **Endothelial Cell Apoptosis in Emphysema**

Emphysema is a lung disease characterized by the loss of alveolar capillary septum, resulting in the impairment of gas exchange. The imbalance of proteases and antiproteases, caused by exposure to cigarette smoke, is thought to be important in the pathogenesis of emphysema. Voelkel and colleagues have suggested that apoptosis of cells in the alveolar septum occurs in emphysema, and have suggested that epithelial and/or endothelial apoptosis may be important in the pathogenesis of the disease (133). Indeed, a role for endothelial apoptosis in emphysema is suggested by the effect of VEGF receptor antagonists that cause endothelial apoptosis *in vitro* and *in vivo* (134–136). The administration of the VEGF antagonist caused emphysema and apoptosis of alveolar wall cells in a rat model (135). In addition, injection of HUVECs caused emphysema in mice and promoted the production of antibodies directed against ECs, suggesting an immune mechanism for the disease (137). The evidence for EC apoptosis in emphysema is more extensively reviewed in Chapter 130.

### **Endothelial Cell Apoptosis and Thrombotic Thrombocytopenic Purpura**

Thrombotic thrombocytopenic purpura (TTP) is a devastating disease characterized by thrombocytopenia, microangiopathic hemolytic anemia, fever, and neurologic and renal

**Table 119-3: Pathophysiologic Conditions Characterized by Endothelial Apoptosis**

<i>Condition</i>	<i>Humans (Refs.)</i>	<i>Animal Models (Refs)</i>
Atherosclerosis	101–103, 108, 109	114, 115
Sepsis	—	123, 124
Ischemia–reperfusion	158, 159	126–128
Radiation	—	130–132
Emphysema	133	134–137
Corpus luteum	141	—
TTP	138	—

dysfunction. Pathology shows characteristic hyalinized thrombi in microvessels. Enhanced EC apoptosis has been observed in the splenic tissues of patients with TTP and the related hemolytic-uremic syndrome (HUS) (138). In addition, plasma from patients with TTP and HUS causes the apoptosis of cultured microvascular ECs (139,140). Interestingly, cultured pulmonary and hepatic microvascular ECs were resistant to TTP plasma–induced apoptosis, and those organs are generally spared in TTP and HUS (139). This suggests that ECs from distinct vascular beds differ in susceptibility to apoptosis.

**Endothelial Cell Apoptosis and the Regression of the Corpus Luteum**

The ovarian follicle has the capacity for rapid microvascular development and regression during the ovulatory cycle. New blood vessels are necessary for the formation and function of the corpus luteum. On the other hand, vessel loss due to luteal EC apoptosis occurs during regression of the corpus luteum (141). Possible biochemical stimuli that promote luteal endothelial apoptosis include angiotensin II, IFN- $\gamma$ , and TNF- $\alpha$  (see Table 119-2).

**Endothelial Cell Apoptosis and the Regulation of Angiogenesis**

As noted earlier, the corpus luteum is an example of a tissue that undergoes angiogenesis that is limited by apoptosis during the luteal regression phase (141). It has been suggested that EC apoptosis may limit angiogenesis involved with inflammation, development, or tumor growth (142). Thus, endothelial apoptosis may be important in limiting neovascularization, and may cause tumor regression. Integrin-mediated interactions with ECM are just one possible regulator of apoptosis limiting angiogenesis (143).

**CONCLUSION**

EC apoptosis is a marker of disease and limits angiogenesis (Table 119-3). EC apoptosis is believed to be an early event

in atherogenesis, stimulated by low blood flow and resulting decreased laminar shear stress. In addition, endothelial apoptosis contributes to plaque rupture and resulting thrombosis. In vivo evidence suggests endothelial apoptosis in sepsis, ischemia–reperfusion and radiation injury, and emphysema. Endothelial apoptosis occurs during regression of the corpus luteum and in limiting angiogenesis in tumors.

Inhibitors of apoptosis, such as caspase inhibitors, are potential treatments to reduce vascular injury. However, use of such drugs may be problematic in that local action is needed.

**KEY POINTS**

- Apoptosis is important in regulating vasculogenesis, angiogenesis, and vessel regression. In addition, endothelial apoptosis regulates vascular functions.
- Extrinsic and intrinsic biochemical pathways and modulators of apoptosis have been described in detail using cultured ECs.
- Endothelial apoptosis is caused by risk factors for atherosclerosis and by other causes of vascular injury in vivo.

*Future Goals*

- To further study and understand biochemical pathways of endothelial apoptosis in human disease
- To determine the therapeutic potential for drugs that modulate endothelial apoptosis in a cell-specific and vascular bed-specific manner

## Endothelial Antigen Presentation

Andrew H. Lichtman

*Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts*

T lymphocyte-mediated cellular immunity is responsible for protection against intracellular pathogens. T cells also mediate pathological responses in autoimmune diseases, chronic inflammatory conditions, and allograft rejection. These protective and pathological roles for T cells require the recognition of antigens on the surface of other cells. This chapter reviews how endothelial cells (ECs) may play a unique role in regulating T cell-mediated immune responses by presenting antigen to circulating T cells within the lumens of blood vessels. Antigen presentation to T cells may be considered a complex output function of ECs, which is dependent on the regulated expression of several intracellular and cell surface proteins. ECs may also become susceptible to both physiological and pathological input signals as a consequence of their intimate relationships with T lymphocytes. In this chapter, a brief overview of the cell biology of antigen presentation to T cells is followed by a discussion of specific features of antigen presentation by ECs.

### BACKGROUND: ANTIGEN PRESENTATION AND T-CELL HOMING

T cells are heterogeneous with respect to effector functions and history of antigen exposure. This heterogeneity is reflected in their differing requirements for activation. Regardless of the subset, T cells must recognize antigen via cell surface antigen receptors – called T-cell receptors (TCRs) – for functional activation to proceed. Most T lymphocytes recognize a complex of a proteolytically derived peptide bound to one of many possible allelic forms of a major histocompatibility complex (MHC) molecule that is expressed on the surface of another cell. These peptide-MHC complexes are the “antigens” to which the TCR binds. The CD4<sup>+</sup> subset of T cells, which includes T cells of the “helper” phenotype, recognize complexes of peptides bound to class II MHC molecules, whereas CD8<sup>+</sup> T cells, which include most cytolytic T lymphocytes (CTL), recognize peptide-class I MHC complexes. Rare subsets of T cells, such as iNKT cells, recognize lipids bound to

the nonpolymorphic MHC-like CD1 molecules. The cells that display the peptide-MHC complexes for T cell recognition are called antigen presenting cells (APCs). Therefore, as a minimum requirement for a cell to perform as an effective APC for a CD4<sup>+</sup> T cell, it must be able to form peptide-class II MHC complexes and display them on the cell surface. Likewise, an APC for CD8<sup>+</sup> T cells must be able to form peptide-class I MHC complexes. The intracellular proteolytic degradation of intact proteins to form MHC-binding peptides and the assembly of the peptide-MHC complexes is called *antigen processing*. Antigen processing involves a complex series of coordinated steps in several subcellular locations, and differs in significant ways between the pathways that generate class I versus class II MHC-associated peptide complexes (1,2).

### Class I Major Histocompatibility Complex Pathway of Antigen Presentation

Class I MHC expression is common to most cell types. The cell surface expression of class I MHC molecules requires assembly of a trimolecular complex that includes a short peptide (~8–11 amino acid residues long) bound within a cleft formed by the N-terminal domains of the class I MHC  $\alpha$ -chain protein, and a noncovalently associated  $\beta$ 2-microglobulin molecule. Class I MHC-associated peptides are derived from cytoplasmic proteins by proteolytic degradation in the proteasome. The proteasome is a multisubunit organelle found in all nucleated cells, which degrades proteins that are tagged for destruction by ubiquitination. Proteasomal degradation of ubiquitinated proteins is an essential housekeeping function of every cell, serving to remove misfolded proteins and to regulate several signal transduction pathways. The immune system has evolved to make use of the proteasomal system to sample cytoplasmic proteins for display by class I MHC molecules. The repertoire of peptides generated by the proteasome may be altered by interferon (IFN)- $\gamma$  stimulation of cells, which induces the expression of new proteasomal subunits. A subset of peptides generated by proteasomes is delivered into the lumen of the endoplasmic reticulum (ER) by the

ATP-driven transporter associated with antigen processing (TAP). Once in the ER, chaperones facilitate the binding of the peptides to newly synthesized dimers of class I MHC  $\alpha$ -chain and  $\beta$ 2-microglobulin. Once peptide is bound, the stabilized complex moves through the Golgi to the cell surface. The result is the display of peptides representative of many cytoplasmic proteins, some of which may be recognized by T cells. In addition, peptides derived from ER resident proteins are presented by class I MHC molecules, and are likely generated by ER-resident proteases. Because class I MHC expression is typical of most cell types, CD8<sup>+</sup> T cells will have the opportunity to survey most cell types for the presence of microbial proteins that are in the cytoplasm, as well as mutated cytoplasmic self proteins. Because most cell types are susceptible to viral infection or potentially oncogenic mutations, the ubiquitous class I pathway is well suited for immune surveillance for viral infection and neoplasia. In addition to sampling proteins synthesized in the cytoplasm of cells, the class I pathway may also “cross-present” protein antigens that have been internalized from the extracellular milieu (3). In this case, endocytosed proteins must gain access to the cytoplasmic proteasome, or be delivered into the ER, for proteolytic degradation. Cross-presentation of exogenous protein antigens to CD8<sup>+</sup> T cells is a property best described in dendritic cells, and is an explanation for how naive microbial-specific CD8<sup>+</sup> T cells can be activated by APCs that are not directly infected by viruses (4).

### Class II Major Histocompatibility Pathway of Antigen Presentation

Constitutive class II MHC expression is restricted to a small number of cell types, compared to class I MHC expression; therefore CD4<sup>+</sup> T cells have a more limited choice of APC partners with which to interact. These class II MHC-expressing cells include dendritic cells, macrophages, and B lymphocytes; these cell types also express T cell costimulatory molecules (discussed later), and are often called *professional APCs*. The dendritic cell is unique in that its primary function appears to be the transport and presentation of protein antigens. It is the only cell type that can efficiently activate naive CD4<sup>+</sup> T cells (5). The proteins represented by class II MHC-bound peptides are largely derived from the extracellular milieu. Endocytosis of these proteins into the endosome/lysosome system of organelles in APCs is the first step of the class II pathway of antigen presentation (6). The peptides are generated from the internalized proteins by proteases active in the acidic environment in these organelles. Newly synthesized class II MHC heterodimers composed of  $\alpha$ - and  $\beta$ -chains, bind trimers of the 30-kD transmembrane invariant chain protein in the ER. The invariant chain blocks the peptide binding groove from occupation by peptides in the ER. In addition, via cell localization signals in its cytoplasmic tail, the invariant chain directs movement of the class II MHC/invariant trimer complex into a late endosome/lysosome compartment, which contains abundant vesicular inclusions called *multivesicular bodies*, and class II MHC-like HLA-DM molecules. The combined action of

the acidic proteases and HLA-DM mediate the removal of the invariant chain and the binding of exogenously derived peptides to a cleft formed by the N-terminal domains of the  $\alpha$ - and  $\beta$ -chains of the class II MHC molecules. The class II MHC peptide binding cleft is open-ended, and can accommodate a broader range of peptide lengths, typically 30 amino acid residues or longer, compared with class I MHC clefts. The final step in this pathway is delivery of the class II MHC peptide complexes to the cell surface by vesicle fusion with the plasma membrane. CD4<sup>+</sup> T cells that interact with class II MHC-expressing APCs can therefore survey a peptide sample of many extracellular proteins.

### Antigen and Cell Traffic in Antigen Presentation

The expression of peptide–MHC complexes (antigens) on APCs will amount to nothing if T cells that recognize those antigens are not in the same location as the APCs. Naive T lymphocytes emerge from the thymus expressing antigen receptors, but with little ability to perform effector functions, and very few naive T cells are specific for any one particular peptide–MHC antigen. Both CD4<sup>+</sup> and CD8<sup>+</sup> naive cells must be activated by APCs in lymphoid tissues to produce large numbers of the effector cells needed to eradicate infections. The major mechanism that has evolved to ensure that rare naive T cells specific for a particular antigen encounter APCs presenting that antigen involves distinct yet overlapping trafficking patterns, which ultimately converge at the level of the parafollicular zones of lymph nodes: T cells routinely recirculate between circulating blood and lymph nodes, whereas APCs (dendritic cells), once activated by microbial products in infected tissues, become motile and move into lymphatics, eventually entering the parafollicular zones of lymph nodes. Rarely, whole microbes, microbial debris, and soluble molecules produced by microbes may enter lymphatics directly, without being associated with cells, and are brought into the lymph node via lymph flow.

In addition to presenting peptide–MHC complexes to T cells, APCs also express membrane molecules that provide signals that synergize with TCR complex–mediated signals to ensure full activation of T cells. These molecules are called *costimulators*, and they bind to receptors on those T cell that are linked to signal transduction pathways that enhance T cell proliferation and differentiation (7). The best defined costimulators are members of the B7 family, of which B7-1 (CD80) and B7-2 (CD86) are the most important. Both B7-1 and B7-2 bind to CD28 on T cells. In humans, LFA-3 (CD58) is an important costimulator that binds to CD2 on T cells. Naive CD4<sup>+</sup> T cells generally have more stringent requirements for costimulation than effector T cells. Naive CD8<sup>+</sup> T cell activation may depend on costimulation, but under conditions of strong innate responses, such as occur with highly cytopathic viral infections, the well-characterized costimulatory pathways appear not to be needed. In the absence of costimulators, recognition of antigen will not lead to activation of naive T cells, and may induce an anergic state such that the T cell will

not be able to respond to antigen a second time, even if costimulators are present. Dendritic cells constitutively express low levels of costimulators, but expression is markedly enhanced by microbial products that bind to Toll-like receptors (TLRs) on the APCs. For example, the expression of CD80 and CD86 increases on dendritic cells after exposure to endotoxin as they migrate from peripheral tissues into lymph nodes. In essence, costimulator expression is a danger signal that ensures naive T cell activation will occur only when infections are present. Effector T-cell responses to antigens are not dependent on costimulation, but the responses may be enhanced by costimulatory molecules, including members of the B7 family that are distinct from B7-1 and B7-2.

Naive T cells, which are generated in the thymus, circulate throughout the body in the blood. They home to lymph nodes, where they leave the circulation. In the lymph node, they have the opportunity to encounter APCs, but if they do not recognize antigen, they move via lymphatics from one lymph node to another until they do recognize antigen or are carried back into the circulation. Naive T cell homing to lymph nodes occurs largely because of their expression of L-selectin and CCR7, which bind to peripheral lymph node addressin (PNAd) and chemokines (CCL19 or CCL21), respectively – molecules that are displayed on the luminal surface of specialized high endothelial venules (HEVs) found in the parafollicular zones of lymph nodes (8). Once a naive T cell recognizes antigen on an APC in a lymph node, it becomes activated, undergoes mitotic division, and gives rise to many differentiated progeny that retain the same antigen specificity as the parent cell but gain effector functions. Many of these effector T cells re-enter the circulation, and circulate into peripheral tissues. During their differentiation, effector T cells express adhesion molecules (including E- and P-selectin ligands) and chemokine receptors (such as CCR5 and CXCR3) that favor migration into sites of inflammation. This migratory phenotype is relatively stable for the life of the effector T cell. The effector cells that get into peripheral inflammatory sites, as well as some that remain in the lymph node, perform the effector functions that aid in eliminating infections. These effector functions include macrophage and B-cell activation by CD4<sup>+</sup> effectors (so called *helper functions*) and direct killing of infected cells by CD8<sup>+</sup> effectors (CTL activity). Most effector T cells will die within days of their generation. Some of the CD4<sup>+</sup> and CD8<sup>+</sup> T cells that are derived from naive T cells have a memory phenotype, and survive in a resting state for long periods. Some of these memory T cells, called *central memory T cells*, may remain in lymph nodes. Others, called *effector memory T cells*, come to reside in peripheral mucosal sites. Memory T cells are responsible for the rapid and amplified responses upon re-exposure to antigens.

#### ENDOTHELIAL ANTIGEN PRESENTATION: GENERAL AND HISTORICAL CONSIDERATIONS

Even before the molecular and cell biological details of antigen processing and presentation summarized here were eluci-

dated, investigators hypothesized that ECs may be important APCs based on the fact that they were the first cells with which T cells come into direct and intimate contact before entering lymph nodes or peripheral tissues. This unique relationship between ECs and T cells has been the basis for a general hypothesis that endothelial antigen presentation leads to the selective transendothelial migration of T cells specific for antigens found in the underlying tissue (9). In other words, ECs may sample the proteins in the surrounding tissue environment, and display them on their luminal surface as peptide–MHC complexes; circulating T cells that recognize these complexes are preferentially able to enter the tissues, compared with T cells that do not (Figure 120.1A). The relevant corollary to this hypothesis is that endothelial antigen presentation is important for the delivery of naive T cells into lymphoid tissues, where the initiation of T cell–mediated immune responses begins, and/or for the efficient delivery of effector T cells to sites where antigen is present in peripheral tissues. For the hypothesis and its corollary to be true, ECs must be able to engage in the antigen processing and peptide display functions typical of all APCs discussed earlier. ECs also would be expected to express costimulatory molecules, especially if they are involved in naive T cell activation. The history of experimental investigation of endothelial antigen presentation can be divided into two parts. The first and still active area of research is the *in vitro* demonstration and analysis of antigen presentation of cultured ECs to cultured T cells (10). The second active but relatively new area of research involves demonstration of endothelial antigen presentation *in vivo*, using experimental animal models.

MHC expression, which is the primary requirement for APC activity, was demonstrated on ECs *in vitro* and *in vivo* many years ago. Class I MHC expression is constitutive on ECs *in vivo*, in large and small arteries and veins, and lower levels of expression are retained on cultured ECs (10). Endothelial class I MHC expression can be upregulated by IFN- $\alpha$ , - $\beta$ , - $\gamma$ . Therefore, ECs, like most cell types, possess the minimal requirement for antigen presentation to CD8<sup>+</sup> T cells. Class II MHC expression by ECs is more variable, depending on species and cytokine exposure. Human microvessels, including postcapillary venules, constitutively express class II MHC in many tissues, but class II MHC expression in other vessels is variable (10,11). Cultured ECs from human or mouse usually lack class II MHC expression, but expression can be induced by IFN- $\gamma$  treatment, regardless of the species or site of derivation (9,12). IFN- $\gamma$  treatment or inflammation induces class II MHC expression on mouse microvasculature, including postcapillary venules *in vivo* (10). Of significance to the possible sites of endothelial antigen presentation *in vivo*, no compelling evidence suggests that HEVs in lymph nodes express class II MHC.

Consistent with their ability to express cell surface peptide–MHC complexes, cultured ECs from various tissue sources can present antigens to CD4<sup>+</sup> and CD8<sup>+</sup> T cells, leading to T-cell activation *in vitro*. Demonstration of antigen-specific activation of human T cells has been encumbered by the requirement

Figure 120.1. Consequences of endothelial antigen presentation. (A) Hypothetically, ECs may process and present antigens produced in surrounding extravascular tissue to circulating T cells that come into close contact with the vessel wall (1). T-cell receptor signals could then promote stable T-cell adherence by inducing integrin activation (2), thereby enhancing diapedesis of antigen-specific T cells (3), which can then interact with tissue APCs (4). ECs may display peptides bound to either class I or class II MHC molecules, and present them to either CD8<sup>+</sup> or CD4<sup>+</sup> T cells, respectively. There is circumstantial evidence for this physiological role of endothelial antigen presentation in immune responses, but definitive experimental proof is lacking. Selectins, chemokines, and junctional proteins, which are known to be involved in T-cell diapedesis are not shown. (B) EC antigen presentation to circulating T cells may result in direct T-cell-mediated damage to the EC. In the example illustrated, a circulating cytolytic T lymphocyte recognizes a peptide-MHC alloantigen presented by the EC (1), leading to a tight adherence (2), and granule release, resulting in EC death (3). CTL killing of ECs in allograft rejection is well substantiated. APC, antigen-presenting cell; ICAM-1, intercellular adhesion molecule-1; MHC, major histocompatibility complex; TCR, T-cell receptor.

of obtaining MHC-matched T cells and ECs, which is a requirement to model physiologic antigen presentation, and by the difficulty in obtaining T-cell populations enriched for a single antigen specificity. Nonetheless, sufficient published evidence supports the conclusion that human ECs in culture can present antigen and activate CD4<sup>+</sup> T cells. The evidence has come from studies using peripheral blood T cells from individuals previously exposed to immunogens and MHC-matched endothelium (13–16). The ECs usually are treated

with IFN- $\gamma$  to induce class II MHC expression. Additionally, cocultures of MHC-disparate human ECs and human T cells (either CD4<sup>+</sup> or CD8<sup>+</sup>) lead to activation of the T cells, indicating that human ECs are capable of presenting alloantigens to T cells (17–19). Mouse T-cell clones or T cells from TCR-transgenic mice, which have single peptide-MHC specificity, can be simulated to proliferate and secrete cytokines in a peptide-antigen-specific manner by coculture with MHC-matched ECs and the relevant protein antigen. This is true for

CD8<sup>+</sup> T cells (20,21) and for CD4<sup>+</sup> T cells, if the ECs are treated with IFN- $\gamma$  in order to upregulate class II MHC (22). The question of whether ECs can cross-present proteins derived from other cells to CD8<sup>+</sup> T cells has been not been clearly resolved by in vitro experiments using purified endothelial cultures, but a study with pancreatic islet cultures does suggest that ECs can cross-present insulin to CD8<sup>+</sup> CTL (23).

The early demonstrations of in vitro endothelial antigen presentation did not address the fundamental differences in the responsiveness of naive versus effector or memory (antigen-experienced) T cells. The migration patterns, sites of activation, and costimulatory requirements of naive versus antigen-experienced cells differ significantly; therefore, the importance of endothelial antigen presentation to these different T cells also may differ significantly.

### ENDOTHELIAL ANTIGEN PRESENTATION TO NAIVE AND ANTIGEN-EXPERIENCED T CELLS: THE ROLE OF COSTIMULATORS

In vitro studies using both mouse and human cells indicate variability in the responsiveness of T cells to endothelial antigen presentation depending on the stage of T-cell differentiation and/or the activation state of the endothelium. Large numbers of naive T cells specific for a particular antigen can be isolated from TCR-transgenic mice, and their response to endothelial antigen presentation can be compared to T cells from the same mouse that have been activated in vitro with the antigen and syngeneic professional APCs. This approach has shown that naive CD4<sup>+</sup> T cells do not become fully activated by culture with ECs plus antigen, but resting effector CD4<sup>+</sup> T cells do (22). In contrast, naive minor histocompatibility antigen (HY antigen)-specific TCR transgenic CD8<sup>+</sup> T cells can be activated by HY-expressing ECs (20). The limited published data are inconsistent with regard to the effect of IFN- $\gamma$  activation of ECs on the responses of naive CD8<sup>+</sup> T cells; in one case IFN- $\gamma$  treatment of ECs inhibited their ability to support antigen-induced responses of naive CD8<sup>+</sup> T cells (20) and, in another case, IFN- $\gamma$  treatment of ECs enhanced naive CD8<sup>+</sup> T-cell responses (24).

The experimental comparison of responses of naive versus antigen-experienced human T cells is difficult to achieve because naive T cells specific for any single protein antigen are very rare in human peripheral blood. However, the frequency of naive human cells reactive to allogeneic MHC antigens is high enough to support a detectable response in vitro, and CD45RA and CD45RO, which are different RNA splice variants of a cell surface glycoprotein, are reasonable, albeit not perfect, markers of naive versus memory T cells, respectively. Naive (CD45RA) human CD8<sup>+</sup> T cells specific for allogeneic MHC do not become activated by allo-MHC-presenting ECs, whereas memory T cells with the same allo-specificity do (25). Overall, in vitro findings are consistent with the interpretation that endothelial antigen presentation is not important

for the activation of naive T cells and the initiation of primary immune responses. This interpretation also is consistent with the lack of class II MHC expression on HEVs, which are the major site of naive T cell-endothelial interaction. Furthermore, as discussed earlier, a large body of data indicate that the molecular information provided by adhesion molecules and chemokines is sufficient for homing of naive T cells into lymph nodes, in the complete absence of cognate antigen.

The failure of naive T cells to respond to endothelial antigen presentation is most likely a reflection of their stringent requirements for costimulation, and the absence of critical costimulatory molecules on ECs. B7-1 or B7-2 are the two molecules that account for the majority of costimulatory activity of APCs for naive CD4<sup>+</sup> T cells in mice and a major part of the activity for naive human CD4<sup>+</sup> T cells. There is very little evidence that B7-1 or B7-2 are expressed on human ECs in vivo. Expression can be induced on mouse liver sinusoidal and glomerular ECs by warm ischemia-reperfusion, which is a model for ischemia-reperfusion injury (26,27), and some expression has been reported on human hepatic sinusoidal ECs under pathological conditions (28). Expression of B7-1 and B7-2 on cultured ECs appears to vary with species and tissue source. For example, cultured pig aortic ECs express B7-1, and not B7-2 (29), whereas mouse hepatic sinusoidal endothelial express B7-2, but not B7-1. Mouse heart microvascular ECs do not express B7-1 or B7-2 (21), while mouse lung microvascular ECs express low levels of B7-1 but not B7-2 (20). With a few exceptions, most published analyses of costimulator expression on cultured human ECs have failed to detect B7-1 or B7-2 expression (30–32). In fact, naive T-cell reactivity to ECs can be induced by exogenous *B7-1* gene expression (33).

Human ECs in vivo and in vitro constitutively express CD58, which provides significant costimulatory activity for previously activated CD4<sup>+</sup> and CD8<sup>+</sup> T cells in vitro (10). CD58-mediated endothelial costimulation of naive human T cells in vitro can be demonstrated only when phytohemagglutinin (PHA) is used as the primary TCR stimulus (33). It is possible that endothelial costimulatory molecules, such as CD58 or members of the B7 family other than CD80 and CD86, do enhance responses of effector or memory T cells to endothelial antigen presentation in vivo. For example, inducible costimulatory molecule ICOS-ligand (B7h) is a B7-family costimulatory molecule that is expressed on ECs, and it contributes to endothelial activation of CD4<sup>+</sup> T cells (34). Although strictly not a costimulatory molecule, CD40 is a tumor necrosis family (TNF)-receptor family molecule expressed on professional APCs that indirectly enhances T-cell activation by stimulating the expression of other costimulatory molecules and cytokines (35). CD154, the ligand for CD40, is expressed on T cells recently activated by antigen. Because ECs from various sources express CD40 (10), it is possible that T cells that have been activated by endothelial antigen presentation can reciprocally activate ECs through the CD154/CD40 pathway. The theoretical net result, which is consistent with in vitro

experimental data, is enhanced bidirectional activation of both T cell and EC.

### T CELLS ON THE MOVE: IN VITRO MODELS WITH IN VIVO RELEVANCE

The ability of cultured ECs to activate T cells in static in vitro culture does not directly address the underlying hypothesis presented at the beginning of this chapter that endothelial antigen presentation promotes selective migration of antigen-specific T cells into tissues where the antigen is present. T cells undertake two general directions of movement with respect to endothelium that can be modeled in vitro; these are movements parallel to the direction of blood flow, and movement through the endothelium.

One potential effect of endothelial antigen presentation to T cells at the apical surface of the EC is the enhancement of adhesive interactions that stop movement of the T cell parallel to flow. The result is stabilized arrest of the T cell in the face of shear stress. In the widely accepted multistep paradigm of leukocyte diapedesis, reviewed in other chapters of this volume, stable arrest is required before transendothelial migration can occur (36). Compelling in vitro and in vivo evidence suggests that chemokines displayed on the endothelial surface activate T-cell integrins via chemokine receptor signaling, and this results in higher-avidity T-cell integrin binding to ECs (37). In vitro, TCR signaling has a similar effect as chemokines in activating T-cell integrins (38). Although the affinity of a TCR for a peptide–MHC complexes is not sufficiently high to contribute to the adhesion, the coreceptor interactions that accompany antigen recognition (CD4 with class II MHC, or CD8 with class I MHC) also could serve adhesive functions. Videomicroscopic analysis of T-cell interactions with endothelium in flow chambers is a potentially informative method for determining if antigen recognition at the apical surface of ECs can promote the stable arrest of T cells in the setting of shear stress. To date, no published data have used this approach. Videomicroscopy has been used to show that T cells that adhere to endothelium in the presence of cognate antigen, but without shear stress, are moderately more resistant to being dislodged when shear flow is applied, compared with T cells that adhered in the absence of antigen (23). This is a predictable result, because it is well known that the adhesion of T cells to APCs typically increases as antigen presentation proceeds. The diameter and molecular phenotype of microvasculature in some tissues, such as postcapillary venules in the skin, suggests ample opportunity for intravascular T cells to interact with ECs (39). Typical flow chamber conditions may be less conducive to T cell–endothelial interactions than in vivo conditions. In tissue microvasculature, flow is often intermittent, the diameter of the postcapillary venules may be less than the diameter of T cells, and therefore prolonged periods occur when T cells are not moving and are closely apposed to ECs.

Studies of transmigration of T cells through endothelial monolayers under static conditions in vitro suggest that T cells that “see” antigen on ECs are more likely to transmigrate than T cells that do not see antigen (20,40). Furthermore, endothelial costimulation – for example, through the ICOS pathway – may enhance transmigration (41).

### DOES ENDOTHELIAL ANTIGEN PRESENTATION OCCUR IN VIVO?

The circumstantial evidence that endothelial antigen presentation occurs in vivo is largely based on kinetic arguments, such as the early expression of class II MHC on vascular ECs prior to central nervous system (CNS) infiltration of CD4<sup>+</sup> T cells in experimental allergic encephalomyelitis (EAE) (42), and evidence of endothelial activation within 2 hours of intradermal injection of purified protein derivative (PPD) in sensitized but not naive primates (43). To provide definitive evidence that ECs actually present antigen to circulating T cells in vivo, the researcher must pick a measurable response that can only be attributable to antigen presentation, then measure that response under conditions in which no other type of APCs besides ECs could be responsible. This is a difficult task to achieve and, to date, there are a paucity of published data from studies that fulfill these requirements. The experimental approaches that have been applied to address endothelial antigen presentation in vivo vary in significant ways, and there are limitations in the interpretation of data obtained from each approach. For example, in some studies, the antigen is expressed on ECs; in others, the ECs cross-present antigen expressed in the tissue. In some studies, the endpoint is migration of antigen-specific T cells into tissues, whereas in other studies, the endpoint is intravascular interactions with the vessel wall. Nonetheless, a cumulative assessment of these different studies is that endothelial antigen presentation does occur in vivo, but the consequences are variable, depending on the vascular bed, T-cell subset, and antigen involved.

To determine if endothelial antigen presentation to T cells of a particular antigen specificity enhances preferential recruitment of those T cells, the measured endpoint is the extravascular accumulation of antigen-specific T cells in the tissues. The possibility always exists that a small number of these T cells that transmigrate out of the vessel independent of endothelial antigen presentation become activated by professional APCs in the tissue. This can lead to enhanced expression of adhesion molecules on nearby ECs, and local chemokine expression that favors migration of memory or effector T cells, regardless of specificity. Enrichment of antigen-specific T cells relative to other T cells in the transmigrated population may reflect proliferative responses of the T cells in the tissue and not preferential migration. It seems most likely that a role for endothelial antigen presentation would occur very early in a peripheral immune response to an infection, perhaps when local innate immune responses have not altered endothelial phenotype

significantly. The upregulation of endothelial adhesion molecules and chemokine expression that accompanies the innate response will permit migration of effector T cells of any specificity. Likewise, endothelial antigen presentation may be important in the case of T-cell recruitment into uninflamed tissues very early in the development of tissue-specific autoimmune diseases or allograft rejection. Adoptive transfer studies in mice indicate that antigen-experienced T cells specific for protein antigens that are synthesized in the extravascular tissue of a particular organ rapidly accumulate in those tissues and cause diseases, but are not detectable in other tissues (44,45). This occurs without any prior inflammatory events in those tissues. These observations are reminiscent of the rapid development of a positive PPD reaction in sensitized individuals, and are consistent with the kinetic argument that the rapid homing of tissue antigen-specific T cells to the relevant tissue site is mediated by endothelial presentation of the antigen.

One general approach to testing whether endothelial antigen presentation does occur *in vivo* is to establish conditions in an experimental animal in which only ECs express a particular MHC allele, then introduce T cells with that MHC restriction into the animal and track those cells. Professional APCs are derived from bone marrow precursors. Irradiation of a mouse, followed by bone marrow transplantation using a donor with a different MHC haplotype from the host, or a gene knockout donor that does not express class I or class II MHC molecules, will result in a chimeric animal in which the radioresistant ECs express different MHC alleles than do the hematopoietically derived APCs. This approach was used to demonstrate that cardiac allografts in which only nonhematopoietically derived cells are allogeneic to the host are rejected by CD8<sup>+</sup> T cells (46), but the explicit role of ECs in activation and recruitment of T cells into the allograft could not be assessed in that model.

An alternative transgenic strategy for studying endothelial antigen presentation *in vivo* is the generation of mice that express a nonmouse protein exclusively in ECs, by use of endothelial-specific promoters (47). This approach suffers from the uncertainty of exclusive endothelial expression of an ectopic transgene, and the possibility that, even though the antigen is synthesized by ECs, it may be cross-presented by another APC. In theory, the transgenic approach could be very useful for intravital visualization of interactions of T cells specific for a particular protein antigen with ECs that produce, process, and present that antigen.

Perhaps the only definitive way of determining if endothelial presentation of tissue antigens to circulating T cells occurs *in vivo* is to inject labeled T cells specific for that antigen into animals and observe by intravital microscopy the interactions of the T cells with endothelium in vessels in the relevant tissue at early time points before any secondary effects of T-cell activation outside the vessel could occur. Quantitative comparisons can be made between the interactions of phenotypically comparable T-cell populations with or without the relevant antigen specificity, or comparisons can be made between interactions of antigen-specific T cells in tissues that do or do not express the relevant antigen. One published study

that used this approach describes enhanced extravasation of male antigen (HY)/H-2<sup>k</sup>-specific CD8<sup>+</sup> T cells across scrotal microvessels in IFN- $\gamma$  treated mice that express H-2<sup>k</sup> MHC molecules, compared to extravasations in mice that express other MHC alleles (48). The enhanced diapedesis was observed after only 10 minutes, although the number of transmigrated cells actually observed was small. Curiously, the amount of T cells adherent to the ECs did not appear to be influenced by the presence of antigen. Although the antigen-enhanced T-cell extravasation in this model may be taken as evidence for endothelial antigen presentation, the physiological relevance of the model may not be broadly applicable, because the T cells used were specific for an antigen produced by the ECs themselves. In other words, the question of whether the endothelium can promote recruitment of T cells specific for antigen present in the surrounding tissues remains unanswered. In the case of CD8<sup>+</sup> T cells, the question can be phrased, "Can ECs cross-present tissue antigens by the class I MHC pathway and thereby enhance CD8<sup>+</sup> T cell recruitment?"

Another published study using a mouse CD8<sup>+</sup> T cell clone specific for an insulin peptide suggests that EC cross-presentation of antigen does promote CD8<sup>+</sup> T-cell recruitment (23). A small number of these T cells were found in the extravascular space around some pancreatic islets 1.5 hours after injection into class I MHC-expressing mice, but not after injection into class I MHC-negative mice. This correlated with islet infiltration by the T cells at later time points in identically treated class I MHC-positive but not class I MHC-negative mice. The recruitment of the T cells into the islets depended on secretion of insulin by the islet cells. A direct demonstration of antigen-dependent T cell-endothelial interactions *in vivo* was not provided in that study, and therefore the conclusion that the antigen presentation by ECs enhanced migration of the T cells is based on the kinetic argument.

## ENDOTHELIAL ANTIGEN PRESENTATION AS A HOMEOSTATIC OUTPUT

Although this discussion has focused on the possible role of endothelial antigen presentation in promoting T-cells recruitment and thereby enhancing adaptive immune responses, it is possible that, in some circumstances, endothelial antigen presentation may serve a homeostatic role in limiting immune responses or maintaining tolerance to self antigens. A few different types of experimental observations do suggest a regulatory role of endothelial presentation. The presence of cognate antigen appears to block transendothelial migration of T cells in some *in vitro* assays, especially when the T cells can be stimulated to divide independent of costimulation (40). ECs inducibly express the PD-L1, a member of the B7 family, which binds to the PD-1 receptor on T cells (49,50). PD-1 transmits negative regulatory signals that block T-cell activation. IFN- $\gamma$  induces PD-L1 expression on ECs, and endothelial PD-L1 can impair both CD4<sup>+</sup> and CD8<sup>+</sup> T cell activation, including CD8<sup>+</sup> T cells killing of antigen-presenting ECs (21,50). In

vivo studies in mice show that PD-L1 expression is markedly upregulated on microvascular endothelium of certain tissues, especially the heart, in response to IFN- $\gamma$  (21). A potentially important physiological role for PD-L1 may be to limit T cell-mediated immune responses. Alternatively, this pathway may serve to limit damage to endothelium by T cells that recognize antigen on endothelial surfaces.

The ECs that line hepatic sinusoids appear to have a specialized role in inducing T-cell tolerance to soluble protein antigens delivered to the liver via the portal circulation (51). Unlike most ECs, liver sinusoidal ECs (LSECs) constitutively express B7-1 and B7-2, as well as class I and class II MHC (52). LSEC presentation of antigen to naive CD4<sup>+</sup> of CD8<sup>+</sup> T cells results in a loss of responsiveness to those antigens, although the mechanisms of this tolerance induction are not well defined (53,54). Thus, liver ECs may be particularly important in maintaining nonreactivity to food proteins, and delivery of alloantigens into the portal circulation may be a method for inducing allograft tolerance.

**ENDOTHELIAL ANTIGEN PRESENTATION PROVIDES A TARGET FOR PATHOLOGICAL T-CELL RESPONSES**

T cells mediate much of the tissue damage in autoimmune disease and allograft rejection, and this damage depends on presentation of tissue antigens to effector T cells. As discussed earlier, evidence from animal models of autoimmunity suggests that endothelial antigen presentation promotes early influx of tissue antigen-specific T cells into previously uninflamed organs. Histopathological observations suggest that ECs are a primary target for T cell-mediated allograft rejection, and CD8<sup>+</sup> CTL play a dominant role in both acute and chronic allograft rejection (55). Allogeneic CTL killing of graft vascular ECs can be considered a consequence of endothelial antigen presentation, in which the antigen is an allogeneic class I MHC-peptide complex (see Figure 120.1B). Allograft rejection has been modeled in immunodeficient mice that receive injections of human T cells and grafts of human skin or human EC-derived synthetic vessels (55,56). Although the actual site of lethal CTL-endothelial contact (e.g., luminal, interendothelial, or abluminal) is not clear from these studies, the models provide compelling data that alloreactive human CD8<sup>+</sup> T cells can be activated by and destroy ECs in vivo.

**KEY POINTS**

- Endothelial antigen presentation is a hypothetical mechanism by which T cells specific for particular antigens may be efficiently directed into the tissues where those antigens are located. This may influence

migration of naive T cells into lymph nodes, and effector T cells into peripheral tissues.

- Extensive in vitro evidence has established that ECs are capable of displaying T-cell antigens (peptide-MHC complexes) and costimulators that are recognized by, and cause the activation of, different subsets of T cells.
- Although a small number of technically diverse studies indicate that endothelial antigen presentation occurs in experimental animals, the contribution of endothelial antigen presentation to protective immune responses in vivo remains technically difficult to demonstrate and of unknown importance.
- Endothelial antigen presentation may have different consequences in different tissue/organ contexts, and may contribute to T-cell tolerance and homeostasis.
- Endothelial antigen presentation provides a target for pathological immune responses, such as in the case of CTL-mediated killing of ECs in allograft rejection.

*Future Goals*

- To establish better experimental models that will permit direct visualization of antigen-dependent T cell-endothelial interactions in vivo, especially models in which the antigen is derived from surrounding tissue cells

**VASCULAR BED/ORGAN  
STRUCTURE AND  
FUNCTION IN HEALTH  
AND DISEASE**

## Introductory Essay

### The Endothelium in Health and Disease

---

William C. Aird

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The endothelium is an expansive organ, reaching to all recesses of the human body. The endothelium plays a critical role in homeostasis. Endothelial cells (ECs) participate in the regulation of vasomotor tone, leukocyte trafficking, coagulation, permeability, antigen presentation, innate immunity, and angiogenesis. ECs display remarkable heterogeneity in structure and function. For example, although most ECs are extremely flat (which minimizes diffusional path length), those of the high endothelial venules (HEVs) are plump and cuboidal. The structure of the intercellular junctions, the absence or presence of fenestrations, and the continuity (or lack thereof) of the abluminal basement membrane are criteria used to differentiate between continuous, fenestrated, and sinusoidal endothelium. The ECs in postcapillary venules are primarily responsible for mediating the adhesion and transmigration of leukocytes, whereas arteriolar endothelium plays a particularly important role in regulating vasomotor tone. ECs are aligned parallel to the direction of blood flow in straight segments of arteries, but not at branch points or curvatures of arteries, or in veins. Protein and mRNA expression varies among different vascular beds. Indeed, state-of-the-art proteomic approaches have uncovered a vast array of vascular bed-specific markers, or vascular “zip codes.”

