## Endothelial Biomedicine

---

The endothelium, the cell layer that forms the inner lining of blood vessels, is a spatially distributed system that extends to all reaches of the human body. Today, clinical and basic research demonstrates that the endothelium plays a crucial role in mediating homeostasis and is involved in virtually every disease, either as a primary determinant of pathophysiology or as a victim of collateral damage. Indeed, the endothelium has remarkable, though largely untapped, diagnostic and therapeutic potential. This volume endeavors to bridge the bench-to-bedside gap in endothelial biomedicine, with the goal of advancing research and development and improving human health. The book is the first to systematically integrate knowledge about the endothelium from different organ-specific disciplines, including neurology, pulmonary, cardiology, gastroenterology, rheumatology, infectious disease, hematology-oncology, nephrology, and dermatology. Moreover, it is unique in its interdisciplinary approach, drawing on expertise from such diverse fields as evolutionary biology, comparative biology, molecular and cell biology, mathematical modeling and complexity theory, translational research, and clinical medicine.

Dr. William C. Aird received his medical degree from the University of Western Ontario in 1985. After completing his internal medicine and chief medical residency at the University of Toronto, he undertook a Hematology fellowship at the Brigham and Women's Hospital, Harvard Medical School. Dr. Aird received his postdoctoral training in the Department of Biology at the Massachusetts Institute of Technology. In 1996, he established an independent research program in the Division of Molecular Medicine at the Beth Israel Deaconess Medical Center. Dr. Aird is currently Associate Professor of Medicine at Harvard Medical School and Chief of the Division of Molecular and Vascular Medicine, at Beth Israel Deaconess Medical Center, Boston, Massachusetts.

*Preface* xxxix

## **PART I: CONTEXT**

### **History of Medicine**

1. The Endothelium in History 5  
*Manfred D. Laubichler, William C. Aird, and  
Jane Maienshein*

### **Evolution, Comparative Biology, and Development**

2. Introductory Essay: Evolution, Comparative  
Biology, and Development 23  
*William C. Aird and Manfred D. Laubichler*
3. Evolution of Cardiovascular Systems and Their  
Endothelial Linings 29  
*Warren W. Burggren and Carl L. Reiber*
4. The Evolution and Comparative Biology of Vascular  
Development and the Endothelium 50  
*J. Douglas Coffin*
5. Fish Endothelium 59  
*Kenneth R. Olson*
6. Hagfish: A Model for Early Endothelium 66  
*Pavan K. Cheruvu, Daniel Gale, Ann M. Dvorak,  
David Haig, and William C. Aird*
7. The Unusual Cardiovascular System of the  
Hemoglobinless Antarctic Icefish 74  
*H. William Detrich III*
8. The Fish Endocardium: A Review on the Teleost  
Heart 79  
*José M. Icardo*
9. Skin Breathing in Amphibians 85  
*Glenn J. Tattersall*

- |   |     |

26. Computer Metaphors for the Endothelium 215  
*Dexter Pratt*

## PART II: ENDOTHELIAL CELL AS INPUT-OUTPUT DEVICE

### Input

27. Introductory Essay: Endothelial Cell Input 227  
*Helmut G. Augustin*
28. Hemodynamics in the Determination of Endothelial Phenotype and Flow Mechanotransduction 230  
*Peter F. Davies*
29. Hypoxia-Inducible Factor 1 246  
*Gregg L. Semenza*
30. Integrative Physiology of Endothelial Cells: Impact of Regional Metabolism on the Composition of Blood-Bathing Endothelial Cells 256  
*Mitchell L. Halperin and Kamel S. Kamel*
31. Tumor Necrosis Factor 261  
*Jordan S. Pober*
32. Vascular Permeability Factor/Vascular Endothelial Growth Factor and Its Receptors: Evolving Paradigms in Vascular Biology and Cell Signaling 266  
*Debarata Mukhopadhyay, Resham Bhattacharya, and Deborah A. Hughes*
33. Function of Hepatocyte Growth Factor and Its Receptor c-Met in Endothelial Cells 285  
*Xue Wang, Augustine M.K. Choi, and Stefan W. Ryter*
34. Fibroblast Growth Factors 291  
*Masahiro Murakami, Arye Elfenbein, and Michael Simons*
35. Transforming Growth Factor- $\beta$  and the Endothelium 304  
*Barbara J. Ballermann*
36. Thrombospondins 324  
*Sareh Parangi and Jack Lawler*
37. Neuropilins: Receptors Central to Angiogenesis and Neuronal Guidance 337  
*Diane Bielenberg, Peter Kurschat, and Michael Klagsbrun*
38. Vascular Functions of Eph Receptors and Ephrin Ligands 345  
*Helmut G. Augustin*
39. Endothelial Input from the Tie1 and Tie2 Signaling Pathway 352  
*Daniel Dumont*

40. Slits and Netrins in Vascular Patterning: Taking Cues from the Nervous System 360  
*Kye Won Park, Lisa D. Urness, and Dean Y. Li*
41. *Notch* Genes: Orchestrating Endothelial Differentiation 368  
*Yasuhiro Funahashi, Carrie J. Shawber, and Jan Kitajewski*
42. Reactive Oxygen Species 375  
*Kaikobad Irani*
43. Extracellular Nucleotides and Nucleosides as Autocrine and Paracrine Regulators within the Vasculature 384  
*Silvia Deaglio and Simon C. Robson*
44. Syndecans 396  
*Eugene Tkachenko, John M. Rhodes, and Michael Simons*
45. Sphingolipids and the Endothelium 403  
*Timothy Hla*
46. Endothelium: A Critical Detector of Lipopolysaccharide 410  
*Jaswinder Kaur and Paul Kubes*
47. Receptor for Advanced Glycation End-products and the Endothelium: A Path to the Complications of Diabetes and Inflammation 419  
*Jean-Luc Wautier and Ann Marie Schmidt*
48. Complement 430  
*Anne Nicholson-Weller*
49. Kallikrein-Kinin System 444  
*Robert Colman*
50. Opioid Receptors in Endothelium 451  
*Kalpna Gupta and Elliot J. Stephenson*
51. Snake Toxins and Endothelium 461  
*Jay W. Fox and Solange M.T. Serrano*
52. Inflammatory Cues Controlling Lymphocyte–Endothelial Interactions in Fever-Range Thermal Stress 471  
*Qing Chen, Kristen Clancy, Wan-Chao Wang, and Sharon S. Evans*
53. Hyperbaric Oxygen and Endothelial Responses in Wound Healing and Ischemia-Reperfusion Injury 480  
*Bryan Belikoff, Wende R. Reenstra, and Jon A. Buras*
54. Barotrauma 489  
*Deborah A. Quinn and Charles A. Hales*
55. Endothelium and Diving 497  
*Alf O. Brubakk, Olav S. Eftedal, and Ulrik Wisløff*
56. Exercise and the Endothelium 506  
*Ulrik Wisløff, Per M. Haram, and Alf O. Brubakk*

57. The Endothelium at High Altitude 516  
*Nicholas L.M. Cruden and David J. Webb*
58. Endothelium in Space 520  
*Janice V. Meck and Ralph E. Purdy*
59. Toxicology and the Endothelium 527  
*Howard D. Beall and J. Douglas Coffin*
60. Pericyte–Endothelial Interactions 536  
*Mark W. Majesky*
61. Vascular Smooth Muscle Cells: The Muscle behind Vascular Biology 545  
*Shivalika Handa, Karolina Kolodziejska, and Mansoor Husain*
62. Cross-Talk between the Red Blood Cell and the Endothelium: Nitric Oxide as a Paracrine and Endocrine Regulator of Vascular Tone 562  
*Sruti Shiva and Mark T. Gladwin*
63. Leukocyte–Endothelial Cell Interactions 576  
*Volker Vielhauer, Xavier Cullere, and Tanya Mayadas*
64. Platelet–Endothelial Interactions 587  
*Patricia B. Maguire, Orina Belton, Niaobh O'Donoghue, Sandra Austin, and Judith Coppinger*
65. Cardiomyocyte–Endothelial Cell Interactions 602  
*Jian Li and Frank W. Sellke*
66. Interactions between Hepatocytes and Liver Sinusoidal Endothelial Cells 609  
*David Semela and Vijay Shah*
67. Stellate Cell–Endothelial Cell Interactions 616  
*Haruki Senoo*
68. Podocyte–Endothelial Interactions 620  
*Susan E. Quaggin*