EC heterogeneity is mediated by two proximate (“how?”) mechanisms. First, biochemical and biomechanical signals within the extracellular environment trigger post-transcriptional and/or post-translational changes in ECs. Because the net signal input varies across the vascular tree (and from one moment to the next), so too does EC output (i.e., cellular phenotype). Second, certain site-specific properties of the endothelium are epigenetically programmed and mitotically heritable. The maintenance of these latter properties are no longer dependent on or influenced by the extracellular milieu. When ECs derived from different vascular beds are cultured under identical conditions *in vitro*, cells tend to lose site-specific properties that are governed by the first mechanism (resulting in phenotypic drift), but retain

those properties that are determined by the second mechanism. Evolutionary (“why?”) explanations for the existence of EC heterogeneity are at best speculative. However, it seems likely that phenotypic heterogeneity serves at least two important purposes. First, it allows ECs to serve the varying needs of the underlying tissue. For example, the tight junctions of the blood–brain barrier protect neurons from fluctuations in the composition of blood (Chapters 123 and 124), whereas the fenestrated, discontinuous endothelium of hepatic sinusoids allows for ready access of nutrient-rich portal venous blood to the metabolic machinery of hepatocytes (Chapter 133). Second, ECs are exposed to so many different microenvironments that they must employ site-specific mechanisms to cope with these differences. For example, ECs in the inner medulla of the kidney are exposed to a profoundly hypoxic and hyperosmolar environment (Chapter 138). Although little is known about the phenotype of these particular cells, it is safe to assume that they are adapted in ways that differ from ECs in oxygen-rich environments such as the pulmonary capillary bed (Chapter 126).

In summary, far from being a giant monopoly of identical cells, the endothelium is a consortium of smaller enterprises, each uniquely adapted to the needs of the local tissue. (As with other consortiums, certain unifying or core properties apply to all constituents.) Our level of understanding of the endothelium varies from one organ to another. The most intensely studied vascular beds are the blood–brain barrier (Chapters 123 and 124); the retina (Chapter 125); the coronary arteries (Chapter 132); the pulmonary and, to a lesser extent, bronchial circulation (Chapters 126 and 127); skin (Chapter 156); and HEVs (Chapter 170). Advances in these various areas have occurred largely within the context of organ-specific disciplines (a subject that we will return to in the final chapter). There has been comparatively little focus on the sinusoidal endothelium of the liver (Chapter 133) and spleen (Chapter 136), the endothelium of the large hepatic vessels (Chapter 134), and the microvascular endothelium of the gastrointestinal tract

(Chapter 135) or adipose tissue (Chapter 137). Recent studies have yielded exciting new insights into the phenotype of placental endothelium (Chapters 160 and 161) and lymphatic ECs (Chapter 169). These chapters cover a wide spectrum of vascular beds. However, the list is by no means exhaustive. Indeed, many vascular beds are not included in this volume, yet they are of tremendous interest to biomedical practitioners, including (but not limited to) ovaries, testes, and other endocrine glands; bone marrow; skeletal muscle; and thymus. These topics may be covered in a subsequent edition of the book.

The two most common terms used to describe the endothelium in disease are EC activation and EC dysfunction. Both terms were initially coined during the 1980s. EC activation describes the response of ECs to an inflammatory stimulus. The activation phenotype varies according to the nature of activation agonist, the net signal input, and the vascular bed of origin. Typically, the phenotype consists of some combination of a proadhesive and procoagulant surface, increased permeability, and release of inflammatory mediators (some might argue that proliferation also qualifies as activation). The term *activation* should not be confused with activity. The normal endothelium is highly active, constantly sensing and responding to changes in the extracellular environment. EC activation describes a phenotype, but does not address the cost of that phenotype to the host. In other words, EC activation may be adaptive or nonadaptive. In contrast, EC dysfunction is by definition nonadaptive. The latter term is used most often to describe abnormalities in endothelial-dependent vasomotor tone in atheromatous conduit arteries. However, because the endothelium is widely distributed, and because it is involved in so many different functions (over and above the regulation of vasomotor tone), the term *dysfunction* should be used more broadly to describe situations in which the EC phenotype – whether it meets some predetermined definition of activation – represents a net liability to the host.

It follows from the previous discussion that the endothelium may display a wide spectrum of phenotypes in disease. Such diversity is underscored in this section of the book. Some chapters are focused on vascular bed–restricted diseases (in reality, none are truly confined to one organ), including those in the brain (Chapters 123 and 124); retina (Chapter 125); lung (acute respiratory distress syndrome in Chapter 128, pulmonary hypertension in Chapter 129, emphysema in Chapter 130, and ischemia–reperfusion in Chapter 131); liver (Chapters 133 and 134); kidney (Chapters 138–140); thyroid (Chapter 151); skin (Chapter 156); placenta (Chapters 160 and 161); penis (Chapter 167); tumors (Chapters 158 and 159); and bone (Chapter 168).

Other chapters cover systemic illnesses that have more widespread effects on the endothelium. These include atherosclerosis (Chapter 132); infection (sepsis in Chapter 141, malaria in Chapter 142, and hemorrhagic fevers in Chapter 143); hematological syndromes (disseminated intravascular coagulation in Chapter 145, thrombotic thrombocytopenic

purpura in Chapter 146, heparin-induced thrombocytopenia in Chapter 147, sickle cell disease in Chapter 148, and antiphospholipid antibody syndrome in Chapter 149); diabetes (Chapter 150); vasculitides and other chronic inflammatory disorders (Chapters 153–155); and the effects of smoking (Chapter 144) and aging (Chapter 152). These disorders involve acquired abnormalities of the endothelium, in contrast to the far less common (yet fascinating) congenital/inherited abnormalities of the endothelium, which are discussed in Chapter 122.

Increasing evidence suggests that the endothelium plays an important role in surgical illness. Thus, we have included chapters on arterial grafts (Chapter 162); burns (Chapter 163); trauma in civilian (Chapter 164) and military (Chapter 165) life; and blood transfusion (Chapter 166).

When considering the role of the endothelium in disease, an interesting and often challenging question is to what extent the endothelium is victim or perpetrator of the underlying pathophysiology. The answer is usually a combination of the two. In many diseases discussed in this section, the primary pathogenesis is nonendothelial in origin. For example, sickle cell disease is caused by a mutation in the hemoglobin gene, yet sickle red blood cells initiate a cascade of events that ultimately ensnare the endothelium. Heparin-induced thrombocytopenia (HIT) is mediated by antiplatelet factor 4-heparin antibodies that are directed primarily towards Fc receptors on the surface of platelets. Platelet activation has profound consequences on the endothelium. The pathogenesis of preeclampsia involves the release of soluble FLT-1 (sFLT-1) from the trophoblasts of the placenta. The soluble form of this receptor competitively inhibits binding of vascular endothelial growth factor (VEGF) to the endothelium. In contrast, some diseases appear to target the endothelium directly. Examples include vasculitides associated with anti-EC antibodies and sinusoidal obstruction syndrome (SOS), in which hepatic sinusoidal ECs are uniquely vulnerable to exogenous and endogenous toxins. Once the endothelium is engaged (either primarily or secondarily), it may contribute in significant ways to the underlying pathophysiology. For example, the interaction between sickle red blood cells and the endothelium results in a vicious cycle of hypercoagulability, hyperadhesiveness, and vascular occlusion. In HIT, the endothelium acquires a procoagulant phenotype that “channels” systemic changes in the hemostatic balance into local thrombus formation. In preeclampsia, sFlt-1–mediated reductions in VEGF reduce endothelial-dependent vasorelaxation. Similarly, anti-EC antibodies and SOS lead to activation and dysfunction of the endothelium.

It is uncommon to find discussions of these various diseases in the same volume. They are normally segregated into organ-specific textbooks. However, we believe that the endothelium should be viewed as an integrated system, one that transcends traditional organ-specific disciplines. Indeed, as this section underscores, the endothelium is a powerful organizing principle in human physiology and pathophysiology.

# Hereditary Hemorrhagic Telangiectasia

## A Model to Probe the Biology of the Vascular Endothelium

Mourad Toporsian and Michelle Letarte

*Hospital for Sick Children, University of Toronto, Ontario, Canada*

A decade ago, it was recognized that mutations in the *ENDOGLIN* (*ENG*) (1) and *ACTIVIN RECEPTOR-LIKE KINASE 1* (*ACVRL1*) (2) genes cause an autosomal dominant disorder known as hereditary hemorrhagic telangiectasia (HHT) type 1 and type 2, respectively. The predominant expression of the corresponding proteins, endoglin and ALK1, on vascular endothelial cells (ECs) and their function as transforming growth factor (TGF)- $\beta$  receptors indicated that HHT is likely associated with perturbations in TGF- $\beta$  signaling in ECs. Mice heterozygous for either gene develop HHT (3–6), and can be used to gain insight into the mechanisms of disease, highlighting the role of TGF- $\beta$  in maintaining vascular integrity and unraveling the potential contribution of other pathways to HHT pathogenesis. Mice totally deficient in either endoglin (3–5) or ALK1 (6) do not survive past midgestation, and their analysis has revealed an essential role for these receptors in vascular development. This chapter provides an overview of HHT as a disorder of the vascular endothelium associated with the generation of abnormal structures such as telangiectases and arteriovenous malformations (AVMs), and discusses the current model of HHT pathogenesis.

### HISTORICAL PERSPECTIVES

Over a century ago, HHT was recognized by the French physician Rendu as a syndrome associating cutaneous telangiectases with recurrent epistaxis (nosebleeds) (7). Following more specific clinical accounts of such manifestations by Osler (8) and the recognition of their familial nature by Weber (9), the new clinical entity was referred to as the Rendu-Osler-Weber syndrome. While the term *hereditary hemorrhagic telangiectasia* was introduced by Hanes in 1909 and is currently preferred, the early eponym is still used to designate this disorder. Until the 1940s, descriptions of clinical manifestations of HHT remained associated mostly with external visible signs, such as frequent epistaxis and small telangiectatic lesions (defined

later) on the skin and in mucous membranes in oral and nasal cavities. Advances in medical imaging then revealed that AVMs—defined as abnormal direct connections between arteries and veins—were present in vital internal organs of HHT patients. AVMs are life-threatening because of their potentially lethal complications, such as hemorrhage, stroke, or brain abscess. HHT is a relatively rare disorder that is still underdiagnosed because of its varied presentation. However, the current estimated incidence is 1 in 5,000 to 8,000 individuals, with no racial or gender predilection worldwide; it can reach as high as 1 in 1,300 people in geographical isolates such as the Dutch Antilles (10).

### VASCULAR LESIONS ASSOCIATED WITH HEREDITARY HEMORRHAGIC TELANGIECTASIA

#### Telangiectases

HHT is an autosomal dominant vascular disorder with age-related penetrance. Frequent nosebleeds are due to telangiectases in the nasal mucosa and are generally the first presenting sign of HHT. By age 21, 90% of individuals have had repeated nosebleeds. Numerous telangiectases can be present on the skin of fingers, chest, lips, eyelids, and along inner linings of mucosal cavities such as the mouth and ear. Most patients also develop telangiectases in the gastrointestinal tract with advancing age, potentially leading to hemorrhage, iron-deficiency, anemia and transfusion-dependence (11).

Telangiectases are relatively common in healthy individuals, but occur with much greater frequency in ataxia-telangiectasia; the calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia (CREST) syndrome; and hereditary benign telangiectasia, and in other conditions such as pregnancy or chronic liver disease. Telangiectases coupled with recurrent epistaxis are characteristic of HHT and, in conjunction with family history and visceral AVMs, serve as the basis for HHT diagnosis. The consensus for clinical diagnosis is summarized by the Curaao criteria: (a)

spontaneous and frequent epistaxis, (b) multiple telangiectases on lips, nose, oral cavity, and fingers, (c) visceral lesions and AVMs in pulmonary, cerebral, or hepatic circulations, and (d) family history of HHT. A definite diagnosis of HHT is made when three out of four criteria are satisfied, whereas a minimum of two criteria renders a diagnosis of “suspected HHT” (12). Genetic screening is available and provides a more definite diagnosis of HHT and of its type.

Telangiectases are mucosal and cutaneous lesions that represent a focal loss of capillaries; they consist of abnormally dilated venules directly connected to dilated arterioles. They contain a single endothelial layer and scant perivascular elastic tissue within the lesion. Braverman and colleagues systematically analyzed electron micrographs of dermal lesion biopsies from HHT patients and provided an overview of their development (13). The smallest clinically detectable lesions (pinpoint size) show a focally dilated postcapillary venule with prominent stress fibers in pericytes along the abluminal border. In lesions of 0.5 mm diameter, the venular lumen is expanded and shows thicker walls, with an increased number of pericytes. The upstream arteriole is dilated but remains connected to the downstream venule via short capillary segments. The 2-mm lesions display markedly dilated and convoluted venules with excessive and often uneven layers of smooth muscle cells; loss of capillaries is present, and a direct connection exists between the dilated arterioles and venules. Such lesions represent small AVMs. Figure 122.1A illustrates a telangiectatic lesion along the gastrointestinal tract.

## Arteriovenous Malformations

Telangiectases or small AVMs can become much larger lesions, with direct connections between arteries and veins. The AVMs are predominantly found in HHT patients in the pulmonary, cerebral, and hepatic circulations. Because they are not externally visible, AVMs can grow to a large size before being detected clinically, and are therefore life-threatening.

### Pulmonary Arteriovenous Malformations

Up to 50% of HHT patients may harbor pulmonary AVMs (PAVMs) (11) and, in fact, their presence should alert the physician to a diagnosis of HHT, because more than 80% of PAVMs are associated with this disorder (14). Rupture of a PAVM or bleeding from an endobronchial mucosal telangiectasia may result in hemoptysis. The prevalence of hemoptysis reaches 6% to 13% in HHT patients harboring PAVMs (11, 14–16). In general, HHT patients with massive pulmonary hemorrhage have a PAVM on the side of the bleeding, although rare cases present with recurrent hemoptysis without any PAVMs and have only endobronchial mucosal telangiectases (17,18). Figure 122.1B illustrates a pulmonary AVM, as revealed by angiography (19). Figure 122.1C represents schematics of a simple type of AVM, characteristic of 90% of cases, and consisting of a single segmental pulmonary artery joining a thin-walled aneurysmal sac drained by a single vein. Other PAVMs are more complex, with two or more feeding arteries and two or more draining veins (20). Embolotherapy (intentional blockage of the AVM feeding artery with coils

Figure 122.1. (A) Image of a telangiectatic lesion along the intestinal mucosa of a patient with HHT. (Courtesy of Dr. N. Marcon, St-Michael's Hospital, University of Toronto.) (B) Right pulmonary angiogram showing a simple PAVM in the right lower lobe (arrowhead). Note the presence of embolization coils (arrow) from prior treatment of a different AVM. (Adapted with permission from Jaskolka J, Wu L, Chan RP, Faughnan ME. Imaging of hereditary hemorrhagic telangiectasia. *Am J Roentgenol.* 2004;183:307–14.) (C) Schematic diagram of a simple PAVM (PA, pulmonary artery; PV, pulmonary vein). This structure is supplied by one segmental artery, which may consist of a single branch (upper panel), multiple branches (middle panel), or multiple branches with a more proximal artery arising from the same feeding artery to the aneurysm (lower panel). Complex PAVMs usually receive blood from many segmental arteries. (Adapted with permission from White RI, Jr., Pollak JS, Wirth JA. Pulmonary arteriovenous malformations: diagnosis and transcatheter embolotherapy. *J Vasc Interv Radiol.* 1996;7:787–804.)

or a balloon to prevent potential hemorrhage) provides an efficient means of treatment, but because most patients have multiple PAVMs that grow with time, patients must be monitored closely and the procedure repeated (16). If untreated, PAVMs can lead to neurological complications. Strokes and transient ischemic attacks occur in close to 40% of HHT patients with PAVMs due to right-to-left shunting of blood and consequently improper filtration of potential clots and bacteria (21).

#### *Cerebral Arteriovenous Malformations*

Five percent to 10% of HHT patients develop cerebral AVMs. However cerebral AVMs are relatively frequent in the general population, and only 2% of cases are associated with HHT (21). Most cerebral AVMs are believed to be congenital lesions occurring mostly in the supratentorial region but of unknown etiology; they consist of multiple arteries and veins, connecting as a fistula without an intervening normal capillary bed (22). An analysis of cases associated with HHT suggests that the appearance in the cortex of multiple micro-AVMs harboring single feeding arteries and draining veins and located in the cortex should raise suspicion of an HHT diagnosis (23).

#### *Hepatic Arteriovenous Malformations*

Liver involvement to various degrees is found in 40% of patients with HHT (24), and is characterized by malformations in hepatic vessels. Early on, microscopic telangiectases are scattered throughout the liver parenchyma, which progressively enlarge to display multiple direct abnormal arteriovenous communications. A recent three-dimensional modeling of the hepatic vasculature in HHT indicates that pathological changes include focal sinusoidal ectasia, direct communications between hepatic arteriolar branches and ectatic sinusoids (arteriovenous shunts), and large communications between the portal and central veins via ectatic sinusoids (portal vein shunts) (25). There are three distinct types of intraparenchymal right-to-left shunts: hepatic artery to hepatic vein, hepatic artery to portal vein, and portal vein to hepatic vein. Increased blood flow through even microscopic AVMs can lead to significant dilatation of the hepatic artery and its branches in the early stages, which progressively become tortuous and tangled with increasing disease severity. The progressive dilatation of the hepatic and/or portal veins and their flow abnormalities are associated with larger arteriovenous shunting. Cirrhosis and liver dysfunction as well as high cardiac output and heart failure due to increasing shunting represent end-stage manifestations of hepatic involvement (26).

### **GENETIC BASIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA**

During the 1990s, linkage studies revealed that mutations in two distinct genes mapping to human chromosomes 9q33–34 and 12q13 and encoding endoglin (*ENG*) and activin receptor-

like kinase (*ACVRL1*) cause HHT type 1 (HHT1) or HHT type 2 (HHT2), respectively (1,2). HHT1 families have a higher prevalence of pulmonary AVMs than do those with HHT2, who tend to have a generally milder phenotype and later onset (14,27). However, hepatic involvement has been observed in both groups of patients. Comprehensive phenotype/genotype correlation studies are needed to ascertain if indeed disease severity and organ specificity are related to the affected gene. About 10% to 20% of families with HHT cannot be accounted for by mutations in *ENG* or *ACVRL1* genes. A genome-wide linkage analysis recently identified an additional locus on chromosome 5 associated with HHT and referred to as HHT3 (28). It will be interesting to see if the product of this new locus is also predominantly expressed in the vascular endothelium and involved in TGF- $\beta$  signaling.

Gallione and colleagues have described patients with a combined syndrome of juvenile polyposis (JP) and HHT (referred to as JPHT) and a functionally inactivating mutation in the *MADH4* gene (coding for the common Smad4), but no mutation in either *ENG* or *ACVRL1* genes (29). This suggests that HHT also can be caused by *MADH4* mutations in this combined syndrome, a further link to impaired TGF- $\beta$  signaling, because the common Smad4 mediates all Smad-dependent signaling.

#### ***ENG* and *ACVRL1* Mutation Analysis**

*ENG* is comprised of 15 exons spanning 30 kb of genomic DNA. As of 2006, 156 different *ENG* mutations have been identified in patients with HHT (30). These mutations are of all types and are distributed in the first 12 exons, which encode the extracellular domain of endoglin. *ACVRL1* has 10 exons distributed over 15 kb. Currently, 123 *ACVRL1* mutations have been reported; more than half are missense substitutions, most of which are in the intracellular kinase domain (30).

Almost 80% of all reported *ENG* mutations cause frame shifts and premature stop codons that should lead to nonsense-mediated mRNA decay resulting in reduced mRNA levels and very unstable mutant proteins. Expression analysis revealed that mutant endoglin proteins are rarely detectable and, if so, are transient species that do not reach the cell surface and are destined for degradation (31). The observations that mutant proteins are unstable suggest that folding is tightly regulated, and that most mutations lead to structural instability and loss of function. Our data support the hypothesis that *ENG* haploinsufficiency leading to 50% reduction in functional protein in ECs is the underlying cause of HHT1 (31). This model implies that the disease is not due to interference by a mutant protein, indicating that the position or type of mutation does not influence disease severity. Analysis of histological sections from HHT1 patients revealed that all blood vessels showed a 50% reduction in endoglin levels, relative to platelet-endothelial cell adhesion molecule (PECAM)-1 (32). Furthermore, cerebral and pulmonary AVMs showed a lower density of endoglin due to the excessive dilatation of the vessels, whereas the endoglin:PECAM-1 ratio remained constant.

These data ruled out the loss of *ENG* heterozygosity as a potential mechanism for the generation of vascular lesions.

The quantification of ALK1 levels in ECs (33) and molecular modeling of the kinase domain mutants (34) also support haploinsufficiency as the underlying cause of HHT2. Of the 123 mutations reported for HHT2 (30), 75% occur in the intracellular kinase domain at highly conserved residues, both across species and among different type I receptors. These likely lead to the generation of misfolded and unstable proteins.

### Other Diseases Associated with *ENG* and *ACVRL1* Mutations

Interestingly, a recent study has identified germline mutations in *ENG* (1711C→T, R571C and 1538 A→G, K513R) as a previously unrecognized cause of juvenile polyposis (JP) syndrome (35). These patients presented with an unusually early onset of JP (ages 3 and 5), with no clinical signs of HHT. Family history was not discussed, and one cannot rule out the possibility that these children may develop HHT later. The specific missense mutations are in conserved residues, do not appear to be normal polymorphic variants, and have not to date been identified in HHT1 patients; nor have protein levels been measured to ascertain if endoglin haploinsufficiency also is associated with these case of JP. This study therefore identifies *ENG* mutations as a possible genetic cause of JP, and it remains to be ascertained if it is due to impaired endoglin function in ECs. One cannot rule out expression of endoglin in a subset of gut epithelial cells that could be more directly implicated in JP and associated with abnormal epithelial cell cycle regulation.

Familial cases of pulmonary arterial hypertension (PAH), as well as a large proportion of somatic cases, are associated with mutations in the bone morphogenetic protein (BMP) receptor II (*BMPRII*) gene (36), which codes for the *BMPRII* receptor that signals through Smad1 and Smad5, a pathway shared by ALK1. Mutations in *ACVRL1* and to a lesser degree *ENG* have been recently associated with PAH (37,38). This apparent higher incidence of PAH in patients with HHT2 versus HHT1 may be related to their lower incidence of PAVMs, structures that would tend to reduce overall pulmonary vascular resistance. A recent study by Harrison and colleagues describes the case of a 3-year-old child with an *ENG* mutation who initially presented with features of PAH and, by 8 years of age, developed signs of HHT (37), at which point pulmonary vascular resistance had declined most likely due to the presence of microvascular PAVMs.

## THE FUNCTIONAL PROTEINS

### Endoglin

Endoglin (CD105) is an integral membrane glycoprotein initially identified on pre-B cells of childhood acute lymphocytic leukemia (39,40). It also is expressed on acti-

vated macrophages, pre-erythroblasts, developing endocardial tissue mesenchymal cells, and in cultured smooth muscle cells and fibroblasts (41). Endoglin also is present on the syncytiotrophoblast throughout pregnancy, and is transiently expressed on the extravillous cytotrophoblasts as they invade the spiral artery during the first trimester of pregnancy (41). Endoglin resides predominantly in the vascular endothelium; it was defined as an EC marker (CD105) in the Fifth International Leukocyte Typing Workshop (42). It is highly expressed on ECs of all vessel types, and considered a sensitive marker of tumor angiogenesis. Quantification of intratumor microvascular density by endoglin staining has prognostic significance in selected neoplasias (43). Indeed, antibodies to endoglin have demonstrated efficacy in animal models for tumor imaging and antiangiogenic therapy, and are promising tools for the treatment of human malignancies (44).

Endoglin is synthesized as a 68-kDa polypeptide chain and subsequently glycosylated at N- and O-linked sites, to yield a 90-kDa monomer. It contains 17 cysteine residues that generate intra- and interchain disulfide bonds, suggesting a complex and tightly regulated folding. At the surface of ECs, endoglin exists as a covalently linked 180-kDa homodimer consisting of a relatively large extracellular region (561 amino acids), a hydrophobic stretch of 25 amino acids spanning the plasma membrane, and a cytoplasmic tail of 47 residues (45), rich in phosphorylated serine and threonine (46). Endoglin is an ancillary receptor (or coreceptor) for TGF- $\beta$ 1 and - $\beta$ 3; it does not signal directly and modulates responses of these cytokines in ECs and other cell types (47). Endoglin is structurally related to betaglycan, the original TGF- $\beta$  type III receptor, with the short cytoplasmic region showing the greatest sequence identity (48,49). Endoglin has therefore been referred to as a type III receptor for the TGF- $\beta$ 1 and - $\beta$ 3 isoforms; betaglycan also binds TGF- $\beta$ 2 and can be found in the extracellular matrix. In transfection studies, endoglin can bind other members of the TGF- $\beta$  superfamily including activin, BMP-7, and BMP-2 when associated with their corresponding receptors (50). The functional implications of these interactions remain to be elucidated under physiological conditions.

Although endoglin is mostly known for its role as a TGF- $\beta$  coreceptor, it is present in vast excess (400,000 molecules/EC) in comparison to TGF- $\beta$  receptors (<2,000/cell), suggesting additional interactions and functions. Indeed, despite its short cytoplasmic tail and lack of obvious functional motifs, endoglin associates with the endothelial nitric oxide synthase (eNOS) activation complex (51), which includes eNOS and its allosteric regulators, heat shock protein 90 (HSP90) and caveolin-1 (Cav-1). Endoglin appears to stabilize the eNOS protein, as demonstrated by a shorter eNOS half-life in ECs from *Eng* heterozygous mice. The same studies suggested that endoglin promotes eNOS/HSP90 interaction during eNOS activation, thus favoring nitric oxide (NO) production (51). These novel findings indicate that endoglin is involved in vasoregulation mediated by its interaction with eNOS, which occurs via its intracellular short cytoplasmic tail. Interestingly,

E, embryonic day

this study also demonstrates that the eNOS-endoglin association occurs in caveolar lipid rafts, subcellular compartments known to harbor many important signaling molecules, thus suggesting that the functional roles of endoglin may be even more diverse than previously recognized.

The cytoplasmic domain of endoglin also interacts with zyxin and zyxin-related protein (ZRP)-1, members of the LIM family implicated in organization of the actin cytoskeleton (52,53). This interaction occurs in the absence of exogenous TGF- $\beta$ . Endoglin regulates the cellular distribution of zyxin and ZRP-1 favoring their association with actin stress fibers and possibly contributing to the structural integrity of ECs. Cytoskeletal organization is critical for angiogenesis, vascular morphology and permeability, inflammatory response, and response to shear stress, all of which are essential mechanisms in maintaining the structural and functional integrity of the vasculature.

### ALK1

ALK1 is a type I serine/threonine receptor kinase of the TGF- $\beta$  superfamily, specifically expressed on ECs. Interestingly, ALK1 expression is much higher in the endothelium of developing and mature arteries than in veins and capillaries (54). It is also found at epithelial-mesenchymal boundaries (54). ALK1 shares a relatively high amino-acid identity to other type I receptors including ALK2, ALK5, ALK4, and ALK3, particularly in the serine/threonine kinase subdomain. The intracellular kinase domain contains a glycine/serine-rich (GS) region that plays an important role in signaling, because its deletion abolishes the ability of T $\beta$ R1 to undergo phosphorylation and to mediate TGF- $\beta$ -dependent responses. The

extracellular domain of ALK1 contains 10 conserved cysteine residues and a potential N-linked glycosylation site. ECs possess a unique TGF- $\beta$  signaling mechanism, which involves an intricate interplay between ALK1, ALK5, and endoglin. These three receptors are important modulators of the TGF- $\beta$ -dependent fine tuning of the activation state of the vascular endothelium (2,55).

### TGF- $\beta$ SIGNALING IN ENDOTHELIAL CELLS AND ITS ROLE IN ANGIOGENESIS

Overall, TGF- $\beta$  is involved in numerous cellular processes including proliferation, differentiation, apoptosis, adhesion, migration, and extracellular matrix deposition in various cell types (see Chapter 35) (56). Compelling evidence from gene ablation studies of TGF- $\beta$ , its receptors, and downstream targets indicate a crucial role for TGF- $\beta$ -mediated responses in cardiovascular development and the maintenance of vascular integrity. The three isoforms – TGF- $\beta$ 1, - $\beta$ 2, and - $\beta$ 3 are expressed in mammalian cells in tissue-specific and developmentally regulated manners. Table 122.1 summarizes the phenotypes of the TGF- $\beta$ -null mice. In particular, TGF- $\beta$ 1 is expressed in endothelial, hematopoietic, and connective tissue cells, and its genetic ablation in mice causes embryonically lethal cardiovascular and hematopoietic defects (56). Some TGF- $\beta$ 1-null pups survive until weaning due to maternal TGF- $\beta$ 1 crossing the placenta during pregnancy and present in the milk; they then die of inflammatory disease (Figure 122.2) (57).

All three TGF- $\beta$  isoforms signal through a heteromeric complex consisting of type I and type II serine/threonine

Figure 122.2. TGF- $\beta$  signaling in ECs. Upon binding of the TGF- $\beta$  dimer to the type II receptor (T $\beta$ RII), the type I receptor is recruited and in turn signals through R-Smads. TGF- $\beta$  generally signals via ALK5 leading to the phosphorylation of Smad 2/3. However, vascular ECs possess a unique TGF- $\beta$  signaling mechanism whereby an additional type I receptor, ALK1, mediates TGF- $\beta$  effects by activation of the Smad 1/5 pathway. The presence of this additional TGF- $\beta$  signaling mechanism underscores the importance of fine tuning TGF- $\beta$ -dependent responses in the vascular endothelium and the essential role for ALK1 in EC function. Although the exact role of endoglin in TGF- $\beta$  pathways remains controversial, current evidence suggests that endoglin modulates TGF- $\beta$  responses in ECs via its interaction with the ALK5- and ALK1-containing receptor complexes and plays a critical role in maintaining a delicate balance between these receptors.

kinase receptors (Figure 122.2). Once the TGF- $\beta$  dimer binds to the type II receptor (T $\beta$ RII), the type I receptor is recruited and in turn signals through receptor Smads (R-Smads). TGF- $\beta$  generally signals via ALK5, leading to the phosphorylation of Smad 2/3. In ECs, an additional type I receptor, ALK1, mediates TGF- $\beta$  effects by activation of the Smad 1/5 pathway (6). However, ALK5 kinase activity and the T $\beta$ RII receptor are needed for optimal ALK1 activation (58). Therefore, ALK1 and ALK5 assemble into a heteromeric receptor complex with T $\beta$ RII, and signal via the Smad 1/5 pathway. Thus, ALK1 is not only restricted to ECs and mutated in HHT2, but also mediates a specific TGF- $\beta$  pathway that must be essential for EC function. Mice deficient in either ALK5, ALK1, T $\beta$ rII, Smad1, and Smad5 all show defective cardiovascular development, substantiating the critical

nature of these receptors and R-Smads in angiogenesis (see Table 122.1).

TGF- $\beta$  plays an important role in determining the properties of the endothelium during angiogenesis. During the activation phase, ECs degrade the perivascular membrane and invade and migrate into the extracellular space, where they proliferate and form a lumen. In the resolution phase, cells stop migrating and proliferating and reconstitute a basement membrane to complete the generation of a new vessel. It was proposed that TGF- $\beta$  signaling via the ALK1–Smad 1/5 pathway is essential for transition from the activation to the resolution phase of angiogenesis by repressing angiogenic factors and proteases and promoting recruitment of smooth muscle cells. Signaling via the ALK5–Smad 2/3 pathway induces secretion of proteases and would therefore promote the activation

phase (6). However, more recent data suggest a diverging model whereby the ALK1:ALK5 ratio determines whether TGF- $\beta$  induces activation (therefore proliferation and migration at a high ratio) or quiescence of the endothelium (at a low ratio) (66). The issue is still very controversial, and the simplest way to interpret current results is to conclude that TGF- $\beta$  regulates angiogenesis via a fine balance between ALK5 and ALK1 signaling.

Endoglin modulates TGF- $\beta$ 1 and TGF- $\beta$ 3 responses in ECs via its interaction with the ALK5- and ALK1-containing receptor complexes (50), and plays a critical role in maintaining the fine balance between these receptors (67). However, the exact function of endoglin in the TGF- $\beta$  pathway is also controversial. Lebrin and colleagues could not grow ECs from *Eng*-null embryos and have suggested that endoglin levels positively regulate growth through potentiation of TGF- $\beta$ /ALK1 signaling (67). Blanco and colleagues also showed that endoglin stimulates ALK1 and interferes with ALK5 signaling (68). Our most recent data indicate that ECs derived from *Eng*-null embryos proliferate faster than do normal cells, are more responsive to growth inhibition by TGF- $\beta$ 1, have a normal ALK5, and an activated ALK1 pathway (69). This would imply that endoglin is not required for TGF- $\beta$ -dependent activation of Smad1 per se, and we suggest that endoglin controls the levels of cell surface receptors and their binding characteristics. Future studies are needed to elucidate how endoglin might regulate TGF- $\beta$  receptor expression and contribute to angiogenesis.

## MURINE MODELS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA

A haploinsufficiency model for HHT implies that a mutation in a single allele results in loss of function, and that *Eng* or *Alk1* heterozygous mice should develop the disease. Indeed, these heterozygous mice show signs of HHT (4,70,71), and recent studies have revealed alterations in vascular homeostasis and hemodynamic properties in the adult mice (51,72).

Strong evidence in favor of a role for endoglin and ALK1 in angiogenesis and vascular development comes from gene knockout studies in mice. *Eng*<sup>-/-</sup> mice die at midgestation from failure to form mature blood vessels in the yolk sac (3–5,73) and the embryo proper as do mice deficient in ALK1 (6,61) and T $\beta$ RII (61) (see Table 122.1). *Eng*-null mice display severe cardiac defects, such as impaired endocardial-mesenchymal transformation, valve formation, and heart septation indicating the involvement of endoglin in cardiac development. *Alk1*-null mice also die at midgestation, and show dilated vessels and structures resembling AVMs (6,62). The angiogenic defect has been ascribed at least in part to decreased vascular smooth muscle cell differentiation and migration in both *Eng*- and *Alk1*-null mice (3,6). However, we believe that the defect originates in the endothelium. A recent study demonstrated that the *Eng*-null yolk sac endothelium secretes less TGF- $\beta$ 1, leading to impaired Smad2-dependent responses

needed for differentiation and migration of the smooth muscle cells (73). Despite the evidence provided by the knockout models of the importance of endoglin and ALK1 in vessel development and maturation, these studies are not informative in terms of HHT pathogenesis, which is associated with the heterozygous condition. For example, arteries from *Eng*<sup>+/-</sup> mice display normal smooth muscle contractile function suggesting that a reduction in smooth muscle cell recruitment, as described in *Eng*<sup>-/-</sup> mice, is unlikely to occur.

### *Eng*<sup>+/-</sup> or HHT1 Mouse

*Eng*<sup>+/-</sup> mice were first generated on the 129/Ola background strain and spontaneously developed signs of HHT such as nosebleeds, telangiectases, dilated thin-walled vessels, and AVMs, with their associated complications (4,74). Moreover, similar to the heterogeneity in clinical manifestations observed in patients with *ENG* mutations, HHT-type lesions are also highly variable between *Eng*<sup>+/-</sup> mice. However, later onset and reduced severity of disease have been demonstrated in *Eng*<sup>+/-</sup> mice with a C57BL/6 background, compared with those with a 129/Ola background. Intercrosses between these two genetic backgrounds have revealed intermediate disease severity, suggesting that both modifier genes and epigenetic factors contribute to disease heterogeneity (74).

To study the contribution of endoglin in the absence of confounding effects due to modifier genes and disease progression, we have focused on the C57BL/6 strain. We recently demonstrated that *Eng*<sup>+/-</sup> C57BL/6 mice display an endothelium-dependent abnormality in arterial vasomotor function, revealed in response to experimentally induced elevations in intravascular pressure (51). Resistance arteries have a reduced myogenic response or ability to contract in response to rises in perfusion pressure and may fail to limit the transmission of excessive hemodynamic stress to downstream more fragile vascular structures. This finding indicates that *Eng* haploinsufficiency is a predisposing factor, and that epigenetic or environmental triggers resulting in specific alterations in endothelial regulation of local blood flow and tone may be required to initiate clinical manifestations of HHT.

### *Alk1*<sup>+/-</sup> or HHT2 Mouse

As seen in HHT2 patients, *Alk1*<sup>+/-</sup> mice also display age-dependent vascular lesions in the skin, oral cavity, and several internal organs (71). Interestingly, some mice have a grossly enlarged liver and high cardiac output indicative of a hyperdynamic condition from a hepatic arteriovenous shunt, usually leading to increased pulmonary pressure and/or heart failure. Unfortunately, vasomotor studies, similar to those done on *Eng*<sup>+/-</sup> mice (51), have not yet been performed on *Alk1*<sup>+/-</sup> mice. Future corroboration of similar vasomotor findings in *Alk1*<sup>+/-</sup> mice would not only confirm the importance of early vasoregulatory alterations in HHT pathogenesis, but would also provide new insight into novel mechanisms involved in

the regulation of vascular tone by endoglin, ALK1, and their associated signaling partners.

### MECHANISMS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA PATHOGENESIS

HHT is a focal disease predominantly affecting the microvasculature of specific organs including the lungs, brain, liver, and skin. This can be explained by a model of pathogenesis that postulates that individuals harboring *ENG* or *Alk1* mutations have an intrinsic defect in their vascular endothelium that predisposes them to the development of vascular lesions, given the proper environmental trigger, such as sudden changes in perfusion pressure.

At first glance, the analysis of lesion development in HHT patients suggests that vascular malformations originate

from inherently abnormal and/or dysfunctional postcapillary venules. However, the presence of stress fibers in pericytes in early postcapillary venular dilatations and excessive, uneven layers of smooth muscle cells in fully developed telangiectases and AVMs are suggestive of hemodynamic stress-induced venular remodeling. Such observations, along with our finding of impaired arterial regulation of local vascular tone in *Eng*<sup>+/-</sup> mice, suggest an alternative model of HHT pathogenesis that is more compatible with our current understanding of vascular physiology.

The autoregulation of local blood flow and pressure is inherent to resistance vessels. The arterial myogenic response maintains constant tissue blood flow despite potentially wide fluctuations in perfusion pressure, and thus preserves the structural integrity of the microcirculation (74). The demonstration by Toporsian and colleagues that *Eng*<sup>+/-</sup> (HHT1) resistance arteries have an endothelium-dependent

Figure 122.3. Model of HHT1 pathogenesis. A pool of endoglin resides in caveolae, where it stabilizes eNOS and acts as a molecular scaffold to bring eNOS and HSP90 in close proximity to one another, facilitating their association during EC activation. Reduced eNOS/HSP90 association in HHT1 leads to increased eNOS-derived  $O_2^{\bullet -}$  and the formation of  $H_2O_2$  (via superoxide dismutase, SOD) and  $ONOO^-$ , which hyperpolarize smooth muscle and impair vascular contractions. Under such circumstances, resistance arteries do not adequately contract in response to sudden rises in intraluminal pressure and would thus fail to limit the transmission of excessive and potentially damaging hydrostatic pressures to downstream structures. This could contribute to the genesis of early HHT1-type vascular lesions such as capillary loss and venular dilatations. Compounds such as  $O_2^{\bullet -}$  or  $ONOO^-$  can oxidize the essential NOS cofactor, tetrahydrobiopterin ( $BH_4$ ), to dihydrobiopterin ( $BH_2$ ), further uncoupling eNOS in HHT1. The preferential release of NO from S-nitroso-hemoglobin (SNO-Hb) in the microvasculature would also favor the local production of  $ONOO^-$  and may explain the focal nature of HHT1. (Adapted with permission from Toporsian M, Gros R, Kabir MG, et al. A role for endoglin in coupling eNOS activity and regulating vascular tone revealed in hereditary hemorrhagic telangiectasia. *Circ Res.* 2005;96:684–692.)

impairment in their ability to contract in response to elevations in intravascular pressure suggests that previous reports of capillary loss and abnormal venular dilatations may indeed be consequences of a preceding functional inability of upstream resistance arteries to protect downstream, more fragile vascular structures from potentially damaging hemodynamic stress (50). The reported venular remodeling in HHT lesions is therefore probably a consequence of alterations in blood flow patterns and exposure to elevated perfusion pressures transmitted by functionally compromised upstream arterioles. This new model of HHT pathogenesis suggests that sudden increases in perfusion pressure would not be well tolerated in patients, providing a possible explanation for the frequent nosebleeds associated with the disease. It also predicts that further impairment of a compromised vasoregulatory mechanism by additional stresses such as hypoxia and inflammation will contribute to disease manifestations. We postulate that individual responsiveness to environmental stresses, related to specific polymorphisms (in putative modifier genes), may account in part for heterogeneity in age-related penetrance and clinical manifestations. The observed impairment in arterial myogenic responsiveness may lead to the generation of AVMs, as supported by a mathematical model of microcirculatory hemodynamics (76). Given the phenotypic similarities in vascular lesions observed in HHT1 and HHT2 patients, future studies demonstrating similar arterial vasomotor abnormalities in *Alk1*<sup>+/-</sup> mice would provide further support for this new model, which contends that endothelium-dependent alterations in the autoregulation of local blood flow and pressure may be the underlying mechanism of HHT pathogenesis. The predominant expression of ALK1 on arterial, compared to capillary and venular, ECs in adult mice would support this model (54).

#### HOW CAN ENDOGLIN AFFECT VASCULAR TONE?

The main factors involved in the minute-to-minute adjustments in vasomotor control are predominantly endothelium-derived and diffusible. They directly affect vascular smooth muscle contractility in response to sudden changes in neurohumoral and hemodynamic stimuli. If early events in the pathogenesis of HHT involve abnormal vasomotor function, endoglin (and potentially ALK1) may be critical in balancing the secretion of endothelium-derived vasoconstrictors and vasodilators, a central mechanism in the local regulation of blood flow and vascular tone. Indeed, *Eng*<sup>+/-</sup> mice display an eNOS-dependent impairment in arterial vasoreactivity, despite reduced levels of this enzyme (51). eNOS activity appears to be uncoupled in *Eng*-null cells as evidenced by severely reduced eNOS/HSP90 association and increased eNOS-derived superoxide (O<sub>2</sub><sup>-</sup>). This suggests a potential scaffolding-like function for endoglin, in which its cytoplasmic tail brings HSP90 into close proximity with caveolar eNOS to ensure NO production. Furthermore, the vasomotor abnor-

malities in isolated mesenteric arteries are reversed by the use of antioxidants, indicating that the products of eNOS-derived O<sub>2</sub><sup>-</sup> lead to the generation of endothelium-derived hyperpolarizing factors that impair smooth muscle contractions and vasomotor tone (51). Recently, Blanco and colleagues have demonstrated that both the extracellular and cytoplasmic domains of endoglin interact with ALK1 (68) suggesting the possibility that eNOS also may be part of this complex. Given the similarities in disease phenotypes between HHT1 and HHT2, future demonstration of ALK1 associating with eNOS and modulating its activation would thereby identify a common biochemical pathway in both disease subtypes and lend support for a causal role of abnormal eNOS activation in the generation of vascular malformations. Figure 122.3 illustrates the association of endoglin with eNOS/HSP90 and the postulated mechanism of HHT1 pathogenesis.

#### KEY POINTS

- *ENG* and *ALK1* mutations are the underlying cause of HHT, a disorder characterized by venous dilations, focal loss of capillaries, and AVMs.
- Endoglin interacts with eNOS and modulates eNOS stability and activation, contributing to the local regulation of vascular tone.
- Early events in HHT pathogenesis may be due to abnormal vasomotor tone, subsequent to the uncoupling of eNOS activity and generation of superoxide.
- Antioxidant therapy may prevent or delay the development of vascular lesions in patients with HHT1.

#### Future Goals

- To define the protein interaction networks associated with endoglin, ALK1, and eNOS to elucidate the pathways critical for normal endothelial function and those defective in HHT and related disorders

## Blood–Brain Barrier

Christian Weidenfeller and Eric V. Shusta

*University of Wisconsin-Madison*

The vascular endothelial cells (ECs) that separate the bloodstream from the brain interior are so impermeable that the brain vasculature is often referred to as the blood–brain barrier (BBB). As a result of its barrier properties, the BBB plays an extremely important role in central nervous system (CNS) homeostasis by protecting neurons from fluctuations in blood composition and from toxic blood-borne substances. Except for small regions of the brain, the barrier properties are found throughout the entire brain and include capillaries, arterioles, and venules as well as larger arteries and veins. As the vessels advance from the meningeal membranes that envelop the brain and into the brain matter, vascular permeability decreases rapidly and barrier-like impermeability arises. Although the BBB permeability for many substances is highly restricted, a multiplicity of molecular transport systems exist to provide the brain with necessary nutrients. The same barrier function that is critical for normal brain function also provides a formidable hurdle for delivery of therapeutics to the brain under conditions of neurological disease.

Although the endothelium provides the barrier properties of the BBB, it is the local brain microenvironment that elicits the unique phenotype. Vascular smooth muscle cells line precapillary arterioles, pericytes share a basement membrane with capillary ECs, astrocytes ensheath the microvessels, and nerve terminals contact the endothelium. Together with the endothelium, these perivascular cell types constitute the so-called *neurovascular unit*. In this chapter, we review the microenvironmental cues that function in BBB maintenance, describe the BBB phenotype in detail, and highlight the role for the BBB in brain diseases such as stroke, multiple sclerosis (MS), and cerebral malaria. Finally, we outline the limitations that the BBB imposes on drug delivery, and introduce strategies that promise to bridge the bench-to-bedside gap for those suffering with debilitating neurological diseases.

### DEVELOPMENT OF THE BLOOD–BRAIN BARRIER CONCEPT

The concept of a barrier system existing in the brain arose during the late 19th century. Bacteriologist Paul Ehrlich observed

that certain aniline dyes, when administered intravenously to small animals, stained all organs except the brain. Ehrlich's interpretation of this observation was that the brain had a lower affinity for the injected dyes. A few years later, Roux and Borrel observed that tetanus toxin injected into cerebrospinal fluid (CSF) caused marked cerebral symptoms, but when administered intravenously produced no discernible cerebral effect. In 1913, Goldman injected the dye trypan blue directly into the CSF of rabbits and dogs and found that the dye readily stained the whole brain but did not enter the bloodstream and thus did not stain other organs. In this way, Goldman again showed that the CNS was separated from the blood by a barrier of some kind (1,2). The correlated findings of these investigators were attributed to special permeability properties of small brain blood vessels. However, the hypothesis that brain endothelium provides the anatomical basis of the observed barrier was not confirmed until the advent of electron microscopy allowed the high-resolution analysis of brain ultrastructure.

Using electron microscopy, Brightman and Reese demonstrated that electron-dense junctions were present between adjacent brain ECs (3). The existence of such tight junctions was used to explain the absence of horseradish peroxidase or microperoxidase in the brain after intravenous injection. The barrier to these molecules was observed regardless of vessel size or association with smooth muscle, confirming the presence of a barrier throughout the entire brain (4).

### BLOOD–BRAIN BARRIER MORPHOLOGY AND ROLE OF THE MICROENVIRONMENT

When the endothelium in the brain is compared with non-brain endothelium, its general lack of permeability stands out as unique. This BBB-defining characteristic is a consequence of the local brain microenvironment. During brain development, newly formed vessels derive from the perineural plexus by angiogenesis. Thus, vessels in the brain are not formed by brain-specific precursors, but develop their BBB properties only after induction by the neural microenvironment (5).

Cross-talk between the ECs and the perivascular brain tissue is therefore essential for the development and maintenance of BBB properties. As further evidence for the role of the microenvironment, when neural tissue was grafted to peripheral sites, vessels invading the neural graft developed BBB properties (6,7). Conversely, when brain vessels invaded peripheral tissue that had been grafted into the brain, no barrier characteristics were observed (7). It is important to recognize that the cross-talk between ECs and perivascular cells is bidirectional. However, for purposes of this discussion, we focus primarily on the flow of information from the microenvironment to the endothelium.

## Endothelium

ECs of the brain microvasculature have a different phenotype compared with nonbrain ECs. They are thin, measuring a mere 100 to 300 nm between luminal and abluminal compartments, and are connected by tight interendothelial junctions. Further distinguishing features of cerebral microvascular ECs include the paucity of pinocytotic activity (clathrin-mediated or caveolae-mediated) (3,8,9), high number of mitochondria (10), and the absence of fenestrations (11). The presence of tight junctions and the absence of fenestrae in brain ECs yields a high transendothelial electrical resistance (TEER) as a result of a reduced paracellular flux of ions and small charged molecules *in vivo* (12). These capillary features are a direct result of the local brain microenvironment. A schematic of the brain capillary and its association with the neurovascular unit is shown in Figure 123.1. The capillary lumen is lined by ECs that are connected with tight junctions at the sites of intercellular clefts. These junctions seal the clefts against even the smallest molecules and convert the EC layer into a closed interface that physically separates the blood from the brain

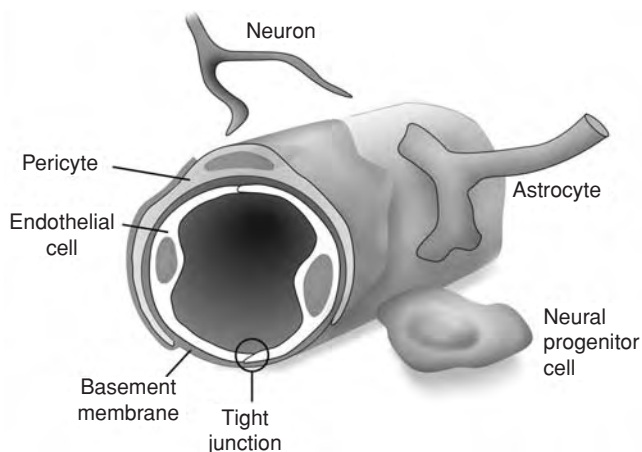

Figure 123.1. Schematic of a brain microvessel cross-section. The cellular composite forms the neurovascular unit. Note the intimate interaction between ECs and pericytes that share a basement membrane. In addition, astrocytes and neurons contact the microvessel surface. Tight junctions form between adjacent ECs. Neural stem or progenitor cells also are found in the proximity of brain microvessels.

interstitium. The phenotype of BBB endothelium is described in more detail below.

## Extracellular Matrix

The abluminal side of the BBB endothelium is surrounded by a robust basement membrane that also encloses pericytes and is contacted intimately by astrocytes. This basement membrane consists of a well-characterized composite of extracellular matrix (ECM) molecules (13). The basement membrane is composed of the ECM molecules collagen, laminin, fibronectin, entactin, heparin sulfate proteoglycans, and chondroitin sulfate proteoglycans. Brain microvascular ECs have improved growth characteristics and are more representative of the *in vivo* situation in terms of permeability and other BBB properties when cells are plated on collagen (14–17), fibronectin (18–21), pronectin F (22), and/or ECM secreted by astrocytes (18). The interactions between all cells of the neurovascular unit and the ECM initiate information flow that helps regulate cell proliferation, differentiation, and polarization of ECs. The ECM also anchors a variety of molecules important in normal brain function such as integrins, growth factors, laminin, and other glycoproteins (23).

## Neurons

Early during embryonic development, neurons are in close contact with developing blood vessels. Although neurons appear early on in the developing brain, astrocytes encase vessels with their end-feet only later in postnatal development (24,25). It also has been observed that neuronal processes directly contact the basement membranes of ECs in the adult brain (26,27). *In vitro* studies provide evidence for neuronal involvement in BBB induction. Neurons influence endothelial occludin expression and sorting (28), induce biochemical activity in the form of  $\gamma$ -glutamyl transpeptidase (GTP) enzymatic activity that functions in mediating glucose uptake (29) and catabolism of  $\gamma$ -glutamyl compounds (30), and increase  $\text{Na}^+/\text{K}^+$  ATPase activity (31). In addition, when cocultured with astrocytes and neurons, ECs were shown to support a serotonergic phenotype in the neurons (32).

## Astrocytes

Astrocytes are one type of glial cell found in the brain whose foot processes encase most of the BBB endothelial surface *in vivo*. Many studies have shown that astrocytes are strong inducers of BBB properties both *in vivo* and *in vitro*. Grafts of astrocytes can induce BBB-like properties in peripheral endothelium (33). In addition, when astrocytes that were positive for the intermediate filament glial fibrillary acidic protein (GFAP) are selectively ablated at the site of invasive CNS injury, the BBB remains impaired and permeable. This effect can be countered by grafting normal astrocytes that foster the repair and restoration of BBB impermeability at the injury site (34). Transgenic mice with astrocytes deficient in GFAP have an

impaired BBB (35), and the GFAP-negative astrocytes are unable to induce a functional BBB in vitro, compared with normal astrocytes (36). Based on these data and the fact that GFAP is upregulated after brain injury, it has been speculated that GFAP may be an important factor for BBB induction, repair, and restoration.

Culturing with astrocyte-conditioned medium (37), astrocyte plasma membranes (31), or astrocytes either in direct contact on opposite sides of a permeable filter (15,38–40) or in indirect contact through a diffusion apparatus (37,41) is critical for the permeability, morphological, and biochemical characteristics of in vitro BBB models. Several transport systems are upregulated in brain endothelial models exposed to glial influence. Upregulation has been documented for the glucose transporter (GLUT)-1, the L- and A-amino acid carrier systems, and P-glycoprotein (25). Astrocyte influences can also induce  $\gamma$ -GTP (39,40,42) and alkaline phosphatase activities (38,43), stimulate growth and glucose utilization (22), and influence the polarity of P-glycoprotein (44). In addition, astrocytes increase the electrical resistance of EC monolayers (39,45), increase the level of peripheral versus distributed actin (19,37), contribute to the complexity and extent of tight junction morphology in vitro (38), and decrease the passive diffusion of impermeable molecules.

### Pericytes

Pericytes are perivascular cells associated with capillaries and postcapillary venules. They are embedded in the basement membrane of the vessels and extend long cytoplasmic processes around the capillary tubes, forming so-called *peg and socket* contacts (46). Pericyte coverage of microvessels varies among vascular beds, and it has been estimated that pericytes invest 22% to 32% of rat brain microvessel surfaces (47). Three major functional roles have been ascribed to pericytes associated with CNS microvasculature. They include contractility, regulation of EC activity, and a role in inflammation. In brain and retina, the adhesive glycoprotein fibronectin has been observed at junctional sites between pericytes and ECs adjacent to adhesion plaques at the pericyte's plasma membrane (48), suggesting a mechanical linkage between the two cells. Two frequently used endothelial markers, angiopoietin and  $\gamma$ -GTP, are also present in pericytes. The presence of  $\gamma$ -GTP in brain pericytes supports the idea that, in addition to ECs, pericytes are important for BBB function (49,50). In vitro experiments using pericytes cocultured with ECs and astrocytes indicated that pericytes may be involved in capillary formation, but only when in the presence of astrocytes (51). Furthermore, pericytes have been shown to exhibit phagocytotic activity and to express macrophage markers, suggesting that pericytes are involved in the immune response at the BBB (52).

### Neural Stem Cells

Yet another cell type within the brain is the neural stem cell (NSC). These cells give rise to neurons, astrocytes, and

oligodendrocytes, and can be found in both the developing and adult brains (53). The regulation of NSC differentiation has not yet been completely clarified, but contact with blood vessels during development may influence their fate towards astrocytic differentiation (24), and therefore NSCs might be important for induction of BBB properties in ECs. In addition, ECs in coculture with NSCs can enhance neuronal differentiation and affect rates of self-renewal (54). Also in adult brain, NSCs are found in close apposition to the vasculature in the so-called *neural stem cell niches* of the hippocampus and subventricular zone (55). Research regarding the interactions between NSCs and ECs is in its nascent stage, but preliminary findings suggest an exciting role for the brain vasculature in the regulation of NSCs, and hence, in the regulation of brain development and repair.

### Soluble Mediators

The BBB phenotype is clearly derived from physical interactions with the underlying matrix and perivascular cells; however, ECs also are responsive to soluble mediators released by the perivascular cells. Unfortunately, the identity of these components is largely unknown. A protein released from astrocytes that has been definitively implicated in the development of barrier function is glial cell line-derived neurotrophic factor (GDNF) (56). Expression of src-suppressed C-kinase substrate (SSeCKS) in astrocytes triggers angiopoietin-1 secretion that can mediate an endothelial barrier tightening in vitro, and SSeCKS positive astrocytes can be found closely interacting with brain microvessels in vivo (57). Also, the use of forskolin to elevate cellular cyclic adenosine monophosphate (cAMP) levels increases the tight junctional complexity and P-face association of the tight junction particles (58). Direct supplementation of cAMP has also been shown to increase barrier function (37) and alkaline phosphatase expression (43). Finally, when hydrocortisone is added to EC cultures, the transendothelial electrical resistance increases dramatically, and permeability to sucrose is reduced to near in vivo levels (59). Taken together, studies have shown that an intact microenvironment is essential for the proper function of the BBB. Thus, to fully understand regulation at the blood–brain interface, it is absolutely necessary to unscramble the cross-talk present between elements of the neurovascular unit.

### BLOOD–BRAIN BARRIER FUNCTION

Generally speaking, the BBB performs three major functions. First, the BBB protects the brain from the blood milieu by virtue of its tight junctions. Although ions, small molecules, peptides, and proteins can pass relatively unrestricted through the endothelial lining in other vascular beds, the brain vasculature lacks fenestrae and has epithelial-like tight junctions. These tight junctions help restrict the uncontrolled passage of hydrophilic substances from the blood to the brain interstitium. In addition, the BBB displays only low levels

of pinocytotic transport, which together with tight junctions help maintain brain homeostasis. Second, the BBB acts as a transport/metabolic barrier that removes metabolites and toxic substances from the brain, and also provides the brain with necessary nutrients. For this reason, BBB ECs contain a multiplicity of transport proteins that regulate the bidirectional transport of nutrients and metabolites into and out of the brain. In addition, efflux transporters remove potentially harmful compounds that enter the ECs due to their high lipophilicity. These transporters are also known as *multidrug resistance proteins*, because during disease conditions, they can dramatically lessen the brain uptake and effectiveness of drug treatments. Finally, the BBB acts as a signalling interface that functions in developmental and immune responses, among others. The origins and implications of the first two functional attributes are discussed in detail in the following sections. The role of the BBB in innate immunity is covered elsewhere in this volume (Chapter 124).

## Physical Barrier

### *Molecular Architecture of Brain Endothelial Cell Junctions*

A striking structural feature of the BBB is the tight junctional complex that provides the molecular basis for the permeability barrier. Tight junctions form a continuous belt around the ECs and seal the paracellular space (4). In electron micrographs of freeze fracture replicas of the plasma membrane, the tight junctions appear as a network of small ridges on one side of the membrane bilayer and complementary grooves on the opposite side of the bilayer (60,61). The molecular structure of the tight junctions has not been completely elucidated, but there is unequivocal evidence for both lipid and protein contributions.

The barrier phenotype is present throughout the entire brain vasculature except in small regions, known as *circumventricular organs*, that are perfused by capillaries without BBB properties and participate in neuroendocrine regulation. In a developing rodent, the brain vasculature is fenestrated until embryonic days (E)11 to E13, during which time tight junctions develop, as the fenestrations typical of peripheral capillaries disappear (62,63). During late embryonic and early postnatal development, the density of tight junction strands increases as maturation continues towards the impermeable adult BBB (64). This process restricts access to substances that normally diffuse freely into a developing embryonic brain.

The tight junctions found in brain capillaries are composed of both integral membrane proteins that link adjacent cells and peripheral membrane proteins that link the junctions to the cytoskeleton. An analysis of liver plasma membrane protein extracts led to the identification of the first transmembrane tight junction component, occludin (65). Occludin is an integral membrane protein with four transmembrane domains and two extracellular hydrophobic loops that mediate cell–cell connections. The cytoplasmic domain of occludin is highly phosphorylated when located in tight junctions (66),

and this phosphorylation can regulate tight junctional permeability (67). Although the exact role of tight junction occludin has not been fully determined, existing data support a regulatory role rather than a barrier-establishing role (68). Interestingly, an occludin-deficient mouse showed no alteration in tight junction integrity, indicating that occludin has either no direct barrier function or its function is redundant and can be replaced by other tight junction components (69). The claudins make up another family of transmembrane proteins located at the tight junctional complex. In contrast to occludin, the claudins appear to play the major role in forming the seal that restricts paracellular transport. At least 24 isoforms of claudins exist, and this broad class confers junctional specificity to different cell types (70,71). Claudin-1 (72), -3 (73), -5 (73–75), and -12 (76) have been identified at the BBB. In contrast to the occludin-deficient mouse, a *claudin-5*-knockout results in an altered tight junction phenotype and increased permeability to small molecules to the brain (76). Junctional adhesion molecule (JAM) is a member of the immunoglobulin superfamily, and is also colocalized at the tight junctional complex (77). JAMs are most likely involved in occludin recruitment and tight junction assembly (78), and they have the ability to increase transcellular resistance in cells not normally forming tight junctions (77,79). The JAM proteins also are involved in the extravasation of monocytes and leukocytes *in vitro* and *in vivo* (77,80,81).

The tight junctions are linked to the cytoskeleton by a variety of accessory proteins in the cytoplasmic compartment. Important for anchoring the transmembrane proteins to the cytoskeleton are protein members of the membrane-associated guanylate kinases (MAGUKs) known as zonula occludens (ZO)-1, -2, and -3. The ZO-1 protein may act as a molecular linker bringing together claudins, ZO-2, ZO-3, cingulin, and actin (82–84). In addition to their structural functions, the MAGUKs act as binding scaffolds for signalling proteins. 7H6 antigen also is located at tight junctions and confers resistance to paracellular transport of macromolecules and metastatic cancer cells (85). The formation and maintenance of tight junctions are regulated by a variety of signaling cascades (86), indicating that tight junctions can respond to various stimuli and pathological conditions (see the section Blood–Brain Barrier Involvement in Disease).

Another important junctional component of brain ECs are the adherens junctions, which, like tight junctions, are linked to the cytoskeleton. The adherens junctions are localized to the basolateral side of the tight junctional complex and form a belt-like structure similar to that seen with the tight junctions. The major components of adherens junctions are vascular endothelial (VE)-cadherin, catenins, plakoglobin, vinculin, and  $\alpha$ -actinin (87). VE-cadherin is a single-transmembrane domain protein that belongs to the cell adhesion molecule superfamily, and it has been reported as being part of the adherens junctions in microvascular ECs (88,89). In epithelial cells, cadherins play a role in the formation and maintenance of the tight junctions and act as an inducer of cell polarity (90,91). Adherens junctions also form connections with the

Figure 123.2. Molecular transport at the BBB. 1, receptor-mediated endocytosis/transcytosis (e.g., transferrin, insulin); 2, transcellular diffusion (e.g., oxygen, small lipophilic compounds); 3, ion channel; 4, carrier-mediated transport (e.g., GLUT1, LAT1); 5, active efflux (e.g., P-glycoprotein, MRP). For a comprehensive summary of BBB transport systems, see Zhang W, Stanimirovic DB. The transport systems of the blood–brain barrier. In: de Vries HE, ed. *The Blood–Brain Barrier and Its Microenvironment*. New York: Taylor & Francis; 2005:103–142.

ECM and play a role in signaling via the basement membrane. Therefore, the physical barrier formed by tight and adherens junctions also can function to regulate the BBB interface.

## Transport/Metabolic Barrier

### *Molecular Transport Mechanisms at the Blood–Brain Barrier*

Because the paracellular permeation of hydrophilic substances is limited by the tight junctions, a transported molecule must travel serially through both the luminal and abluminal membranes (Figure 123.2). Therefore, brain blood vessels must have additional transporter systems to meet the high energy demands of the brain. Indeed, the BBB acts as a selective barrier that modulates the influx and efflux of substances through a highly regulated composite of transport systems. A sampling of these is outlined here.

Carrier-mediated transport mediates the trans-BBB flux of small molecule energy sources, vitamins, and nutrients such as hexoses, monocarboxylic acids, amino acids, amines, and nucleosides (92,93). These carriers are highly stereospecific channels found on both endothelial membranes that mediate trans-BBB transport via the endothelial cytoplasm (see Figure 123.2). The two carrier-mediated transporters supporting the highest rate of facilitated saturable transport are the glucose (GLUT1) (94,95) and monocarboxylic acid (monocarboxylate transporter [MCT] -1) transporters (96–98). GLUT1 expression is mainly associated with the microvasculature in the brain (99,100). It is distributed asymmetrically at the BBB with an approximately threefold higher expression level on the abluminal plasma membrane compared with the luminal membrane. Its expression level is similar in the cortex, hip-

pocampus, and cerebellum, while it is significantly lower in the olfactory bulb (101). Like GLUT1, MCT1 is expressed at both the luminal and the abluminal plasma membranes. It is crucial for the transport of lactic acid and ketone bodies to the developing brain (97). Bidirectional transport studies in vitro demonstrated that MCT1 can mediate both the uptake and efflux of monocarboxylic acids (102). To supply appropriate amounts of nutrients to the brain, some transporters not only are expressed at higher levels, but also exist as isoforms that exhibit higher affinity for their substrates. For example, the large amino acid transporter type (LAT)-1 is expressed at higher levels at the BBB than in any other tissue (103), and it has a much higher substrate affinity compared to neutral amino acid carriers localized in either the endothelium or resident cells of other tissues (104). Transport of choline as well as other molecules having quaternary ammonium groups occurs at the BBB (105). Adenosine, vitamins, and small neutral and acidic amino acid transport also have been observed at the BBB.

Receptor-mediated endocytosis also is prevalent at the BBB interface. Because nonspecific uptake of bloodstream components is limited by the lack of pinocytosis, the microvascular endothelium is equipped with receptors that mediate the selective uptake and trans-BBB transport of circulating peptides and proteins. After binding to the receptor on the luminal side of the BBB, the ligand is endocytosed and transported via the vesicular trafficking system to the abluminal side of the BBB, where the vesicle fuses with the plasma membrane and releases its cargo (see Figure 123.2). Several so-called receptor-mediated transcytosis systems have been identified in the brain microvasculature. The BBB insulin receptor has been shown to mediate the brain uptake of insulin, and results in measurable

brain insulin concentrations (106). Iron is essential for all cell types and is carried in plasma and interstitial fluids by transferrin. To mediate the transport of iron-containing transferrin across the BBB, brain ECs express transferrin receptors that allow the coupled entry of iron into the brain (107,108). Leptin (109) and low-density lipoprotein (LDL) (39,110) also have been demonstrated to transport across the BBB. Ion transport and astrocyte-regulated aquaporin-based transport of water are important in maintaining homeostasis of the brain environment and have been reviewed elsewhere (111–113).

### *Metabolic Transformation*

The combination of impermeable barriers and selective transport mechanisms is not the only means whereby the BBB helps protect the brain from uncontrolled chemical fluctuations within the interstitial fluid. Compounds that enter the ECs due to either their lipophilic nature or their affinity to a molecular transporter can be converted by metabolic processes into chemical compounds incapable of traversing the abluminal membrane. For example, L-dopa is carried into the cytoplasm of the EC by the LAT1 transporter (114), and uncontrolled passage across the abluminal membrane would be undesirable, because this compound is a precursor for dopamine. Once in the EC cytoplasm, these substances are enzymatically converted to dopamine and dihydroxyphenylacetic acid and are thus sequestered in the EC. This phenomenon is found for a broad array of compounds and is referred to as the *metabolic BBB*. Clearly the metabolic barrier must be considered when devising a brain treatment strategy, for example the use of L-dopa for Parkinson disease (115–117).

### *Multidrug Resistance at the Blood–Brain Barrier*

As stated earlier, one of the main functions of the BBB is the protection of the brain from potentially harmful endogenous and exogenous compounds. The tight junctions seal the paracellular cleft against many solutes, but lipophilic substances can enter the cells via plasma membrane diffusion. Once in the cytoplasm, these substances can be rapidly effluxed by carrier-mediated efflux transporters. Members of the ATP-binding cassette (ABC) superfamily play an important role at the BBB. In particular, P-glycoprotein (also known as *multidrug resistance* [MDR]-1) and the multidrug-resistance associated proteins (MRP) have been demonstrated to be BBB components. P-glycoprotein was first identified in cancer cells (118), but also is expressed by normal cells in intestine, liver, and brain (119). P-glycoprotein is predominantly localized to the luminal membranes of BBB ECs and is responsible for the efflux of small-molecule substrates and therapeutics (120) from the ECs cytoplasm back into the blood vessel lumen (121). Various transporters in the MRP family have been shown to be expressed in brain endothelium on both the luminal and abluminal membranes (122,123), although the levels and species specificity are somewhat in question at this time (121). Recently, a novel brain multidrug resistance protein (BMDP) that is only distantly related to P-glycoprotein, but has high

amino acid sequence similarity to the human breast cancer resistance protein (BCRP), was identified at the BBB (124).

Current genomics efforts indicate that transporters comprise between 10% to 15% of the expressed genome of the BBB (75,125,126), while transporter genes are only estimated to appear at a frequency of 3% to 5% in the human genome (127). Due to this impressive variety of transporters expressed at the BBB, a large amount of work remains to fully characterize this specialized transport interface.

## **BLOOD–BRAIN BARRIER VERSUS OTHER VASCULAR BARRIER SYSTEMS**

Although the BBB is referred to as a unique vascular bed throughout this chapter, it is important to acknowledge that other endothelial barriers exist in the body. The blood–retinal barrier of the vascularized inner retina of the eye has many properties similar to that of the BBB, but permeability is higher (128). A peripheral blood–nerve barrier exists, although it is substantially more permeable than the BBB (129). The blood–testes barrier is endowed with impermeability characteristics by the Sertoli cells that surround a comparatively permeable endothelium. Finally, the blood–CSF barrier of the brain is clearly distinct from the BBB in both its barrier and transport characteristics. It is found at the site of the choroid plexus, and it is comprised of tightly apposed epithelial cells rather than ECs (130). Continued research focusing on these vascular and epithelial barriers promises to provide additional comparisons with the structure and function of the BBB.

## **BLOOD–BRAIN BARRIER INVOLVEMENT IN DISEASE**

The BBB interface has been implicated in a number of diseases. This section highlights its involvement in a selected subset of these diseases from the perspective of barrier and immune function.

### **Human Immunodeficiency Virus**

The BBB can be the target of viral, fungal, and bacterial infections. As an example, the human immunodeficiency virus (HIV) can cause neural disorders such as HIV encephalitis or acquired immunodeficiency syndrome (AIDS) dementia complex (131). Vascular changes have been noted in the brains of AIDS patients in the form of increased diameter of the cortical microvessels and thinning of the basal lamina of the blood vessels (132). In addition, HIV has been found to infect brain ECs both in vivo (133,134) and in vitro (135,136). The virus can enter the brain through the migration of infected monocytes and lymphocytes across the BBB (137–139) or the blood–CSF barrier (139,140), but evidence also suggests that the transendothelial passage of free HIV virus via adsorptive

endocytosis can occur (138). Regardless of the mode of entry, HIV encephalitis and AIDS dementia correlate with the presence of monocyte infiltration and subsequent microglial activation (131).

HIV-infected monocytes elicit an inflammatory response and stimulate adhesion properties of the BBB through the release of cytokines and inflammatory mediators such as tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , and interferon (IFN)- $\gamma$  (141–143). In vitro studies demonstrated that EC adhesion molecules E-selectin and vascular cell adhesion molecule (VCAM)-1 can then be upregulated to support the binding and migration of HIV-infected monocytes across the BBB and into the brain (138,144). The basement membrane is also a target of HIV proteins, because the transmigration process requires degradation of the basement membrane, and HIV proteins stimulate matrix metalloproteinase (MMP)-2 secretion (145). Expression of the tight junction proteins occludin and ZO-1 is decreased upon increased monocyte infiltration in AIDS patients (146,147). Based on these mechanistic observations described, the BBB appears to be intimately involved in the pathogenesis of AIDS in the central nervous system.

### Cerebral Malaria

Cerebral malaria is an example of parasitic invasion of the brain. Cerebral malaria is caused by infection with *Plasmodium* parasites, with *Plasmodium falciparum* being the most common and serious pathogen. Most infected people suffer a mild febrile illness, but infection also can lead to serious complications, including multiorgan failure. In cases of cerebral malaria, CNS symptoms such as coma, seizures, and increased intracranial pressure can occur. Cerebral malaria is the most serious malarial complication, leading to about 0.5 million deaths per year (148). For patients with cerebral malaria, brain microvessels contain significantly more parasitized red blood cells than do those in patients with noncerebral malaria (149). The first step in cerebral malaria is the interaction of parasitized erythrocytes with the microvasculature in the CNS. How exactly BBB-sequestered parasitized erythrocytes cause the neurological syndrome is not well understood, because the infected erythrocytes remain in the vascular lumen. Cerebral malaria in the animal model can be associated with a complete BBB breakdown (150), but in human pathology the BBB is not affected to this extent. Studies have shown that parasitized red blood cells attach to the endothelial plasma membrane, with the EC forming pseudopodia into the capillary lumen (149). There is also evidence for adhesion receptor-mediated events (151) such as binding of parasitized red blood cells to the endothelial receptor molecules CD36, intercellular adhesion molecule-1 (ICAM-1), and CD31 as well as to thrombospondin and chondroitin sulfate A. In addition, alteration in the distribution of the junction-associated proteins occludin, ZO-1, and vinculin suggests a mechanism for brain vessel permeability (152). For further details on cerebral malaria, the reader is referred to Chapter 142.

### Stroke

Stroke is the result of an injured or occluded vessel in the brain that leads to ischemic insult and edema formation. Hypoxia results in increased BBB permeability, leakage of plasma components across the BBB, and neuronal cell death, whereas reperfusion causes further damage in the affected regions because of increases in reactive oxygen species (153). Increased expression of the adhesion receptors E-selectin (154), P-selectin, and ICAM-1 may result in leukocyte recruitment to postcapillary microvessels (155). In addition, alteration of intracellular calcium concentrations and calcium-activated signaling pathways can trigger changes in junctional protein expression and distribution (156). When in vitro BBB models of rat brain ECs in coculture with astrocytes were subjected to hypoxic conditions, a 25% decrease in TEER after 4 hours of hypoxia and 95% decrease after 8 hours was observed (157). The presence of astrocytes reduced the decrease in TEER after a 4-hour hypoxic insult (157). Paracellular transport also was increased in bovine brain ECs following long duration hypoxia (24–48 hours), whether astrocytes were present (158,159). Tight junction occludin, ZO-1, and ZO-2 protein expression levels were unaltered but were relocated from cell junctions during hypoxia (159). Actin expression increases after reoxygenation and is accompanied by an increase in occludin, ZO-1, and ZO-2 protein expression and a coordinate decrease in the paracellular permeability. Finally, the basement membrane integrity is impaired in ischemic conditions (160) and may be due in part to metalloproteinase-based degradation (161). Stroke complications can be exacerbated by junctional rearrangement and breach of the BBB, and thus the BBB could prove to be an increasingly important target for therapeutic intervention.

### Multiple Sclerosis

MS is a chronic inflammatory disease of the CNS manifested by BBB disturbance, local edema, and demyelination (162). Magnetic resonance imaging with contrast enhancement has demonstrated that inflammatory damage to blood vessels occurs at an early stage in the pathogenesis of MS (163,164) with local perfusion changes occurring prior to BBB breakdown (165). Experimental autoimmune encephalomyelitis (EAE) is an animal model of demyelinating disease that possesses certain pathological and clinical features of human MS. This model has provided much of the molecular basis for our understanding of MS progression and is referred to frequently here. As in the pathogenesis of aforementioned diseases like cerebral malaria or AIDS, ICAM-1 (EAE and human MS) and VCAM-1 (human MS) are upregulated at BBB endothelial sites and correlate with disease activity (166,167). These alterations may be caused by proinflammatory cytokine release (IFN- $\gamma$ , TNF- $\alpha$ ) from activated immune cells that can lead to alterations in tight junction integrity and thus BBB impermeability. As an example of the changes in tight junction integrity, abnormal levels and distributions of ZO-1 and occludin have

been observed in the brains of MS patients (168). Claudin-3 is also selectively downregulated in BBB tight junctions near vascular lesions in a murine EAE model (73). Modulation of the BBB in EAE can lead to immune cell entry into the CNS, via the tight junction complex, channels or pores formed in the tight junction complex, or by emperipolesis (169). Recent genomics studies also have identified expression of myelin basic protein (MBP) at the BBB, and microvascular expression of MBP was confirmed by *in situ* hybridization (170,171). Taken together, these findings raise the possibility that the BBB may play an even more active role in MS pathogenesis than was previously anticipated by contributing to the T-cell recruitment process.

### Brain Tumors

Significant alteration of the vascular architecture occurs in high-grade gliomas and metastatic brain tumors, whereas the vascular environment in low-grade gliomas is similar to that found in nondiseased brain (172). Whereas normal brain capillaries have diameters around 5 microns, tumor capillaries are much larger on average (up to 40 microns). In addition, the larger tumor vessels are very tortuous and irregularly spaced, unlike the angioarchitecture observed in normal brain capillaries (173–175). Higher permeability and loss of BBB function is associated with changes in the tight junctions, presence of fenestrae, and increases in vesicular trafficking. For example, studies of human brain tumor tight junction composition indicated that claudin-1 expression was lost, whereas claudin-5 and occludin expression was downregulated in hyperplastic vessels. Meanwhile, ZO-1 expression was unaffected (176,177). The net effect on the integrity of the blood–tumor barrier can be demonstrated by studies that confirmed a higher level of leakage of serum components from tumor vessels (174,178). However, a leaky blood–tumor barrier is not a universal attribute of tumor tissue in the brain. Certain tumors are resistant to fluorescein uptake (376 D) indicating a tight blood–tumor barrier (178), and size-dependent leakage kinetics govern transport across the blood–tumor barrier (179). In addition, multidrug resistance (i.e., P-glycoprotein) is still intact in glioma vessels, limiting the efficacy of chemotherapeutics (171,180). Thus, drug delivery to brain tumors still can be hampered in many instances.

### Other Diseases

The BBB also is involved in a broad variety of other CNS diseases such as Parkinson disease (181), Alzheimer disease (182), hypertension (183), and the class of CNS complications resulting from bacterial, fungal, and viral infection (184). The preceding section underscores the importance of understanding the BBB regulatory mechanisms in health and disease. In many CNS diseases, the BBB may not be fully compromised, and therapeutic intervention may be desired in the presence of a still-functioning BBB. Therefore, it is critical to have brain drug targeting and delivery strategies that have the capacity to overcome the BBB.

### TREATMENT OF BRAIN DISEASE: THE BLOOD–BRAIN BARRIER BOTTLENECK

Although the brain vasculature provides a large surface area (estimated to be over 21 m<sup>2</sup> from 400 miles of capillaries in human brain) for drug delivery, the physical, transport, and metabolic barriers presented by the brain vasculature greatly inhibit the uptake of substances from the blood. This has significant consequences for brain drug delivery and serves to limit the options available for therapy. To pass the physical barrier, candidate drugs must be both small (<500 D) and lipophilic (185). Once such a drug has entered the BBB, it may be metabolized or inactivated inside the EC or excluded by efflux transporters, and thus have limited access to underlying neural tissue. Because of these restrictions, 98% of small-molecule pharmaceuticals and almost all gene and protein medicines are excluded from the brain by the BBB (186). Therefore, only with special targeting strategies (discussed here) can these impermeable medicines cross the BBB. This highlights the challenge of delivering drugs to brain tissue. To date, only depression, schizophrenia, chronic pain, and epilepsy can be treated with small-molecule drugs that are not specifically targeted (186). Promising therapeutic candidates exist for many diseases including Parkinson disease, brain tumors, MS, and stroke, but they lack the ability to be transported into the brain parenchyma.

### Invasive Strategies

One method to bypass the BBB is the use of neurosurgical techniques to introduce drugs directly into brain tissue. Strategies requiring neurosurgery are used for the implantation of polymer particles infused with a drug, but the treatment volume is limited because the extracellular fluid in brain tissue is rather static, and simple molecular diffusion only allows for a modest penetration distance of 2 to 3 mm (187). A similar method involves the direct injection of drugs into the brain ventricles. The penetration into brain tissue also is limited for intraventricular injections because this brain fluid is rapidly cleared and turned over four to five times daily by absorption across the arachnoid villi into the general circulation (93,188). To overcome these problems, convection-enhanced diffusion via intracerebral infusion of fluid can be used to increase drug concentrations over a larger region of brain tissue. Experiments using Rhesus monkeys indicate that drug distribution in the perfused region may be increased substantially (189), but bulk flow can adversely affect the brain, leading to astrogliosis (190). A similar strategy has been used to administer GDNF to the putamen of human patients as a potential treatment for Parkinson disease (191). These invasive strategies can have success if limited treatment volumes are required, such as those arising from localized, nonmetastatic brain tumors. However, for chronic conditions requiring a repetitive treatment regimen or for those diseases that affect large portions of the brain, a noninvasive drug delivery strategy is generally preferable.

BBB disruption is another invasive method that can be used to overcome the delivery problem while at the same time increasing the volume of distribution. Reversible disruption of the BBB has been investigated using hyperosmolar solutions, or vasoactive BBB disruption with histamine (192), serotonin (193), or bradykinin peptides (194,195) to reversibly disrupt the BBB and allow free paracellular passage of molecules from the blood into the brain. Although this method can be administered through the bloodstream, it is listed as an invasive approach because the process of opening the BBB can lead to toxic effects, because solutes and immune machinery normally excluded from brain gain free access (196,197).

### **Noninvasive Delivery via the Vasculature**

A major challenge and priority is to develop novel methods that utilize the endogenous BBB molecular transport network as a conduit for transendothelial drug transport. These transport systems can be clustered into three general groups: nonspecific uptake, carrier-mediated transport, and receptor-mediated transport.

#### *Protein Transduction Domains*

Cationic protein transduction domains (PTD) fall into the realm of nonspecific carriers. One such example is the HIV TAT peptide, which is an 11-amino acid HIV-TAT sequence that mediates rapid translocation into cells. Although HIV TAT was shown to gain access to the brain interstitium after intraperitoneal injection (198), subsequent pharmacokinetic analysis indicated that the rapid clearance and broad organ uptake would necessitate prohibitively high doses (199). In general, PTDs suffer from a lack of selective targeting, which leads to widespread distribution throughout the body.

#### *Carrier-Mediated Transport of Therapeutics*

Carrier-mediated drug transport relies on the presence of endogenous transmembrane proteins that are selective and stereospecific for small-molecule solutes. For example, the Parkinson drug L-dopa gains entry to the brain by utilizing the LAT1 (114). The successful transport through the BBB is a result of L-dopa mimicking the structure of phenylalanine. However, due to the stereospecificity and steric constraints imposed by these selective membrane pores, applications are potentially limited. As another pertinent example, it is likely that the efflux of the AIDS drug zidovudine or azidodeoxythymidine (AZT) progresses in a carrier-mediated fashion (200). This exemplifies another significant problem that arises when carrier-mediated transport or membrane diffusion is used for drug delivery. The presence of efficient efflux transporters such as P-glycoprotein, MRP, and BMDP greatly limit brain uptake in many circumstances. Thus, inhibition of these efflux transporters often is presented as a strategy to enhance transport across the BBB.