### Coupling

69. Introductory Essay: Endothelial Cell Coupling 629  
*Michael Simons*
70. Endothelial and Epithelial Cells: General Principles of Selective Vectorial Transport 632  
*Rolf Kinne*
71. Electron Microscopic–Facilitated Understanding of Endothelial Cell Biology: Contributions Established during the 1950s and 1960s 643  
*Ann M. Dvorak*
72. Weibel–Palade Bodies: Vesicular Trafficking on the Vascular Highways 657  
*Charles J. Lowenstein, Craig N. Morrell, and Munekazu Yamakuchi*

73. Multiple Functions and Clinical Uses of Caveolae in Endothelium <i>Lucy A. Carver and Jan E. Schnitzer</i>	664
74. Endothelial Structures Involved in Vascular Permeability <i>Radu V. Stan</i>	679
75. Endothelial Luminal Glycocalyx: Protective Barrier between Endothelial Cells and Flowing Blood <i>Bernard M. van den Berg, Max Nieuwdorp, Erik Stroes, and Hans Vink</i>	689
76. Endothelial Cell Cytoskeleton <i>Christopher V. Carman</i>	696
77. Endothelial Cell Integrins <i>Joseph H. McCarty and Richard O. Hynes</i>	707
78. Aquaporin Water Channels and the Endothelium <i>Alan S. Verkman</i>	714
79. Ion Channels in Vascular Endothelium <i>Xiaoqiang Yao</i>	721
80. Regulation of Angiogenesis and Vascular Remodeling by Endothelial Akt Signaling <i>Ichiro Shiojima and Kenneth Walsh</i>	729
81. Mitogen-Activated Protein Kinases <i>Natalia V. Bogatcheva and Alexander D. Verin</i>	737
82. Protein Kinase C <i>Alex Toker</i>	746
83. Rho GTP-Binding Proteins <i>Allan Murray</i>	753
84. Protein Tyrosine Phosphatases <i>Arne Östman and Kai Kappert</i>	764
85. Role of $\beta$ -Catenin in Endothelial Cell Function <i>Anna Cattelino and Stefan Liebner</i>	773
86. Nuclear Factor- $\kappa$ B Signaling in Endothelium <i>Kaiser M. Bijli and Arshad Rahman</i>	784
87. Peroxisome Proliferator-Activated Receptors and the Endothelium <i>Jonathan D. Brown and Jorge Plutzky</i>	796
88. GATA Transcription Factors <i>Takashi Minami</i>	806
89. Coupling: The Role of Ets Factors <i>Peter Oettgen</i>	812
90. Early Growth Response-1 Coupling in Vascular Endothelium <i>Levon M. Khachigian and Valerie C. Midgley</i>	818
91. KLF2: A “Molecular Switch” Regulating Endothelial Function <i>Zhiyong Lin and Mukesh K. Jain</i>	822

92. NFAT Transcription Factors 828  
*Takashi Minami*
93. Forkhead Signaling in the Endothelium 834  
*Md. Ruhul Abid and William C. Aird*
94. Genetics of Coronary Artery Disease and Myocardial Infarction: The MEF2 Signaling Pathway in the Endothelium 847  
*Stephen R. Archacki, Sun-Ah You, Quansheng Xi, and Qing Wang*
95. Vezf1: A Transcriptional Regulator of the Endothelium 855  
*Frank Kuhnert and Heidi Stuhlmann*
96. Sox Genes: At the Heart of Endothelial Transcription 861  
*Neville Young and Peter Koopman*
97. Id Proteins and Angiogenesis 868  
*Robert Benezra and Erik Henke*

## Output

98. Introductory Essay: Endothelial Cell Output 879  
*William C. Aird*
99. Proteomic Mapping of Endothelium and Vascular Targeting in Vivo 881  
*Lucy A. Carver and Jan E. Schnitzer*
100. A Phage Display Perspective 898  
*Amado J. Zurita, Wadih Arap, and Renata Pasqualini*
101. Hemostasis and the Endothelium 909  
*William C. Aird*
102. Von Willebrand Factor 915  
*Tom Diacovo*
103. Tissue Factor Pathway Inhibitor 922  
*Alan E. Mast*
104. Tissue Factor Expression by the Endothelium 932  
*Gernot Schabbauer and Nigel Mackman*
105. Thrombomodulin 939  
*Marlies Van de Wouwer and Edward M. Conway*
106. Heparan Sulfate 947  
*Nicholas W. Shworak*
107. Antithrombin 960  
*Nicholas W. Shworak*
108. Protein C 973  
*Marlies Van de Wouwer and Edward M. Conway*
109. Vitamin K–Dependent Anticoagulant Protein S 982  
*Björn Dahlbäck*

110. Nitric Oxide as an Autocrine and Paracrine Regulator of Vessel Function 988  
*William C. Sessa*
111. Heme Oxygenase and Carbon Monoxide in Endothelial Cell Biology 994  
*Hong Pyo Kim, Stefan W. Ryter, and Augustine M.K. Choi*
112. Endothelial Eicosanoids 1004  
*Kenneth K. Wu*
113. Regulation of Endothelial Barrier Responses and Permeability 1015  
*Joe G.N. Garcia*
114. Molecular Mechanisms of Leukocyte Transendothelial Cell Migration 1030  
*F. William Luscinskas*
115. Functions of Platelet-Endothelial Cell Adhesion Molecule-1 in the Vascular Endothelium 1037  
*Peter J. Newman and Debra K. Newman*
116. P-Selectin 1049  
*Rodger P. McEver*
117. Intercellular Adhesion Molecule-1 and Vascular Cell Adhesion Molecule-1 1058  
*Silvia Muro*
118. E-Selectin 1071  
*David Milstone*
119. Endothelial Cell Apoptosis 1081  
*Elizabeth O. Harrington, Qing Lu, and Sharon Rounds*
120. Endothelial Antigen Presentation 1098  
*Andrew H. Lichtman*

**PART III: VASCULAR BED/ORGAN STRUCTURE AND FUNCTION IN HEALTH AND DISEASE**

121. Introductory Essay: The Endothelium in Health and Disease 1111  
*William C. Aird*
122. Hereditary Hemorrhagic Telangiectasia: A Model to Probe the Biology of the Vascular Endothelium 1113  
*Mourad Toporsian and Michelle Letarte*
123. Blood–Brain Barrier 1124  
*Christian Weidenfeller and Eric V. Shusta*
124. Brain Endothelial Cells Bridge Neural and Immune Networks 1140  
*Kevin J. Tracey and Christine N. Metz*

125. The Retina and Related Hyaloid Vasculature:  
Developmental and Pathological  
Angiogenesis 1154  
*Laura Benjamin*
126. Microheterogeneity of Lung Endothelium 1161  
*Troy Stevens*
127. Bronchial Endothelium 1171  
*Elizabeth Wagner and Aigul Moldobaeva*
128. The Endothelium in Acute Respiratory Distress  
Syndrome 1178  
*Mark L. Martinez and Guy A. Zimmerman*
129. The Central Role of Endothelial Cells in Severe  
Angioproliferative Pulmonary Hypertension 1193  
*Norbert F. Voelkel and Mark R. Nicolls*
130. Emphysema: An Autoimmune Vascular Disease? 1199  
*Norbert F. Voelkel and Laimute  
Taraseviciene-Stewart*
131. Endothelial Mechanotransduction in Lung:  
Ischemia in the Pulmonary Vasculature 1202  
*Shampa Chatterjee and Aron B. Fisher*
132. Endothelium and the Initiation of  
Atherosclerosis 1214  
*Myron I. Cybulsky*
133. The Hepatic Sinusoidal Endothelial Cell 1226  
*Laurie D. DeLeve*
134. Hepatic Macrocirculation: Portal Hypertension  
As a Disease Paradigm of Endothelial Cell  
Significance and Heterogeneity 1239  
*Winston Dunn and Vijay Shah*
135. Inflammatory Bowel Disease 1248  
*Ossama A. Hatoum and David G. Binion*
136. The Vascular Bed of Spleen in Health and  
Disease 1255  
*Péter Balogh*
137. Adipose Tissue Endothelium 1265  
*Gary Hausman*
138. Renal Endothelium 1271  
*Bruce Molitoris*
139. Uremia 1278  
*Jan T. Kielstein and Danilo Fliser*
140. The Influence of Dietary Salt Intake on  
Endothelial Cell Function 1287  
*Paul W. Sanders*
141. The Role of the Endothelium in Systemic  
Inflammatory Response Syndrome and Sepsis 1294  
*Laszlo M. Hoesel and Peter A. Ward*

142. The Endothelium in Cerebral Malaria: Both a Target Cell and a Major Player 1303  
*Valéry Combes, Jin Ning Lou, and Georges E. Grau*
143. Hemorrhagic Fevers: Endothelial Cells and Ebola-Virus Hemorrhagic Fever 1311  
*Tatiana A. Afanasieva, Victoria Wahl-Jensen, Jochen Seebach, Herrmann Schillers, Dessy Nikova, Ute Ströher, Heinz Feldmann, and Hans-Joachim Schnittler*
144. Effect of Smoking on Endothelial Function and Cardiovascular Disease 1320  
*Rajat S. Barua and John A. Ambrose*
145. Disseminated Intravascular Coagulation 1332  
*Marcel Levi*
146. Thrombotic Microangiopathy 1337  
*Jeffrey Laurence*
147. Heparin-Induced Thrombocytopenia 1344  
*Andreas Greinacher and Theodore E. Warkentin*
148. Sickle Cell Disease Endothelial Activation and Dysfunction 1352  
*Robert P. Hebbel*
149. The Role of Endothelial Cells in the Antiphospholipid Syndrome 1360  
*Jacob H. Rand and Xiao-Xuan Wu*
150. Diabetes 1370  
*Angelika Bierhaus, Hans-Peter Hammes, and Peter P. Nawroth*
151. The Role of the Endothelium in Normal and Pathologic Thyroid Function 1386  
*Jamie Mitchell, Anthony Hollenberg, and Sareh Parangi*
152. Endothelial Dysfunction and the Link to Age-Related Vascular Disease 1397  
*Jay M. Edelberg and May J. Reed*
153. Kawasaki Disease 1405  
*Jane C. Burns*
154. Systemic Vasculitis: Autoantibodies Targeting Endothelial Cells 1411  
*Miri Blank, Sonja Praprotnik, and Yehuda Shoenfeld*
155. High Endothelial Venule-like Vessels in Human Chronic Inflammatory Diseases 1419  
*Jean-Philippe Girard*
156. Endothelium and Skin 1431  
*Peter Petzelbauer, Marion Gröger, Robert Loewe, and Rainer Kunstfeld*
157. Angiogenesis 1444  
*Helmut G. Augustin*

158. Tumor Blood Vessels 1457  
*Harold F. Dvorak*
159. Kaposi's Sarcoma 1471  
*Kimberly E. Foreman*
160. Endothelial Mimicry of Placental Trophoblast Cells 1479  
*Hartmut Weiler and Rashmi Sood*
161. Placental Vasculature in Health and Disease 1488  
*S. Ananth Karumanchi and Hai-Tao Yuan*
162. Endothelialization of Prosthetic Vascular Grafts 1501  
*Thomas S. Monahan and Frank W. LoGerfo*
163. The Endothelium's Diverse Roles Following Acute Burn Injury 1506  
*Rob Cartotto*
164. Trauma-Hemorrhage and Its Effects on the Endothelium 1513  
*Yukihiro Yokoyama and Irshad H. Chaudry*
165. Coagulopathy of Trauma: Implications for Battlefield Hemostasis 1523  
*Anthony E. Pusateri and John B. Holcomb*
166. The Effects of Blood Transfusion on Vascular Endothelium 1533  
*Christopher G. Silliman*
167. The Role of Endothelium in Erectile Function and Dysfunction 1541  
*Muammer Kendirci and Wayne J.G. Hellstrom*
168. Avascular Necrosis: Vascular Bed/Organ Structure and Function in Health and Disease 1550  
*Chantal Séguin*
169. Molecular Control of Lymphatic System Development 1553  
*Darren Kafka and Young-Kwon Hong*
170. High Endothelial Venules 1568  
*Jean-Marc Gauguet, Roberto Bonasio, and Ulrich H. von Andrian*
171. Hierarchy of Circulating and Vessel Wall-Derived Endothelial Progenitor Cells 1589  
*David A. Ingram and Mervin C. Yoder*

#### PART IV: DIAGNOSIS AND TREATMENT

172. Introductory Essay: Diagnosis and Treatment 1599  
*Mansoor Husain*
173. Circulating Markers of Endothelial Function 1602  
*Andrew D. Blann, William Foster, and Gregory Y.H. Lip*

174. Blood Endothelial Cells <i>Robert D. Simari, Rajiv Gulati, and Robert P. Hebbel</i>	1612
175. Endothelial Microparticles: Biology, Function, Assay and Clinical Application <i>Yeon S. Ahn, Lawrence Horstman, Eugene Ahn, Wenche Jy, and Joaquin Jimenez</i>	1621
176. Molecular Magnetic Resonance Imaging <i>Susan B. Yeon, Andrea J. Wiethoff, Warren J. Manning, Elmar Spuentrup, and Rene M. Botnar</i>	1637
177. Real-Time Imaging of the Endothelium <i>Peter L. Gross</i>	1654
178. Diagnosing Endothelial Cell Dysfunction <i>Aristides Veves and Roy Freeman</i>	1659
179. Statins <i>James K. Liao</i>	1668
180. Steroid Hormones <i>James K. Liao</i>	1674
181. Organic Nitrates: Exogenous Nitric Oxide Administration and Its Influence on the Vascular Endothelium <i>John D. Parker and Tommaso Gori</i>	1682
182. Therapeutic Approaches to Altering Hemodynamic Forces <i>José A. Adams</i>	1690
183. Stent- and Nonstent-Based Cell Therapy for Vascular Disease <i>Michael R. Ward, Duncan J. Stewart, and Michael J.B. Kutryk</i>	1698
184. Building Blood Vessels <i>James B. Hoying and Stuart K. Williams</i>	1712
185. Gene Transfer and Expression in the Vascular Endothelium <i>Michael J. Passineau and David T. Curiel</i>	1725
186. Drug Targeting to Endothelium <i>Vladimir R. Muzykantov</i>	1734

## PART V: CHALLENGES AND OPPORTUNITIES

### Complexity

187. Introductory Essay: Complexity and the Endothelium <i>Ary L. Goldberger</i>	1751
188. Agent-Based Modeling and Applications to Endothelial Biomedicine <i>Gary An</i>	1754
189. Scale-Free Networks in Cell Biology <i>Eivind Almaas and Albert-László Barabási</i>	1760

190. Cell Fates as Attractors: Stability and Flexibility of Cellular Phenotypes <i>Sui Huang</i>	1767
191. Equation-Based Models of Dynamic Biological Systems <i>Gilles Clermont, Yoram Vodovotz, and Jonathan Rubin</i>	1780

---

## EDITOR

### **William C. Aird, M.D.**

Associate Professor of Medicine  
Harvard Medical School  
Chief, Division of Molecular and Vascular Medicine  
Center for Vascular Biology Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

## ASSOCIATE EDITORS

### **Helmut G. Augustin, D.V.M., Ph.D.**

Department of Vascular Oncology and Metastasis  
German Cancer Research Center Heidelberg (DKFZ) and  
Center for Biomedicine and Medical Technology  
Mannheim (CBTM), Germany