#### *Receptor-Mediated Transport of Therapeutics*

As an alternative approach, receptor-mediated transport mechanisms that use the endosomal trafficking system are more compatible with the delivery of a wider range of drug cargo. Receptor-mediated transport involves the binding of an extracellular epitope of a cell surface receptor and triggering of an energy-intensive transcytosis process. This method has been successful in allowing for noninvasive transport of small-molecules (201), proteins (202–204), genes (205,206), nanoparticles (207), and liposomes up to 100 nm in size (206,208). Commonly targeted receptors are the LDL receptor (209), the transferrin receptor (202,206), and the insulin receptor (210,211). Similar, less specific processes involving absorptive-mediated transcytosis have been used with cationized proteins (212,213) that promote receptor clustering and activation of the transcytosis pathway. Such strategies often target the cell surface receptor in ways that do not disrupt the normal transport of endogenous ligand. Therefore, the impact on normal metabolic pathways is limited. In addition, this strategy is not limited by the size and shape requirements of carrier-mediated transport. Although early results derived from the receptor-mediated delivery process are promising because of the capacity to deliver drugs or drug carriers of various sizes and composition, this strategy also has some serious drawbacks that must be addressed for general clinical success. The present methods rely on receptors that are ubiquitously expressed, such as the transferrin and insulin receptors. This leads to mistargeting of potentially expensive drugs that also may have unwanted side effects in tissues other than the brain. In addition, the present methodologies generally result in a low fraction (1%–4%) of the injected dose actually reaching the brain target (201,210,211,214). However, if side effects and drug costs are not a concern, the transferrin and insulin transcytosis systems are very promising. For example, these systems result in beneficial pharmacologic responses after noninvasive delivery of brain-derived neurotrophic factor (BDNF) in rodent stroke models (203) and of tyrosine hydroxylase gene replacement therapy in Parkinson disease models (215).

#### *Nanoparticles and Liposomes as Drug Carriers*

Another exciting approach that can circumvent efflux transporters and allow for controlled release of drug in brain tissue is the use of nanoparticles or liposomes. Both nanoparticles and liposomes have been used in promising proof-of-concept studies. Their preparation is simple and scalable, and they can be designed for controlled rates of release. Nanoparticles made of polybutylcyanoacrylate (PBCA) coated with polysorbate 80 have been researched extensively (216) and were shown to be capable of delivering drugs to the brain (217). As an example of nanoparticle efficacy, intravenously injected doxorubicin-loaded, polysorbate 80-coated nanoparticles led to a 40% cure rate in rats with intracranially transplanted glioblastomas (218,219). The mechanisms for nanoparticle entry into the brain are not yet fully understood, but the polysorbate-coated nanoparticles

were found to bind apolipoprotein E from blood-plasma and may mimic LDL. ECs express receptors for LDL at their luminal membrane, and this may provide a mode for brain entry. Although the mechanism of brain uptake is still unresolved, the labile nature of the particles in vivo leads to short-lived pharmacologic effects (220) and possible BBB permeabilization (221). To date, nanoparticles also suffer from a lack of brain targeting.

Antibody-targeted liposomes represent another exciting strategy for noninvasive drug delivery to the brain. Liposomes are vesicles with a phospholipid bilayer surrounding an aqueous solution. Unstabilized liposomes are removed rapidly from circulation by macrophages of the reticuloendothelial system in liver, spleen, and bone marrow (222). Incorporation of gangliosides or polyethylene glycol (PEG) derivatized lipids can prolong the half-life in vivo (223,224). Long-circulating PEG liposomes have a minimal affinity for healthy tissue in vivo and therefore provide a comparatively inert platform for drug delivery. However, the BBB permeability for unconjugated liposomes is limited (225). To overcome this problem, liposomes can be coupled with cationized proteins or antibodies against the transferrin or insulin receptors. In a recent study, liposomes were coupled with antibodies (immunoliposomes) against both the mouse transferrin receptor and the human insulin receptor. After immunoliposome injection into mice with transplanted human glial brain tumors, the transferrin receptor enabled transport across the murine tumor vasculature, whereas the insulin receptor permitted transport across the nuclear membrane of the human brain cancer cells (226). The drug payload in this case was an expression plasmid encoding antisense mRNA against the human epidermal growth factor receptor gene (EGFR). Mice treated with these liposomes had an increased lifespan compared with control mice injected with control liposomes. Phase I clinical trials with PEG-stabilized immunoliposomes are promising (227), but specific brain targeting is still limited due to the lack of availability of efficient brain targeting vectors. Similar to immunoliposomes, coupling nanoparticles with antibodies against brain microvasculature-specific receptors also could enhance target specificity. However, information about brain endothelium-specific receptors is still lacking. Genomic and proteomic studies may help to identify new possible targets for immunotargeted drug delivery (228).

#### KEY POINTS

- By virtue of its impermeable phenotype, the BBB plays a significant role in regulating the flow of information and material into and out of the brain.
- Understanding the participation of the BBB in disease is critical for the appropriate design of therapeutic intervention for many neurological diseases.

- The BBB presents a significant hurdle in progressing from the bench to the bedside.

#### Future Goals

- To further elucidate the cellular interplay of the neurovascular unit's role in health and disease; genomics, proteomics, and imaging technologies are currently being brought to bear on BBB research and will likely facilitate this process.
- To develop new strategies that allow brain drug targeting and noninvasive BBB permeability for clinical realization; such development of novel drug delivery strategies will likely require the combination of such interdisciplinary skills as antibody engineering, materials science, and pharmacokinetics.

## Brain Endothelial Cells Bridge Neural and Immune Networks

Kevin J. Tracey and Christine N. Metz

*The Center for Patient-Oriented Research, The Feinstein Institute for Medical Research,  
Manhasset, New York*

The brain has the highest metabolic rate of any organ structure in the human body. Although the human brain contributes only 2% to the total body weight, it uses approximately 16% of the body's cardiac output and accounts for nearly 25% of the body's oxygen consumption (1). Brain-associated endothelium includes all endothelial cells (ECs) found within the brain, including ECs of the blood–brain barrier (BBB) and circumventricular organs (CVOs) (Figure 124.1). One of the major functions of the endothelium within the brain is to direct the flow of oxygenated blood. It is estimated that approximately 600 to 700 mL of blood flows through the carotid arteries and their branches every minute to distribute oxygenated blood to the anterior portion of the brain. The capillaries, the principal vasculature within the brain, are very important components of the brain's supply system. Because of their small diameter and large number per volume of brain tissue, these capillaries provide a large surface area for delivering adequate supplies of glucose and oxygen.

### BLOOD SUPPLY TO THE BRAIN

The circulatory system supplying the human brain is detailed in several references (2–4). Briefly, the brain receives its arterial supply from the carotid and vertebral arteries, which begin extracranially and run through the neck and base of the skull to reach the cranial cavity. At the base of the ear, the carotid artery bifurcates into internal and external branches. The external carotid supplies blood to the skull and meninges (membranous areas of connective tissue that envelop the brain and spinal cord consisting of the dura matter [outer layer], arachnoid [middle layer], and pia mater [inner layer closest to brain]), while the internal carotid artery provides blood to the brain (anterior portion of brain, eye, and forebrain). The internal carotid artery gives off the ophthalmic artery and then trifurcates into the posterior communicating artery, anterior cerebral artery, and middle cerebral artery. The ante-

rior and middle cerebral arteries are terminal branches of the internal carotid artery. The anterior cerebral artery supplies the frontal lobes and the medial aspects of the parietal and occipital lobes. The middle cerebral artery (also known as the “artery of stroke”) forms the largest branch of the internal carotid artery and supplies the frontoparietal somatosensory cortex. The smallest branch of the internal carotid artery, the posterior communicating artery, connects to the posterior cerebral artery, which supplies the occipital and inferior temporal lobes, including the hippocampus. The brain also receives blood via the vertebral arteries. The vertebral arteries develop from the subclavian arteries and supply or give rise to vessels that deliver blood to the spinal cord, brainstem, cerebrum, cerebellum, thalamus, hypothalamus, and portions of the posterior medial parietal lobes, and the medial, inferior temporal, and occipital lobes. Cerebral arteries emerging from the internal carotid and vertebral arteries anastomose at the base of the brain to form the Circle of Willis (also known as the cerebral arterial circle or the arterial Circle of Willis). This arrangement of arteries creates redundant vasculature that permits continuous blood flow and maintains an adequate blood supply to the brain even when any one of the smaller arteries within the Circle, or arteries feeding into the Circle, become blocked.

### VENOUS DRAINAGE FROM THE BRAIN

The return flow of the cranial and spinal blood supply occurs through two venous systems. Cerebral (internal and external) and cerebellar (superior and inferior) veins drain blood from the brain (2–4). The internal cerebral veins (also known as the veins of Galen) drain the deep parts of the brain. Venous blood flows peripherally and centrally via superficial cerebral veins and deep cerebral veins, respectively, into the venous sinuses. The venous sinuses drain through the internal jugular vein.

#### Blood–brain barrier (BBB)

- Physiological barrier formed by brain capillary ECs
- Prevents passage of substances into the brain
- Expresses selective transport systems and receptors

#### Circumventricular organs (CVOs)

- Highly vascularized organs
- Primarily around 3rd and 4th ventricles e.g., choroid plexus, subfornical organ, area postrema, pineal organ, and posterior pituitary gland

Figure 124.1. The BBB protects the brain from peripheral immune system mediators. The brain/CNS receives oxygenated blood from the peripheral circulation, but it is protected from peripheral immune system mediators (cellular and noncellular) under normal physiological conditions. The BBB-EC barrier prevents the passage of hydrophilic substances and immune cells from the peripheral circulation. Unlike the continuous ECs of the BBB, ECs of the CVOs are semipermeable.

## OVERVIEW OF THE STRUCTURAL PROPERTIES OF THE ENDOTHELIUM WITHIN THE BRAIN

### Barrier Properties of Blood–Brain Barrier Endothelial Cells

One important difference between the circulation in the periphery (nonbrain regions of the body) and the majority of the brain is that most hydrophilic substances can easily pass from the circulation into peripheral tissues. By contrast, under normal conditions most factors present in the blood (excluding very small molecules such as amino acids, glucose, or lipid-soluble molecules [e.g., caffeine, ethanol]) cannot pass through the walls of brain ECs that form the BBB because of their location on a continuous basal lamina (5–7). As a result, the BBB protects the brain from circulating substances that could threaten brain homeostasis (see Figure 124.1). The continuous ECs of the BBB differ from fenestrated ECs (non-BBB-ECs containing small pores or fenestrae approximately 80–100 nm in diameter) typically found in most endocrine glands. BBB-ECs exhibit tight junctions of high electrical resistance that seal cell-to-cell contact sites between adjacent ECs. Unlike fenestrated ECs and sinusoidal ECs (typically found in the liver), BBB-ECs have low pinocytotic activity and selec-

tive intracellular transport systems that prevent the passage of most molecules between tissues and blood, except in conditions where the integrity of the BBB is compromised (8–10). Finally, because the BBB limits the bulk flow of water across monolayers, the BBB also controls volume regulation within the central nervous system (CNS).

In contrast to the endothelial monolayer of the BBB, CVOs found within the brain (located primarily around the third and fourth ventricles) are devoid of a continuous EC barrier and exhibit areas of permeability along their endothelium (see Figure 124.1) (11–14). CVOs are highly vascularized and specialized organs. Examples of CVOs include the pineal organ (releases melatonin, neuropeptides), subfornical organ (regulates thirst), posterior pituitary gland (releases oxytocin, vasopressin), area postrema (vomiting center), and choroid plexus (produces/maintains cerebral spinal fluid). The choroid plexus is comprised of fenestrated capillaries surrounded by a layer of polarized epithelial cells (also known as ependymal cells) joined by tight junctions (15,16). Molecules that cross the vasculature of the choroid plexus must then penetrate the ependymal layer before mixing with the cerebral spinal fluid. Because very few proteins pass into the cerebral spinal fluid, it is believed that whereas the ECs of the choroid

plexus are somewhat permeable, the ependymal layer is not. Like CVOs, the vasculature of brain tumors is semipermeable (17).

### **Cerebrovascular Innervation and the Regulation of Cerebral Blood Flow**

Another important function of ECs within the brain is to regulate blood flow through interactions with the sympathetic and parasympathetic pathways. Based on the high demand for oxygenated blood within the brain, one of the major functions of brain arterial ECs is to regulate cerebral blood flow (through vasodilation and vasoconstriction). Sympathetic and parasympathetic pathways innervate most of the cerebrovasculature (e.g., larger vessels of the Circle of Willis, small pial arteries, and arterioles). Sympathetic-noradrenergic fibers secrete potent vasoconstricting substances, whereas the parasympathetic cholinergic fibers release vasodilating neurotransmitters. Vessels penetrating the brain parenchyma lack adrenergic innervation in most areas of the brain (18). Sympathetic-noradrenergic fibers arise from the superior cervical ganglion and run along the internal carotid artery as a solid nerve (internal carotid nerve). These fibers follow pial arteries and arterioles, and innervate some portions of the Circle of Willis (19). The secretion of norepinephrine and neuropeptide Y by these fibers induces vasoconstriction (20).

Cerebral blood flow is regulated primarily through cholinergic innervation of the brain vasculature. Cholinergic neurotransmitters acetylcholine (ACh) and vasoactive intestinal peptide (VIP) are potent vasodilators of human cranial arteries. The elements of a cholinergic system (acetylcholinesterase and choline acetyltransferase or ChAT) have been extensively studied using brain-derived ECs with somewhat inconsistent results. Some studies report a lack of expression of ChAT, the enzyme responsible for ACh production, by brain ECs (21,22), whereas other studies demonstrate ChAT activity/expression by these same cells (associated with capillaries, arterioles, microvessels) (23–26). The expression of ChAT by many other cell types throughout the body, including T lymphocytes, epithelial cells, mesothelial cells, smooth muscle cells, and ECs, has been established (27). Despite the controversy regarding the production of ChAT by brain ECs, both cerebral arteries and capillary ECs bind [<sup>3</sup>H]-QNB (a highly specific cholinergic muscarinic antagonist), demonstrating the presence of muscarinic cholinergic receptors (mAChRs) within the brain vasculature (microvessels) (23,28). These receptors found in the cerebral microcirculation are proposed to mediate vasoconstriction, vasodilation, and activation of nitric oxide synthase (NOS) (29). It is postulated that cortical microvessels receive cholinergic input originating from basal forebrain neurons to increase cortical perfusion and dilate intracortical microvessels (30). Brain ECs receive cholinergic signals via ACh–mAChR interactions and produce nitric oxide (NO), a potent vasodilator. Similarly, other cell types found in the periphery (nonbrain regions) expressing mAChRs (e.g., keratinocytes and ECs) are believed to be responsive to cholinergic

stimulation. For example, ACh induces contractions and endothelium-dependent relaxation of isolated human pulmonary arteries (that express mAChRs), however, the source of the ACh produced in vivo is not clear (31). Because ACh is degraded almost instantaneously by acetylcholinesterases, it is possible that ACh derived from ECs themselves or neighboring cells reacts with arterial ECs to regulate blood flow. Based on the high demand for oxygen by brain-associated tissues, compromised blood flow within the brain's microcirculation is detrimental to the host.

In addition to its role in the regulation of blood flow, adrenergic innervation of brain microvessels has been implicated in the regulation of BBB permeability (32,33). Brain capillary ECs express adrenergic receptors (34,35), and receptor–ligand interactions are proposed to weaken the integrity of the BBB and allow the influx of numerous peripherally derived inflammatory mediators into the brain during sepsis or infection (36).

### **Brain Endothelial Cells Are Targets and Producers of Inflammatory Mediators: The Neural–Immune Interface**

There are numerous examples of diseases (resulting from known/unknown pathogens and non-pathogen-associated factors) that affect the brain, including sepsis, encephalomyelitis, cerebral malaria, multiple sclerosis, trauma, hypertension, ischemia, and Alzheimer disease (AD). Both exogenous agents (pathogens, toxins, and/or drugs) and endogenous factors (biological influences produced by host cells) alter BBB permeability, damage neuronal cells, and modify cerebral blood flow (37–40). While serving as the brain's barrier, BBB-ECs play a critical role in sensing inflammatory mediators produced in the periphery (nonbrain regions) and found in the circulation (outside the brain) during these diseases and conditions. Brain ECs are targets for inflammatory mediators produced by local cells found in the brain (e.g., microglial cells). In addition to sensing endogenous host mediators, BBB-ECs and non-BBB brain ECs participate in the host's innate immune response (i.e., immediate nonspecific reaction to invading pathogens) through the expression of cell surface receptors with broad specificity for pathogens and specific receptors for endogenous host-derived factors (e.g., cytokines). In response to receptor–ligand interactions, these brain ECs produce a wide range of potent substances (including cytokines, chemokines, complement factors, and vasoactive agents) that can disrupt the BBB, alter cerebral vascular circulation, and/or damage neuronal cells. In many cases, these substances increase leukocyte recruitment to the BBB and are associated with the release of additional leukocyte-derived inflammatory mediators. These substances, in turn, can further increase BBB permeability and permit the flow of harmful inflammatory mediators, cells, toxins, or pathogens into this previously protected compartment, thereby compromising brain homeostasis. Although the neurological effects of numerous infections and trauma have been recognized for many years, only recently has the direct

relationship between the brain and the host innate immune response been explored.

In this chapter, we review the experimental evidence supporting the interaction between the brain – particularly brain ECs – and soluble and cellular factors of the innate immune response (both as a receiver of signals and a producer of signals) and neuroimmune interactions. In addition, we describe how the elements (both cellular and soluble) of the innate immune system (in the presence and absence of infection) alter the functions of brain ECs and how brain ECs influence neural degeneration and disease progression during two distinct conditions – sepsis and AD.

### COMPARISON OF BRAIN ENDOTHELIAL CELLS AND PERIPHERAL (NONBRAIN) ENDOTHELIAL CELLS

As described in the overview of structural properties of BBB-ECs, the most prominent difference among BBB-ECs (primarily microvasculature) and non-BBB brain ECs (including ECs associated with CVOs) and nonbrain ECs is their barrier function (see Figure 124.1). BBB-ECs form a barrier because they are organized in a continuous monolayer lacking both intercellular clefts and pinocytotic vessels. By contrast, most other non-BBB-ECs (including CVO-ECs) are fenestrated (or sinusoidal) and contain intercellular clefts and pinocytotic vesicles (8,9). Furthermore, BBB-ECs contain more mitochondria than other ECs, enabling them to supply energy to the multiple energy-dependent transporters found in the BBB (41,42). The high metabolic capacity of BBB-ECs may be associated with carrier-mediated transport activities of the BBB-ECs.

Numerous structural differences between brain and peripheral blood vessels exist. Most of the cerebral vessels (excluding vessels that penetrate the brain parenchyma) are innervated (43). Most cerebral vessels (excluding the larger vessels of the Circle of Willis) are microvessels with internal diameters 300 microns or greater (with most  $\leq 100$  microns) and many of these microvessels are interconnected to form intricate bundles of tubing for efficient blood flow (44). Finally, brain arteries and arterioles (unlike nonbrain arteries and arterioles) have a single internal elastic lamella (instead of internal and outer elastic lamellae) (44). This structure is believed to contribute to brain aneurysms (or berry aneurysms) that classically occur at the point where the cerebral artery departs from the Circle of Willis.

The most comprehensive comparative studies of brain ECs versus peripheral or nonbrain ECs, at the cellular level, evaluated cerebral microvascular ECs versus human umbilical vein ECs (HUVECs). HUVECs, easily isolated from the large vein of the umbilical cord, are not microvascular (like most brain-ECs) and therefore, may not be the best comparative EC-type. ECs isolated from the brain exhibit many similarities to peripheral ECs (HUVECs); they express von Willebrand factor (vWF) antigen (a reliable cell marker for ECs), contain Weibel-Palade bodies (granules specific

for ECs), and demonstrate complex junctional structures (45,46). Similarly, both human cerebral microvessel ECs (prepared from brain tissue [gray matter] after removing the pia mater and arachnoidea from the cerebrum and dissecting out the white matter) and peripheral ECs (HUVECs) express adhesion molecules, integrins, proteases, proangiogenic factors, chemokines, cytokines, growth factors, and cytokine/chemokine receptors (47).

When exposed to interferon (IFN)- $\gamma$ , lipopolysaccharide (LPS), and tumor necrosis factor (TNF), primary brain capillary ECs (established from white matter) produce lower amounts of interleukin (IL)-1 $\beta$  and soluble intercellular adhesion molecule (ICAM)-1 compared with HUVEC (48). The reduced immunoresponsiveness of brain ECs may be due to their limited cellular interactions with elements of the host immune system. Alternatively, the observed reduced immunoresponsiveness by brain ECs may reflect *ex vivo* culture conditions rather than the actual activity/function of these cells within the brain *in vivo*.

The most detailed study comparing mRNA expression by normal human brain ECs (cerebral capillaries isolated from the gray matter) and peripheral (nonbrain) ECs (HUVECs) identified certain genes preferentially expressed exclusively by brain ECs. These include vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF)-2, insulin-like growth factor (IGF) binding proteins-1, -5, and -6, follistatin (an angiogenic protein), integrin- $\beta 5$  and integrin- $\alpha 1$ , and transforming growth factor (TGF)- $\beta 2$  among others (47). By contrast, other genes were expressed by HUVECs, but not brain ECs, including platelet-endothelial cell adhesion molecule (PECAM)-1 and ICAM-2 (adhesion molecules); Tie2 and angiopoietin-2 (angiogenic factors); matrix metalloprotease (MMP)-8, -10, and -13 (proteases); CXCR4 (chemokine receptor); FLK-1 (VEGF receptor 2); and RANK (activating receptor activator of nuclear factor [NF]- $\kappa B$ ) (47).

When analyzed for protein expression, human brain ECs (prepared from brain tissue [gray matter] after removing the pia mater and arachnoidea from the cerebrum and dissecting out the white matter) express factors associated with neuroprotective and growth supporting activities, as well as immunoregulating and angiogenic functions (47). Basal brain-derived neurotrophic factor (BDNF) and stem cell factor (SCF) expression was five times greater in brain ECs compared with HUVECs, whereas TGF- $\beta 2$  expression by brain ECs was 10 times greater than in HUVECs. Although VEGF and follistatin protein levels were undetectable in basal HUVEC cultures, human brain EC cultures contained 300 and 13 pg/mL, respectively. Furthermore, levels of IL-6 and monocyte chemoattractant protein (MCP)-1 (immunoregulatory mediators) were sixfold higher or greater in the brain EC cultures. Several recent studies suggest that IL-6 (49) and MCP-1 are neuroprotective (50). Brain ECs, but not HUVECs, expressed detectable levels of two receptors (at the protein level) involved in EC proliferation, differentiation, and angiogenesis: epidermal growth factor receptor (erbB1) and oncostatin M receptor  $\beta$ -subunit (47).

Together, these and other studies suggest that cerebral microvessel ECs express cell subtype-specific genes and proteins associated with neuroprotective functions, inflammatory responses, cell differentiation, blood flow regulation, and angiogenesis. These patterns are likely to reflect the unique functions of brain ECs. It is important to note that, whereas comparisons of brain-derived ECs versus peripheral ECs following *ex vivo* culturing are useful, the conclusions of these types of studies are limited to *in vitro* and *ex vivo* conditions; that is, they may not be useful for assessing the functions/phenotypes of these cells *in vivo* because the results of such studies are biased by isolation procedures, culture conditions, EC type (e.g., arteriole, venule, large vessel, capillary), and origin or tissue type/location. An important goal is to develop improved methods for assaying brain and nonbrain ECs within the context of their native environment. In addition, the isolation of specific brain EC subsets (BBB-ECs, CVO-ECs, arterial ECs, venous ECs, etc.) would allow for the comparison of these different subsets. Such tools might include the use of laser capture microdissection, rapid isolation procedures, and/or the use of *in vivo* phage display.

#### INTERACTIONS BETWEEN BRAIN ENDOTHELIUM AND IMMUNE MEDIATORS (SOLUBLE AND CELLULAR) IN DISEASE

##### Brain Endothelial Cells Receive Signals from the Host Immune System and Produce Inflammatory Signals

Under certain circumstances, brain ECs receive inflammatory signals generated within the brain by local immune cells (e.g., microglial cells, also known as brain macrophages). Several studies support the concept that circulating proinflammatory factors generated by cells of the peripheral immune system (i.e., the host immune system outside the brain) during infection, trauma, ischemia, or inflammation signal to the brain to evoke further neural and host inflammatory responses. ECs of the BBB form tight junctions and prevent the passage of most inflammatory mediators (produced by the peripheral immune system present in circulation) into the brain under normal conditions (see Figure 124.1). In some cases, disruption of the BBB allows the passage of mediators into the brain. However, numerous additional mechanisms have been proposed to describe how immune system-derived factors produced outside the brain reach the brain (either by physically entering the brain or by eliciting a response without entering the brain, i.e., via nerve fibers).

First, some cytokines and mediators produced in the periphery (outside the brain) can pass the intact BBB by interacting with specific BBB-EC-associated active, saturable transport systems (Figure 124.2). Examples include the putative IL-1 $\alpha$  transport system observed in the rat BBB (51,52) and the TNF transporter found in the mouse brain (53,54). Once transported across the BBB, IL-1 is believed to induce fever, neuroendocrine activation, and behavioral changes dur-

ing disease, in part, through the production of prostaglandins (PGs). These BBB-expressed transporters are regulated, in part, by the adrenergic system (55). In the case of TNF, both the p55 and p75 TNF receptors are necessary for transport across the BBB (56). Although detailed cellular and intracellular events involved in transporting TNF and IL-1 across the EC barrier are lacking, these transport systems bind their ligands in a saturable and competitive manner and then transfer the factors into the brain tissue without disrupting the BBB (56). It is not clear exactly how these transporters differ from receptors; Pan and Kastin have described “transporters” as a means to chaperone factors into the brain parenchyma from the circulation without degradation by BBB-ECs (56). Similarly, numerous specific membrane transporters involved in the passage of glucose (e.g., GLUT1), electrolytes, drugs, and other substances are localized throughout the brain.

Second, cytokines produced by immune cells (outside the brain) and found in the peripheral circulation bind to receptors present on peripheral nerves that send signals to the brain. In this case, peripherally derived cytokines induce inflammatory responses within the brain without actually entering the brain. An example of this type of messaging system is the expression of cytokine receptors by trigeminal ganglions in the periphery that activate the hypothalamus-pituitary-adrenal (HPA) axis (57). Similarly, peripheral cytokines interact with the afferent branches of the vagus nerve (58) that terminate in the nucleus tractus solitarius (NTS) of the brainstem medulla and prompt brain responses to infection and inflammation (see Figure 124.2). The afferent limb of the vagus nerve innervates many internal organs including the heart, lungs, gastrointestinal tract, and liver, and is thus well positioned to transmit host innate immune response-derived signals from peripheral tissues to the brain (59). In addition to receiving signals from the periphery, the vagus nerve responds through the release of neurotransmitters. The principal neurotransmitter released from the axon terminals of postganglionic vagal fibers following stimulation is ACh. It has been shown that ACh released by the efferent vagus nerve interacts with  $\alpha$ -7-nicotinic ACh receptors ( $\alpha$ 7-nAChR) expressed by macrophages within the periphery to deactivate them (suppressing proinflammatory cytokine production) *in vitro* following LPS stimulation and *in vivo* during experimental sepsis (see Figure 124.2) (60–62). This novel pathway, referred to as the cholinergic anti-inflammatory pathway, represents a new function of the efferent vagus nerve: a negative feedback loop that inhibits inflammatory cytokine production and modulates both systemic and local inflammatory responses in experimental models (59,63,64). Evidence is lacking for the direct interaction between ACh produced by vagus nerve stimulation and receptors expressed on target cells.

Although previous studies have focused on the effects of cholinergic stimulation on peripheral cytokine production during infection and inflammation, the possibility remains that cholinergic stimulation also exerts anti-inflammatory

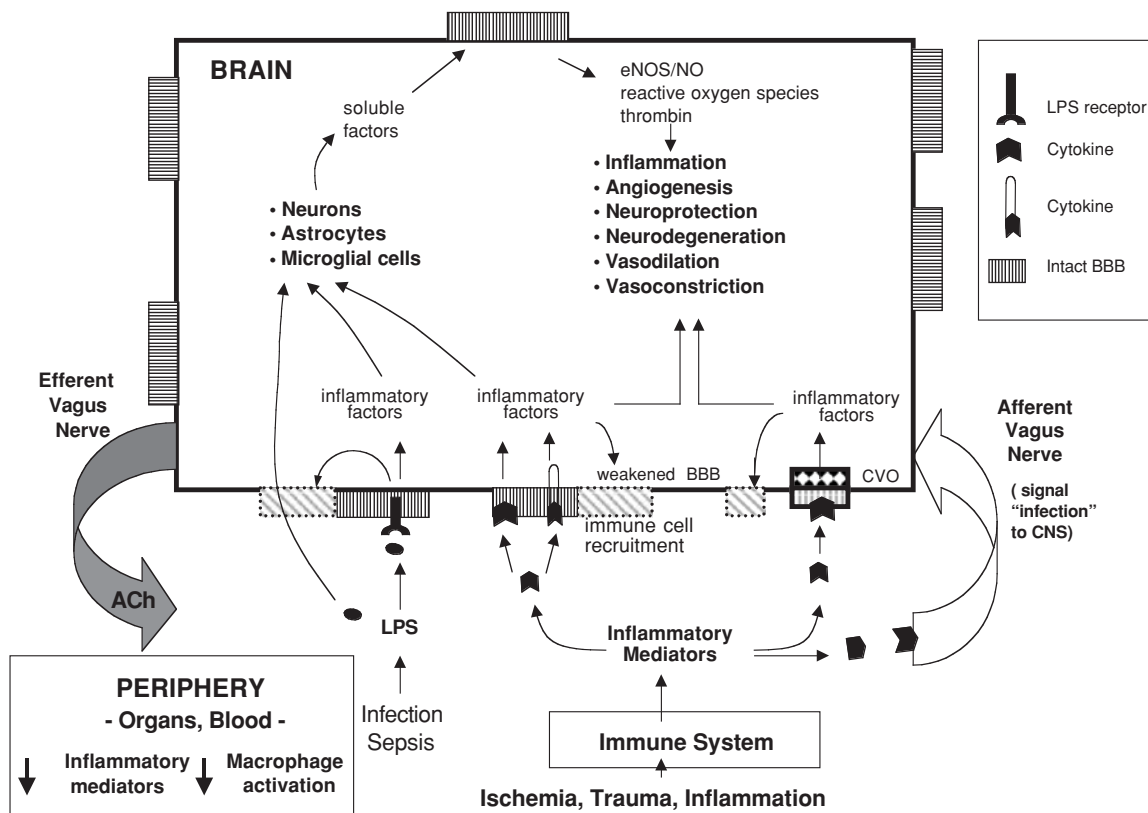

Figure 124.2. Brain EC-immune system interactions during infection and sepsis. Immune mediators produced in the periphery during inflammation and sepsis bind receptors of the afferent vagus nerve and signal to the brain that peripheral inflammatory responses have been initiated. The brain responds by releasing ACh via the efferent vagus nerve to suppress macrophage activation in the periphery. In addition, peripherally derived inflammatory mediators, pathogen products (e.g., LPS), and immune cells bind to BBB-ECs via receptors and transporters to invoke further inflammatory responses that weaken the integrity of the BBB. Peripherally derived inflammatory mediators gain access to the brain through a permeable BBB (and possibly CVOs) and elicit further inflammatory responses by local microglial cells, astrocytes, and neurons. Thus, neural EC-immune interactions regulate inflammation, angiogenesis, neurodegeneration/neuroprotection, and vasoconstriction/vasodilation within the brain during infection and sepsis.

responses within the brain (65). Interestingly, cerebral microvascular ECs and peripheral ECs express the  $\alpha 7$ -nAChR and respond to cholinergic stimulation (66–68). Although it is not clear whether ACh released by the stimulation of the vagus nerve can reach the endothelium (due to its degradation by acetylcholinesterases), cholinergic stimulation of the endothelium can be mediated via cholinergic drugs, including nicotine (which can easily enter the brain by crossing the BBB). Based on these observations and what is known about the cholinergic anti-inflammatory pathway, ECs within the brain and periphery may represent potential targets of cholinergic stimulation, leading to reduced EC inflammatory responses (e.g., adhesion molecule expression, cytokine/chemokine production) and associated leukocyte recruitment during infection. These studies are the focus of ongoing investigations in the laboratory of one of the authors of this chapter (CNM).

Third, cytokines and other pro-inflammatory mediators may gain access to the brain by passing through CVOs (see

Figure 124.2). As describe earlier, CVOs, highly vascularized and specialized organs, are small barrier-deficient areas of the brain located periventricularly (e.g., the subfornical organ, choroid plexus, posterior pituitary gland, area postrema, and pineal gland). CVO-ECs are somewhat permeable and lack a continuous EC barrier found among BBB-ECs. These CVOs provide mechanisms for releasing brain-derived substances (e.g., the secretion of hormones into the systemic circulation) and potentially receiving nonbrain-derived factors into the brain. Non-BBB-ECs within the cerebral vasculature (mostly within the choroid plexus and meninges) express the IL-1 receptor type 1 (IL-1R1) (69). Although many studies suggest the entry of molecules into the brain parenchyma via CVOs, solid experimental evidence supporting this theory is lacking. It has been proposed that IL-1 and TNF pass through CVOs to activate the febrile response through activation of neurons in the anterior hypothalamus (70). Others argue that it is unlikely that molecules pass across the choroid plexus into the cerebral spinal fluid despite the fenestrated ECs due

to the tight junctions between choroid epithelial (ependymal) cells surrounding the ECs (71). Evidence against the considerable permeability of CVOs to cytokines and other peripherally (nonbrain)-derived factors is provided by studies showing that the passage of IL-1 $\alpha$  across CVOs (subfornical organ and choroid plexus) was very restricted due to tightly packed ependymal cells (72).

As discussed earlier, cerebral vascular ECs, including those associated with the BBB and CVOs, express receptors for circulating inflammatory mediators found during infection/inflammation (e.g., cytokines, leptin, and LPS) (73). Following receptor engagement, ECs can secrete secondary mediators (e.g., NO and PGE<sub>2</sub>) that are associated with disruption of the BBB and/or induce further inflammatory responses within the brain (see Figure 124.2). For example, PGE<sub>2</sub> produced by ECs following receptor–ligand interactions can cross the BBB to stimulate temperature increases induced through the activity of preoptic neurons (74). Examples of cytokine receptors found on brain ECs include: IL-1R1, IL-6R, IFN- $\gamma$  receptor (IFN $\gamma$ -R)-1 (69,75). The IL1-R1 is expressed by ECs found mainly in the choroid plexus and meninges (69). *IL1-R1* mRNA expression found in the rat brain endothelium (both luminal and abluminal sides) of the organum vasculosum laminae terminalis (OVLT), a CVO, is constitutive and further enhanced by inflammatory mediator stimulation following intracerebral IL-1 $\beta$  or IL-6 injection (76). *IL-6* mRNA signals are observed in the cerebral cortex, hippocampus, and amygdala associated with blood vessels (76). Brain ECs (both CVO-ECs and BBB-ECs) also express receptors for leptin, which allows the passage of circulating leptin into the brain tissue and cerebral spinal fluid (77). In addition, brain ECs isolated from LPS-treated rats express LPS receptors (at the mRNA level) including *TLR2*, *TLR4*, and *CD14* (78). These LPS–EC and cytokine–EC interactions are believed to increase the permeability of the BBB and activate a series of inflammatory signals by ECs (and other cells) within the brain (78).

### **In Response to Inflammatory Signals, Brain Endothelial Cells Produce Numerous Proinflammatory Mediators**

Brain ECs can produce numerous inflammatory factors, including IL-1 family members, IL-6,  $\beta$ -chemokines, and endothelial NOS (eNOS). Several brain regions lacking the BBB (the choroid plexus, meninges, median eminence, paraventricular nucleus, and arcuate nucleus) express IL-1 $\beta$  and IL-1 receptor antagonist (IL-1ra), with inductions observed following LPS treatment (79). *IL-1 $\beta$*  mRNA expression is found within the brain vasculature (BBB region), acting on IL-1 type 1 receptors localized at the interface between vasculature and perivascular glia (80). IL-1 $\beta$  release enhances inflammatory responses within the brain (e.g., stimulating production of PGE<sub>2</sub> by ECs) (81). By contrast, it has been proposed that IL-1ra expression protects the cerebral vascu-

lature and surrounding cells during inflammation (82). Brain ECs (microvessel) constitutively express IL-6, and this basal expression can be enhanced by IL-1 $\beta$  stimulation (83,84). IL-6 production by brain endothelium may promote vascularization (under normal conditions and during the healing of brain injuries) (85). Moreover, IL-6 may function as a neuroprotective agent within the brain by protecting neurons from oxidative damage (49,84,86). By contrast, using an experimental model of pneumococcal meningitis, IL-6 has been shown to enhance the permeability of the BBB, suggesting that IL-6 produced by ECs within the BBB may weaken its barrier function (87).

$\beta$ -Chemokines play an important role in recruiting immune cells to sites of inflammation and infection. Untreated human brain microvessel ECs express low basal levels of *MIP-1 $\beta$*  and regulated on activation, normal T-cell expressed and secreted (*RANTES*) mRNA and expressions are significantly upregulated by cytokine stimulation (88). LPS injection (experimental endotoxemia) induces MCP-1 expression within the brain, specifically within BBB and non-BBB vascular-associated structures (89). MCP-1 expression is thought to contribute to the early chemotactic events during cerebral inflammation. Recruitment of cytokine-secreting leukocytes to the BBB would further compromise its barrier function.

eNOS expression by brain ECs contributes to NO production within the brain. NO is the most potent vasodilator, and its production is considered to be essential for normal brain physiology. In an experimental model of sepsis using eNOS knockout mice, Connelly and colleagues showed that eNOS (via NO production) serves as an inflammatory mediator by promoting upregulation of inducible nitric oxide synthase (iNOS), and its expression significantly impacts sepsis-associated mortality (90). Constitutively expressed NO also regulates EC-associated adhesion molecule expression, leukocyte activation, and leukocyte adhesion (91). Therefore, EC-derived NO might regulate cell trafficking during infection within the brain.

Thus, brain ECs are not only targets of immune mediators, but also contribute to immune responses through the production of numerous immunomodulatory factors.

### **THE POTENTIAL ROLE OF BRAIN ENDOTHELIAL CELLS IN MEDIATING NEUROLOGICAL DYSFUNCTION DURING INFECTION AND SEPSIS**

As discussed earlier, brain ECs have the capacity to produce numerous soluble factors during inflammation and infection. These mediators may play important roles in disrupting the BBB and regulating cell migration, neurodegeneration, brain-associated inflammatory responses, vasculogenesis, and cerebral blood flow. These processes may contribute to the neurological impairment commonly observed during

sepsis. Approximately 50% of patients with progressive sepsis develop encephalopathy (or diffuse brain dysfunction) (92). Similarly, 70% of patients with bacteremia exhibit neurological symptoms ranging from lethargy to coma (93,94). In bacteremic patients, mortality directly correlates with the severity of the neurological symptoms (as measured by electroencephalograms) (94). The clinicopathological changes in sepsis-associated encephalopathy are similar to those reported in acute hemorrhagic leukoencephalitis (AHLE) (95). AHLE presents with fever, headache, stupor, confusion, delirium, and/or coma and is characterized by CNS necrosis, hemorrhage, and demyelination of the white matter (96). Although numerous studies support the hypothesis that sepsis-associated encephalopathy is due, in part, to the disruption of the BBB by proinflammatory mediators and/or EC-mediated transport of cytokines with subsequent brain inflammatory responses, additional evidence suggests that local microvascular dysfunction resulting in impaired cerebral blood flow and increased cerebrovascular resistance also contributes to sepsis encephalopathy (97). Together these observations suggest that brain-associated ECs may significantly contribute to the neurological impairment observed during sepsis (see Figure 124.2).

#### **THE ROLE OF BRAIN-ASSOCIATED ENDOTHELIAL CELLS IN SEPSIS: THERAPEUTIC IMPLICATIONS**

Based on their functional capacity, brain ECs are potential therapeutic targets for the treatment of infection/sepsis, including sepsis-associated neurological impairment. Activated protein C (APC), an anticoagulant and anti-inflammatory agent approved by the FDA for the treatment of severe sepsis in humans (98) has been shown to exert anti-inflammatory, antithrombotic, and neuroprotective effects in a murine model of stroke (99). Therefore, APC may help improve neurological responses observed during sepsis in addition to regulating peripheral coagulant/thrombotic activity. Drugs that alter NO production during sepsis also may be useful for preventing or treating encephalopathy during sepsis due to their effects on improving cerebral blood flow (97). A recent study reports the therapeutic effect of nicotine, a cholinergic agonist, in reducing mortality in experimental sepsis (62). Cholinergic agonists are postulated to interact with  $\alpha 7$ -nAChRs expressed by macrophages and possibly ECs to deactivate them and suppress proinflammatory cytokine production (61,68). These observations imply that cholinergic agonists may interact with  $\alpha 7$ -nAChR-expressing cells (present in the periphery and/or in the brain) to inhibit excessive cellular activation and inflammatory responses during sepsis. Finally, factors that protect the BBB from disruption or repair the disrupted BBB would be of interest for treating patients with severe infections and/or sepsis.

#### **ALZHEIMER DISEASE**

##### **The Role of Brain Endothelial Cells in Alzheimer Disease: the Evidence**

Despite intense investigative efforts by numerous laboratories around the world, the pathological basis for AD remains unclear. Sepsis often is associated with infectious agents and clearly involves a systemic host immune response, whereas systemic (i.e., nonbrain regions) involvement during AD has not been firmly established. Although numerous studies support the presence of an altered peripheral immune system in AD patients, the mechanistic understanding of how the peripheral immune system plays a role in AD is not understood. Several studies suggest a decline in peripheral immune responsiveness in AD patients, as evidenced by the reduced production of TNF and IL-6 by LPS-treated peripheral blood cells obtained from AD patients when compared with age-matched control blood cells (100–102). By contrast, other studies suggest increased peripheral inflammation during AD, as evidenced by increased levels of circulating IL-6, TNF, and leptin (103,104). Despite the controversy over the role of the peripheral immune system in AD pathogenesis, most studies agree that microglial cells, innate immune cells of myeloid origin present in the central nervous system, contribute to brain inflammation observed during AD (Figure 124.3) (20,105). In addition, several suggested mechanisms for AD implicate the role of the brain vasculature and local EC-immune interactions in neuronal destruction (106). In this section, we review several lines of evidence for the relationship between the brain-associated endothelium/vasculature and AD pathogenesis (107,108) and how immune mediator (cellular or soluble)-EC interactions within the brain might regulate AD progression (Figure 124.3).