### **Ary L. Goldberger, M.D.**

Professor of Medicine, Harvard Medical School  
Director, Margret and H.A. Rey Institute for Nonlinear  
Dynamics in Medicine and Associate Director  
Division of Interdisciplinary Medicine and  
Biotechnology  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

### **Mansoor Husain, M.D.**

Director, Heart & Stroke Richard Lewar Centre of  
Excellence in Cardiovascular Research  
Associate Professor of Medicine  
University of Toronto, Toronto  
Ontario, Canada

### **Manfred D. Laubichler, Ph.D.**

Professor of Theoretical Biology and History of Biology  
Affiliated Professor of Philosophy School of Life  
Sciences and Centers for Biology and Society and  
Social Dynamics and Complexity  
Arizona State University Tempe  
Tempe, Arizona

### **Jane Maienschein, Ph.D.**

Regents' Professor, President's Professor, and Parents  
Association Professor  
Director, Center for Biology and Society  
Arizona State University Tempe  
Tempe, Arizona

### **Jan E. Schnitzer, M.D.**

Scientific Director  
Professor of Cellular & Molecular Biology  
Director of Vascular Biology & Angiogenesis  
Program  
Sidney Kimmel Cancer Center  
San Diego, California

### **Michael Simons, M.D.**

A.G. Huber Professor of Medicine and Pharmacology  
and Toxicology  
Chief, Section of Cardiology  
Director, Angiogenesis Research Center  
Dartmouth Medical School, Dartmouth Hitchcock  
Medical Center  
Hanover, New Hampshire

## ARTISTIC CONSULTANT

### **Steven Moskowitz**

Advanced Medical Graphics  
Boston, Massachusetts

## CONTRIBUTORS

### **Md. Ruhul Abid, M.D., Ph.D.**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Molecular and Vascular Medicine and Center  
for Vascular Biology Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**José A. Adams, M.D.**

Director, Division of Neonatology  
Mount Sinai Medical Center  
Miami Beach, Florida

**Tatiana A. Afanasieva, Ph.D.**

Institute of Physiology  
Technical University  
Dresden, Germany

**Eugene R. Ahn, M.D.**

Fellow, Wallace H. Coulter Laboratory  
Division of Hematology/Oncology  
Department of Medicine  
University of Miami School of Medicine  
Miami, Florida

**Yeon S. Ahn, M.D.**

Professor of Medicine  
University of Miami School of Medicine  
Wallace H. Coulter Laboratory  
Division of Hematology/Oncology  
Department of Medicine  
Miami, Florida

**William C. Aird, M.D.**

Associate Professor of Medicine  
Harvard Medical School  
Chief, Division of Molecular and Vascular Medicine  
Center for Vascular Biology Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Eivind Almaas, Ph.D.**

Center for Network Research and Department  
of Physics  
University of Notre Dame  
Notre Dame, Indiana

**John A. Ambrose, M.D.**

Professor of Medicine  
University of California at San Francisco  
Chief of Cardiology  
University of California at San Francisco  
Fresno, California

**Gary An, M.D.**

Assistant Professor of Surgery  
Division of Trauma/Critical Care  
Northwestern University Feinberg School  
of Medicine  
Chicago, Illinois

**Wadiah Arap, M.D.**

M.D. Anderson Cancer Center  
University of Texas  
Houston, Texas

**Stephen R. Archacki, M.D.**

Center for Cardiovascular Genetics  
Department of Molecular Cardiology  
Lerner Research Institute  
Cleveland Clinic and Cleveland State University  
Cleveland, Ohio

**Chaitanya A. Athale, Ph.D.**

Complex Biosystems Modeling Laboratory  
Harvard-MIT (HST) Athinoula A. Martinos Center for  
Biomedical Imaging  
Massachusetts General Hospital-East  
Charlestown, Massachusetts

**Helmut G. Augustin, D.V.M., Ph.D.**

Department of Vascular Oncology and Metastasis  
German Cancer Research Center Heidelberg (DKFZ) and  
Center for Biomedicine and Medical Technology  
Mannheim (CBTM), Germany

**Sandra Austin, Ph.D.**

Department of Molecular Medicine  
Conway Institute, University College Dublin, Belfield  
Dublin, Ireland

**Barbara J. Ballermann, M.D.**

Professor of Medicine  
CRC Chair in Endothelial Cell Biology  
Director, Division of Nephrology and Immunology  
University of Alberta, Edmonton  
Alberta, Canada

**Péter Balogh M.D., Ph.D.**

Department of Immunology and Biotechnology  
Faculty of Medicine, University of Pécs  
Pécs, Hungary

**Albert-Laszlo Barabasi, Ph.D.**

Emil T. Hofman Professor of Physics  
Department of Physics, Center for Network Research  
and Department of Physics  
University of Notre Dame  
Notre Dame, Indiana

**Rajat S. Barua, M.D., Ph.D.**

Cardiology Fellow  
Division of Cardiology  
Department of Medicine  
University of California at San Francisco  
Fresno, California

**Howard D. Beall, Ph.D.**

Department of Biomedical and Pharmaceutical  
Sciences  
The University of Montana  
Missoula, Montana

**Bryan Belikoff, Ph.D.**

New England Inflammation and Tissue  
Protection Institute  
Northeastern University  
Boston, Massachusetts

**Orina Belton, Ph.D.**

Department of Molecular Medicine,  
Conway Institute  
University College Dublin  
Belfield, Dublin, Ireland

**Robert Benezra, Ph.D.**

Member, Memorial Sloan-Kettering Cancer Center  
New York, New York

**Laura Benjamin, Ph.D.**

Associate Professor of Pathology  
Harvard Medical School  
Department of Pathology  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Resham Bhattacharya, Ph.D.**

Department of Biochemistry and Molecular Biology  
Mayo Clinic College of Medicine  
Mayo Clinic Cancer Center  
Rochester, Minnesota

**Diane R. Bielenberg, Ph.D.**

Assistant Professor, Harvard Medical School  
Vascular Biology Program  
Department of Surgical Research, Children's Hospital  
Boston, Massachusetts

**Angelika Bierhaus, Ph.D.**

University of Heidelberg  
Department of Medicine I and Clinical Chemistry  
University of Heidelberg  
Heidelberg, Germany

**Kaiser M. Bijli, Ph.D.**

Research Associate, Division of Neonatology  
Department of Pediatrics, School of Medicine and  
Dentistry  
University of Rochester  
Rochester, New York

**David G. Binion, M.D.**

Associate Professor of Medicine  
Medical College of Wisconsin  
Director, IBD Center, Froedtert Memorial  
Lutheran Hospital  
Milwaukee, Wisconsin

**Miri Blank, M.D.**

Research Unit of Autoimmune Disease and Department  
of Medicine B, Sheba Medical Center, Tel-Hashomer  
and the Sackler Faculty for Medicine  
Tel-Aviv University, Israel

**Andrew D. Blann, Ph.D.**

Hemostasis Thrombosis and Vascular Biology Unit  
University Department of Medicine, City Hospital  
Birmingham, United Kingdom

**Natalia V. Bogatcheva, Ph.D.**

Vascular Biology Center  
Medical College of Georgia  
Augusta, Georgia

**Roberto Bonasio, Ph.D.**

The Immune Disease Institute  
Department of Pathology, Harvard Medical School  
Boston, Massachusetts

**Rene M. Botnar, Ph.D.**

Professor of Biomedical Imaging  
Department of Nuclear Medicine  
Technische Universität München  
Munich, Germany

**Jonathan D. Brown, M.D.**

Cardiovascular Division, Brigham and Women's  
Hospital  
Harvard Medical School  
Boston, Massachusetts

**Alf O. Brubakk, M.D., Ph.D.**

Professor of Applied Physiology  
Department of Circulation and Medical Imaging  
Norwegian University of Science and Technology  
Trondheim, Norway

**Jon A. Buras, M.D.**

Research Associate Professor  
New England Inflammation and Tissue  
Protection Institute  
Northeastern University  
Boston, Massachusetts

**Warren W. Burggren, Ph.D.**

Dean, College of Arts and Sciences, Professor,  
Biological Sciences  
University of North Texas  
University of North Texas  
Denton, Texas

**Jane C. Burns, M.D.**

Professor and Chief, Division of Allergy, Immunology,  
and Rheumatology  
Department of Pediatrics  
Rady Children's Hospital San Diego and UCSD School  
of Medicine  
La Jolla, California

**Christopher V. Carman, Ph.D.**

Assistant Professor of Medicine  
Harvard Medical School  
Division of Molecular and Vascular Medicine  
and Center for Vascular Biology Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Rob Cartotto, M.D. FRCS(C)**

Ross Tilley Burn Centre, Sunnybrook Health  
Sciences Centre  
Department of Surgery  
University of Toronto  
Toronto, Ontario, Canada.

**Lucy A. Carver, Ph.D.**

Vascular Biology & Angiogenesis Program  
Sidney Kimmel Cancer Center  
San Diego, California

**Anna Cattelino, Ph.D.**

IFOM-Fondazione Istituto FIRC di Oncologia  
Molecolare  
Milano, Italy

**Shampa Chatterjee, Ph.D.**

Research Assistant Professor  
Physiology  
University of Pennsylvania  
Philadelphia, Pennsylvania

**Irshad H. Chaudry, Ph.D.**

Professor of Surgery, Microbiology, Physiology & Biophysics  
 Vice Chairman, Department of Surgery  
 Director, Center for Surgical Research  
 University of Alabama at Birmingham  
 Birmingham, Alabama

**Qing Chen, M.D., Ph.D.**

Department of Immunology  
 Roswell Park Cancer Institute  
 Buffalo, New York

**Pavan K. Cheruvu**

Medical Student, Harvard Medical School  
 Beth Israel Deaconess Medical Center  
 Boston, Massachusetts

**Augustine M.K. Choi, M.D.**

Division of Pulmonary  
 Allergy, and Critical Care Medicine  
 The University of Pittsburgh School of Medicine  
 Pittsburgh, Pennsylvania

**Sameer S. Chopra, Ph.D.**

Departments of Medicine, Pharmacology, and Cell & Developmental Biology  
 Vanderbilt University School of Medicine  
 Nashville, Tennessee

**Aldo Ciau-Uitz, Ph.D., M.R.C.**

Molecular Haematology Unit  
 The Weatherall Institute of Molecular Medicine  
 University of Oxford, John Radcliffe Hospital,  
 Headington  
 Oxford, United Kingdom

**Kristen Clancy**

Department of Immunology  
 Roswell Park Cancer Institute  
 Buffalo, New York

**Gilles Clermont, M.D., M.Sc.**

Department of Critical Care Medicine  
 University of Pittsburgh Center for Inflammation and Regenerative Modeling  
 University of Pittsburgh  
 Pittsburgh, Pennsylvania

**J. Douglas Coffin, Ph.D.**

Associate Professor for Molecular Genetics  
 The University of Montana  
 Department of Biomedical & Pharmaceutical Sciences  
 Missoula, Montana

**Robert Colman, M.D.**

Sol Sherry Professor of Medicine  
 Temple University School of Medicine  
 Philadelphia, Pennsylvania

**Valéry Combes, Ph.D.**

Department of Pathology  
 Faculty of Medicine  
 The University of Sydney  
 Camperdown, Australia

**Edward M. Conway, M.D., M.B.A., Ph.D.**

Group Leader, Professor of Medicine  
 VIB Department of Transgene Technology and Gene Therapy, K.U. Leuven  
 Leuven, Belgium

**Judith Coppinger, Ph.D.**

Department of Molecular Medicine  
 Conway Institute, University College Dublin  
 Dublin, Ireland

**Loren Cordain, Ph.D.**

Department of Health and Exercise Science  
 Colorado State University  
 Fort Collins, Colorado

**Nicholas L.M. Cruden, B.Sc. (Hons), M.B., Ch.B., M.R.C.P.**

Specialist Registrar in Cardiology University  
 of Edinburgh  
 Edinburgh, United Kingdom

**Xavier Cullere, Ph.D.**

Department of Pathology  
 Center for Excellence in Vascular Biology  
 Brigham and Women's Hospital  
 Boston, Massachusetts

Division of Human Gene Therapy  
 Departments of Medicine, Obstetrics and Gynecology, Pathology, Surgery, and the Gene Therapy Center  
 University of Alabama at Birmingham  
 Birmingham, Alabama

**Myron I. Cybulsky, M.D.**

Professor of Laboratory Medicine and Pathobiology,  
 University of Toronto  
 Senior Scientist  
 Toronto General Research Institute,  
 University Health Network, Toronto  
 Ontario, Canada

**Björn Dahlback, M.D., Ph.D.**

Professor of Blood Coagulation Research  
 Lund University Department of Laboratory Medicine  
 Clinical Chemistry, Wallenberg Laboratory, University  
 Hospital  
 Malmö, Sweden

**Peter F. Davies, Ph.D.**

Robinette Foundation Professor of Cardiovascular  
 Medicine, Pathology and Laboratory Medicine, and  
 Bioengineering  
 Director, Institute for Medicine & Engineering,  
 University of Pennsylvania  
 Philadelphia, Pennsylvania

**Silvia Deaglio, M.D.**

Visiting Assistant Professor  
 Harvard Medical School  
 Beth Israel Deaconess Medical Center  
 Boston, Massachusetts

**Thomas S. Deisboeck, M.D.**

Assistant Professor of Radiology  
Harvard Medical School  
Director, Complex Biosystems Modeling Laboratory  
Harvard-MIT (HST) Athinoula A. Martinos Center for  
Biomedical Imaging  
Massachusetts General Hospital-East  
Charlestown, Massachusetts

**Laurie D. DeLeve, M.D., Ph.D.**

Professor of Medicine  
Division of Gastrointestinal and Liver Diseases  
University of Southern California Keck School  
of Medicine  
Los Angeles, California

**H. William Detrich III, Ph.D.**

Professor of Biochemistry and Marine Biology  
Department of Biology, Northeastern University  
Boston, Massachusetts

**Thomas G. Diacovo, M.D.**

Department of Pediatrics and Pathology  
Columbia University, New York  
New York

**Daniel Dumont, Ph.D.**

Professor, Department of Medical Biophysics  
University of Toronto  
Director, Molecular and Cellular Biology  
Sunnybrook Research Institute, Toronto  
Ontario, Canada

**Winston Dunn, M.D.**

GI Research Unit  
Division of Gastroenterology and Hepatology,  
Mayo Clinic  
Rochester, Minnesota

**Ann M. Dvorak, M.D.**

Professor of Pathology, Harvard Medical School  
Department of Pathology, Beth Israel Deaconess  
Medical Center  
Boston, Massachusetts

**Harold F. Dvorak, M.D.**

Professor of Pathology, Harvard Medical School  
Department of Pathology, Beth Israel Deaconess  
Medical Center  
Boston, Massachusetts

**S. Boyd Eaton, M.D.**

Departments of Anthropology and Radiology  
Emory University Atlanta, Georgia

**Jay M. Edelberg, M.D., Ph.D.**

GlaxoSmithKline, King of Prussia, Pennsylvania  
Department of Medicine, Weill Medical College of  
Cornell University, New York  
New York

**Olav S. Eftedal, M.Sc. (Eng.), M.D., Ph.D.**

Department of Circulation and Medical Imaging  
Norwegian University of Science and Technology  
Trondheim, Norway

**Arye Elfenbein, Ph.D.**

Angiogenesis Research Center  
Dartmouth Medical School, Dartmouth Hitchcock  
Medical Center  
Hanover, New Hampshire

**Sharon S. Evans, Ph.D.**

Professor of Oncology  
Department of Immunology, Roswell Park  
Cancer Institute  
Buffalo, New York

**Heinz Feldmann, Ph.D.**

Special Pathogens Program  
National Microbiology Laboratory  
Public Health Agency of Canada  
Department of Medical Microbiology and  
Infectious Diseases  
University of Manitoba, Winnipeg  
Manitoba, Canada

**Claire Fernandez, Ph.D.**

M.R.C. Molecular Haematology Unit  
The Weatherall Institute of Molecular Medicine,  
University of Oxford  
John Radcliffe Hospital, Headington  
Oxford, United Kingdom