AD is characterized by deficits in the production of ACh within the brain resulting in poor cerebral perfusion (Figure 124.3). Locally released ACh (from nerves and/or other ACh-releasing cell types, such as smooth muscle cells and possibly ECs, themselves) within the brain binds to heterogeneously expressed mAChRs expressed by the endothelium. ACh-mAChR interactions within the brain trigger endothelium-related NO production, which leads to cerebral vasodilation and increased blood flow. In AD, impaired ACh production and/or ACh-mAChR interactions with resultant decreased cerebral perfusion are proposed to contribute to neuronal damage. Acetylcholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine) that facilitate cholinergic transmission are a class of U.S. Food and Drug Administration (FDA)-approved drugs used for improving both cognitive and behavioral dysfunctions associated with AD (109). Recent studies using experimental models of AD show that acetylcholinesterase inhibitors also inhibit inflammatory cytokine production (IL-1) within the brain, suggesting multiple mechanisms for acetylcholinesterase inhibitors for the treatment of AD (110). Of course, other neurotransmitters may be involved in the course of AD,

Figure 124.3. Brain EC-immune cell interactions during Alzheimer disease (AD). Unlike sepsis, the role of the peripheral immune system in the pathogenesis of AD is not known. ACh deficits within the brain lead to vasoconstriction, hypoxia, decreased cerebral perfusion, and resultant inflammatory responses by ECs and microglial (immune) cells during the pathogenesis of AD. Morphological changes in the brain's blood vessels (i.e., thickening of the basement membrane) lead to focal vasoconstriction and further hypoxia. Amyloid fibril deposition along the basement membrane of the brain's blood vessels promotes angiogenic responses by ECs and inflammation, as evidenced by microglial cell accumulation. Inflammatory mediators produced by microglial cells weaken the BBB-EC barrier. Local EC-immune cell interactions within the brain regulate numerous processes that contribute to AD pathogenesis, including hypoxia and the production of neurotoxic factors, reactive oxygen species, angiogenic factors, and inflammatory mediators.

including somatostatin, dopamine, and  $\gamma$ -aminobutyric acid (111).

Histopathological examination of the brain microvasculature in AD shows an increase in the basement membrane surrounding vessels and areas of vascular constriction. Early reports describe the presence of senile plaques containing amyloid fibrils that appear to be produced in the basement membranes of capillary ECs and then spread into the parenchyma (112). In addition, inflammation (demonstrated by the presence of reactive microglial cells and astrocytes) within the vicinity of amyloid plaques and surrounding the microvasculature are observed during AD (20,105). The cause of this inflammatory response is not known; however, it may be due to the presence of cytokines (IL-1, IL-6, TNF) in the CNS (secreted, in part, by activated microglial cells and/or astrocytes) and/or by the synthesis and deposition of  $\beta$ -amyloid (which might induce cytokine production within the brain) (20,113). This inflammatory state probably impacts microvessels surrounding regions of  $\beta$ -amyloid deposition and alters the integrity of the BBB (106). Most capillaries within the

cerebral cortex show signs of degeneration, and microvessels exhibit sites of constriction in terminal arterioles (112). These studies examining the relationship between vascular degeneration and neural injury suggest that capillary and vascular changes occur first and are followed by neural damage and dysfunction; they support the hypothesis that aberrations in the brain microvasculature associated with perfusion deficits lead to neural degeneration in AD patients.

Evidence of altered angiogenesis is observed in the brains of AD patients. It is hypothesized that ECs within the brains of AD patients are activated to promote angiogenesis due to brain hypoxia and localized inflammation (114). Products released by activated microglial cells in areas of  $\beta$ -amyloid deposition may induce angiogenesis. Using a genome-wide expression profiling approach, Pogue and coworkers confirmed significant changes in the gene expression associated with stress-induced angiogenesis in brains of AD patients (115). Consistent with these findings, AD is associated with increased levels of angiogenic factors (e.g., VEGF and TGF- $\beta$ ) in the cerebrospinal fluid (CSF) (116). Furthermore, a recent study

revealed that amyloid  $\beta$ -peptides, integral components of the senile plaques and vascular deposits in AD brains, promote angiogenesis by inducing EC proliferation, migration, and pseudocapillary formation in vivo (117). Although this study clearly shows the angiogenic activity of amyloid  $\beta$ -peptides, the results are not consistent with a previous report demonstrating the antiangiogenic effect of amyloid  $\beta$ -peptides in vitro and in vivo (118). Although the role of angiogenesis in AD pathogenesis remains controversial, several lines of support exist for it.

One of the most recent postulates is that the brain endothelium itself synthesizes neurotoxic factors, including reactive oxygen species that induce neuronal cell death (119) and a toxic peptide (thrombin) that selectively kills cortical neurons (120). Thrombin released from cultured brain ECs can be induced by inflammatory mediators (LPS, IL-1 $\beta$ , IL-6, IFN- $\gamma$ , and TNF), NO releasing compounds, and by protein kinase C (PKC) inhibition. Thrombin appears to have both direct and indirect (via its cleavage of apoE4) neurotoxic effects (121). Because thrombin also promotes EC migration, proliferation, and survival (122), it may recruit additional ECs or microglial cells to the sites of damage and sustain the release of neurotoxic factors by accumulating ECs (see Figure 124.3). If the production of neurotoxic factors by brain ECs contributes to AD pathogenesis, what causes the production/release of these factors by brain ECs – activated microglial immune cells (in response to  $\beta$ -amyloid)?

### The Role of Brain Endothelial Cells in Alzheimer Disease: Therapeutic Implications

The brain vasculature appears to play a significant role in the pathogenesis of AD through multiple mechanisms, including inflammatory, hemostatic, and angiogenic responses. Each represents a potential target for therapeutic intervention. ECs within the brain play an important role regulating blood flow in AD and mediate some of the effects of acetylcholinesterase inhibitors. Indeed, acetylcholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine) relieve, in part, the cholinergic defect observed in AD (109,123). Drugs such as nonsteroidal anti-inflammatory agents and statin-type drugs used to treat inflammatory diseases involving the endothelium (e.g., atherosclerosis) also appear to reduce the risk of AD (114,124,125). These drugs may alter the inflammatory responses of the endothelium (induced by innate immune microglial cells) to reduce neural damage and improve disease outcome in AD patients. Other drugs (including nonsteroidal anti-inflammatory drugs, statins, histamine H<sub>2</sub>-receptor blockers, calcium-channel blockers, and other antiangiogenic agents) that modulate deviant angiogenic responses of brain ECs also may be useful in treating and preventing AD (114). Finally, microglial cells appear to regulate some EC and non-EC inflammatory responses within the brain during AD and therefore, offer another potential target for AD therapeutics.

### NOVEL RESEARCH TOOLS TO STUDY THE ROLE OF BRAIN ENDOTHELIAL CELLS IN DISEASE

The functional characteristics of ECs and their associated vasculature are specific and determined, in part, by their location (organ, artery versus vein versus capillary) and the organism's overall state of health (within the brain/CNS and in the periphery). One major obstacle to improving our understanding of the role of brain vascular ECs and associated vasculature in disease is a lack of tools with which to study specific populations of brain ECs. In many studies, brain ECs are isolated and studied under ex vivo conditions. Although these studies provide important information about some of these unique populations of cells, they are limited by isolation procedures and/or culture conditions, and thus do not fully describe the functional role of ECs within the brain under normal conditions and during disease pathogenesis. In addition, methods used to isolate specific EC populations within the brain are limited. In vivo studies of the vasculature are difficult because the endothelium is one-layer thick and spread out. One recently described model system to assess the function of specific genes expressed by brain ECs employs the use of the brain-specific *vWF* gene promoter fragment (–487–+247) that targets the expression of the LacZ marker gene to brain vascular ECs in transgenic mice (126). Along these lines, transgenic mice whose brain ECs express human amyloid  $\beta$ -precursor protein have been generated and will be studied (126,127). Similarly, the expression of other specific genes (e.g., neuroprotective) by brain ECs, and interactions between brain ECs and microglial cells during infection/sepsis and AD, will be interesting to explore.

#### KEY POINTS

- Although most brain ECs are primarily microvascular, they vary depending on location within the brain. BBB-ECs exhibit tight junctions (i.e., are impermeable to most substances), low pinocytotic activity, and lack fenestrations and intercellular clefts. ECs of CVOs are fenestrated and exhibit areas of permeability (see Figure 124.1). However, it is believed that ependymal cells surrounding the CVO ECs limit the transport of circulating factors into the brain.
- Brain ECs serve multiple functions in normal physiology. Tight junctions seal the contacts between continuous ECs within the BBB and prevent interactions between the brain and elements of the peripheral immune system. This barrier function of brain ECs is critical to prevent the unregulated entry of pathogens and systemic inflammatory

mediators into the brain compartment. Under normal conditions, brain ECs have limited interactions with immune cell-derived mediators. However, during infection/sepsis and AD, brain ECs serve as a bridge between neural and immune networks (see Figures 124.2 and 124.3). In some cases, peripheral immune cells or mediators interact with brain ECs and, in other cases, brain ECs interact with brain immune cells (microglial cells). During disease states, immune cell–brain EC interactions can evoke responses within the brain (inflammatory, angiogenic, neurological responses) and in the periphery (immune responses). Finally, brain ECs are not only targets of immune mediators: Brain ECs produce numerous immunomodulatory factors.

- During infection and sepsis, inflammatory mediators produced in the periphery (nonbrain regions) signal to the brain (through multiple mechanisms involving ECs, immune cells, and nerves) to elicit neurological responses (see Figure 124.2). The brain endothelium is an important cell type involved in this process: It detects and sends signals within the brain and between the brain and the periphery. Brain ECs modulate leukocyte recruitment, vasculogenesis, wound healing responses, vasodilation/vasoconstriction, coagulation/fibrinolytic activity, and both neurodegenerative and neuroprotective responses that trigger both central and peripheral effects.
- Although an altered peripheral immune system is observed during AD, the role of the peripheral immune system in mediating AD pathogenesis is not clear. The roles of brain ECs in AD pathogenesis are illustrated in Figure 124.3. Both morphological and biochemical aspects of brain endothelium are believed to be critical factors in mediating the neural damage associated with AD progression: (a) altered basement membrane structure, (b) amyloid deposition along the basement membrane, (c) aberrant angiogenesis, and (d) microvascular constriction leading to hypoxia and inflammatory responses in the brain are proposed to be the early events in AD pathogenesis. In addition, the endothelium is a potential source of neurotoxic factors implicated in neural cell damage during AD. Clearly, EC–microglial cell interactions contribute to the pathogenesis of AD.
- Based on their localization, structure, and function, brain-associated ECs represent potential targets for therapeutic strategies for the treatment of both infection/sepsis and AD.

# The Retina and Related Hyaloid Vasculature

## Developmental and Pathological Angiogenesis

---

Laura Benjamin

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The vasculature in the developing eye (Figure 125.1A) has been an excellent model system to study both normal angiogenesis and remodeling, as well as unique aspects of the central nervous system (CNS) vasculature. Like the rest of the CNS, microvasculature of the retina consists of endothelial cells (ECs), pericytes, and glial cells that form a barrier to tightly regulate transport from the blood into the tissue. In the retina, it is called the blood–retinal barrier (BRB). But other vascular beds in the eye are also useful for the study of developmental mechanisms (Figure 125.1B). For example, the first vasculature to form in the developing eye is the hyaloid vasculature, which feeds the early lens and spontaneously regresses as the retinal vessels form and become competent to supply the nutritional needs of the growing and metabolically demanding retina. Another specialized vasculature in the eye is the choroidal vasculature, which feeds the back of the retina through diffusion throughout the retinal pigmented epithelium. This vascular bed, like that of the retina proper, often is compromised in ocular diseases such as retinopathy and macular degeneration. This chapter, however, focuses on the study of the retinal and hyaloid vasculatures, because they have been especially useful in the elucidation of basic molecular and cellular mechanisms of vascular development.

In rodents, the hyaloid blood vessels form during embryogenesis but regress in the first week of postnatal development. During that time, the first retinal blood vessels form a primitive network of capillaries that progressively spread from the optic disc outward toward the periphery of the retina. This occurs on the surface of the retina adjacent to the vitreous, on top of the layer referred to as the ganglion cell layer (GCL). In the second week, these vessels sprout posteriorly toward the photoreceptors and then form a second primitive network parallel to the first, but just above the photoreceptor layer called the outer plexiform layer (OPL). During this time, the first layer is undergoing a remodeling toward a more mature

vasculature, and all layers of the retina are increasing in cellularity. In humans, these processes are prenatal, but in most experimental smaller rodents and small mammals (such as cats and dogs), the completion of retinal development occurs in the postnatal period. Thus, in these animals, both the observation and intervention with ocular vascular development is feasible.

It has been speculated that an inhibitor of angiogenesis signals for the retinal vessels to stop just above the photoreceptor layer and prevents their invasion and disruption of this sensitive neuronal system. Some support for this theory comes from finding natural inhibitors of angiogenesis in parts of the eye, such as pigment epithelium-derived factor (PEDF) expression in the retinal pigmented epithelium (RPE) and the vitreous. The location of PEDF probably serves to inhibit retinal vitreal invasion and choroidal retinal invasion, but establishes the principle that inhibitors can be a part of natural program to limit angiogenesis into the neural portions of the retina. Thus, we might expect that an inhibitor exists that determines the limits of retinal angiogenesis at the interface of the vascular and nonvascular zones of the retina. PEDF has been used by multiple investigators to inhibit retinal neovascularization into the vitreous and choroidal neovascularization into the RPE layer (1–7). In addition, overexpression of a positive stimulator of blood vessel growth and migration such as vascular endothelial growth factor (VEGF) can override the presumed natural inhibition and allow vascular invasion of the photoreceptor layer from the retinal vessels above, albeit in a pathological manner (8). As the rodent grows larger in the third week of postnatal life, a more rudimentary vascular layer eventually forms by sprouting from the vessels that connect the two parallel vascular plexus. This intermediate vascular layer that forms between the first two is the inner plexiform layer (IPL). In humans, the entire retina matures earlier, and retinal vessels form in the third trimester before a full-term birth.

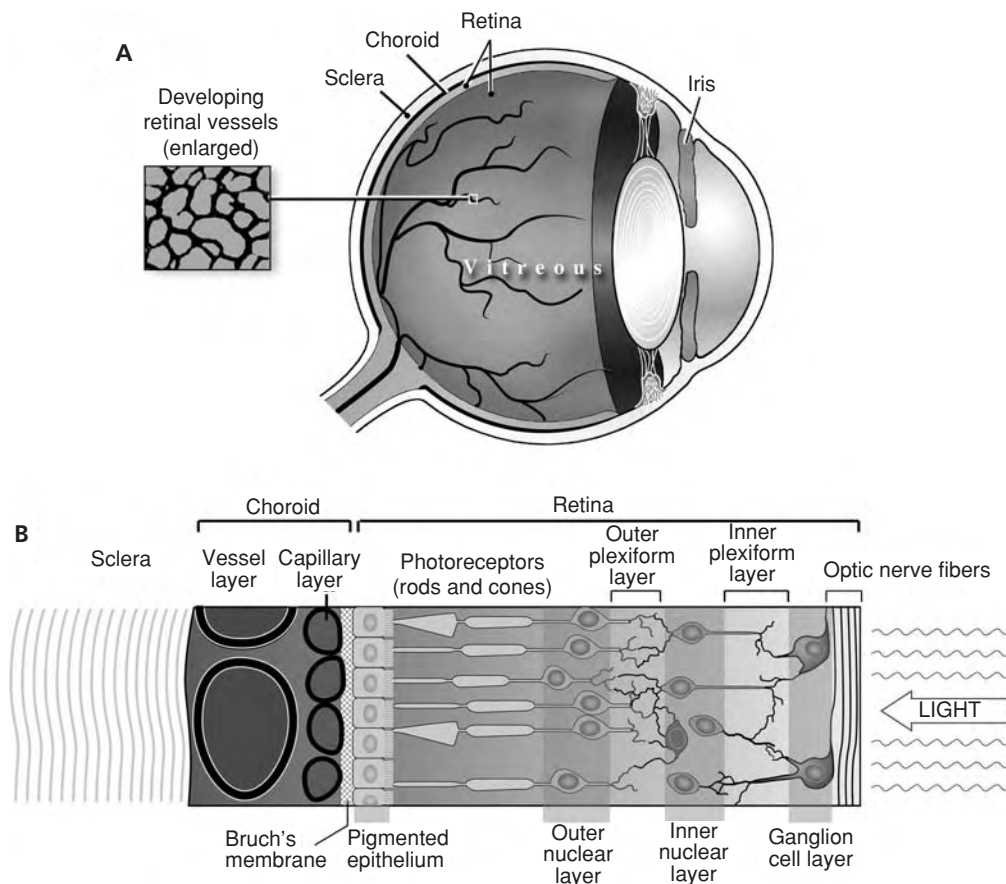

Figure 125.1. (A) The structures of the eye show the position of the retina, a cup-shaped organ holding the vitreous fluid. Within this cavity, the early hyaloid blood vessels are used to support the embryonic lens and developing retina. Another primitive vasculature, the pupillary membrane, covers the iris until its maturation, characterized by a programmed regression similar to the hyaloid vasculature. (B) The retina gets its blood supply from two sources: the deep capillary plexus and the choroid. The deep capillary plexus closest to the vitreous extends its network of vessels from the superficial surface adjacent to the vitreous, called the ganglion cell layer, through the inner nuclear layer. Most of the oxygen and nutrients supplied to the outer nuclear layer and photoreceptors in the retina come from the posterior side of the retina via the choroid and must diffuse through the Bruch's membrane and the retinal pigment epithelium to reach the retina.

## ANGIOGENESIS

Angiogenesis, as opposed to vasculogenesis, relies more heavily on chaotic proliferation and primitive vessel formation than on a predetermined, patterned development. This process leads to an initial homogenous web of capillaries most easily visualized in tissues in which the architecture is planar, such as the yolk sac, retina, and perineural vascular plexus of the embryo. The initial web appears random, and organized blood flow is impossible with so many loops and bridges between vessels. However, a process called *microvascular remodeling* occurs, which rapidly transforms the initial web into an organized and heterogeneous vascular tree (9). The processes involved in remodeling are believed to be a combination of hemodynamic forces from flow, alterations in the microenvironmental levels of hypoxia as a result of oxygenated flow,

and cell–cell interactions and signaling. The formation of this initial web and its subsequent remodeling can be elegantly visualized in the retina by dissecting and flat-mounting the retina after immunostaining of ECs and other cell types such as pericytes, astrocytes, and microglia (10). Perfusion with fluorescent proteins prior to resection of the eye is another way to visualize the functional vasculature and also is employed often.

Pathological angiogenesis can be analyzed using a model to simulate the disease of retinopathy of prematurity (ROP) (also called oxygen [ $O_2$ ]-induced retinopathy [OIR]). This disease afflicts premature human infants born while their retinas are still immature; it is characterized by excessive and improper proliferation of blood vessels in the retina and into the vitreous (11). It can be modeled by placing the rodent in a high- $O_2$  environment for 5 days, during which time many immature

blood vessels regress and new vessel formation is inhibited (12). Upon return to room air (normoxia), the retinal tissue senses a deficiency in oxygenation and becomes ischemic. The response to severe ischemia is responsible for the robust pathological angiogenesis that ensues.

In the rodent model, in addition to abnormal vessels (called *glomeruloid vessels*) that break through the inner limiting membrane and invade the vitreous, large regions of the retina are left unrepaired and avascular. This model is most similar to the human disease retinopathy of prematurity. However, one difference between this animal model of retinopathy and human retinopathy associated with diseases such as diabetes is that the pathophysiological insult (hyperoxia) is transient, and the healthy animal is eventually able to repair its vasculature spontaneously. Nonetheless, the study of the pathological stage in this model has been informative regarding molecules and drugs that can modulate the neovascularization process as proof-of-principles that may apply to human eye disease as well as other vascular proliferative disorders such as tumor angiogenesis.

#### THE RETINA IS A VALUABLE MODEL SYSTEM FOR INVESTIGATING VESSEL FORMATION

Analysis of molecular pathways that influence both the initial vessel formation and subsequent remodeling has been approached in several ways. Soluble factors have been injected into the vitreous during development and their impact visualized. Systemic drugs have been used to interrupt vascularization. Transgenic animals directing gene expression to parts of the eye that are near the retina (for example, lens-specific expression of secreted molecules is used to affect the retina via diffusion through the vitreous) or directly to the retinal vasculature have been informative. And, studies of developmental and pathological angiogenesis in genetically mutant mice have revealed subtleties in vascular function that can be difficult to observe in other organs.

Selected examples that illustrate these principles include landmark studies of VEGF function that first demonstrated the power of this molecule to act as a survival factor for newly formed blood vessels and simultaneously revealed the molecular nature of the ROP animal model. In 1995, Eli Keshet published a series of experiments that demonstrated the importance of VEGF in promoting vascular survival (13). Immediately before placing newborn rats into a hyperoxia chamber, Keshet and colleagues injected VEGF-A into one vitreous and saline into the other. In the control eye, the O<sub>2</sub>-induced vascular regression typifies the first stage of ROP/OIR. In the VEGF-injected eye, the blood vessels were protected from this regression. Related studies on retinal VEGF expression in this model strongly implicated the O<sub>2</sub>-sensitive properties of VEGF in mediating pathology (14,15). Glial cells in the retina play a key role in sensing hypoxia-ischemia in normal development, when they strongly express *VEGF* mRNA in the avascular zones of the retina in advance of vessel formation in those regions. Similarly, during the pathological ROP/OIR

model, hyperoxia downregulates glial VEGF production, causing regression of newly formed vessels and cessation of neoangiogenesis. Return to normoxia leads to massive ischemia and VEGF production in both glial and neuronal cells. Thus, we now understand the importance of tissue oxygenation and hypoxia in the initiation of both developmental (physiological) angiogenesis and, when excessive, in pathological angiogenesis (16,17). Targeting VEGF or its receptors has been the objective of many therapeutic approaches to retinopathy (18–23). Overexpression of VEGF induces pathological angiogenesis when expressed in regions of the eye that are near retina (8,24,25).

Other growth factors, such as insulin-derived growth factor (IGF)-1, also have been implicated in the pathology of retinopathy and have been promoted as therapeutic targets (26,27). Similarly, overexpression and loss-of-function of other angiogenic cytokines such as angiopoietins (Angs) have demonstrated differential effects on vascular structure and function that reveal unique features of their action. *Ang2*-null mice are viable but, in the retina, a defect occurs in hyaloid regression that has secondary effects on retinal vascularization (28–35). These studies further demonstrate the dependence of retinal vascular development on hyaloid regression. Ang1 modulation of vascular permeability, its expression in mural cells, and its ability to restore normal patterning to retinal vessels in the absence of pericytes has also been elucidated by virtue of the unique properties of the retina (36–38).

Notably, loss-of-function studies also have been informative for a variety of genes without lethal phenotypes. Much also has been learned from the study of null mutations that showed no developmental phenotype but had profound effects on pathological angiogenesis. A striking example is the null mutation for placental growth factor (PlGF), a VEGF family member that selectively interacts with VEGF receptor 1 (VEGFR1), but not VEGFR2. PlGF-mediated activation of VEGFR1 is required for pathological angiogenesis of the retina (20,39).

The retina has been particularly useful for visualizing sprouting angiogenesis, because the planar expansion of the primary plexus allows for a clear whole-mount view of the sprouting tips as they progress across the retinal surface. A combination of immunohistochemistry, *in situ* hybridization, and confocal microscopy has allowed for a detailed view of the molecules involved. For example, visualization of VEGF tethered to the surface of the astrocytes, and colocalization with VEGF receptors on the cytoplasmic extensions in endothelial tip cells, beautifully demonstrate the molecular signaling of VEGF in action (40). Visualization of the sprouting tips also permitted the identification of the mild vascular developmental defects associated with the loss of RhoB. Loss of this GTPase leads to apoptotic tip cells, in part due to downregulation of Akt signaling and other molecular changes required for tip cell response to VEGF (41). Thus, the retina has proved instrumental in the analysis of gene function for a variety of different developmental stages and processes in large part because of the ease of visualizing multiple stages of vascular development and disease in this organ.

## APOPTOSIS AND REMODELING IN VASCULAR DEVELOPMENT

Although many *in vivo* assays are available for vessel formation, few are as revealing as the hyaloid and retinal vessels for the study of remodeling and its associated vascular regression and EC apoptosis. The programmed regression of the hyaloid vessels is one of only a few examples of developmentally programmed apoptosis of entire vessels (as opposed to the vessel segments that are eliminated in microvascular remodeling). A similar process occurs in the pupillary vascular membrane that covers the iris. The hyaloid and pupillary vasculatures are transient structures. The hyaloid vasculature serves its only function to nourish the lens until the retina and its vasculature develop. These vessels emanate from the optic disc and are suspended in the vitreous. They consist of ECs thickly covered by pericytes and contacted by resident macrophages/microglia. A series of elegant experiments by Richard Lang and colleagues over the years has demonstrated an important role of macrophages in the apoptosis and regression of these two vasculatures (42,43). Early studies visualized the association of macrophages with constrictions in the vessel that preceded vessel atrophy and apoptosis. More recently, a variety of genetic models have been employed to dissect the molecular basis of regression. In mice deficient in macrophages, such as the *PU.1*-null mice, hyaloid vessel formation is defective. In addition, *wnt-7b* secreted by macrophages was shown to induce proliferation of the hyaloid endothelium and to be a prerequisite for programmed cell death (44). Similarly, *Ang2*-null mice were defective in hyaloid and pupillary regression and, given that *Ang2* and VEGF are expressed by pericytes, Lang attributed hyaloid regression to a loss of pericyte-derived ligands (29,45). This series of studies has helped build on the hypothesis that multiple cues are involved in regulating hyaloid development and regression, and that the proliferative signal in the presence of *Ang2* leads to apoptosis. These findings not only contributed to our understanding of developmental programmed cell death of the eye vasculature, but also pointed to fundamental principles in signals that lead to apoptosis in a proliferating and developing vascular bed during microvascular remodeling. The data are consistent with the studies in tumors, in which *Ang2* and VEGF determine whether co-option leads to further angiogenesis or vascular regression (46,47).

Similarly, studies in the retina itself have revealed important principles of remodeling. Early studies of pericytes, the perivascular mural cells that cover retinal capillaries, revealed a coincidence in expression of smooth muscle actin (SMA), a marker of differentiated pericytes, and remodeling during the earliest phases of microvascular remodeling. ECs produce platelet-derived growth factor (PDGF)-BB, a chemoattractant and growth factor for those pericytes having the PDGF  $\beta$ -receptor (PDGFR $\beta$ ). Disruption of the pericyte–endothelial association by injection of PDGF-BB into the vitreous resulted in aberrant remodeling due to disruption of the normal PDGF-BB gradient, again consistent with the association of pericytes and the ability of pericytes to promote microvascu-

lar survival and normal remodeling of the microvasculature (48).

This same principle of pericyte protection of blood vessels from apoptosis has been seen in multiple tissues and settings, and with multiple molecular pathways. For example, gene targeting of EC PDGF-B expression leads to reductions in pericyte number and increased vascular fragility (49,50). In pathological retinal angiogenesis, PDGF-B inhibition also exacerbates ischemic retinopathy (51).

The ability of pericytes to protect blood vessels from VEGF loss was first described in the developing retinal vasculature, and then described in the process of tumor angiogenesis (48,52). This stabilizing function of pericytes in cancer has been further substantiated by studies showing that inhibition of pericytes by small molecule inhibitors to PDGFR $\beta$  enhances antiangiogenic therapy and vessel loss (53). As discussed previously, the expression of *Ang2* interferes with pericyte–EC interactions and leaves ECs vulnerable to apoptosis in the absence of survival factors such as VEGF-A (29,33). This relationship between *Ang2* and VEGF had been inferred from expression patterns of *Ang2* and VEGF in tumor studies (46,47). Taken together with the phenotypes of *Ang2* loss and overexpression in the eye, a hypothesis has been established that *Ang2* functions to antagonize vessel stability in the absence of VEGF, but cooperates in inducing neovascularization in the presence of VEGF. VEGF-A–mediated survival function also has been reproduced with PlGF homodimers and PlGF/VEGF heterodimers, which are all similarly capable of protecting retinal blood vessel from oxygen ablation (20,54).

It has been speculated that VEGF- and *Ang1*-induced survival function is mediated by Akt signaling in multiple *in vitro* assays (55–58). In support of this, Akt signaling in the retina correlates with hyperoxia exposure *in vivo*. A test of this hypothesis was recently demonstrated using a transgenic model in which activated Akt can be expressed in ECs on demand via tetracycline regulation. Using this model, it was shown that, like VEGF, activation of the Akt signaling pathway can protect ECs from apoptosis in hyperoxia (59). Thus, the retina has provided a vehicle for the study of vascular remodeling and apoptosis that has elucidated several common principles of microvascular development.

## THE DEVELOPMENT AND FUNCTION OF NONENDOTHELIAL CELLS IN RETINAL ANGIOGENESIS

In addition to ECs surrounded by pericytes, the retinal vasculature also contains glial cells (astrocytes and Müller cells). Astrocytes in the superficial vascular bed abutting the vitreous surround the blood vessels and contribute to the unique features of the BRB, similar to the rest of the CNS (60). Astrocytes are not only important for providing increased barrier function in the mature retina, but also play a pivotal role in the development of the retinal blood vessels (61). As the first vascular inhabitants of the newly forming retina, they lay the template on which ECs migrate and adhere, and they

secrete important cytokines (e.g., VEGF) and adhesion proteins. Recent studies support a role for R-cadherin expression in mediating the effect of glial cells on vessel patterning: Antibodies to this protein inhibited branching and patterning of the inner vascular bed (62). Although astrocyte bodies are found in the superficial vascular layer abutting the vitreous, they extend processes inward to contact the endothelium in the deeper layers. Astrocytes express glial fibrillary acidic protein (GFAP) and are responsive to PDGF-A. Another glial cell in the retina is the Müller cell, which is found in the deeper layers and is associated with sprouting vessels that penetrate to form the deeper vascular beds. A recent study found that prolonged hyperoxia exposure allowed for a more normal vascular development, rather than a pathological neovascularization associated with the ROP assay described earlier. One hypothesis to explain this was that the glial cells within the deeper layers were preserved because no overwhelming ischemia was present in this protocol, and suggested that their sensitivity to extreme hypoxia might be an essential aspect of the ROP pathology (63).

Microglia are small multiprocessed cells that reside in the retina before vascularization in a regular spatial array. Microglia are phagocytotic cells that express major histocompatibility complex (MHC) class I and II antigens and some macrophage markers (64,65). They can be found in association with the sprouting tips of blood vessels, but also appear to come in and out of the forming vasculature during the early stages of vessel formation and remodeling. Although they have been associated with hyaloid regression and response to ischemia in pathological settings, little attention has been paid to the role of microglia in retinal vascular development and remodeling (42,66,67).

## CONCLUSION

This chapter focused primarily on lessons learned about vascular development from the study of the retinal vasculature and the associated hyaloid vessels. Other equally specialized and important vasculatures exist in the eye, such as the limbal vessels and choroid. Both of these vascular beds have been instructive in their own ways, and have relevance to important human diseases. However, for the study of normal developmental angiogenesis, in large part because of its accessibility and timing, the retina is a valuable model system. We have really just begun to unravel the molecular mechanisms that govern EC differentiation, specialization, and vascular morphogenesis. As we continue to explore new molecules and molecular interactions, no doubt the retina will continue to be a valuable tool in the analysis of developmental structure and function. Of the many interesting questions left unanswered, the study of the retina seems likely to shed light on questions of tip cell migration and guidance, mural cell interactions, and perhaps the complexity of molecular signaling in the development and function of blood vessels in general and blood vessels of the CNS in particular.

## NOTE ADDED IN PROOF

A recent publication beautifully illustrates the utility of the eye as a model for novel regulation of the vasculature. The authors have shown that the cornea, which remains avascular in most animals, does so by expressing a soluble form of a VEGF receptor, sFLT, which prevents VEGF signaling. Quite interestingly, this study was able to correlate lack of sFLT expression as a change that distinguishes the cornea of the Florida manatee, one of the only animals known with blood vessels in the cornea. Vascularization of the cornea is usually associated with a pathological condition and is an obstruction for vision. However, the vessels in the manatee are small enough to only minimally interfere with the vision of this unusual animal (68).

## KEY POINTS

- The rodent retina and associated hyaloid vasculature are excellent model systems to study normal and pathological angiogenesis.
- Cell–cell interactions, such those occurring among macrophages, ECs, and pericytes in the regressing hyaloid, or pericytes and ECs in the remodeling retinal vasculature, are fundamental for normal development.
- The role of VEGF-A as a survival factor, and the related signaling pathways involved in remodeling of the vasculature, has been most clearly illustrated in the retinal vasculature.
- Fundamental observations regarding EC biology as they relate to normal angiogenesis and angiogenesis in disease continue to be pioneered through the study of the rodent retina. Examples include endothelial tip cell function and regulation in sprouting angiogenesis, the role of the specialized macrophages (microglia) in microvascular development and pathology, and the study of glial and pericyte regulation of the BRB.

## *Future Goals*

- To develop a deeper molecular understanding of how the retinal blood vessels are formed, remodeled, and functionally maintained, with attention to the cross-talk between the ECs, pericytes, astrocytes and microglia
- To develop applications to diseases such as diabetes and macular degeneration, which will become apparent with a better understanding of the normal regulation of vascular structure and function in this organ

## Microheterogeneity of Lung Endothelium

---

Troy Stevens

*Center for Lung Biology, University of South Alabama College of Medicine, Mobile*

Endothelium forms a contiguous cell layer that separates blood from underlying tissue, in each of the body's organs. Cells comprising the endothelial system share common functions, including the ability to form a semipermeable barrier and an antiadhesive surface, produce vasoactive autocooids, move cells and chemical substances across their barrier, and transduce biophysical forces. These shared roles and the ability of endothelial cells (ECs) to adapt to localized environmental cues have led to the pervasive view that their behavior is dominantly controlled by local tissue environment.

Definitive evidence supports the idea that environmental stimuli adjust EC behavior on a moment-by-moment basis. However, heterogeneous endothelial behaviors are not only evident in cells from different organs, they are evident along the arterial-capillary-venule axis of a single organ and, indeed, they exist even among immediately adjacent cells. Such an incredible diversity brings into question whether environmental influences are sufficient to account for this phenotypic heterogeneity.

It has become clear that not all ECs arise from similar progenitors during development. Angiogenesis – the formation of new blood vessels from existing ones – occurs in large pulmonary blood vessels, whereas vasculogenesis – the formation of new blood vessels from blood islands – occurs within the lung's microcirculation. It is still debated as to whether these processes are fully distinct in nature, or whether they reflect interrelated developmental processes, although it is evident that multiple different mesenchymal precursor cells participate in endothelial biogenesis. It is likely that these different cells become uniquely imprinted as a part of their development. Such epigenetic modifications to chromatin, including methylation and acetylation, produce a stable cell memory that is vascular site-specific. The lung's circulation provides insight into the highly discrete function of ECs aligned along the arterial-capillary-venule axis. This chapter describes our current understanding of lung EC heterogeneity, considering both environmental and epigenetic contributions to phenotype specification.

### ENDOTHELIAL HETEROGENEITY IN DIFFERENT PULMONARY VASCULAR SEGMENTS

Lungs receive more than 100% of the cardiac output, because they are simultaneously perfused by both the systemic (i.e., blood delivered from the left ventricle) and pulmonary (i.e., blood delivered from the right ventricle) circulations. The lung's systemic circulation provides oxygenated blood to the airways and vasovasorum to support tissue metabolic activity, whereas the lung's pulmonary circulation provides deoxygenated blood to the alveolar-capillary membrane for gas exchange. The pulmonary circulation is unique among all vascular beds, because it is the only vascular bed to receive 100% of the cardiac output, yet maintain a low blood pressure in the face of high flow rates. In contrast to the systemic circulation, blood entering the lung through the pulmonary artery possesses a "mixed venous"  $pO_2$  ( $\sim 40$  mm Hg), whereas post-capillary blood possesses the highest  $pO_2$  levels in the body following gas exchange across the alveolar-capillary membrane ( $\sim 100$  mm Hg) (Figure 126.1A).

By examining the pulmonary circulation's organization, it is easy to appreciate the distinctive structures of extra-alveolar and alveolar blood vessels (Figure 126.1A, B). Extra-alveolar vessels exhibit a tree-like branching pattern, from large-to-small vessels on the arterial side and from small-to-large vessels on the venous side of the circulation. Capillaries, in contrast, exhibit a web-like appearance. Although blood flow occurs continuously through extra-alveolar blood vessels, it can be discontinuous in certain capillary segments. Indeed, capillaries exhibit recruitment (of new capillary loops) and distention of vessels in response to either increased blood flow or increased venous pressure.

Pulmonary arteries and veins can be discriminated by their anatomical locations within the lung, although they are structurally more alike than are arteries and veins in the systemic circulation. Indeed, the muscle layer is smaller in a pulmonary artery than it is in a systemic artery. Pulmonary artery ECs reside on a basement membrane that separates the intima from

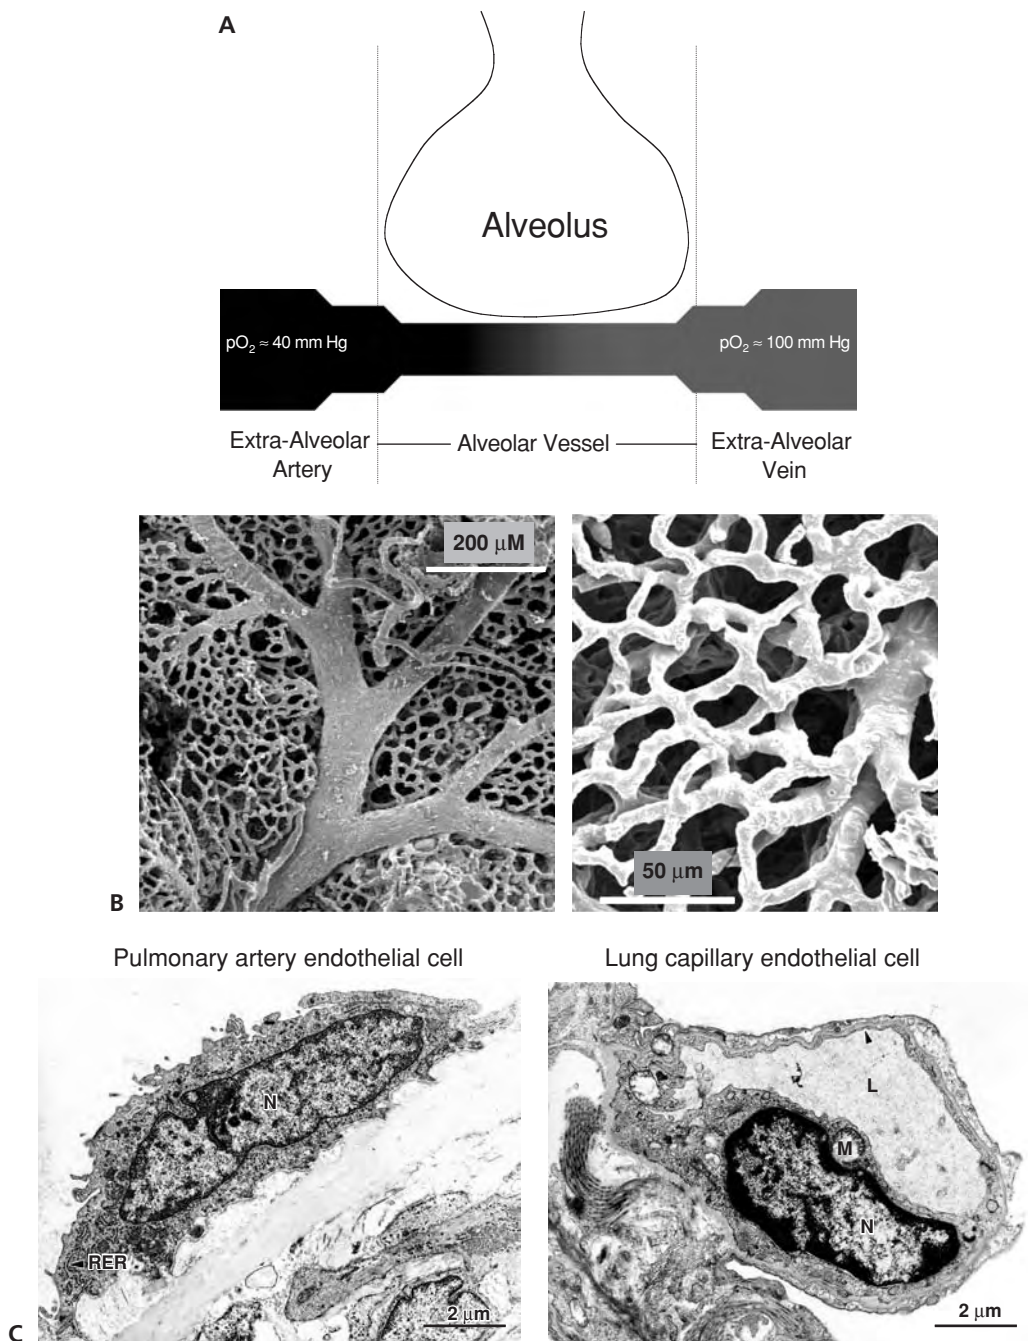

Figure 126.1. Endothelial heterogeneity exists along the arterial-capillary-venule axis in the pulmonary circulation; this structural and functional heterogeneity is apparent when extra-alveolar and alveolar ECs are compared. (A) The pulmonary artery arises from the right ventricle and branches into progressively smaller arterioles. Ultimately, small arterioles deliver deoxygenated (“mixed venous”) blood to a dense capillary septal network. Capillaries drain blood into small venules that progressively increase in size to a large vein that returns blood to the left atria and ventricle, to provide oxygenated blood to the systemic circulation. Capillaries comprise the “alveolar” vessels, whereas conduit arteries and veins comprise “extra-alveolar” vessels. (B) Scanning electron micrographs of methyl methacrylate-perfused corrosion casts reveal the lung vascular architecture. The arterial segments (*left panel*) give rise to progressively smaller vessels that follow a tree-like branching pattern. Capillary segments, however, exhibit a more web-like appearance. For experimental details see Ref. 9. (C) Pulmonary artery and capillary ECs are shown by transmission electron microscopy. Pulmonary artery ECs reside on a thick basement membrane that separates the intima from the underlying smooth muscle layer. Capillary ECs reside on a thin matrix layer and are adjacent to underlying type I pneumocytes. Capillary ECs possess thin cytoplasmic extensions that allow for efficient gas exchange in blood and alveoli. For experimental details see King J, Hamil T, Creighton J, et al. Structural and functional characteristics of lung macro- and microvascular EC phenotypes. *Microvasc Res.* 2004;67(2):139–151.

underlying smooth muscle cell layers (see Figure 126.1C) (1). Pulmonary artery ECs can interact with as many as six adjacent cells, which are all generally aligned in the direction of blood flow (2). The nucleus of these large vessel ECs is located in the cell's center and is surrounded by endoplasmic reticulum, Golgi apparatus, and mitochondria. In some instances, the endoplasmic reticulum can be seen extending adjacent to apical, basal, and lateral cell membranes.