**Aron B. Fisher, M.D.**

Professor, Physiology and Medicine, Director, Institute  
for Environmental Medicine  
University of Pennsylvania Medical Center  
University of Pennsylvania  
Philadelphia, Pennsylvania

**Danilo Fliser, M.D.**

Assistant Professor of Medicine  
Department of Internal Medicine  
Division of Nephrology  
Medical School Hannover  
Hannover, Germany

**Kimberly E. Foreman, Ph.D.**

Associate Professor  
Department of Pathology  
Breast Cancer Research Program  
Cardinal Bernardin Cancer Center, Loyola  
University Chicago  
Maywood, Illinois

**William Foster, Ph.D.**

Hemostasis Thrombosis and Vascular  
Biology Unit  
University Department of Medicine  
City Hospital, Birmingham  
United Kingdom

**Jay W. Fox, Ph.D.**

Professor and Assistant Dean of Research Support,  
Microbiology  
University of Virginia School  
of Medicine  
Charlottesville, Virginia

**Roy Freeman, M.D.**

Professor of Neurology  
Harvard Medical School  
Director, Center for Autonomic and Peripheral  
Nerve Disorders  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Yasuhiro Funahashi, Ph.D.**

Department of Obstetrics and Gynecology  
Institute of Cancer Genetics  
Columbia University Medical Center, New York  
New York

**Daniel Gale**

Harvard University  
Undergraduate Student, Beth Israel Deaconess  
Medical Center  
Harvard Medical School  
Boston, Massachusetts

**Joe G.N. Garcia M.D.**

Lowell T. Coggeshall Professor of Medicine  
Chairman, Department of Medicine, Pritzker School  
of Medicine  
University of Chicago  
Chicago, Illinois

**Jean-Marc Gauguier, M.D., Ph.D.**

The Immune Disease Institute  
Department of Pathology  
Harvard Medical School  
Boston, Massachusetts

**Jean-Philippe Girard, Ph.D.**

Head, Laboratory of Vascular Biology  
Deputy-Director, Institute of Pharmacology and  
Structural Biology, CNRS UMR 5089  
Toulouse, France

**Mark T. Gladwin, M.D.**

Chief, Vascular Medicine Branch, NHLBI  
Critical Care Medicine Department, Clinical Center  
National Institutes of Health, Vascular Medicine Branch  
National Heart Lung and Blood Institute  
Bethesda, Maryland

**Ary L. Goldberger, M.D.**

Professor of Medicine, Harvard Medical School  
Director, Margret and H.A. Rey Institute for Nonlinear  
Dynamics in Medicine and Associate Director  
Division of Interdisciplinary Medicine  
and Biotechnology  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**James A. Gordon, M.D., M.P.A.**

Director, Gilbert Program in Medical Simulation  
Harvard Medical School  
Assistant Professor of Medicine  
Department of Emergency Medicine  
Massachusetts General Hospital  
Boston, Massachusetts

**Tommaso Gori, M.D., Ph.D.**

Department of Internal  
Cardiovascular and Geriatric Medicine  
University of Siena  
Siena, Italy

**Georges E.R. Grau, M.D.**

Chair of Vascular Immunology  
Department of Pathology  
Faculty of Medicine  
The University of Sydney  
Camperdown, Australia

**Andreas Greinacher, M.D.**

Professor and Head, Department of Transfusion  
Medicine  
Institute of Immunology and Transfusion Medicine  
Ernst-Moritz-Arndt-University-Greifswald  
Greifswald, Germany

**Marion Gröger, Ph.D.**

Department of Dermatology  
Division of General Dermatology Medical  
University Vienna  
Vienna, Austria

**Peter L. Gross, M.D.**

St. Michael's Hospital, University of Toronto, Toronto  
Ontario, Canada

**Rajiv Gulati M.B., Ch.B.**

Assistant Professor of Medicine  
Division of Cardiovascular Diseases, Mayo Clinic  
Rochester, Minnesota

**Kalpna Gupta, Ph.D.**

Assistant Professor  
Department of Medicine  
Division of Hematology  
Oncology and Transplantation  
University of Minnesota Medical School  
Minneapolis, Minnesota

**David Haig, Ph.D.**

Professor of Biology  
Department of Organismic and Evolutionary  
Biology  
Harvard University, Cambridge, Massachusetts

**Charles A. Hales, M.D.**

Professor of Medicine, Harvard Medical School  
Pulmonary and Critical Care Unit, Department  
of Medicine  
Massachusetts General Hospital  
Boston, Massachusetts

**Mitchell L. Halperin, M.D.**

Emeritus Professor of Medicine  
University of Toronto  
Division of Nephrology, St. Michael's Hospital, Toronto  
Ontario, Canada

**Hans-Peter Hammes, M.D., Ph.D.**

Department of Medicine V, University of Mannheim  
Germany

**Shivalika Handa, Ph.D.**

Candidate, Department of Laboratory Medicine &  
Pathobiology  
University of Toronto, Toronto  
Ontario, Canada.

**Per M. Haram, M.D., Ph.D.**

Department of Circulation and Medical Imaging  
Norwegian University of Science and Technology  
Trondheim, Norway

**Alan R. Hargens, Ph.D.**

Professor of Orthopaedic Surgery  
University of California, San Diego  
UCSD Medical Center  
San Diego, California

**Elizabeth O. Harrington, Ph.D.**

Pulmonary Vascular Research Laboratory, Providence VA  
Medical Center  
Associate Professor of Medicine  
The Warren Alpert Medical School of  
Brown University  
Providence, Rhode Island

**Ossama A. Hatoum, M.D.**

Froedtert Memorial Lutheran Hospital  
Medical College of Wisconsin  
Milwaukee, Wisconsin

**Gary J. Hausman**

Research Physiologist, USDA – ARS and University  
of Georgia  
Athens, Georgia

**Robert P. Hebbel, M.D.**

Regents Professor, George Clark Professor  
Vice-Chairman for Research  
Department of Medicine  
Director, Vascular Biology Center, University of  
Minnesota  
Minneapolis, Minnesota

**Wayne J.G. Hellstrom, M.D.**

Professor of Urology  
Chief, Section of Andrology Tulane University Health  
Sciences Center  
Department of Urology  
New Orleans, Louisiana

**Erik Henke, Ph.D.**

Memorial Sloan-Kettering Cancer Center,  
New York  
New York

**Timothy Hla, Ph.D.**

Professor of Cell Biology  
Director, Center for Vascular Biology, University of  
Connecticut Health Center  
Farmington, Connecticut

**Laszlo M. Hoesel, M.D.**

University of Michigan Health Systems  
Department of Pathology  
Ann Arbor, Michigan

**John B. Holcomb, M.D., F.A.C.S., C.O.L., M.C.**

U.S. Army, Clinical Professor of Surgery, University of  
Texas Health Science Center, San Antonio  
Texas Trauma Consultant for The Surgeon General,  
Commander  
Commander, U.S. Army Institute of Surgical Research  
Fort Sam Houston, Texas

**Anthony Hollenberg, M.D.**

Associate Professor of Medicine  
Harvard Medical School  
Chief, Thyroid Unit, Beth Israel Deaconess  
Medical Center  
Boston, Massachusetts

**Young-Kwon Hong, Ph.D.**

Assistant Professor, Department of Surgery and  
Biochemistry & Molecular Biology  
Norris Comprehensive Cancer Center  
University of Southern California  
Los Angeles, California

**Lawrence Horstman, BS**

Research Associate, Wallace H. Coulter Laboratory  
Division of Hematology/Oncology  
Department of Medicine  
University of Miami School of Medicine  
Miami, Florida

**James B. Hoying, Ph.D.**

Associate Professor, Department of Surgery  
University of Louisville  
Chief, Division of Cardiovascular Therapeutics  
Cardiovascular Innovation Institute  
Louisville, Kentucky

**Grace Huang, M.D.**

Instructor in Medicine, Harvard Medical School  
Director, Office of Educational Technology, Shapiro  
Institute for Education and Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Sui Huang, M.D., Ph.D.**

Assistant Professor of Surgery, Vascular Biology  
Program  
Department of Surgery  
Children's Hospital, Harvard Medical School, Boston and  
Harvard Stem Cell Institute  
Cambridge, Massachusetts

**Deborah A. Hughes, Ph.D.**

Department of Biochemistry and Molecular Biology  
Mayo Clinic College of Medicine  
Mayo Clinic Cancer Center  
Rochester, Minnesota

**Mansoor Husain, M.D.**

Director, Heart & Stroke Richard Lewar Centre of  
Excellence in Cardiovascular Research  
Associate Professor of Medicine  
University of Toronto, Toronto  
Ontario, Canada

**Richard O. Hynes, Ph.D.**

Center for Cancer Research and Howard Hughes  
Medical Institute  
Massachusetts Institute of Technology  
Cambridge, Massachusetts

**José M. Icardo**

Department of Anatomy and Cell Biology  
University of Cantabria  
Santander, Spain

**Donald E. Ingber, M.D., Ph.D.**

Judah Folkman Professor of Vascular Biology  
Department of Pathology, Harvard Medical School  
Vascular Biology Program, Departments of Surgery  
and Pathology  
Children's Hospital, Boston, Massachusetts

**David A. Ingram, M.D.**

Department of Pediatrics, Herman B. Wells Center for  
Pediatric Research  
Indiana University School of Medicine  
Indianapolis, Indiana

**Kaikobad Irani, M.D.**

Associate Professor of Medicine, Cardiovascular Institute  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania

**Mukesh K. Jain, M.D.**

Case Western Reserve University  
Cleveland, Ohio

**Joaquin J. Jimenez, M.D.**

Assistant Professor of Medicine, Wallace H. Coulter  
Laboratory Division of Hematology/Oncology  
Department of Medicine  
University of Miami School of Medicine  
Miami, Florida

**Peter Lloyd Jones, Ph.D.**

Associate Professor of Pathology & Laboratory Medicine  
Director, Penn-CMREF Center for Pulmonary  
Hypertension Research  
Institute for Medicine & Engineering  
University of Pennsylvania, Philadelphia

**Klaus D. Jürgens, Ph.D.**

Professor of Physiology, Zentrum Physiologie,  
Medizinische Hochschule  
Hannover, Germany

**Wenche Jy, Ph.D.**

Assistant Professor of Medicine  
Wallace H. Coulter Laboratory Division of  
Hematology/Oncology  
Department of Medicine, University of Miami School  
of Medicine  
Miami, Florida

**Darren Kafka, Ph.D.**

Department of Surgery and Norris Comprehensive  
Cancer Center  
Keck School of Medicine, University of Southern  
California  
Los Angeles, California

**Kamel S. Kamel, M.D.**

Professor of Medicine, University of Toronto,  
St. Michael's Hospital  
Toronto, Ontario, Canada

**Kenneth L. Kaplan**

Associate Director, Collaborative Initiatives at MIT  
Associate Director, Urban Design Lab,  
Earth Institute  
Columbia University

**Kai Kappert, M.D.**

Cancer Centrum Karolinska  
Department of Oncology-Pathology,  
Karolinska Institutet  
Stockholm, Sweden

**S. Ananth Karumanchi, M.D.**

Associate Professor of Medicine  
Harvard Medical School, Beth Israel Deaconess  
Medical Center  
Boston, Massachusetts

**Jaswinder Kaur, Ph.D.**

Candidate, Department of Physiology and  
Biophysics  
University of Calgary, Calgary  
Alberta, Canada

**Muammer Kendirci, M.D.**

Department of Urology, Sisli Etfal Training and  
Research Hospital  
Istanbul, Turkey

**Levon M. Khachigian, Ph.D., D.Sc.**

Professor and Head Transcription and Gene Targeting  
Laboratory Centre for Vascular Research  
Prince of Wales Hospital  
University of New South Wales  
Sydney, Australia

**Jan T. Kielstein**

Assistant Professor of Medicine  
Stanford University Medical School  
Falk Cardiovascular Research Center, Stanford,  
California; and Department of Internal Medicine,  
Division of Nephrology  
Medical School Hannover, Germany

**Hong Pyo Kim, Ph.D.**

Division of Pulmonary, Allergy, and Critical  
Care Medicine  
The University of Pittsburgh School  
of Medicine  
Pittsburgh, Pennsylvania

**Rolf Kinne, M.D., Ph.D.**

Max Planck Institut für Molekulare Physiologie  
Dortmund, Germany

**Jan Kitajewski, Ph.D.**

Departments of Pathology and Obstetrics and  
Gynecology  
Institute of Cancer Genetics, Columbia University  
Medical Center, New York  
New York

**Michael Klagsbrun, Ph.D.**

Patricia K. Donahoe Professor of Surgery  
 Department of Surgery, Harvard Medical School  
 Vascular Biology Program, Children's Hospital  
 Boston, Massachusetts

**Karolina Kolodziejska, Ph.D.**

Candidate, Department of Laboratory Medicine &  
 Pathobiology  
 University of Toronto, Toronto  
 Ontario, Canada

**Peter Koopman, Ph.D.**

Institute for Molecular Bioscience  
 The University of Queensland  
 Brisbane, Australia

**Paul Kubes, Ph.D.**

Director, Institute of Infection, Immunity and  
 Inflammation  
 Department of Physiology and Biophysics  
 University of Calgary, Calgary  
 Alberta, Canada

**Frank Kuhnert, Ph.D.**

Postdoctoral Fellow, Department  
 of Medicine  
 Division of Hematology  
 Stanford University School of Medicine  
 Stanford, California

**Rainer Kunstfeld, M.D.**

Department of Dermatology  
 Division of General Dermatology, Medical  
 University Vienna  
 Vienna, Austria

**Peter Kurschat, Ph.D.**

Harvard Medical School  
 Vascular Biology Program, Department of Surgical  
 Research, Children's Hospital  
 Boston, Massachusetts

**Michael J.B. Kutryk, M.D., Ph.D.**

The Terrence Donnelly Vascular Biology  
 Laboratories  
 St. Michael's Hospital, and The McLaughlin Centre for  
 Molecular Medicine and the Department  
 of Medicine  
 University of Toronto, Toronto  
 Ontario, Canada

**Eckhard Lammert, Ph.D.**

Max Planck Institute of Molecular Cell Biology and  
 Genetics  
 Dresden, Germany

**Manfred D. Laubichler, Ph.D.**

Professor of Theoretical Biology and History  
 of Biology  
 Affiliated Professor of Philosophy School of Life Sciences  
 and Centers for Biology and Society and Social  
 Dynamics and Complexity Arizona State University  
 Tempe  
 Tempe, Arizona

**Jeffrey Laurence, M.D.**

Professor of Medicine, Weill Medical College of Cornell  
 University  
 Attending Physician, New York Presbyterian  
 Hospital  
 New York, New York

**Jack Lawler, Ph.D.**

Professor of Pathology, Harvard Medical School  
 Department of Pathology, Beth Israel Deaconess  
 Medical Center  
 Boston, Massachusetts

**Michelle Letarte, Ph.D.**

Molecular Structure and Function, Hospital for Sick  
 Children, University of Toronto, Toronto  
 Ontario, Canada

**Marcel Levi, M.D., Ph.D.**

Professor of Medicine, University of Amsterdam  
 Chairman, Department of Medicine  
 Academic Medical Center, Amsterdam  
 The Netherlands

**Dean Y. Li, M.D.**

Department of Oncological Sciences  
 Program in Human Molecular Biology and Genetics  
 Division of Cardiology, School of Medicine, University  
 of Utah  
 Salt Lake City, Utah

**Jian Li, M.D., Ph.D.**

Assistant Professor of Medicine  
 Harvard Medical School  
 Division of Cardiology, Beth Israel Deaconess  
 Medical Center  
 Boston, Massachusetts

**James K. Liao M.D.**

Associate Professor of Medicine  
 Harvard Medical School  
 Director, Vascular Medicine Research, Brigham and  
 Women's Hospital  
 Boston, Massachusetts