Lung capillary ECs reside near type I pneumocytes (see Figure 126.1C) (1). Only a thin basement membrane separates these two cell layers, unlike most of the body's capillaries. Multiple capillary loops exist within individual septa, so that vascular and airway surface area is optimally matched. Capillary ECs typically contact two neighboring cells and are not flow-aligned *per se*. The nucleus of these cells is located in the cell's center, and is also surrounded by endoplasmic reticulum, Golgi apparatus, and mitochondria. These cells possess a high number of specialized membrane invaginations – caveolae – which serve as an important site for the communication between extra- and intracellular environments. The cytoplasmic extensions of capillary ECs are extremely thin and exclude organelles from the lateral cell borders. Thus, the anatomical organization of pulmonary artery and capillary ECs is remarkably diverse.

The lung's circulation (and airway) is well-ordered to optimize gas exchange. Successful gas exchange requires that the endothelium in all the lung's vascular segments limit fluid, solute, and macromolecular access to interstitial and alveolar compartments. The earliest studies evaluating fluid flux across whole-organ vascular beds suggested that the pulmonary circulation was relatively permeable (3). These studies considered the entire pulmonary circulation as one homogeneous unit, although the permeability results were generally taken to reflect capillary barrier function, because the capillaries dominate pulmonary vascular surface area. We have learned that this idea is not entirely correct.

Several investigative groups have utilized functional measurements to divide the lung circulation into precapillary, capillary, and postcapillary segments, to assess regional differences in endothelial barrier properties (3). Although the required experimental approaches are technically challenging, these studies have all come to the same conclusion: Capillary ECs form a very restrictive barrier relative to pre- (i.e., arteriole) and postcapillary (i.e., venule) segments. The most compelling work resolved that, under basal conditions, approximately 40% of fluid flux occurs across capillary and venule segments, respectively, whereas approximately 20% of fluid flux occurs across the arterial segment (4). When these values are standardized to vascular surface area, it becomes apparent that capillary ECs exhibit a 58-fold and 26-fold more restrictive barrier function than do arterial and venule ECs, respectively. Despite the thin cytoplasmic regions and the very limited contact (i.e., junctional apposition) with immediately adjacent cells, capillary ECs exhibit a tremendous resistance to transcellular fluid flux.

Under basal conditions, some fluid, solute, and macromolecule flux occurs across the EC barrier of all lung vas-

cular segments. A negative interstitial pressure clears this fluid into the lymphatics so that gas exchange across the alveolar-capillary membrane is not impaired by an increase in diffusion distance (3). Inflammatory conditions disrupt endothelial cell-cell junctions and result in intercellular gap formation that allows fluid exudation. If this exudative flux exceeds the rate of fluid clearance, interstitial and potentially alveolar edema occurs.

Studies assessing inflammation-induced permeability edema noted that a common first finding was perivascular cuffing around arteries and veins (3). These results were largely taken to mean that the negative interstitial pressure limits fluid accumulation at the alveolar-capillary membrane, so that fluid only accumulates at the alveolar-capillary membrane after interstitium becomes hydrated or lymphatic fluid clearance becomes compromised. However, in 1968, Whayne and Severinghaus (5) reported that hypoxia caused perivascular cuffing without concomitant disruption of the alveolar-capillary membrane, and without alveolar edema, suggesting the possibility that hypoxia selectively increased extra-alveolar EC permeability without disrupting the alveolar-capillary barrier. These results were therefore incompatible with the idea that increased lung permeability primarily reflected a loss of capillary endothelial barrier function, because the capillary segment represented the largest surface area.

Subsequent work by other labs revealed that different inflammatory agents target discrete lung vascular sites; that is, they increase EC permeability in a region-specific manner. Oxidants like hydrogen peroxide, for example, increase permeability across extra-alveolar ECs and not alveolar ECs (6,7), whereas mechanical injury, oleic acid, and 5,6- or 14,15-eicosatetraenoic acid selectively increases capillary EC permeability (3,4). Taken together, these findings suggest EC heterogeneity contributes to site-specific vascular responses.

This idea was largely borne out by studies using the plant alkaloid thapsigargin, which inhibits the sarcoplasmic, endoplasmic reticulum calcium ATPase (SERCA). SERCA inhibition depletes calcium in the endoplasmic reticulum and promotes calcium entry across the plasma membrane through store-operated calcium entry pathways. By combining measurements of lung fluid filtration with immunohistochemistry and electron microscopy, it became evident that thapsigargin – e.g. the activation of store-operated calcium entry – was sufficient to increase extra-alveolar EC permeability, and not capillary EC permeability (8). Indeed, thapsigargin induces intercellular gaps between endothelium in arteries and arterioles and veins and venules, from small pre- and postcapillary (~25  $\mu\text{m}$ ) to extrapulmonary vessels. Pretreating the pulmonary circulation with a type 4 phosphodiesterase inhibitor, rolipram, prevented thapsigargin from increasing permeability in extra-alveolar ECs and revealed thapsigargin-induced capillary permeability (9). Thus, extra-alveolar and alveolar ECs possess different calcium channels or calcium regulatory mechanisms that are discretely activated during the process of inflammation to discriminate among vascular segments.

### MARKERS OF ENDOTHELIAL CELL HETEROGENEITY IN THE INTACT PULMONARY CIRCULATION

Studies performed in the intact pulmonary circulation suggest many functional demarcations exist between extra-alveolar and alveolar ECs. Evidence that lung microvascular ECs possess an enhanced barrier function should translate into a definable difference in adhesion molecule expression. Vascular-endothelial (VE)-cadherin is the best-described molecular determinant of the EC adherens junction. ECs from all pulmonary vascular segments express VE-cadherin (2) but, interestingly, an infusion of an antibody that inhibits VE-cadherin homotypic interaction causes fulminant, hemorrhagic pulmonary edema, suggesting VE-cadherin plays an important role in capillary EC-EC adhesion (10). Some evidence suggests that capillary ECs express more VE-cadherin than do extra-alveolar ECs, although this finding is not entirely clear (2). Indeed, Bhattacharya and colleagues (11,12) have shown that capillary ECs may express E-cadherin either in addition to, or in place of, VE-cadherin; and capillary ECs also possess a high abundance of N-cadherin (T. Stevens, unpublished observations). Thus, the adherens junction in lung capillary ECs possesses a unique distribution of cadherins that may contribute to the enhanced barrier function of these cells.

Molecules in the coagulation cascade are differentially expressed among pulmonary vascular segments. The Weibel-Palade body (WPB) is a cigar-shaped organelle that contains von Willebrand factor (vWF). vWF in WPBs is a high molecular weight polymer. Its stimulated release into the circulation recruits platelets to an injury site, thereby promoting hemostasis. The membrane of WPBs contains P-selectin. Thus, in addition to releasing vWF, the stimulated secretion of WPBs increases EC surface expression of P-selectin to facilitate leukocyte recruitment (2). It is generally believed that ECs in "larger" blood vessels possess more WPBs than do capillary ECs.

Thrombin triggers the stimulated secretion of WPBs, at least in part by initiating a calcium transition. Recently, Wu and colleagues (13) have demonstrated that pulmonary capillary ECs express a voltage-gated, "T"-type calcium channel that is not expressed in ECs from extra-alveolar vessels. Thrombin activation of the T channel provides a calcium source that induces vWF secretion. Thus, the findings of Wu and colleagues (13) indicate a significant heterogeneity exists in not only in the molecular architecture of WPBs from extra-alveolar and alveolar ECs, but also in the signaling mechanisms that control their stimulated secretion.

Lung capillary ECs express a high level of angiotensin-converting enzyme (ACE). This ACE expression pattern is unique to lung, because in the systemic circulation ACE expression is most prominent in ECs of larger arteries and arterioles, with minimal capillary EC expression (14). A single pass of blood through the pulmonary circulation is sufficient to clear bradykinin from the circulation (as ACE inactivates bradykinin), and to convert angiotensin I to angiotensin II.

Because angiotensin II is a vasoconstrictor that also stimulates aldosterone secretion to regulate blood volume, lung capillary ECs play a role in the control of systemic blood pressure.

### LECTINS DEMARCATe ENDOTHELIAL CELL PHENOTYPES IN THE PULMONARY CIRCULATION

Given the structural and functional transition between extra-alveolar and alveolar ECs (Figure 126.2; for color reproduction, see Color Plate 126.2), investigators sought to identify approaches that could resolve the unique molecular anatomy of these cells in their *in vivo* environment. ECs possess a glycocalyx coat that generates a negative charge barrier and limits fluid and solute permeation across the barrier. Lectins are plant and animal proteins that interact selectively with well-defined carbohydrate moieties. Thus, lectins are useful in discriminating among EC phenotypes that differ in their glycocalyx properties.

Because lung microvascular ECs possess an enhanced barrier function relative to extra-alveolar ECs, it is reasonable to hypothesize that they also possess a distinctive glycocalyx coat. The screening of lectin binding to lung ECs *in vivo* and *in vitro* revealed that alveolar ECs preferentially interact with *Griffonia simplicifolia* and *Glycine max*, whereas pulmonary artery ECs preferentially interact with *Helix pomatia* (1). Both *G. simplicifolia* and *G. max* effectively discriminate alveolar ECs in multiple species, whereas *H. pomatia* appears to be most effective in rat. Nonetheless, it is evident using these lectins that different EC phenotypes abut one another at branch points where extra-alveolar ECs give rise to capillary segments (see Figure 126.2). Although *G. simplicifolia*-positive cells are seen

Figure 126.2. Infusion of TRITC-labeled *H. pomatia* and FITC-labeled *G. simplicifolia* in the intact pulmonary circulation demonstrate a clear demarcation in cell phenotype in vessels 20 to 30  $\mu\text{m}$  in diameter. Note that no spectral overlap occurs, indicating ECs interact with either lectin but do not interact with both lectins. *In situ* epifluorescence images were tested and produced by Dr. Abu-Bakr Al-Mehdi. For color reproduction, see Color Plate 126.2.

immediately adjacent to *H. pomatia*-positive cells, no overlap in lectin binding occurs.

Lectins also have proven useful for isolating and purifying cultures of distinctive EC phenotypes. For example, coupling the Ryan technique for isolating lung capillary ECs from the peripheral lung with incubation of *G. simplicifolia*-coated beads allows enrichment of microvascular ECs (14). These cultures, as with pulmonary artery EC cultures, retain their lectin-specific interaction profile (Figure 126.3A). Moreover, because lectins are agglutinins, binding studies can be complemented with functional measurements to resolve different phenotypic behaviors. Confluent monolayers trypsinized into single-cell suspensions agglutinate in a cell- and lectin-specific manner, illustrating that lung macro- and microvascular ECs retain this phenotypic property in culture through multiple passages (Figure 126.3B).

It is easy to resolve macro- and microvascular ECs by visual inspection. Coculture of these cell types reveals a discrete cell-cell border at which pulmonary artery and microvascular cells grow together (see Figure 126.3C). Although they form a cell-cell junction, the molecular make-up of this junctional complex is different among the cell types. For example, surface expression of the activated leukocyte cell adhesion molecule (ALCAM; CD166) is prominent in microvascular ECs, and is absent in pulmonary artery ECs (15). It is apparent in coculture experiments that ALCAM is present between adjacent microvascular ECs but is absent at both the macro-microvascular and macro-macrovascular EC border. In addition, just as in the intact circulation, lectins retain their ability to discriminate these cell types in coculture experiments (Figure 126.4; for color reproduction see Color Plate 126.4) (15).

### STABLE PHENOTYPES IN CULTURED ENDOTHELIAL CELLS

It is well recognized that passaging cells leads to phenotypic drift. For this reason, cell biologists interested in physiological applications commonly use primary or early passage cells for study. Even then, important questions remain regarding how well the behaviors of cells in culture resemble their in vivo behavior(s). Indeed, detailed comparisons between the proteomes of lung ECs in vivo and in culture reveal a significant shift in protein abundance; for example, only approximately half the integral membrane proteins and plasma membrane-associated proteins were commonly expressed when in vivo and in vitro comparisons were made (16). Thus, the process of isolating and culturing cells changes the expression (abundance) of multiple proteins, as does the act of passaging cells in culture.

Nonetheless, certain EC behaviors are retained in culture, as illustrated in the preceding section, and these behaviors accurately reflect the cell's in vivo function. Findings that lung macro- and microvascular ECs retain their differential lectin-binding patterns suggest that cells possess a memory of their vascular origin. Chi and colleagues (17) recently examined this

idea by comprehensively screening mRNA expression patterns in 53 different EC types. All cells were cultured under similar environmental conditions, yet the investigators were able to discriminate among "like" and "unlike" phenotypes from their expression profiles. Indeed, global mRNA expression profiling resolved arterial, venule, and capillary fingerprints among the cells in culture.

The idea that ECs exhibit mitotically heritable, site-specific functions in vitro was borne out in studies evaluating barrier function. As in the intact circulation, cultured microvascular ECs express a unique complex of adhesion molecules that contribute to an enhanced barrier property. In addition to VE-cadherin, lung capillary ECs express N-cadherin (Troy Stevens, unpublished observations) and possibly E-cadherin (11,12). The microvascular ECs exhibit a higher resting electrical resistance than do their macrovascular counterparts, and they are more restrictive to water and macromolecular flux (15). All the above site-specific properties are maintained in tissue culture over multiple passages.

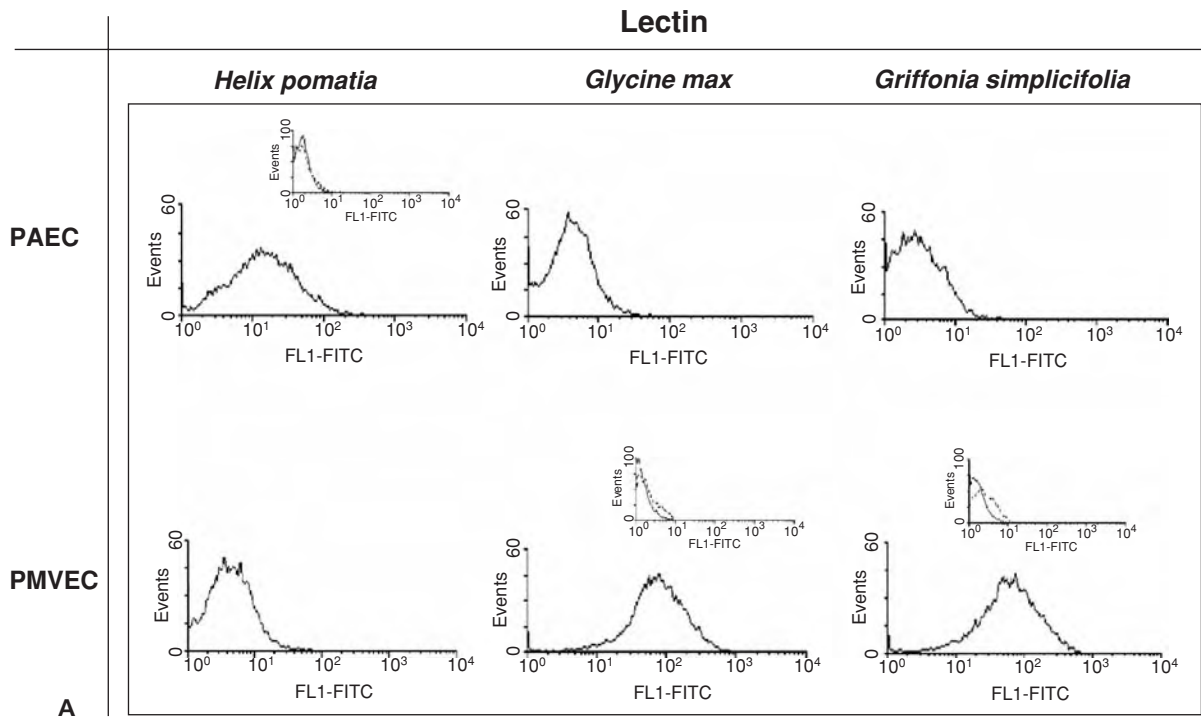

Lung microvascular ECs are also relatively insensitive to barrier disruption induced by inflammatory agonists. Thrombin, for example, maximally disrupts the pulmonary artery EC barrier in vitro within a 1 to 7 U/mL concentration range, whereas at least 10-fold higher concentrations are required to disrupt the microvascular EC barrier (18). Thrombin produces long-lasting gap formation in the pulmonary artery ECs, whereas gap formation is transient in lung microvascular ECs. This finding has led to the appreciation that microvascular cells move very rapidly, perhaps as a built-in mechanism for protecting the alveolar-capillary membrane from edema formation.

The effect of thrombin, or soluble protease-activated receptor ligands, on segment-specific permeability has not yet been examined in vivo. However, we have shown that thapsigargin induces extra-alveolar leak without directly increasing capillary permeability. Thapsigargin similarly increases permeability across pulmonary artery ECs in culture, and it is not sufficient to increase permeability across lung microvascular ECs (19). Interestingly, just as in the intact circulation, rolipram pretreatment prevents thapsigargin from inducing gaps in pulmonary artery ECs and reveals thapsigargin-induced gaps in microvascular ECs (9). Functional responses to the activation of store-operated calcium entry are therefore retained in cultured ECs, as they are in the intact pulmonary circulation. Thus, there is a growing interest in determining the signal transduction mechanisms responsible for controlling this site-specific EC behavior.

### ENVIRONMENTAL CONTROL OF SEGMENT-SPECIFIC ENDOTHELIAL CELL FUNCTION

Evidence that macro- and microvascular ECs retain functionally discrete phenotypes under the same environmental condition does not detract from observations that environmental

Figure 126.4. *G. simplicifolia* recognizes pulmonary microvascular ECs in coculture experiments. Pulmonary artery and microvascular ECs were cocultured, grown to confluence, and labeled with FITC-labeled *G. simplicifolia*. Only microvascular ECs interact with the lectin. For color reproduction, see Color Plate 126.4.

influences modulate EC behavior. However, it does bring into question how biophysical forces and various circulating chemical substances interact with macro- and microvascular endothelium. Very little work is available to address this important issue, although recently Al-Mehdi and colleagues (20) have assessed the EC response to flow. Although many EC culture studies are performed under static, nonflow conditions, this static environment clearly does not reflect the complex in vivo setting involving blood flow and its accompanying transmural pressure and shear stress forces. Typically, the application of perfusion to static EC cultures induces cell realignment in the direction of flow. ECs reorganize their shape from a polygonal orientation to one that is more elongated. Pulmonary artery ECs undergo this reorientation, just as do conduit cells from the systemic circulation. In contrast, lung microvascular ECs do not flow-align, even when exposed to very high levels of shear stress (20). Nonetheless, mitochondria reorganize in microvascular ECs exposed to prolonged flow, indicating that these cells do sense and respond to mechanical perturbation. Moreover, flow cessation in flow-adapted microvascular ECs induces calcium entry through T-type calcium channels and promotes oxidant production (21,22). Thus, it is clear that lung macro- and microvascular ECs each

respond uniquely to environmental cues. These findings illustrate the importance of using physiologically appropriate cell sources to examine functional adaptation to environmental insults.

The complexity of environmental cues that influence EC behavior is only beginning to be appreciated. It is quite likely that unique cell–cell communication in pulmonary arteries/veins (e.g., EC to smooth muscle) and capillaries (e.g., EC to epithelial), and in matrix components within the basement membrane of extra-alveolar versus alveolar blood vessels, influence segment-specific EC function. It is also likely that different oxygen tensions in arterial (i.e., mixed venous  $pO_2$ ) and venous (i.e., arterial  $pO_2$ ) vessels contribute to segment-specific EC function. Detailed studies will be needed for us to better understand how environmental stimuli adjust segment-specific EC behavior.

### ON ENDOTHELIAL CELL SPECIFICATION

It is not presently clear how ECs gain a stable functional memory – that is, how they establish mitotically heritable site-specific properties. However, studies of the developing pulmonary vascular circulation may shed some provocative insight into this issue. In 1997, DeMello et al. (23) used a Mercox corrosion cast model to visualize the developing mouse (20-day gestational period) pulmonary circulation by electron microscopy. Their studies revealed that the earliest evidence for pulmonary arterial development was in the pseudoglandular phase (ranging from embryonic day [E]9–16) of lung development. Only rudimentary arterial segments could be visualized at the beginning of this phase; the pulmonary circulation did not connect with capillary segments and did not return to the left ventricle. It was not until approximately E14 – near the end of the pseudoglandular phase of lung development – that arterial segments were continuous with capillary loops and ultimately with pulmonary veins. Despite the inability to visualize an “intact” circulation at E9 to 12, transmission electron microscopy demonstrated rudimentary blood lakes developing in the lung’s mesenchyme. Thus, DeMello and colleagues (23) reasoned that two distinct events lead to the eventual formation of a mature pulmonary vascular bed, including angiogenesis of precapillary vessels and vasculogenesis of capillary vessels. The key event in this model is a fusion between angiogenic and vasculogenic vessels at midgestation, near the end of the pseudoglandular phase of lung development.

←  
Figure 126.3. (A) FACS analysis reveals that macro- and microvascular ECs isolated and cultured retain their ability to uniquely interact with lectins. Insert pictures show control cells without lectin treatment, and cells treated with  $\alpha$ -GalNAc to block *H. pomatia*,  $\beta$ -GalNAc to block *G. max*, and  $\alpha$ -galactose to block *G. simplicifolia*. (B) Because lectins are agglutinins, their ability to agglutinate cells in the presence of trypsin was examined. *H. pomatia* agglutinates macrovascular ECs, whereas *G. max* and *G. simplicifolia* agglutinate microvascular ECs. For experimental details see King J, Hamil T, Creighton J, et al. Structural and functional characteristics of lung macro- and microvascular EC phenotypes. *Microvasc Res.* 2004;67(2):139–151. (C) Pulmonary artery ECs and pulmonary microvascular ECs were cocultured on gridded coverslips and observed as they grew to confluence. Pulmonary artery ECs cocultured with pulmonary microvascular ECs always generated a discernible border, illustrating unique cell recognition patterns.

There remains significant controversy as to whether this model accurately reflects the events that underlie lung vascular development. Indeed, serial sectioning of lungs from mice expressing reporter genes under the control of an endothelial-“specific” promoter has provided evidence that capillary development occurs continuously, along with the development of larger arteries and veins (24–26). These studies suggest the possibility that, in the DeMello and colleagues research (23), small capillary loops were associated with feeder vessels but could not be perfused by the Mercox solution. Thus, the exact origin of extra-alveolar and alveolar ECs remains in question.

Interestingly, work in transgenic animals has provided some mechanistic insight into what controls site-specific vascular development. In comprehensive works by multiple different labs, disruption of vascular endothelial growth factor (VEGF) signal transduction uniformly interrupts capillary development (15). In contrast, the disruption of the Notch signaling mechanism interrupts pulmonary artery development (15). Thus, these studies together suggest distinct molecular programs may be engaged as cells within different vascular locations gain endothelial specification.

Recent studies by Stewart and colleagues (27) incriminated nitric oxide (NO) in normal lung vascular development. These investigators examined endothelial NO synthase (*eNOS*)<sup>-/-</sup> mice, and discovered that approximately 25% of the mice died from respiratory failure within 48 hours of birth. Upon closer inspection, it was determined that capillaries developed independently of arteries and veins, suggesting the presence of artery-to-vein anastomoses, in which blood bypassed the alveolar-capillary membrane altogether. Capillaries, while present, had not simplified to form normally thin alveolar-capillary membranes. The lung vascular structures in these *eNOS*<sup>-/-</sup> mice resembled those of the alveolar-capillary dysplasia in children. Moreover, these findings of Stewart and colleagues (27) generally support the work of DeMello and colleagues (23), and suggest that NO participates in some fusion event that is essential for the eventual continuity of the lung’s circulation.

At present, there is no consensus as to the independent or combined roles of angiogenesis and vasculogenesis in lung vascular development. While this issue remains an important one, a consensus point is that extra-alveolar and alveolar EC differentiation and specification occurs in different physical locations. Insight from various transgenic models supports the idea that unique gene expression programs are in place to guide appropriate EC development and to ensure that the cell functions in a manner appropriate for its vascular site. Thus, it is likely that cell-specific environments imprint highly distinctive characteristics early in the developmental course.

Although cell-specific behaviors may be imprinted early in development, there is currently no understanding of how this memory is maintained either as one ages or, indeed, when cells are placed in culture. Our group has only begun to address this issue. Because the genome is identical in cells of the body

(including ECs from different vascular locations), we questioned whether proteins that control master regulatory transcriptional programs are differentially expressed among lung macro- and microvascular ECs. Histones fulfill an important role in controlling global gene expression by condensing DNA into heterochromatin and euchromatin. By controlling which DNA sequences are accessible to transcription factors, histones regulate global gene expression as a mechanism of imprinting. Interestingly, histones 2A and 2B were both overexpressed in lung microvascular ECs (when compared to pulmonary artery ECs), as was the nucleosome assembly protein. The functional significance of this observation remains to be determined, although these findings suggest that proteins organizing chromatin structure may fulfill an important role in phenotype specification, likely by controlling the activity of global transcription programs. Future studies will be required to rigorously determine the role that chromatin structure plays in endothelial phenotype specification.

#### IMPLICATIONS OF ENDOTHELIAL CELL HETEROGENEITY IN PULMONARY VASCULAR DISEASE

It is not often that we consider exactly why a disease process manifests itself in any specific vascular locale. However, the idea that ECs possess a site-specific phenotype suggests that imprinting may contribute to lesion site-specificity. We have already illustrated this point in our review of the developmental literature, in which *eNOS*<sup>-/-</sup> mice that died from respiratory failure early in the postnatal period exhibited an alveolar-capillary dysplasia-like anatomy (27). These findings were taken to suggest that NO fulfills an important role in the fusion of extra-alveolar and alveolar blood vessels. We have also seen that circulating inflammatory agonists can target either extra-alveolar or alveolar ECs to increase permeability in a site-specific way (3,4,6–8). Thus, there is a growing awareness that EC phenotypes contribute to the site of vascular injury.

Primary pulmonary hypertension is a rare, progressive disorder that also involves EC dysfunction. There are two prominent aspects of this disease (28). A first lesion is found in large- and intermediate-sized precapillary blood vessels, and is characterized by medial and adventitial hypertrophy/hyperplasia. Smooth muscle layers extend distally into normally nonmuscularized or poorly muscularized vascular segments, contributing significantly to the increase in pulmonary artery pressure and vascular resistance. A second lesion is found predominantly in severe forms of pulmonary hypertension, and is localized to small precapillary vessel segments, commonly originating at vessel bifurcations. This “plexiform lesion” is a lumen-occluding mass comprised of ECs that have lost the “law of the monolayer.” We were particularly interested in the source of ECs found in the plexiform lesion. Histological sections show cells extending from the intima of small

Figure 126.5. Plexogenic lesions are comprised of cells that interact with *G. simplicifolia*. (A) Although these lesions may extend into large blood vessels, serial sectioning reveals the initiating locus is typically a small, precapillary arteriole. This histological section of a plexogenic lesion from a patient shows EC staining for ALCAM (DAB). The arrows show sites in the vessel wall where ECs appear to have lost their intimate contact and grown into the lumen. (B) Human lung specimens from patients with severe pulmonary hypertension were used to analyze plexogenic lesions for their ability to interact with lectins. This 70- $\mu\text{m}$  lesion interacts selectively with *G. simplicifolia* and not *H. pomatia* (not shown), suggesting cells with a microvascular EC phenotype are present in the lesion. Tissue was evaluated by confocal microscopy with 0.35- $\mu\text{m}$  Z-axis sectioning and reconstructed into a 3D image. The image was then rotated 360 degrees from the lateral position I–VI and pictures captured.

precapillary vessels into the lumen (Figure 126.5A), suggesting at least some of the cells in the lumen could be of a “microvascular origin.” We therefore examined whether ECs in the plexiform lesion interact with *G. simplicifolia*. Cell clusters within the lumen did, indeed, interact with this marker of microvascular ECs, suggesting that they were of a microvascular EC phenotype (Figure 126.5B). Much more definitive evidence will ultimately be required to assure that cells causing the plexiform lesions arise from microvascular ECs within the vessel wall. However, these findings provide provocative support for the idea that the EC phenotype contributes to the site of vascular injury.

## CONCLUSION

Although we now recognize that ECs along a single vascular segment are highly specialized, as highlighted by the comparisons between extra-alveolar and alveolar ECs, we know very little about how such phenotype specification occurs and is maintained. We have limited information about how environmental cues interact uniquely within a given vascular segment to modify EC behavior or, in extreme circumstances, to contribute to the site-specificity of vascular disease. Indeed, the continued, rapid advance of our field will require the detailed consideration of not only how environmental cues modify EC behavior, but more specifically how these environmental influences interact with ECs within (or obtained from) a physiologically relevant vascular location.

## KEY POINTS

- Extra-alveolar and alveolar ECs possess a stable memory of their vascular origin, which influences the cell’s response to environmental cues and establishes a site-specific cell phenotype.
- Extra-alveolar and alveolar ECs possess distinct behaviors, including barrier function, in which alveolar ECs form a more restrictive barrier than do extra-alveolar ECs.
- Extra-alveolar and alveolar ECs retain a memory of their *in vivo* phenotypes, even when studied in culture under similar environmental conditions.
- EC phenotype, which is determined by the cell’s vascular origin and its interaction with local environmental influences, contributes to the site-specific nature of vascular disease.

## Future Goals

- To determine molecular mechanisms responsible for EC phenotype specification
- To map signaling matrices in extra-alveolar and alveolar ECs that encode their unique responses to (patho-)physiologically relevant environmental stimuli

## Bronchial Endothelium

Elizabeth Wagner and Aigul Moldobaeva

*Johns Hopkins Asthma and Allergy Center, Baltimore, Maryland*

The bronchial circulation is poorly accessible and dwarfed in size by the pulmonary vasculature. Studies highlighting the unique attributes of the bronchial endothelium are few in number and represent a contemporary work-in-progress. Despite the current paucity of information regarding bronchial endothelial phenotypes, it has long been recognized that bronchial vessels undergo structural changes in pathological states. Most notable among these changes are dilation, neovascularization, and contribution to bronchial mucosal swelling.

Perhaps the first documentation of disease-associated bronchial neovascularization (hence, bronchial endothelial proliferation) is found in one of Leonardo da Vinci's anatomical drawings (circa 1513 A.D.) (Figure 127.1). Close scrutiny of a tuberculous cavity in a terminal lung unit shows bronchial vessels supplying the walls of the cavity. Whether da Vinci used artistic license in his depiction of the vasculature has been argued over the years (1).

In 1847, Rudolph Virchow demonstrated an association between chronic pulmonary artery obstruction and a proliferative bronchial phenotype (2). He interpreted these studies to suggest pulmonary vascular ischemia leads to compensatory recruitment of systemic bronchial vessels to ischemic regions. Others more recently have speculated that obstruction of even small pulmonary vessels (e.g., within a tuberculous cavity) is sufficient to induce proliferation of bronchial vessels (3).

In his original textbook (1892), Sir William Osler noted that during an asthma attack "the hyperaemia and swelling of the mucosa . . . explain well the hindrance to inspiration and expiration" (4). Although mechanisms regulating endothelial cell (EC) barrier function were not known at the time, the clinical consequences certainly were.

These and other gross morphology-based findings provided important insights into the unique features of the bronchial circulation in health and disease. Speculation about a putative role of the endothelium in mediating these properties would have to wait not only for the discovery of this cell layer, but also for the recognition that ECs are more than an inert barrier. Over the past decades, advances in ultrastructural methodology (e.g., electron microscopy), cell culture

techniques, and molecular biology have paved the way for identifying and characterizing site-specific phenotypes of the bronchial endothelium that bear relevance to homeostasis and pathophysiology.

### STRUCTURE

The bronchial vasculature originates from the aorta or, in some species, the intercostal arteries (5–7). The bronchial artery courses to the dorsal aspect of the carina, where it bifurcates and sends branches down the mainstem bronchi (Figure 127.2). This vascular bed perfuses the airways from the level of the carina to the terminal bronchioles. The bronchial arteries send arterioles throughout the airway adventitia that connect with capillaries that are prominent in both the adventitia as well as the mucosa of the airway wall. Thus, the bronchial vasculature forms parallel vascular plexuses, situated on either side of the airway smooth muscle. In the intraparenchymal airways, postcapillary venules collect bronchial venous drainage and drain into pulmonary venules and/or alveolar capillaries that drain into pulmonary veins and the left atrium. Additionally, the bronchial artery sends branches to large pulmonary vessels as vasa vasorum, nerves, and the visceral pleura.

The developmental origin of the bronchial circulation is not well established. Previous studies of human vascular development demonstrate that the bronchial artery arises as an outgrowth from the aorta between the ninth and twelfth week of gestation, a somewhat later time point compared with the pulmonary circulation (8,9). One or two vessels extend from the dorsal aorta and form along the cartilaginous plates of the large airways. The vessels extend longitudinally along the airways to the lung periphery as far as the terminal bronchioles. This pattern is suggestive of an angiogenic (as distinct from vasculogenic) process. However, the mechanisms underlying development of other segments of the bronchial circulation remain unclear. For example, it is not known to what extent angiogenesis or vasculogenesis (from mesoderm) contributes to the formation of fine bronchial capillaries within

Figure 127.1. Leonardo da Vinci's drawing of purported bronchial circulation. Arrow points to a tuberculous cavity in a terminal lung unit supplied by bronchial vessels. Figure 127.2. Schematic of the bronchial vasculature. Arrows indicate the site of bronchial arterial perfusion of airways, pleura and vasa vasorum of large pulmonary vessels.

Figure 127.3. Scanning electron micrographs of the luminal surface of rat tracheal venular endothelium: A and B control, C and D after substance P. Regions marked by asterisks are enlarged in B and D. Bars, 5  $\mu\text{m}$  for A and C; 1  $\mu\text{m}$  for B and D. (Reproduced with permission from Baluk P, Hirata A, Thurston G, et al. Endothelial gaps: time course of formation and closure in inflamed venules of rats. *Am J Physiol.* 1997;272:L155–170.)

the bronchial wall (namely the mucosal plexus), the vasa vasorum of large pulmonary vessel walls, or bronchial–pulmonary anastomoses.

Relatively little is known about the morphology or site-specific markers of the endothelium lining the bronchial vasculature. Capillaries are predominantly continuous and, in healthy mammals, lacking in fenestrations. Electron micrographs of the luminal surface of rat tracheal venules (Figures 127.3A/B and 127.4A) reveal uniform cell borders (arrows) that are narrow and closely apposed. Only recently have investigators been successful in isolating airway ECs and studying them *in vitro* (10,11).

#### BRONCHIAL ENDOTHELIUM IN HEALTH AND DISEASE

As with other vascular beds, the endothelial lining of the bronchial vasculature has been implicated in the control of vascular smooth muscle contraction/relaxation (hence blood

**Table 127-1: Comparison of Bronchial and Pulmonary Vascular Beds**

	<i>Bronchial</i>	<i>Pulmonary</i>
Surface area	Low	High
Arterial oxygen	High	Low
Arterial pressure	High	Low
Arterial resistance	High	Low
Blood flow	Low (<3% CO)	High (100% CO)
Primary function	Nutrient delivery; thermoregulation, humidification of airways	Gas exchange
Proliferative capacity	High	Low
Role for NO in vasomotor tone	Yes	Yes
Role for ACE	Yes	Yes
Leukocyte recruitment	Postcapillary	Capillary

CO, cardiac output

flow), barrier function, substrate metabolism, and leukocyte recruitment, among other common functions. Given that the bronchial and pulmonary circulations carry out distinct functions, it is not surprising that endothelium from these blood vessels express different phenotypes. For example, alveolar (pulmonary) capillaries form a tight barrier to prevent fluid accumulation and compromise in oxygen delivery, whereas bronchial capillaries play an active role in thermoregulation and humidification of ambient air. Bronchial artery ECs display a more robust proliferative capacity compared with their pulmonary counterparts, a difference that is consistent with a role for the bronchial circulation in compensating for pulmonary artery hypoperfusion. A comparison of the two lung circulations is provided (Table 127-1) and several of these features are highlighted in the next sections.

### Vasomotor Tone

Previous physiological studies have demonstrated the importance of endothelial-derived substances in modulating bronchial vascular resistance. For example, systemic infusion of N-(G)-nitro-L-arginine methyl ester (L-NAME), an inhibitor of endothelial nitric oxide synthase (eNOS), resulted in decreased bronchial blood flow in sheep (13,14). Bronchial vasodilators such as bradykinin, acetylcholine, inhaled  $\beta$ -agonists, ionic and nonionic contrast media all function partially through the release of endothelial-derived nitric oxide (NO) (12–14). Cyclooxygenase inhibitors likewise have been shown to elicit endothelium-dependent vasoconstriction (15). Intra-arterial delivery of the potent EC-derived vasoconstrictor endothelin-1 caused a significant increase in bronchial vascular resistance in sheep (16).

These results are in keeping with observations in other systemic arteries. However, the functional significance of vasomotor regulation in the bronchial circulation is unique. For example, we and others have shown that the level of blood flow through the bronchial circulation can affect both the magnitude and time course of agonist-induced airway smooth muscle constriction by contributing to the passive wash-out of an inhaled or intra-arterial agonist (17,18). Thus, changes in airway wall perfusion due to airway EC activation may modulate airway reactivity. Additionally, changes in bronchial vascular perfusion have been shown to affect the function of vascular uptake of soluble particles deposited on airway epithelial surface (19). Thus, modulation of bronchial vascular perfusion by endothelial-derived factors can affect airway function.

### Metabolism

Few studies have focused directly on the metabolic capability of the bronchial endothelium. Using an in situ perfused sheep bronchial artery preparation, Grantham and colleagues

Figure 127.4. (A) Transmission electron micrograph showing normal EC junctions of rat tracheal venular endothelium. (B) ECs gaps with finger-like projections after exposure to substance P. (Reproduced with permission from Baluk P, Hirata A, Thurston G, et al. Endothelial gaps: time course of formation and closure in inflamed venules of rats. *Am J Physiol.* 1997;272:L155–170.)

demonstrated that intra-arterial administration of an angiotensin-converting enzyme (ACE) inhibitor significantly depressed metabolism of a synthetic peptide substrate for ACE (20). These authors concluded that the bronchial circulation is pharmacokinetically and metabolically active with respect to bradykinin breakdown, and that the enzyme(s) responsible for this metabolic activity is present on the surface of the vascular lumen. We confirmed in sheep the importance of ACE activity in the bronchial circulation *in vivo* by demonstrating the inhibition of bradykinin-mediated bronchial vasodilation after treatment with an ACE inhibitor (11). We also have demonstrated that, under *in vitro* conditions, cultured bronchial microvascular ECs express ACE, and that the levels and activity of this enzyme are comparable to those of pulmonary ECs. These experiments suggest an important regulatory role for bronchial endothelial ACE in the metabolism of kinin peptides known to contribute to airway pathology.

### Vascular Barrier Function

Numerous studies involving animal models as well as autopsy specimens of human lungs have provided evidence for the propensity of the systemic airway circulation to contribute to abnormal fluid accumulation in both the bronchial wall and lumen. Most notably, inflammatory cytokines have been shown to induce the formation of gaps in the endothelium of postcapillary venules, which leads to exudation of plasma and protein into the interstitium (21). Figures 127.3C/D and 127.4B show electron micrographs of tracheal venular gap formation after intravenous challenge with the inflammatory mediator, substance P (21). Long, finger-like processes are shown to bridge the gaps between ECs.

To evaluate the molecular mechanisms responsible for gap formation and secondary transudation of fluid, we have recently isolated, cultured, and studied ECs from large bronchial arteries (conduit vessels) and bronchial microvessels from sheep (10). Compared with ECs from the bronchial artery, bronchial microvascular ECs displayed increased permeability both at baseline and in response to edematogenic substances, including bradykinin and thrombin. These findings run counter to those usually observed in the *in vitro* and *in vivo* studies of pulmonary endothelium, in which the microvascular endothelial barrier has been shown to be more restrictive than conduit vessel endothelium. The relative differences in permeability between bronchial and pulmonary microvascular ECs are consistent with their established roles in mediating airway humidity and alveolar dryness, respectively. Importantly, the cell culture data suggest that these differences are mitotically heritable and thus epigenetically programmed.

It has been proposed that the bronchial endothelium, by a unique mechanism of cross-talk, may contribute to the barrier function of pulmonary endothelium (22). Although the existence of bronchial artery-derived vasa vasorum in pulmonary vessels has long been recognized, the functional significance of these capillary networks has remained under-

explored. Vasa vasorum have been identified in pulmonary arterioles of 200  $\mu\text{m}$  diameter (23). Furthermore, in a sheep ischemia-reperfusion lung injury model, perfusion of the bronchial artery during pulmonary artery ischemia and reperfusion, or pulmonary artery reperfusion alone, significantly attenuated the increase in pulmonary endothelial permeability that occurred in the absence of bronchial artery perfusion (22). Because bronchial artery perfusion during the reperfusion phase alone was effective at reducing injury, this result excludes the possibility that mere nutrient flow through broncho-pulmonary anastomoses accounted for the preserved barrier function. These results raised the interesting hypothesis that the bronchial endothelium generates and transfers a protective substance to the pulmonary endothelium during pulmonary artery reperfusion. NO produced by bronchial endothelium is a likely, shear-induced antioxidant candidate. Subsequent preliminary studies demonstrated that perfusion of the bronchial circulation during pulmonary artery reperfusion with a NOS inhibitor attenuated the protective effect in this model. These results further highlight the potential heterogeneity of EC responses to ischemia with regard to barrier function as well as basic enzymatic function during ventilated ischemia. Furthermore, they provide evidence that the systemic circulation of the lung can have an impact on functional attributes of the pulmonary vasculature.

### Leukocyte Recruitment

Leukocyte recruitment in other organs receiving systemic blood supply has been shown to involve an orchestrated series of molecular interactions between rolling leukocytes and ECs in postcapillary venules. Given that the bronchial circulation is systemic in nature, it seems likely that similar mechanisms hold true for leukocyte transendothelial migration in this vascular bed. Indeed, we recently have confirmed this hypothesis, using intravital microscopy of lipopolysaccharide (LPS)-treated airways in rats (24). Moreover, we have demonstrated that ventilatory stress imposed on bronchial endothelium (airway distension) induces leukocyte recruitment in the airway (25).

### Angiogenesis

#### *Chronic Thromboembolism*

Angiogenesis in the adult lung involves the invasion of systemic vessels (bronchial, intercostal arteries) into ischemic lung parenchyma while the pulmonary vasculature remains relatively inert. In this regard, the bronchial circulation has been compared to "Mother or the Red Cross; normally accepted and unsung, but capable of giving vital help when needed" (5). Bronchial arteriograms in patients with chronic thromboembolic disease demonstrate the unique capacity of these systemic vessels to proliferate and invade the ischemic lung parenchyma. Both a dilated bronchial artery as well as a fine meshwork of vessels distal to the pulmonary occlusion can be seen (Figure 127.5) (26). Neovascularization of

Figure 127.5. Bronchial arteriogram in a patient with thromboembolic pulmonary hypertension. The dilated bronchial artery is clearly seen, as well as a mesh of small bronchial vessels connected to the pulmonary arterial branches downstream to the embolic occlusion. White arrows point to bronchial arterial branches and black arrows point to pulmonary arterial branches distal to the occlusion. (Reproduced with permission from Endrys J, Hayat N, Cherian G. Comparison of bronchopulmonary collaterals and collateral blood flow in patients with chronic thromboembolic and primary pulmonary hypertension. *Heart*. 1997;78:171–176.)

the systemic circulation into the lung after pulmonary artery obstruction has been confirmed and studied in humans (26), sheep (27), dogs (28), pigs (29), guinea pigs (30), rats (31), and mice (32). Systemic blood flow to the lung has been shown to increase to as much as 30% of the original pulmonary blood flow after pulmonary artery occlusion (28,33). In a mouse model of chronic pulmonary thromboembolism, the proangiogenic C-X-C chemokines were shown to play a major role in vascular proliferation (34). This observation adds further support to a growing body of evidence that the Glu-Leu-Arg (ELR)-containing C-X-C chemokines and their G-protein-coupled receptor CXCR2 promote angiogenesis in several lung diseases (35).

Notably, in studies of non-small cell lung cancer (36) and idiopathic pulmonary fibrosis (37), the ELR+ C-X-C chemokines have been shown to be proangiogenic, whereas the ELR- C-X-C chemokines exhibit angiostatic properties. Based on these data, it was hypothesized that differences in proangiogenic potential of systemic versus pulmonary ECs may be explained by vascular bed-specific differences in chemokine responsiveness (38). In support of this hypothesis, macrophage inflammatory protein (MIP)-2 (an ELR-containing C-X-C) was shown to promote migration of cultured mouse aortic ECs, but not pulmonary artery ECs. Expression of the MIP-2 G-protein-coupled receptor CXCR2 did not differ between cell types. However, cathepsin S, a proteolytic enzyme important for EC motility (39), was shown to exhibit increased protein and activity in chemokine-treated aortic ECs, relative to similarly treated pulmonary ECs. These

results demonstrate one potential mechanism that may contribute to lung EC subtype-specific differences in angiogenic potential.

### Inflammation

Inflammation can contribute significantly to bronchial vascular remodeling and life-threatening hemoptysis. Hemoptysis in the vast majority of patients originates from the systemic, rather than pulmonary vasculature, and the bronchial vessels are involved almost universally. However, the etiology of hemoptysis requiring therapeutic embolization is variable, and the pathology of bronchial vessels leading to this acute condition is poorly understood. Several studies have focused on the chronic inflammation of asthma and airway vascular remodeling. Li and Wilson demonstrated increased vascular density in biopsy specimens of subjects with mild asthma compared with normal control volunteers (40). However, Chu and colleagues showed that only biopsy specimens from asthmatic subjects with concurrent *Mycoplasma pneumoniae* infections demonstrated significantly increased vessel numbers (41). Rodent models of inflammation have been employed to study alterations in airway vascularity, and have demonstrated increased vessel numbers, size, and permeability characteristics. Airway remodeling following *M. pulmonis* infection showed mouse strain-dependent changes in tracheal vascularity (42). Sustained alterations in the tracheal vasculature were reversed by corticosteroid treatment (43). Additionally, tracheal vessels in rats exposed to *M. pulmonis* demonstrated a significantly increased permeability in the airway vasculature when challenged with substance P after inflammation was induced (44). These results, along with the clinical features of hemoptysis, suggest that proliferating bronchial vessels express abnormal barrier function.

### Hypoxia

Although the bronchial vasculature has been shown to dilate acutely during hypoxic ventilation (45,46), its proliferative capacity during chronic hypoxia has not been established. Clinically, bronchial vessels appear not to proliferate during primary pulmonary hypertension (47). However, a recent study demonstrated proliferation of the pulmonary vasa vasorum in a neonate exposed to chronic hypoxia (48). It has been suggested that blood vessels that transport venous blood, such as the systemic veins and pulmonary artery, depend more on the network of vasa vasorum than on luminal oxygen to support metabolism (49). A recent study of Davie and colleagues demonstrated a marked increase in the vascular density of the pulmonary artery adventitial vasa vasorum coincident with significant pulmonary artery hypertension (48). Furthermore, these investigators confirmed that chronic hypoxia resulted in an increase in circulating bone marrow-derived progenitor cells (c-kit<sup>+</sup> cells), which also were incorporated into the new vasa vasorum within the wall of the pulmonary artery. Thus, this suggests that blood-borne progenitor cells to be delivered to the site of neovascularization may be required for this remodeling process.

## KEY POINTS

- Bronchial endothelium shares the characteristic features of other systemic vascular beds, and its responses are frequently in contrast to pulmonary endothelium.
- EC-derived factors modulate vascular smooth muscle tone as they do other systemic vessels.
- Leukocyte recruitment and vascular leak occur at postcapillary sites.
- Bronchial endothelium is involved in the vigorous angiogenic response to pulmonary parenchymal ischemia.

## Future Goals

- To focus studies of lung pathologies associated with the systemic circulation of the lung on the basic cellular mechanisms of bronchial ECs, despite the difficulty in accessing bronchial endothelium
- To elucidate the unique attributes of bronchial relative to pulmonary endothelial function

## The Endothelium in Acute Respiratory Distress Syndrome

---

Mark L. Martinez and Guy A. Zimmerman

*University of Utah, School of Medicine, Salt Lake City*

The pulmonary endothelium, poised at the interface between air, blood, and tissue, provides both rapid and sustained responses to local and systemic perturbations. This complex vascular structure occupies a surface area of 120 m<sup>2</sup> and forms the intimal lining of the pulmonary arterial, venous, and capillary beds with a single continuous layer of endothelial cells (ECs) linked to each other by specialized junctions (1). The alveolar endothelium is intimately related to the alveolar epithelium both in terms of anatomic location and functions that include oxygen (O<sub>2</sub>), carbon dioxide, water and solute transport, and barrier regulation; disruption of barrier functions of the alveolar capillary membrane is an early and critical event in the pathogenesis of acute respiratory distress syndrome (ARDS) (see later and Box 128.1). Alveolar epithelial function, which is beyond the scope of this chapter, has recently been reviewed (2).

Once thought of as passive, semipermeable conduits for nutrient and O<sub>2</sub> delivery – and in the lungs, contributing to separation of blood from air (1) (Box 128.1) – ECs were dismissed as structural bystanders with little or no capacity to respond to activating signals with changes in phenotype or function (3). During the 1950s, electron microscopic observations that ECs contain secretory granules, together with ongoing physiological studies of EC–leukocyte interactions, implicated the endothelium as an active participant in both physiological and pathophysiological responses to injury and inflammation (4–6). Subsequent studies clearly demonstrated that, even under normal physiological conditions, the “quiescent” endothelium is far from inactive and is involved in multiple homeostatic functions. These include, but are not limited to, cellular and nutrient trafficking, angiogenesis and vasculogenesis, regulation of vascular tone, and maintenance of blood fluidity and vascular barrier function (3–7). It is evident that ECs can respond to a host of physical and biochemical stimuli to become *activated* in both home-

ostatic and disease states (3–7) (Figure 128.1). EC activation in response to extracellular signals from mechanical forces, coagulation factors, cytokines, soluble growth factors, bacterial products, and toxins, and interactions with circulating platelets and leukocytes is mediated by an array of intracellular transduction pathways, leading to rapid and, in some cases, sustained functional changes. These functional alterations can lead to proinflammatory, procoagulant, and vasoconstrictive or vasodilatory responses. When these processes become dysregulated, host tissue damage and organ-specific or systemic illness with endothelial components occurs (3–5,7) (see Figure 128.1). Many of these general features of endothelial biology and function have been established using models of systemic endothelium, and have not been completely validated for pulmonary ECs (5,7). Nevertheless, these paradigms appear to be relevant to lung EC behavior under normal conditions and in ARDS; they are emphasized here. Furthermore, systemic EC function frequently is altered in ARDS (see Box 128.1).

Injury and dysregulated responses of the pulmonary endothelium are principal mechanisms in a pathologic spectrum termed *acute lung injury* (ALI) and, in its most severe form, ARDS (8,9) (see Figure 128.1). The original term, *adult respiratory distress syndrome*, evolved from a seminal report in 1967 that described 12 patients with acute onset of pulmonary injury, with characteristic radiographic and pathophysiological features that were unresponsive to traditional modes of mechanical ventilation (10). It is now known that ALI/ARDS occurs with substantial frequency in children, resulting in modification of the term (9). After early work in the field indicated that pulmonary edema is a central component of ARDS, the concept that widespread EC injury is fundamental to the pathogenesis of the syndrome emerged (9) (see Box 128.1). Subsequently, clinical guidelines established the descriptors ALI and ARDS to represent varying degrees

**Text Box 128.1: Definitions, Clinical Features, and Physiology of ARDS (8–10,12,15)**

ARDS is the most severe manifestation of injury to the alveolar-capillary units of the lung (alveolar-capillary membrane), a spectrum now termed *acute lung injury* (ALI). Thus ALI and ARDS are a continuum. Consensus definitions based on physiologic and radiographic abnormalities are utilized to distinguish them in clinical practice and investigation. ALI and ARDS are initiated by acute injury to the alveolar-capillary membrane. The initial insult can be delivered via the blood to the alveolar capillaries, or to the alveolar epithelial cells on the gaseous side of the alveolar-capillary units. Ultimately, both ECs and epithelial cells are involved in the pathogenesis of ARDS. Sepsis, aspiration, infectious syndromes such as influenza or SARS, and trauma with shock and/or multiple transfusions are major etiologies for ALI and ARDS in large studies. A variety of other insults can induce ALI and ARDS, including inhalation injury, pancreatitis, and drowning. Iatrogenic manipulations including hyperoxia, ventilation with high tidal volumes (ventilator-induced lung injury; VILI), and transfusion (transfusion-related lung injury; TRALI) can initiate or propagate ALI. ALI/ARDS can resolve or progress to multiple organ failure, pulmonary vascular obstruction and/or destruction, or pulmonary fibrosis.

The cardinal feature of early ARDS is flooding of the alveoli with pulmonary edema fluid rich in protein. This is termed *increased-permeability edema* (also caused by noncardiogenic pulmonary edema) to contrast with *high-pressure edema*, which results from increased pulmonary capillary hydrostatic pressure, usually due to high filling pressures in the left side of the heart. Increased-permeability edema results from altered barrier function of the alveolar capillaries, the largest capillary bed in the body, causing increased transfer of water and protein out of the vessels into the alveolar interstitium at any given microvascular hydrostatic and oncotic pressure (altered permeability coefficient in the Starling equation). Altered barrier function of the alveolar capillaries is thought to be due to acute inflammatory injury in most cases. Increased permeability of the epithelial barrier due to loosening or disruption of tight junctions between alveolar epithelial cells, which are normally tighter than those of the alveolar ECs, then results in flooding of protein-rich fluid from the interstitium into the alveolar space. Increased microvascular pressure in the alveolar capillaries due to excessive fluid administration or inter-

current cardiac dysfunction can exacerbate accumulation of edema fluid when alveolar barrier function is disrupted. Nevertheless, the utility of invasive monitoring to guide fluid management in ARDS remains controversial and is the subject of a current study in the multicenter ARDS network.

Additional features of early ALI/ARDS include alveolar epithelial cell death and denudation of the basement membrane, diffuse inflammation, and deposition of hyaline membranes. Hyaline membranes are complexes of protein and cellular debris on the alveolar surface that form in part from fibrin deposition, linking coagulation responses to alveolar-capillary membrane injury. This constellation of events results in a characteristic light and electron microscopic pattern termed *diffuse alveolar damage*.

ARDS often is considered to be isolated to the lungs, but the syndrome frequently causes systemic manifestations, and is a principal cause of multiple-organ failure. This may in part result from the effects of mediators generated in the lungs on systemic ECs. In addition, triggers of ALI/ARDS, such as sepsis, trauma, and shock, cause systemic EC activation and injury. Thus, in many cases, ARDS is a systemic syndrome, and studies that focus on systemic ECs have relevance to ALI/ARDS.

of respiratory impairment due to increased-permeability pulmonary edema, and consensus definitions based on the chest radiograph and physiological alterations were developed (8,11,12). Multiple studies indicated that this pathophysiologic spectrum results from lung cellular responses, including responses of the alveolar endothelium and epithelium, to a variety of intrinsic and extrinsic injurious agents (8,9,11–15) (see Figure 128.1 and Box 128.1). Because ALI and ARDS represent points on a spectrum of clinical severity (8,12,15), for the remainder of this chapter the term ARDS will be synonymous with ALI except where indicated.

Ongoing investigations into the functional and phenotypic changes of ECs in ARDS have resulted in altered concepts and paradigms when compared to those proposed at the time of initial clinical description of the syndrome more than 30 years ago (9). Nevertheless, most of these concepts are based on inference from studies of systemic endothelium and from studies in experimental systems, rather than on direct observations of ECs in the lungs of patients with ARDS (5). Furthermore, our ability to *translate* experimental studies of ARDS has been limited and has resulted in only a handful of moderately successful clinical interventions (8,9,14,15), indicating how much we have left to accomplish.

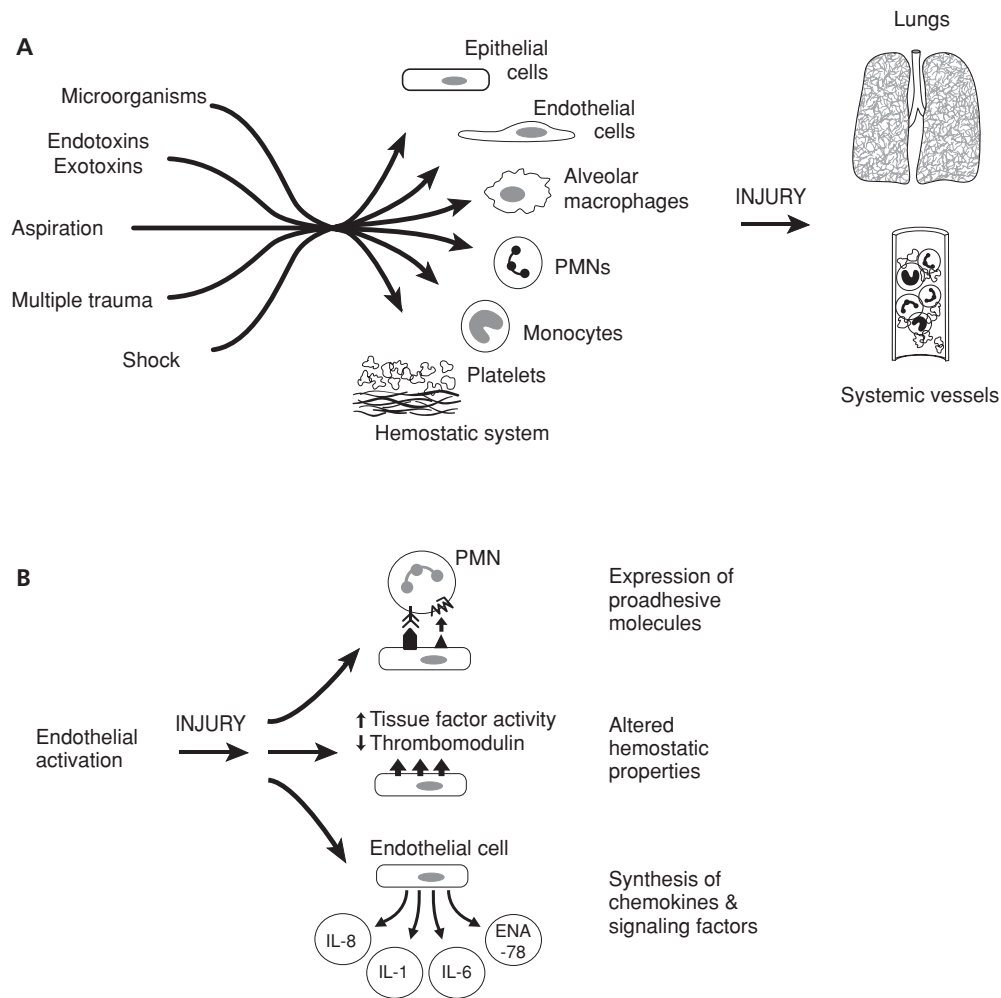

Figure 128.1. EC injury and activation are key features of ARDS. (A) Acute lung injury and ARDS are triggered by a variety of inciting factors that can directly or indirectly injure ECs or induce their activation. Other cellular and molecular systems participate and interact with ECs in ARDS, including leukocytes, platelets, and components of the coagulation cascade. Dysregulated endothelial responses and EC injury contribute to diffuse alveolar-capillary damage, which is a hallmark of ARDS (see Box 128.1). Evidence suggests that systemic vessels are also dysfunctional in some conditions that underlie ARDS, including sepsis. (B) Microbial products, such as LPS, cytokines, oxidants, and other mediators can cause endothelial activation in ARDS (A). Changes in EC function and phenotype in response to activation include synthesis of adhesion molecules or their translocation from subcellular stores, alterations in surface hemostatic properties, new expression of chemokines and cytokines, and synthesis of PAF, a phospholipid signaling factor. See text for details. (Adapted with permission from Zimmerman GA, McIntyre TM. Pathogenesis of sepsis and septic-induced lung injury. In: Matthay MA, ed. *Lung Biology in Health and Disease*. ### THE STUDY OF ENDOTHELIUM IN ACUTE RESPIRATORY DISTRESS SYNDROME

Alveolar-capillary membrane injury resulting in respiratory failure due to infections, trauma, or the aspiration of gastric contents has long been recognized (7,9,13,15–17) (see Figure 128.1). Observations made during the Vietnam conflict indicated that the development of protein-rich increased-permeability pulmonary edema, sometimes called “Da Nang lung,” could accompany nonpulmonary trauma, and that this

fatal pulmonary edema was not, in fact, due to excessively vigorous fluid resuscitation. These findings implied that: (a) indirect injury to the pulmonary capillary endothelium had occurred, and (b) disruption of the alveolar capillary barrier was potentially mediated by ill-defined soluble factors (9,17). A significant body of evidence supporting a role for inflammatory mediators in the pathogenesis of ARDS then accumulated from biochemical studies of the sera and bronchoalveolar fluid (BALF) of ARDS patients, coupled with observations in animal models and cultured ECs (9,18–21). It is generally

Figure 128.2. The endothelial phenotype is altered in lung vessels in ARDS. (A) Lung section from an individual without lung injury dying of acute head trauma. PA, pulmonary artery. (B) Microvessels in injured lung tissue from a patient with ARDS display surface P-selectin (dark staining, arrow). (C) Pulmonary venular (PV) ECs in a lung section from a patient dying from ARDS stain positively for ENA-78 (arrow). Capillary ECs were also positive for ENA-78 (not shown), as were alveolar macrophages (AM), some smooth muscular cells (M), and intra-alveolar PMNs (not shown). (D) EC in the intima of a pulmonary artery (PA) in a lung section from a subject dying of ARDS stain intensely for COX-2. Staining for surface P-selectin (B), ENA-78 (C), and COX-2 was absent or much less evident in endothelium in vessels from subjects dying without acute lung injury or ARDS (A). See Ref. 5 for additional details. (Panel C reproduced with permission from Imaizumi T, et al. Human endothelial cells synthesize ENA-78: relationship to IL-8 and to signaling of PMN adhesion. *Am J Respir Cell Mol Biol.* 1997;17:181–192; panels A, B, D are used with permission from K. Albertine, G. A. Zimmerman, unpublished observations.) For color reproduction, see Color Plate 128.2.

accepted that EC injury, activation, and increased permeability are key facets of ARDS, in addition to epithelial injury (5,8,9). A fundamental corollary is that inflammatory and hemostatic mediators and agents of injury can directly or indirectly activate ECs to produce dysregulated changes in their phenotype and function (5,7,9,22,23) (see Figure 128.1). A second corollary is that the pulmonary microvascular EC is the critical vascular cell involved in ARDS because of the large surface area of the lung microvascular bed and because the alveolar-capillary membrane is the principal site of injury (Box 128.1). Nevertheless, macrovascular ECs also are involved (Figure 128.2; for color reproduction, see Color Plate 128.2). A third corollary is that activated or injured ECs can release or synthesize products, such as von Willebrand factor (vWF) or other soluble components, that can be used as biomarkers of the nature and severity of endothelial injury in ARDS (8,24). Some products and factors released from activated or injured ECs can circulate and exert systemic effects (8,9).

As previously mentioned, reductionist approaches led to development of in vitro culture systems, and resulted in major

advances in our understanding of EC biology (4,5,7,25). The ability to isolate, culture under defined conditions, and readily manipulate human ECs in culture has been extraordinarily informative regarding in vivo events that occur in the vessel wall in general and activation of ECs in ARDS in particular. However, it is clear that the potential exists for loss of specialized endothelial functions that are associated with native vessels or specific organ microenvironments when ECs are introduced into culture, and that there are phenotypic differences in ECs harvested from different vascular beds (26,27). Nevertheless, the study of cultured human ECs has been invaluable. For example, virtually all the adhesion and signaling molecules involved in endothelial interactions with leukocytes (6) were identified using human ECs prior to passage or in early passage culture. In addition, inferences made from these in vitro systems have been validated by in vivo models and further used as a basis for investigation of endothelial-specific activities (28–30). These surrogate systems complement clinical observations and provide a framework on which to develop more sophisticated in vivo cell biological approaches that can be translated to the bedside (5,7,31). More recently, efforts have been made to culture and study ECs derived from the lung, including macrovascular and microvascular ECs from pulmonary and bronchial circulations, and to characterize cell subtype-specific differences in phenotype (26).

#### EFFECTORS OF ENDOTHELIAL CELL ACTIVATION AND INJURY IN ACUTE RESPIRATORY DISTRESS SYNDROME: CYTOKINES AND BEYOND

Endothelial activation is accomplished by outside-in signaling to intracellular transduction cascades initiated by multiple surface receptors that receive signals from inflammatory, thrombotic, or mechanical stimuli (5,7). Diverse response patterns are then induced that result in physiological or pathological characteristics, depending on the nature of the stimuli and type of EC. Common clinical predispositions result in the generation of cytokines, oxidants, proteases, and physical stimuli that trigger EC activation in ARDS (Figure 128.1). Early studies focused on reactive oxygen species (ROS) and serine proteases released from activated polymorphonuclear neutrophils (PMNs) sequestered in the injured pulmonary vascular bed as key mediators of EC activation and injury (8,9). More recent work has emphasized the important role of cytokines, although it is clear that they are unlikely to be a final common pathway to EC activation in ALI/ARDS (5,8,9,31).

Cytokines are ubiquitous mediators of inflammation. These soluble polypeptides serve as chemical messengers whose generation can orchestrate either a proinflammatory state and tissue injury (e.g., tumor necrosis factor [TNF]- $\alpha$  and interleukin [IL]-1) or an anti-inflammatory state with tissue healing (e.g., IL-10 and IL-13) (9). Recent clinical observations indicate that using a lung-protective ventilator strategy

not only decreases the mortality in patients with ALI but also reduces proinflammatory cytokine levels and the number of neutrophils in the bronchoalveolar lavage fluid of these patients (14,32).

In the lung, cytokines are produced primarily by interstitial and alveolar macrophages, which are resident in normal lung (1) and are activated in lung injury (8,9). Pulmonary ECs also may synthesize cytokines in ARDS (5,8). Cytokine receptors on ECs regulate phenotype and function in acute inflammatory responses, hemostasis, and thrombosis; acquired immunity; and cellular and vascular remodeling. Each of these variables is of clinical import in the development and resolution of ARDS (8,9). Cytokine receptors mediate intercellular communication pathways and transmit outside-in signals to intracellular effectors, including mitogen-activated protein kinase (MAPK) cascades, phosphoinositide 3-kinase (PI3K), ceramide turnover, and conserved nuclear signaling pathways that utilize the nuclear factor (NF)- $\kappa$ B and Janus kinase (JAK)/signal transducers and activator of transcription (STAT) families (33–39). Two of the most extensively characterized cytokines acting on human ECs are TNF- $\alpha$  and IL-1, which induce expression of genes that code for E-selectin and other adhesion molecules, IL-6, endogenous expression of TNF- $\alpha$  and IL-1 themselves, ENA-78 and other chemokines, cyclooxygenase (COX)-2, and degranulating factors for neutrophils and platelets (22,23,40–43). Thus, ECs not only respond to cytokines via at least a dozen constitutively expressed receptors, but also possess the capacity to synthesize and secrete some of the ligands recognized by these receptors, providing the basis for autocrine signaling loops (42,43). Newly discovered cytokines, such as high mobility group box (HMGB1), which mediates later events in temporal sequences in clinical and experimental lung injury and may have prognostic and therapeutic significance, also continue to be described (44,45). Local amplification involving juxtacrine and paracrine signaling between ECs and sequestered leukocytes or platelets also may contribute to the pathogenesis of ARDS, based on observations in experimental systems (Figure 128.3). Local and spatially restricted events of this nature are, however, difficult to detect *in vivo* and in the clinical setting using current methodology (31).

An example of complex cytokine signaling between leukocytes and ECs involves IL-6 and the soluble component of its heterotrimeric signal-transducing receptor (see Figure 128.3). IL-6, known to be increased in the sera and BALF of patients with ARDS (8,32), is incapable of activating resting human ECs due to the lack of a constitutively expressed  $\alpha$ -subunit of the IL-6 receptor (IL-6R $\alpha$ ) on these cells (46,47). Human neutrophils release the IL-6R $\alpha$ , which can then associate with homodimers of glycoprotein 130 (GP130) basally present on ECs (46,48). Association of soluble IL-6R $\alpha$  with transmembrane GP130 homodimers constitutes a competent heterotrimeric receptor that recognizes endogenously synthesized (or exogenously generated) IL-6, inducing new expression of inflammatory or thrombotic gene products (46–48). This system has been worked out using cultured systemic ECs;

it is not yet known if it operates in ARDS. Nevertheless, it provides a mechanistic paradigm by which neutrophils can signal ECs in a “retrograde” fashion (46). Additional observations indicate that it may mediate transition from an acute inflammatory response with accumulation of neutrophils to a more chronic inflammatory state with recruitment of mononuclear cells, due to the pattern of chemokines generated by IL-6-stimulated ECs (47,48). Chronic inflammation is a feature of progressive, sustained ALI that may contribute to devastating late complications in subsets of patients with ARDS, including pulmonary fibrosis and pulmonary hypertension (9,31). Interestingly, neutrophil synthesis and release of IL-6R $\alpha$  can be induced by platelet activating factor (PAF), a phospholipid mediator that may have important roles in ARDS, based on both experimental and clinical studies (49). Multiple links between cytokine, chemokine, and lipid mediator pathways exist (31,49). Contributing to the complexity, effector cells in addition to leukocytes may be intermediates in signaling cascades relevant to ARDS. As an example, human platelets can release IL-1 and activate ECs via this mechanism, using previously unrecognized pathways of synthesis of the cytokine (see Figure 128.3) (49).

Sepsis is the most common cause of ARDS, and is the leading cause of mortality from this syndrome (8,9,49,50). In addition to recognizing local or systemically produced cytokines and other signaling molecules, ECs are capable of responding to bacterial products, such as lipopolysaccharide (LPS) and lipid-modified bacterial proteins with complex changes in inflammatory phenotype (49) (see Figure 128.1). LPS, alone or in concert with endogenous mediators, directly elicits the synthesis of proinflammatory cytokines and the surface expression of adhesion molecules and tissue factor activity. In some cases, it induces apoptosis of ECs (49,51–54). Identification and characterization of Toll-like receptors (TLRs), members of a family of proteins that allow host cells to recognize pathogen-associated molecular patterns (PAMPs) in an innate fashion, has generated new insight into endothelial and leukocyte signaling by LPS and other microbial products (49,52,54,55). TLRs, acting together with a complex group of adaptor and LPS recognition proteins (55), activate intracellular signal transduction cascades linked to gene regulatory pathways and to other effector mechanisms in ECs in a manner similar to that induced by cytokines (49,55). Human macrovascular and microvascular ECs express TLR2 and TLR4, and use them to differentially recognize and respond to components of gram-positive or gram-negative bacteria, fungi, and mycobacteria (52,56). The patterns of TLRs expressed on uninjured and injured animal and human ECs still are being characterized (49). LPS is specifically recognized by TLR4, resulting in outside-in signaling mediated by downstream effector cascades (54,57,58). Experimental studies in murine models demonstrate important differences in activated endothelial interactions depending on the specific microbial factor, systemic versus local challenge, and the TLR and CD14 phenotype (59). Each of these variables may be critical in sepsis-induced ARDS in humans (49).

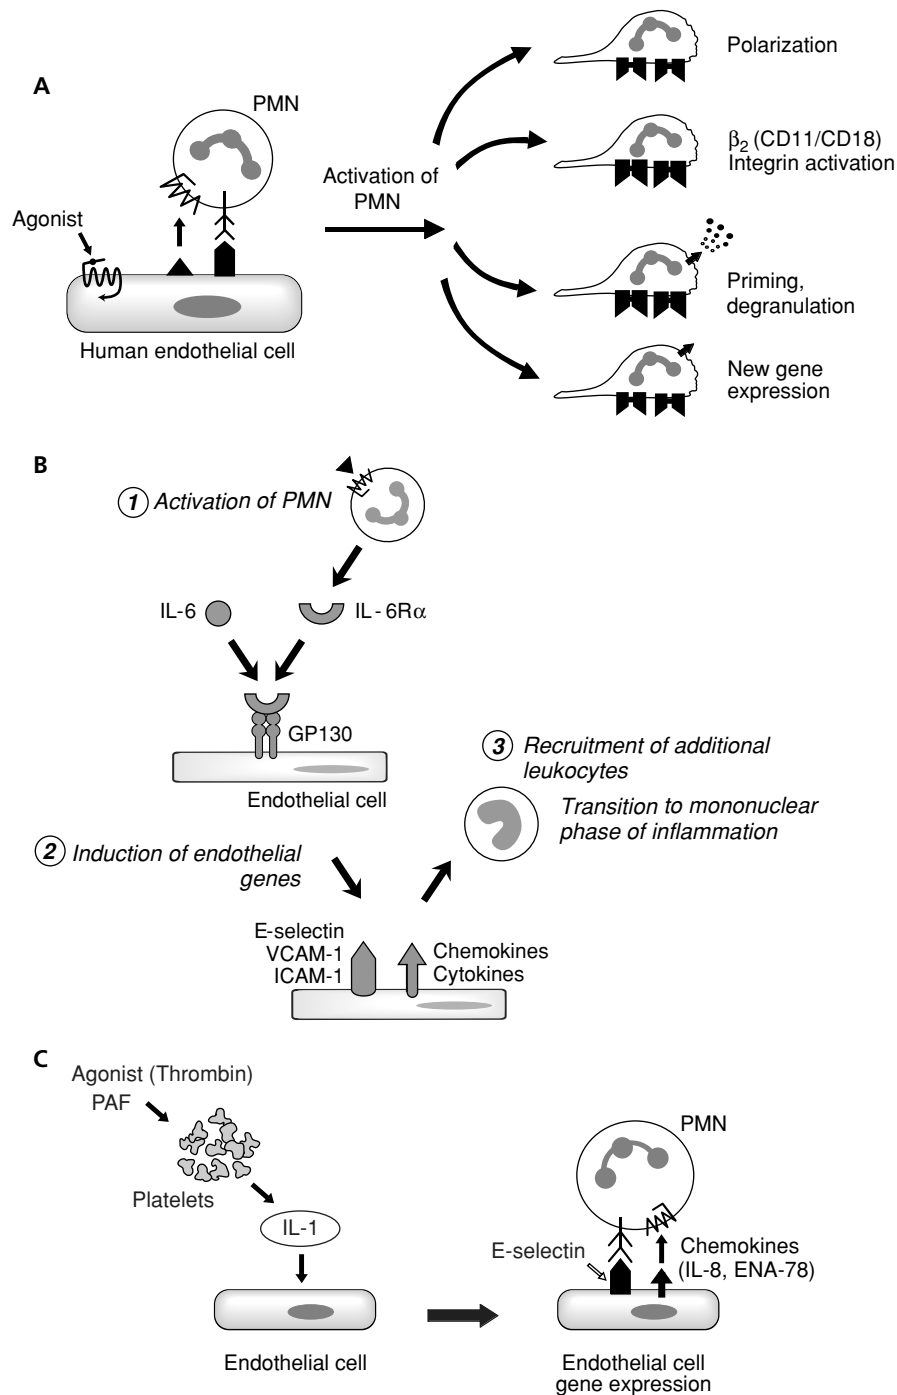

Figure 128.3. Mechanisms of endothelial–leukocyte and platelet–endothelial–leukocyte interaction that may be relevant to pulmonary vascular injury in ARDS. (A) Human EC activated by thrombin, cytokines, and other agents relevant to ARDS display specific patterns of adhesion and signaling molecules for PMNs. This results in local accumulation and activation of PMNs. Local activation of PMNs induces functional changes that can initiate or amplify inflammation injury. (B) Activation of PMNs can induce synthesis and release of IL-6R $\alpha$ , which can then mediate retrograde signaling (trans-signaling) of ECs, resulting in the expression of endothelial genes that mediate the recruitment of additional leukocytes and transition to the mononuclear phase of inflammation. PAF and IL-8, which are synthesized by activated ECs, induce release of IL-6R $\alpha$  from human PMNs. (C) Human platelets synthesize and release IL-1 $\beta$  when stimulated with PAF or thrombin. IL-1 $\beta$  can then signal the expression of genes for E-selectin and chemokines by ECs, resulting in adhesion and local activation of PMNs. (Adapted with permission from Zimmerman GA, McIntyre TM. Pathogenesis of sepsis and septic-induced lung injury. In: Matthay MA, ed. *Lung Biology in Health and Disease*. New York: Marcel Dekker, 2003.)

### ALTERED ENDOTHELIAL BARRIER FUNCTION IN ACUTE RESPIRATORY DISTRESS SYNDROME

Increased microvascular EC permeability is a hallmark of ARDS (8,9) (see Box 128.1). Evidence also suggests that altered EC permeability occurs in systemic vessels in patients with ARDS, particularly those with sepsis and/or multiple organ failure (31) (Box 128.1). Highly specialized junctional structures that link adjacent cells in the interconnected monolayers of ECs that line vascular channels regulate paracellular permeability and influence the transmigration of leukocytes from the intravascular space to the extravascular milieu (60,61). Signals from activated leukocytes may alter endothelial junction and barrier characteristics in inflammatory vascular injury, including ARDS (61,62) (Figures 128.1 and 128.3). EC–matrix interactions mediated by basolateral integrins also influence permeability (4), providing both cellular attachment and outside-in signals that modify specialized intercellular junctions. As many as four types of junctions may mediate EC–EC interactions (60), although this has not been completely defined in the lung (1,62). Adherens junctions and tight junctions are critical in regulating permeability and cell polarity, and are modified by inflammatory mediators and thrombotic signals (60,61), including recently identified sphingosine-1-phosphate (S1P) (discussed later), thrombin, and other receptor-mediated agonists. Disruptions of the integrity of the EC barrier occur through changes in these multimolecular junctional structures and their interacting cytoskeletal elements, and they are likely key sites of dysregulation and increased vascular permeability during ARDS (61,62) (Box 128.1). Lung endothelial heparan sulfates recently have been identified as signaling components that link cytoskeletal reorganization with barrier dysfunction, and they also may be pulmonary endothelial sensors of shear (61).

Sphingomyelin, an abundant cell membrane component, was considered primarily a structural lipid for years. It is clear that its conversion to ceramide by sphingomyelinases and, subsequently, to S1P is important in both extra- and intracellular signaling pathways. S1P is released primarily by activated platelets, and is recognized by a family of five surface G-protein–coupled receptors, termed *S1P receptors* (S1PR) (63). This delivers outside-in signals to target cells that have S1PRs. The intracellular generation of S1P, resulting in subsequent mobilization of calcium ( $\text{Ca}^{2+}$ ) and activation of NF- $\kappa$ B, provides a mechanism for second-messenger function in ECs (64). Initial interest in a role for S1P in increased-permeability edema in lung injury (Box 128.1) came from *in vitro* observations of cultured endothelium. In this model, S1P induced adherens junction assembly and cytoskeletal arrangement in an *in vitro* model of angiogenesis (65). In a more recent report, silencing of the S1PR<sub>1</sub> using selective knockdown by RNA interference profoundly altered EC phenotype and modified synergistic interactions in the TNF- $\alpha$  signaling pathway (66). Building on the observation that platelets and unidentified platelet factors can stabilize or reverse pulmonary vascular leak in animal models (67), recent studies of both small and

large animal models generated evidence that exogenous S1P attenuates lung injury by decreasing endothelial permeability. These experimental systems were based on conditions relevant to ARDS, including ventilator-induced lung injury (VILI) and endotoxin challenge (68,69). The findings support a role for S1P as a barrier-enhancing agonist. In addition, they give further credibility to the utility of *in vitro* models in the development of new therapeutic strategies relevant to lung vascular injury and ARDS, because the original observations were made in cultured human umbilical vein ECs (HUVECs) (65).

### ENDOTHELIAL CELL REGULATION OF HEMOSTASIS IN ACUTE RESPIRATORY DISTRESS SYNDROME

*In situ* thrombosis with fibrin microthrombi and platelet deposition on damaged endothelium was first reported in the lungs of ARDS patients at autopsy in 1976 (70). It has been demonstrated subsequently in other studies (8,31,49). Normally, the resting (nonactivated) endothelial bed is responsible for maintaining an antithrombotic and fibrinolytic surface to facilitate blood flow through the pulmonary vasculature, acting in concert with soluble regulators of coagulation in the plasma and, potentially, mechanical forces transmitted from the adjoining alveoli. In response to injurious stimuli, the endothelium changes phenotype, resulting in a prothrombotic and antifibrinolytic surface. When this process becomes dysregulated, the switch in EC phenotype initiates or amplifies pathological thrombosis and provides a mechanism that couples endothelial activation to leukocyte accumulation and other inflammatory responses (3–7,49). For example, human ECs respond to stimulation with thrombin by translocating P-selectin to their surfaces and synthesizing PAF – molecular events that mediate EC-dependent neutrophil adhesion (5,6) (see Figure 128.3). Evidence suggests that the switch to a proinflammatory and prothrombotic EC phenotype occurs in subjects with ARDS (5,8,9,49). Endothelium in pulmonary arteries and veins, in addition to microvessels in the alveolar-capillary membrane, can be involved in some patients (see Figure 128.2) (49).

The generation of tissue factor activity is a pivotal step in hemostasis and in pathological intravascular thrombosis (71–73). Tissue factor initiates the coagulation cascade by accelerating factor VIIa–dependent activation of factors IX and X, generating thrombin by sequential protease-dependent steps in the tissue factor pathway. Tissue factor is highly thrombogenic and normally found in only minute amounts in the blood. In sepsis, tissue factor expression is reported to be diffusely present on lung cells including endothelium, neutrophils, and monocyte/macrophages (71). The origin(s) of tissue factor under these conditions is not yet clear. When cells that display tissue factor are exposed to plasma, thrombin is generated and fibrin is deposited on their surfaces. Expression of tissue factor activity on ECs is induced by bacterial products and proinflammatory mediators (TNF- $\alpha$ , IL-1 $\beta$ , IL-6, C-reactive

protein) *in vitro* (4), but factors that trigger its regional expression by endothelium in the lung remain in question (21,49,71). In addition, tissue factor–containing complexes may mediate outside-in signaling via protease-activated receptors (PARs) (discussed later). In contrast to fibroblasts and epithelial cells, the tissue factor/VIIa complex does not directly activate ECs. Rather, tissue factor-VIIa-mediated signaling in ECs requires the formation of a ternary complex involving factor X, tissue factor, and VIIa (72). Recently, blockade of the tissue factor pathway in baboons by competitive inhibition with active site-modified VIIa was reported to attenuate lung injury and decrease inflammatory cytokines in an established model of sepsis (73).

Recent experimental and clinical evidence suggests a role for signaling by coagulation proteases in endothelial responses in tissue injury. This may be important in the generation of platelet-fibrin microthrombi in ARDS (70,72). Protease-mediated signaling also may provide a molecular means for the interplay, or cross-talk, between the coagulation and inflammatory systems (49). Human ECs constitutively express surface PARs, a family of heptahelical G-protein–coupled receptors that recognize thrombin and certain other serine proteases, and transmit outside-in signals via proteolytic cleavage of a specific extracellular domain to uncover a new N-terminus that functions as a tethered ligand to activate the receptor (3,4). Thrombin, the central effector protease in the coagulation cascade, activates ECs directly via PAR-1 and -4, thereby promoting adhesion of leukocytes, synthesis of PAF and, under some conditions, the release of cytokines and alteration of barrier functions (3–7,62). Signaling via PARs provides ECs with a mechanism to regulate diverse cellular responses to local thrombin generation in physiological host defense and in vascular injury. It is unknown whether PAR expression by pulmonary or systemic ECs is altered in ARDS.

Resting endothelium has the ability to regulate hemostasis through mechanisms that include factor Xa endocytosis and a display of heparin-like glycosaminoglycans and dermatan sulfate that bind and sequester antithrombin III (ATIII) and thrombin. Mechanisms that localize and limit coagulation to sites of EC injury or activation under physiological conditions include thrombomodulin (TM), tissue factor pathway inhibitor (TFPI), ATIII, and proteins C and S (4). TFPI is a 42-kDa Kunitz-type inhibitor that is stored in a subset of EC granules and distributed to the cell surface (74). To a lesser extent, TFPI is found associated with megakaryocytes and platelets and, in soluble form, it acts by inhibiting the activity of the tissue factor/VIIa/Xa pathway (4,7,75). The role that TFPI plays in regulating coagulation cascades in ARDS is incompletely understood. *In vivo*, TFPI expression has been detected largely on endothelium of the microvasculature (75). LPS and cytokines have only a slight effect on TFPI expression by cultured ECs *in vitro*; furthermore, plasma levels of TFPI do not change in coagulopathies associated with sepsis (71). Because of the large granular stores of TFPI in endothelium, plasma levels may not reflect local activity in the lungs, and it is unclear if the increase in tissue factor relative to TFPI reported in these

conditions represents a pathological imbalance between these two mediators (71,76). In a baboon model of sepsis, an infusion of TFPI was shown to increase survival and reduce lung injury and, in a phase II clinical trial in patients with severe sepsis, a trend was noted toward improved survival and lung function score with the infusion of recombinant TFPI (77). Nevertheless, a phase III clinical trial was negative.

TM, a constitutively expressed integral membrane protein found on microvascular and macrovascular ECs *in vitro* and *in vivo*, provides a further link between inflammation and coagulation. TM acts as an extracellular modifier of locally generated thrombin by binding to it and inhibiting its procoagulant activities, while enhancing its ability to activate circulating protein C, thereby generating the active form (APC) (4). Thus, this system provides a mechanism that changes thrombin to an anticoagulant molecule that activates an endogenous regulator of clotting, protein C. APC, together with the EC-derived cofactor protein S, inhibits factors Va and VIIa, thus providing a feedback inhibition loop on thrombin generation that is proportional to the magnitude of the hemostatic stimulus under regulated physiological conditions (4). TM can be cleaved from the EC surface by neutrophil elastase to produce soluble TM, which also can interact with thrombin to facilitate its activation of protein C and further enhance its profibrinolytic actions (78).

Similar to the procoagulant tissue factor pathway, the anticoagulant TM, in conjunction with APC, has complex regulatory and signaling functions (78,79). Endothelial-bound TM mediates the thrombin-dependent generation of APC. APC in turn activates the serine protease receptor, PAR-1, resulting in inhibition of NF- $\kappa$ B nuclear translocation, cytokine production, and expression of EC surface adhesion molecules (79,80).<sup>1</sup> The APC-mediated activation of PAR-1 requires binding of APC to an EC-specific coreceptor, endothelial protein C receptor (EPCR). *In vitro* and *in vivo* studies have demonstrated that inflammatory mediators that may be active in sepsis induce downregulation of both TM and EPCR on ECs, suggesting a compromise in the APC-generating capacity of the endothelium. Based on these data, as well as the observation that protein C levels are reduced in the majority of patients with severe sepsis, the therapeutic potential of recombinant human APC has been expectantly investigated in preclinical and clinical studies. In a large randomized controlled trial in patients with severe sepsis and evidence for failure of at least one organ, a 96-hour infusion with recombinant human APC was shown to decrease overall mortality by 6.1%, with a relative reduction of 19.4%. There was also a more rapid resolution of respiratory dysfunction and an increased number of ventilator-free days (81). Recent observations further indicate that APC can modify leukocyte–EC interactions in *in vivo* models (82), and reduce the accumulation of PMNs in the alveoli of human volunteers challenged with LPS (83).

1 As discussed elsewhere in this volume, an interesting and unresolved question is whether/how APC and thrombin mediate distinct phenotypic changes in EC by activating the same receptor (PAR-1).

A trial of recombinant APC in ALI/ARDS is in progress (M. Matthay, personal communication).

ECs may alter the regulation of fibrinolysis in ARDS through the synthesis of a complex group of factors including plasminogen, plasminogen activator inhibitors (PAI), and receptors for fibrinolytic agonists (4). ECs synthesize two forms of PAI, PAI-1 and -2 (4). PAI-1 is more active against tissue-type plasminogen activator (t-PA), which converts plasminogen to plasmin, a serine protease that degrades fibrin. In a recent *in vitro* study of cultured human macro- and microvascular ECs harvested from pulmonary vascular beds, it was reported that stimulation with TNF- $\alpha$  or LPS upregulated PAI-1 and -2 in parallel with downregulation of t-PA, a condition consistent with fibrin deposition *in vivo* (84). Previous studies reported that ECs obtained from the pulmonary microvascular bed of ARDS patients had a decreased "fibrinolytic potential," with decreased t-PA:PAI ratios when stimulated with LPS or TNF- $\alpha$  (85), although the mechanisms involved were not delineated. If present *in vivo*, such alterations may contribute to the pathophysiology of ARDS triggered by sepsis (49) as well as other predisposing conditions (see Figure 128.1).

Cumulative evidence suggests that the balance between anticoagulant and prothrombotic characteristics of the endothelium is altered in ARDS, and that molecular cross-talk between the inflammatory and coagulation systems is likely to be involved, although much remains to be learned. Cellular components of thrombi, including platelets and myeloid leukocytes, have the potential to initiate or amplify EC signaling and activation, adding to the complexity of these molecular interactions (see Figure 128.3) (49). Specific dissection of these interactions in ARDS may yield new approaches to therapy (31,49).

### ENDOTHELIAL CELL REGULATION OF BLOOD FLOW IN ACUTE RESPIRATORY DISTRESS SYNDROME

Dysregulated pulmonary blood flow in ARDS is characterized by reduced pulmonary vasoconstriction in areas of alveolar hypoxia and vasoconstriction in areas of well-ventilated lung. This results in pronounced arterial hypoxemia due to ventilation-perfusion mismatching. Increased-permeability pulmonary edema that floods the alveoli, and the presence of hyaline membranes, further compound the gas exchange abnormalities (8,9) (see Box 128.1). The concomitant pulmonary arterial hypertension seen in many of these patients results in right ventricular dysfunction in some cases. Blood flow in the pulmonary vasculature is regulated, in large part, by vasoactive signaling factors generated by endothelium. These are thought to act primarily in a local fashion to modify vascular tone, caliber, responses to other stimuli, and hemodynamic variables (4). Nitric oxide (NO) and prostacyclin (PGI<sub>2</sub>) are key endothelial-derived vasodilators. They also modify platelet responses and, in some cases, leukocyte-endothelial interac-

tions (4). Thus, they have both direct and indirect vasoregulatory activities. In addition, ECs synthesize vasoconstrictor substances that are important in both acute and chronic pulmonary vascular responses. The most important of these are the endothelins (86).

ECs generate the free radical NO by converting L-citrulline to L-arginine in an enzymatic process catalyzed by NO synthases (NOS) in the presence of oxygen and nicotinamide adenine dinucleotide phosphate-oxidase (NADPH) (4). NO is a cell-permeant gas with a half-life of approximately 6 seconds. It mediates intercellular interactions in a paracrine fashion, and binds the heme-prosthetic group of guanylate cyclase in vascular smooth muscle cells, maintaining basal vascular tone and inducing vasorelaxation (4). During hypoxic vasoconstriction, it has been shown that inhaled NO (iNO) selectively dilates the pulmonary vasculature without systemic effects (87,88). NO production is catalyzed by three known NOS isoenzymes, including a "constitutive" form found primarily in ECs, eNOS, and inducible forms, iNOS and nNOS, which are upregulated by several proinflammatory mediators. The isoenzyme eNOS is involved in mediating basal vascular tone, and its expression and/or activity may be further increased by outside-in signaling via receptors for certain EC agonists (4). Therapeutically, inhaled NO has been shown to improve oxygenation in some animal models; however, clinical trials in patients with ARDS have failed to show a consistent decrease in mortality or improvement in respiratory endpoints (8,89). Characterization of the local concentrations of NO in the lungs of patients with ARDS has not been achieved.

Prostaglandins are endogenously produced by ECs through the actions of the microsomal COXs (prostaglandin H synthases). Arachidonic acid, released from membrane phospholipids in response to cellular activation (4,88), is converted to intermediates by COX-1 and -2 and to downstream products by linked eicosanoid synthases (4). PGI<sub>2</sub>, the first EC-derived vasodilator to be described, also was shown to be a potent inhibitor of platelet activation and aggregation and to exhibit anti-inflammatory properties (4). Another COX product, thromboxane A<sub>2</sub> (TXA<sub>2</sub>), is a potent pulmonary vasoconstrictor, increases EC permeability, and is a chief agonist for platelet aggregation (90). The COX-1 isoform is constitutively expressed in some endothelial beds, and PGI<sub>2</sub> generated by this enzyme is important in physiological vasoregulation and as a local antithrombotic signal (90). The inducible COX-2 is expressed in ECs in response to stimulation with IL-1, TNF- $\alpha$ , LPS, and other inflammatory and thrombotic mediators (90,91). Depending on the cell type and downstream prostaglandin synthases, COX-2 generates PGI<sub>2</sub>, PGE<sub>2</sub>, and other prostaglandins, in addition to the vasoconstrictor thromboxane. In cultured porcine pulmonary ECs cytokines and LPS, stimulation increased the concentration of TXA<sub>2</sub> relative to PGI<sub>2</sub>, consistent with the hypothesis that the balance between vasoconstricting and vasodilating prostaglandins is influenced by inflammatory signals (92). Prostaglandins and thromboxane have homeostatic effects on blood flow

distribution to areas of better ventilation in the lung, an issue of importance in the pathobiology of ARDS. In a series of patients with ARDS, infusion of a fat emulsion that shifted the balance of prostanoids toward the vasodilator PGI<sub>2</sub> resulted in a worsening of oxygenation, presumably by relieving hypoxic vasoconstriction and thereby increasing pulmonary shunt physiology (93). Earlier trials of vasodilator prostaglandin analogs as therapeutic agents in ARDS also were unsuccessful (8). Although this could suggest a role for TXA<sub>2</sub> in the management of ARDS because of its vasoconstricting properties, its prothrombotic and proinflammatory effects argue against this strategy. A confounding variable in the interpretation of clinical studies of eicosanoid administration is that the factors that regulate the expression of endogenous EC COX (see Figure 128.2) and eicosanoid synthases in ALI and ARDS are largely unknown, and alterations in their expression in the injured lung relative to endothelium in the uninflamed normal lung have not been clearly defined. In addition to regulating vascular tone and blood flow, recent *in vitro* evidence indicates that COX products influence EC motility and repair of endothelial EC injury (94), indicating additional roles in damaged pulmonary vessels that may affect the outcome of ARDS.

Endothelin (ET)-1 is produced primarily by ECs, and is a potent pulmonary vasoconstrictor (86,95). ET-1 also potentiates the constrictor functions of catecholamines. Preproendothelin-1 is transcriptionally induced by inflammatory cytokines, hypoxia, shear, ischemia, and ATIII, and is processed to ET-1 by ET-converting enzyme (86). ET-1 signaling occurs via two G-coupled-protein receptors. ET<sub>A</sub> is expressed on smooth muscle cells and mediates sustained vasoconstriction, whereas ET<sub>B</sub> is displayed primarily on ECs, where it mediates transient vasodilation by inducing NO and PGI<sub>2</sub> release. ET-1 previously has been shown to be increased in the lungs of patients who died with ARDS (96,97). In the serum of patients with sepsis-induced ARDS, ET-1 levels correlated both with the degree of hypoxemia and severity of organ damage (98). A subsequent small study with an inhaled ET-1 antagonist reported significant improvement in gas exchange, decreased pulmonary pressures, and decreased pulmonary shunt (95). Expression of ET-1 in parallel with NOSs has been analyzed in the lungs of patients dying of ARDS, an approach that can yield key information relevant to the patterns of vasoactive mediators that are generated (5,96). Nevertheless, changes in expression of the EC receptor systems, together with regional patterns of generation of the ET-1 and NO ligands in injured pulmonary vessels, remain incompletely characterized in ALI and ARDS.

#### **INTERACTIONS OF ENDOTHELIAL CELLS WITH LEUKOCYTES AND PLATELETS IN ACUTE RESPIRATORY DISTRESS SYNDROME**

Leukocytes and platelets traverse the circulatory system during inflammatory and immune surveillance, adhering to inflamed

endothelium, exposed subendothelial matrix, and to each other (4–7,49). Interaction between leukocytes and activated pulmonary endothelium is a requisite feature of host defense against infection and repair of injury. In contrast, however, dysregulated adhesion and signaling between myeloid leukocytes and ECs are key early events in the pathological lung injury that leads to ARDS (5,8,9,31,49) (see Figure 128.1). Over the last 20 years, mechanisms that govern adhesive and signaling interactions between myeloid leukocytes and activated ECs have been extensively studied and the results extended to other classes of leukocytes (4,6). These results are reviewed elsewhere in this volume. Neutrophils, monocytes, and monocyte-derived macrophages are involved in the inflammatory responses and parenchymal damage associated with ARDS, with neutrophil adhesion and migration through the endothelium a key paradigm in this process (5,8,9) (see Figures 128.1 and 128.3).

*In vivo* and *in vitro* models of inflammation, both leukocytes and platelets interact with activated ECs on injured vessels through a multistep cascade (4–7). Initially, leukocytes are tethered to activated ECs followed by rolling, localized signaling, tight adhesion dependent on activation of leukocytes, and subsequent transmigration between endothelial junctions in a sequence orchestrated by selectins, signaling molecules, and leukocyte integrins (4,6,7). Although the rolling of leukocytes occurs in pulmonary arterioles and venules under experimental conditions, leukocyte rolling does not occur in capillaries because of their size and, potentially, differences in expression of selectins, compared with their display by systemic microvascular beds (99). How these observations relate to injured and remodeled vessels in the lungs of patients with ARDS is largely unknown. Adhesion molecules such as P-selectin are displayed on endothelium in vessels of various sizes in the lungs of some patients with ARDS, as are signaling chemokines that can induce neutrophil accumulation and activation (5,49,100) (see Figure 128.2). Further, adhesion molecules can be displayed in a regional fashion by lung endothelium in response to clinically relevant perturbations of experimental preparations (59), and may influence leukocyte accumulation and sequestration (59,101). Leukocyte sequestration in the pulmonary microvascular bed also involves intercellular aggregation (49) and changes in deformability of the circulating cells (99). Cellular and molecular mechanisms that regulate adhesion, activation, and accumulation of myeloid and mononuclear leukocytes (Figures 128.1, 128.2, and 128.3) are key targets for future investigation aimed at interventional strategies in ALI and ARDS (6,8,9,31,49).

Mechanisms that govern the interaction of platelets with leukocytes in ARDS, and the influence of these mixed-cell aggregates on activated or injured pulmonary ECs, are incompletely characterized but ultimately may be targets for therapeutic intervention (8,9,49). Evidence suggests that platelets and leukocytes may be sequestered in pulmonary microvascular beds as a result of the initial formation of cellular aggregates in flowing blood, and that platelet-leukocyte signaling may induce fibrin thrombi in the

pulmonary and synthetic vessels of some patients with ARDS (5,7,49).

### ENDOTHELIAL CELL RESPONSE TO OXIDATIVE STRESS IN ACUTE RESPIRATORY DISTRESS SYNDROME

Oxidative stress occurs when there is an imbalance between the production of ROS and reactive nitrogen species (RNS) and the ability of specific antioxidant pathways to detoxify these activities. Activated neutrophils and macrophages are sources of oxidant species in ARDS (8). As outlined in previous sections, ECs influence the accumulation and activation of neutrophils and other myeloid leukocytes in ARDS; therefore, they may influence local generation of ROS. Relevant ROSs include hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), superoxide ( $\text{O}_2^-$ ), hydroxyl radical ( $\text{OH}^-$ ), and hypochlorous acid ( $\text{HOCl}$ ), which are key leukocyte-derived products (102). ROSs generated from therapeutic and supraphysiologic administration of  $\text{O}_2$  (103,104) can initiate or amplify ALI and ARDS (89) (see Box 128.1). Injured or activated ECs may themselves generate ROS. Pulmonary ECs exposed to as little as 30 minutes of hyperoxia produced intracellular free radicals ( $\text{O}_2^-$  and  $\text{H}_2\text{O}_2$ ) of mitochondrial origin in an in vitro model using ovine ECs (104). In addition, endothelium generates ROS through the expression of an NADPH oxidase under the control of the IL-6 family of cytokines and hypoxic stimuli in vitro; this enzyme has enhanced expression in both the endothelium and epithelium in ARDS patients (102). NO-derived species including nitrite and peroxynitrite ( $\text{ONOO}^-$ ) have been implicated in acute lung injury by virtue of their roles in oxidation of proteins, lipids, and DNA (103,105). To minimize oxidative damage, human lungs have evolved complex enzymatic and nonenzymatic antioxidant systems, several of which are regulated through interactions involving vascular endothelium (106).

ECs are capable of responding to exogenous oxidants by generating specific intracellular signals, in addition to being nonspecifically injured by ROS. The production of intracellular oxidants in response to cytokines or other mediators increases the expression of certain adhesion molecules in experimental systems (107,108). The pro-oxidant enzyme, xanthine oxidase (XO), binds to glycosaminoglycans on the surface of ECs both in vivo and in vitro in a heparin-reversible manner (109,110). XO is released in response to cellular injury, and was reported to mediate the pulmonary sequestration of neutrophils in an in vivo rat model of lung injury (110). In addition to producing site-specific oxidative injury via binding to ECs, XO promotes neutrophil adhesion to cultured ECs via  $\text{H}_2\text{O}_2$ -dependent PAF signaling and engagement of P-selectin and intercellular adhesion molecule (ICAM)-1 via their respective ligands in vivo (111). Conversely, the lipid soluble antioxidant,  $\alpha$ -tocopherol (vitamin E), which is present in all cell membranes and consumed during scavenging roles, has been shown to reduce the surface expression of EC adhesion molecules in response to IL-1 $\beta$  in vitro (112). Further-

more, in a mouse model, intraperitoneal  $\alpha$ -tocopherol was reported to decrease the translocation of neutrophils across the endothelium and to protect against lung injury induced by aerosolized LPS, independent of transcription factors NF- $\kappa$ B and AP-1 (103). These experimental observations suggest that oxidative stress can both injure ECs and deliver signals that promote EC-leukocyte interactions and other responses (see Figures 128.1 and 128.3), but specific mechanisms that operate in ARDS remain to be characterized.

### CONCLUSION

Epidemiologic studies indicated that mortality from ALI and ARDS was on the order of 60% during the mid-1980s. With recent developments in supportive care for the critically ill, changes in intensive care unit (ICU) organization, and new ventilator strategies, mortality decreased to less than 40% in some settings (50). Nevertheless, this remains a staggering cost in lives lost, given the incidence of ARDS across the globe (8,9,50,113), and morbidity in survivors also is substantial. Only in the past several years have treatment strategies aimed at modulating the host inflammatory and coagulant responses seemed attainable. Yet many of these approaches have had therapeutic shortcomings rather than success, likely a reflection of our lack of insight into the precise cellular and molecular mechanisms underlying ARDS (9,31) and – specific to this chapter – the precise alterations in ECs in this complex syndrome. The field also is limited by a lack of animal models that recapitulate the clinical syndromes of ALI and ARDS, although current in vivo systems have utility nevertheless (see Box 128.2). Thus, much is left to be learned (9,31). Generation of these requisite insights is the goal for the future.

#### *Text Box 128.2: Animal Models of ALI/ARDS*

No generally accepted animal model of ARDS exists (9,31), in part because of the multiple clinical conditions that can trigger ALI (see Box 128.1). In addition, the relationship of preclinical animal models to the human syndromes of ALI and ARDS is problematic because of the short-term protocols for most animal models compared to the more prolonged nature of the course of ALI/ARDS in human subjects, together with the limited number of experimental variables in animal studies. This contrasts with the usual multiplicity of clinical variables, including pattern of ventilation, inspired oxygen tension, drugs and antibiotics, and nutritional regimens in ICU management (8,9,31). Nevertheless, animal models have been extremely useful for the dissection of pathophysiologic features, particularly those that contribute to increased-permeability lung edema (see Box 128.1),

and for proof-of-principle studies of pathologic mechanisms, pathophysiologic assessment, and therapeutic intervention (9,31). Most recently, mouse models have been developed in attempts to capitalize on the advantage of genetic manipulation (9,31).

The most commonly employed murine models relevant to ALI/ARDS focus on experimental sepsis and aspiration injury. These are two of the most common triggers of human ALI/ARDS (8,9,15) (Box 128.1). Intravascular, intraperitoneal, and intratracheal challenge with bacterial LPS, alone or in combination with other inflammatory stimuli, has commonly been used (38,59,68,69,114). Cecal ligation and puncture, which causes polymicrobial peritonitis and a septic syndrome in mice and rats (115,116), often is argued to be more clinically relevant. Aspiration models frequently involve direct intratracheal instillation of acid (114,116,117). “Two hit” models, in which more than one triggering injury is delivered, may have greater clinical relevance (31). Recent studies exploring the roles of TLRs, other surface receptors, signaling pathways, adhesion molecules, and signature patterns of transcript expression have utilized these models of ALI (31,38,59,114–117). Murine experiments focused on adhesion pathways in leukocyte trafficking in the lung were recently reviewed (99).

#### KEY POINTS

- A key pathogenetic feature in ARDS and ALI is dysregulated change in the phenotype and function of pulmonary and systemic ECs, resulting from cellular injury and/or activation by cytokines and other inflammatory and hemostatic agonists.
- Activated or injured ECs synthesize, display on their surfaces, and release products that contribute to the pathogenesis of ALI and ARDS in response to cytokines, microbial products, oxidants, and physical stimuli
- In vitro culture and in vivo model systems, despite their limitations, have been useful in developing current paradigms of cellular and molecular responses relevant to ARDS.

#### Future Goals

- To develop more sophisticated in vivo cell biological approaches that will be critical in our ability to translate our in vitro observations into bedside treatments

# The Central Role of Endothelial Cells in Severe Angioproliferative Pulmonary Hypertension

Norbert F. Voelkel and Mark R. Nicolls

*University of Colorado Health Sciences Center, Denver*

Pulmonary hypertension (PH) can be transient, intermittent (caused by hypoxia or sleep apnea), or chronic. Chronic PH is most frequently irreversible because of significant pulmonary vascular alterations, a process that has been termed *remodeling* (1). The pathophysiological mechanisms of PH may be approached by considering the following two equations:

$$\Delta P = Q \times R \quad (\text{Equation 1})$$

$$R = 8\eta L/r^4 \quad (\text{Equation 2})$$

For many decades, investigators believed that intense pulmonary vasoconstriction (thus a reduction in radius or  $r$ ) was responsible for the changes in pressure and vessel remodeling in many forms of severe PH (2–5). However, it is not clear whether vasoconstriction *always* occurs and is *necessary* for the development of severe pulmonary vascular hypertension. Unfortunately, acutely reversible PH (as defined by a significant reduction in the mean pulmonary artery pressure after administration of a vasodilator) is rare in adult patients (6,7). However, it occurs more frequently in children (8), where it may represent a distinct form of severe PH (9). In addition to smooth muscle proliferation, the pathology of most cases of severe, chronic, and irreversible PH consists of an abnormal proliferation of endothelial cells (ECs) within the vascular lumen (10,11). The presence of these lesions has led to the term *severe angioproliferative pulmonary hypertension* (SAPPH). In contrast, patients with PH associated with pulmonary embolism do not have angioproliferative lesions. Frequently, they display central, large-vessel clots that can be surgically removed by thromboendarterectomy.

No early diagnosis is possible for SAPPH. Moreover, the disease is not amenable to serial assessment of pulmonary vascular reactivity concomitant with histological evaluation of the lung resistance vessels. Thus, the degree to which vasoconstriction contributes to the pathogenesis of SAPPH remains uncertain.

Although atherosclerotic lesions can be documented in the main pulmonary artery and large-diameter arterial branches, SAPPH is a disease of microscopically fine precapillary arterioles. Exuberant growth of ECs leads to vascular occlusion at sites distal to bifurcations (10,11). Plexiform (or glomeruloid) proliferative lesions are the *sine qua non* signature lesions in SAPPH. These lesions occur both in primary or idiopathic arterial PH (IAPH) (12), and in secondary forms of severe PH, including left-to-right shunt, human immunodeficiency virus (HIV), or human herpesvirus (HHV)-8 infections (12–14), or a number of collagen vascular autoimmune diseases (e.g., systemic lupus erythematosus [SLE], scleroderma, or Sjögren syndrome) (15). An overlap of collagen vascular diseases with IAPH was recognized many years ago (4,16), because a significant number of patients with IAPH present with antinuclear antibodies (ANA), antiphospholipid antibodies, and Raynaud phenomenon (17). Concentric intima fibrosis, generating so-called onionskin lesions of the pulmonary precapillaries and coronary microvessels (18), frequently is observed in patients with scleroderma/calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia (CREST)-associated PH. The myocardial microvessel involvement likely causes a cardiomyopathy, which may account for the worse prognosis of patients with PH associated with the CREST variant of scleroderma. This chapter focuses on the contribution of ECs to the development of severe PH.

## PULMONARY MICROVASCULAR ENDOTHELIAL CELLS

The impressively large metabolic capacity of the lung's microvascular endothelium was recognized during the 1970s. The first experiments demonstrating uptake and removal functions used radioactively labeled compounds such as serotonin and prostaglandin E (PGE)<sub>2</sub>, which were quantitatively

taken up during the first passage through the lung, after injection or infusion. Pioneers of the first hour were Alain Junod (19), Norman Gillis (20), and Christopher Dawson (21).

Using the isolated perfused rat lung preparation, it could be shown that arachidonic acid is quantitatively removed by the lung endothelium and converted to prostacyclin, its major cyclooxygenase (COX) product (22). Unfortunately, these early explorations of lung EC metabolic capacity and function did not lead to the development of a practical clinical test for EC damage in acute lung injury or severe PH.

Pulmonary microvascular ECs reside in the alveolar capillaries and extend into precapillary arterioles with diameters of 100 to 250  $\mu\text{m}$  and postcapillary venules. These ECs can be histochemically and functionally distinguished from those of large pulmonary arteries and veins (23). For example, macrovascular pulmonary ECs bind the *Helix pomatia* lectin, whereas microvascular pulmonary ECs bind the *Griffonia simplicifolia* lectin, express the activated leukocyte cell adhesion molecule (ALCAM)-1, and grow faster than do large vessel ECs. Macrovascular ECs align in the direction of blood flow, whereas microvascular cells do not (23). CD34<sup>+</sup> cells seem to be more frequent among capillary ECs (24), and CD34<sup>+</sup>, c-kit<sup>+</sup> cells may represent bone marrow-derived multipotent precursor cells (25). Whereas clear-cut differences exist between the phenotype of microvascular and macrovascular ECs, they share the expression of many genes, including endothelial nitric oxide synthase (eNOS), prostacyclin synthase, platelet-endothelial cell adhesion molecule (PECAM)-1, and caveolin-1. An interesting exception is vascular endothelial growth factor (VEGF), which is expressed and released in particularly high levels in microvascular ECs (at least in vitro). We postulate that this capacity to release large amounts of VEGF serves as an *autocrine survival strategy* of these cells (23).

#### ENDOTHELIAL CELL PROLIFERATION IN SEVERE PULMONARY HYPERTENSION

Chronic pulmonary vasoconstriction, including hypoxic vasoconstriction, leads to muscularization of the pulmonary arterioles, but not routinely to EC growth and lumen obliteration (1). The best known and well-studied model of pulmonary vascular remodeling is that of chronic hypoxia-related PH (26–29). In IAPH, hypoxic vasoconstriction is not involved, because the administration of 100% of oxygen via a breathing mask to patients with IAPH does not change the pulmonary artery pressure (it is important to remember that the term *idiopathic* is used because the cause of the PH is unknown). This fact alone – the absence of hypoxic vasoconstriction in most cases of severe PH – raises the question of what causes such “exuberant” EC proliferation in IAPH (11). Several studies, in succession, showed that the ECs in the complex vascular lesions were phenotypically abnormal (10,30–34), that EC growth in IAPH was monoclonal (35), that ECs in these lesions expressed mutated genes (36) and

**Table 129-1: Immunohistochemical Characterization of the Plexiform Lesion EC Phenotype in SAPPH**

	<i>Protein Expressed or Overexpressed</i>	<i>Protein Expression Diminished or Lost</i>
VEGF	++	Prostacyclin synthase –
KDR	++	Prostacyclin receptor –

eNOS	+	Smad –
Survivin	+	Caveolin-1 –
P16	+	Heme oxygenase –
c-Myc	+	
$\beta$ -catenin	++	

lost expression of tumor suppressor proteins, and, finally, that the cells in the lesions were entirely devoid of apoptotic events (33).

The plexiform lesions in SAPPH are, so far, the only reported exception to the “law of the endothelial monolayer.” Why this law has been broken in the precapillary arterioles in SAPPH is a matter of intense investigation. Conceptually, one may consider the “glomeruloid” plexiform lesions to represent a type of intravascular angiogenesis (37), and indeed, the lesion cells express a repertoire of angiogenesis markers, including VEGF, FLK-1/VEGF receptor 2 (VEGFR2), hypoxia-inducible factor (HIF)-1 $\alpha$ , and hydroxycarbon nuclear translocator (ARNT) (Table 129-1). We have developed both animal (38) and cell models (discussed later) to investigate these fundamental problems of pulmonary vascular pathobiology. These endeavors have been motivated largely by the fact that these angioproliferative lesions may not be reversible, and they may form the basis of the pulmonary hypertension in IAPH.

In addition to angioproliferation, the plexiform or glomeruloid lesions also display features of inflammation. Whether the presence of inflammatory lesions is a cause or consequence of the pulmonary vascular disease has not been resolved. The presence of mast cells – which are angiogenic – in the lesions was described more than 30 years ago (39). These cells can synthesize and release histamine, leukotrienes, and VEGF and, together with T and B lymphocytes and clusters of macrophages, may provide a footprint of a localized immune response. Given that SAPPH can be associated both with autoimmunity (as in SLE) or with immune insufficiency (as in HIV infection) (40), it remains unclear what the antigenic target is in this inflammatory response. It is a striking

fact that many disorders characterized by SAPPH also have significant incidences of autoantibody production. Antibody deposition in the pulmonary arteries of these patients has been already noted in SLE and Sjögren's syndrome. Additionally, patients with IAPH have been shown to have elevated plasma levels of interleukin (IL)-1 and IL-6 (41). Notably, IL-6 protects ECs from apoptosis (42) and IL-1 increases the expression of HIF-1 $\alpha$  (43). A number of studies have demonstrated anti-EC antibodies in patients with SLE and scleroderma who also have SAPPH (44–46).

#### VASCULAR ENDOTHELIAL GROWTH FACTOR AND LUNG VASCULAR HOMEOSTASIS

VEGF is 50,000 times more potent in inducing vascular permeability than is histamine (47), yet the VEGF gene and protein are abundantly expressed in the adult, nongrowing lung – an organ that is required to stay “dry” if it is to serve one of its major functions: oxygen uptake and gas exchange. VEGF ligand binds preferentially to ECs, and the binding of VEGF to human umbilical vein ECs or bovine pulmonary artery ECs can be dramatically decreased by either cationic drugs such as protamine or anionic drugs like suramin. Rapid uptake and binding also can be demonstrated in the intact, integrated circulation of the isolated, perfused lung (48). We continue to be impressed by Harold Dvorak's experiments showing that high adenoviral-mediated VEGF expression resulted in angiogenesis and the formation of glomeruloid structures (49), and that angioproliferation is both VEGF dose- and time-dependent. On the other end of the VEGF expression and action spectrum are lung VEGF deficiency states that lead to a loss of lung microvessels (50) and emphysema (see Chapter 130). Taken together, these findings suggest that a homeostatic lung structure maintenance program is present (51) that significantly relies on the correct “amount” and precise timing of VEGF signaling. Indeed, it is possible that VEGF is one of the most important components of this lung structure maintenance program, because its role transcends vascular biology, stabilizes lung epithelial cell function, controls EC–lymphocyte immune interactions, and inhibits vascular smooth muscle cell apoptosis via binding to VEGF receptors (52).

#### VASCULAR ENDOTHELIAL GROWTH FACTOR RECEPTOR BLOCKADE CAUSES ENDOTHELIAL CELL APOPTOSIS AND CONCOMITANTLY ELEVATED SHEAR STRESS LEADS TO ENDOTHELIAL CELL PROLIFERATION

Because cause-and-effect experiments cannot be conducted in human SAPPH, we developed the first animal model of angioproliferative PH (38). The model is based on the knowledge that VEGF is an obligatory survival factor for ECs (53) and that shear stress inhibits EC apoptosis (54). To generate SAPPH, we inject adult rats with a subcutaneous dose of

the combined VEGFR1 and -2 antagonist SU5416, and subject the animals to chronic hypoxia, which causes pulmonary vasoconstriction (38) and increased shear stress. Severe angioproliferative PH occurs within 3 to 5 weeks. Instead of raising shear stress by means of chronic hypoxic vasoconstriction, shear stress also can be raised by pneumonectomy, which generates the condition in which the entire cardiac output must be accommodated by the remaining lung. The combination of pneumonectomy and SU5416 VEGFR inhibition also causes pulmonary angioproliferation (55). Because VEGFR blockade induces EC apoptosis under *in vitro* conditions (53), we postulated that initial EC apoptosis in our model was followed by proliferation of the surviving (apoptosis-resistant) ECs, to the point of lumen obliteration (38). We tested this hypothesis directly in the CellMax system (an artificial plastic microtube system, seeded with ECs) by adding apoptosed ECs to the perfusing cell culture medium. Indeed, the addition of apoptosed ECs caused a proliferation of the original ECs (56). Based on our own data, which show that pulmonary microvascular ECs secrete *in vitro* large amounts of VEGF, we postulate that the maintenance of pulmonary microvascular ECs largely depends on their autocrine VEGF production (23) and signaling, and that the ECs that survive VEGFR blockade become VEGF-independent and apoptosis-resistant. This now raises the larger question: What is the nature of the VEGFR blockade-resistant cells? There can be no doubt that the plexiform lesion cells are phenotypically switched (abnormal); they display a protein expression pattern that can be interpreted as growth-promoting and anti-apoptotic (Table 129.1). The “wisdom” of this proliferating cell phenotype is to turn off antiproliferative genes, like prostacyclin synthase (32) and peroxisome proliferator-activated receptors (PPAR)- $\gamma$  (33), and express antiapoptotic proteins, like Bcl-2 and survivin (N. Voelkel, unpublished observations). The phenotypic switch of ECs in SAPPH likely can be caused by multiple initiating events, including EC apoptosis (56) and viral infections (40,57). We shall return to this theme in the following section.

Sakao and colleagues (unpublished data) recently showed that commercially available human pulmonary microvascular ECs (HPMVECs) contain a small amount of CD34<sup>+</sup> EC precursor cells, which not only survive SU5416-induced EC apoptosis, but expand in number during subsequent EC passages – apparently as a consequence of the SU5416 (VEGF receptor blockade)-induced selection pressure. Thus, the “nature” of the apoptosis-surviving EC in these experiments is, in part, a c-kit<sup>+</sup> CD34<sup>+</sup> precursor cell, which, in cell culture, further transdifferentiates into  $\alpha$ -smooth muscle actin<sup>+</sup> and tyrosine hydroxylase<sup>+</sup> cells (Sakao, unpublished data) – that is, cells that display smooth muscle and neuronal cell features. Whether c-kit<sup>+</sup> CD34<sup>+</sup> precursor cells are involved in the formation of plexiform lesions is unknown. However, the angioproliferative lumen occlusion in the animal model, combined with EC data that illustrate the emergence of apoptosis-resistant proliferating ECs, provide us with a cell biological concept for the formation of plexiform lesions.

Figure 129.1. In severe angioproliferative PH, distal precapillary arterioles are the critical sites of structural changes. The model depicted in this figure postulates EC apoptosis as the initiating event. EC apoptosis can be triggered by toxins, hemodynamic stress, and cell–cell interactions. In contrast to normal vessel cell turnover, apoptosis-resistant ECs emerge and start to proliferate. At this point, the “law of the monolayer” has been broken. EC transdifferentiation into smooth muscle cells also may take place and play a role in the vessel remodeling.

## ENDOTHELIAL CELL GROWTH AND VIRAL INFECTIONS

It is tempting to speculate that viral infection of ECs can alter DNA methylation and thus the expression of genes directly involved in cell growth and apoptosis control (58). Although examples in support of such a mechanism have been described (59), nothing is known about pulmonary microvascular EC methylation control of growth factor genes, or whether they are targeted by viral infection. Presently, it can only be postulated that, for example, the HHV-8 v-cyclin or G-protein–coupled receptor proteins could methylation-dependently upregulate *VEGF* gene expression in infected ECs. Although a tropism of HHV-8 for ECs has been established, it is unknown whether or how HIV infection affects growth of ECs in vivo, in patients with SAPPH, or whether it is the state of immunosuppression that permits the SAPPH to occur. VEGF protein (ligand) plasma levels are apparently not increased in HIV-infected patients (60).

## FUTURE DIRECTIONS

What is needed is the thorough examination of the pathological precapillary arteriolar ECs from the lungs of patients with SAPPH ex vivo. Cell surface markers are available (Table 129-1) that allow differential sorting of phenotypically normal and abnormal cells. Cell lines must be established for the different phenotypes. These cells then can be subjected to “therapeutic trials” – as has been done for decades with various cancer cell lines. Viral infection of human pulmonary microvascular ECs – including those from patients with SAPPH – is feasible and will provide mechanistic data: How does the virus infection alter the gene expression pattern of these ECs, their growth and survival potential, and more?

## THERAPEUTIC IMPLICATIONS

Presently, we have very little information whether the established treatments for SAPPH affect the angioproliferative obliterating lesions. For example, when lung tissue from patients with SAPPH who had failed continuous intravenous prostacyclin therapy were examined and compared with the tissues of patients who had not been treated with prostacyclin, no difference in the number of plexiform lesions and thickness of intima and media of nonobliterated arterioles was found (61). Why is SAPPH so difficult to treat? We believe the answer is twofold: because the patients do not come to clinical attention during the (perhaps) autoimmune initiation phase of the disease, and second, established angioproliferative lesions manifest altered EC and vascular smooth muscle phenotypes. If disobliteration is the therapeutic goal, then we must understand the biology of these “bad phenotypes.” It follows that little insight can be gained by studying the behavior of normal ECs in cell culture experiments.

### KEY POINTS

- The vascular pathobiology of “primary” and most forms of secondary SAPPH is primarily driven by lumen-obliterating growth of phenotypically abnormal ECs (Figure 129.1).
- The phenotypically abnormal ECs are likely cells that have survived while neighboring cells of the monolayer underwent apoptosis. The initial apoptosis could be caused by anti-EC antibodies, as a direct or indirect consequence of a viral infection or

subsequent to the interaction of an antigen presenting EC with lymphocytes.

- Effective future treatment of established SAPPH will transcend the presently used vasodilator drugs and target the abnormal EC phenotypes.