**Andrew H. Lichtman, M.D., Ph.D.**

Associate Professor of Pathology, Harvard Medical  
 School  
 Department of Pathology, Brigham and Women's  
 Hospital  
 Boston, Massachusetts

**Stefan Liebner, Ph.D.**

Institute of Neurology, University Frankfurt  
 Frankfurt, Germany

**Zhiyong Lin, Ph.D.**

Case Western Reserve University  
 Cleveland, Ohio

**Gregory Y.H. Lip, M.D.**

Consultant Cardiologist and Professor of Cardiovascular  
 Medicine  
 Director – Haemostasis Thrombosis & Vascular Biology  
 Unit, University Department of Medicine  
 City Hospital, Birmingham, United Kingdom

**Robert Loewe, M.D.**

Department of Dermatology  
Division of General Dermatology Medical University  
Vienna  
Vienna, Austria

**Frank W. LoGerfo, M.D.**

William V. McDermott Professor of Surgery  
Harvard Medical School  
Chief, Division of Vascular Surgery  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Jin Ning Lou, Ph.D.**

Institute of Clinical Medical Sciences  
China-Japan Friendship Hospital  
Beijing, China

**Charles J. Lowenstein, M.D.**

Professor, Departments of Medicine  
and Pathology  
The Johns Hopkins University School  
of Medicine  
Baltimore, Maryland

**Qing Lu, Ph.D.**

Pulmonary Vascular Research Laboratory  
Providence VA Medical Center  
Assistant Professor of Medicine  
The Warren Alpert Medical School of  
Brown University  
Providence, Rhode Island

**F. William Lusinskas, Ph.D.**

Associate Professor of Medicine  
Harvard Medical School  
Brigham and Women's Hospital  
Boston, Massachusetts

**Nigel Mackman, Ph.D.**

John Parker Professor of Medicine  
University of North Carolina at  
Chapel Hill  
Chapel Hill, North Carolina.

**Patricia B. Maguire, Ph.D.**

Molecular Medicine Group, Conway Institute  
School of Medicine and Medical Science  
University College Dublin  
Dublin, Ireland

**Jane Maienschein, Ph.D.**

Regents' Professor, President's Professor, and Parents  
Association Professor  
Director, Center for Biology and Society, Arizona State  
University Tempe  
Tempe, Arizona

**Mark W. Majesky, Ph.D.**

Professor, Departments of Medicine & Genetics,  
Associate Director  
Carolina Cardiovascular Biology Center  
University of North Carolina at  
Chapel Hill  
Chapel Hill, North Carolina

**Warren J. Manning, M.D.**

Professor of Medicine and Radiology  
Harvard Medical School  
Section Chief, Non-invasive Cardiac Imaging, Beth Israel  
Deaconess Medical Center  
Boston, Massachusetts

**Mark Martinez, M.D.**

Instructor in Medicine, University of Utah School  
of Medicine  
Salt Lake City, Utah

**Alan E. Mast M.D., Ph.D.**

Investigator, Blood Research Institute  
The Blood Center of Wisconsin  
Milwaukee, Wisconsin

**Tanya Mayadas, Ph.D.**

Associate Professor of Pathology, Harvard Medical School  
Department of Pathology  
Center for Excellence in Vascular Biology, Brigham and  
Women's Hospital  
Boston, Massachusetts

**Joseph H. McCarty, Ph.D.**

Department of Cancer Biology, Unit 173,  
University of Texas – M. D. Anderson Cancer Center,  
1515 Holcombe Boulevard,  
Houston, Texas

**Rodger P. McEver, M.D.**

Eli Lilly Distinguished Chair in Biomedical Research,  
Member and Head  
Cardiovascular Biology Research Program  
Oklahoma Medical Research Foundation  
Oklahoma City, Oklahoma

**John H. McVey, Ph.D.**

Group Leader Haemostasis and Thrombosis, Reader in  
Haemostasis and Thrombosis  
MRC Clinical Sciences Centre, Imperial College London,  
Hammersmith Hospital Campus  
London, United Kingdom

**Janice V. Meck, Ph.D.**

NASA/Johnson Space Center  
Houston, Texas

**George A. Mensah, M.D., F.A.C.P., F.A.C.C., F.C.P. (SA) Hon**

Distinguished Scientist, Heart Disease and Stroke  
Prevention, National Center for Chronic Disease  
Prevention and Health Promotion, Centers for  
Disease Control and Prevention  
Atlanta, Georgia

**Christine N. Metz, Ph.D.**

Associate Investigator, Director, Laboratory of Medicinal  
Biochemistry  
The Feinstein Institute for Medical Research, North  
Shore-LIJ Health System  
Manhasset, New York

**Valerie C. Midgley, Ph.D.**

Center for Vascular Research, Prince of Wales Hospital  
University of New South Wales  
Sydney, Australia

**Takashi Mikawa, Ph.D.**

Department of Cell and Developmental  
Biology  
Cornell University Medical College  
New York, New York

**Ronald W. Millard, Ph.D.**

Professor of Pharmacology & Cell Biophysics  
University of Cincinnati College of Medicine  
Cincinnati, Ohio

**David Milstone, Ph.D.**

Department of Pathology, Brigham and Women's  
Hospital, Harvard Medical School  
Boston, Massachusetts

**Takashi Minami, Ph.D.**

Associate Professor, University of Tokyo  
Tokyo, Japan

**Jamie Mitchell, M.D.**

Beth Israel Deaconess Medical Center  
Harvard Medical School  
Boston, Massachusetts

**Aigul Moldobaeva, Ph.D.**

Research Associate, Division of Pulmonary and Critical  
Care Medicine

Johns Hopkins Asthma and Allergy Center  
Johns Hopkins University  
Baltimore, Maryland

**Bruce Molitoris, M.D.**

Division of Nephrology  
Indiana Center for Biological Microscopy  
Indiana University School of Medicine  
Indianapolis, Indiana

**Thomas S. Monahan, M.D.**

Division of Vascular Surgery  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Craig N. Morrell, Ph.D.**

Departments of Pathology and Comparative  
Medicine  
The Johns Hopkins University School  
of Medicine  
Baltimore, Maryland

**Steven Moskowitz**

Advanced Medical Graphics  
Boston, Massachusetts

**Debabrata Mukhopadhyay, Ph.D.**

Professor, Department of Biochemistry and Molecular  
Biology  
Mayo Clinic College of Medicine  
Mayo Clinic Cancer Center  
Rochester, Minnesota

**Masahiro Murakami, M.D., Ph.D.**

Angiogenesis Research Center & Section  
of Cardiology  
Dartmouth Medical School  
Dartmouth Hitchcock Medical Center  
Hanover, New Hampshire

**Silvia Muro, Ph.D.**

Research Assistant Professor of Pharmacology  
Institute for Translational Medicine and Therapeutics  
Institute for Environmental Medicine  
University of Pennsylvania Medical School  
Philadelphia, Pennsylvania

**Allan G. Murray, M.D.**

Associate Professor of Medicine  
University of Alberta, Edmonton  
Alberta, Canada

**Vladimir R. Muzykantov M.D., Ph.D.**

Associate Professor of Pharmacology and Medicine  
Director, Targeted Therapeutics Program, Institute of  
Translational Medicine and Therapeutics (ITMAT)  
Sr. Investigator, Institute for Environmental Medicine  
(IFEM)

University of Pennsylvania School of Medicine  
Philadelphia, Pennsylvania

**Peter P. Nawroth, M.D.**

University of Heidelberg  
Department of Medicine I and Clinical Chemistry  
University of Heidelberg  
Heidelberg, Germany

**Randolph M. Nesse, M.D.**

Professor of Psychiatry  
University of Michigan  
Ann Arbor, Michigan

**Debra K. Newman, Ph.D.**

Associate Investigator, Blood Research Institute  
The Blood Center of Wisconsin  
Milwaukee, Wisconsin

**Peter J. Newman, Ph.D.**

Vice President for Research  
Walter A. Schroeder Associate Director, Blood Research  
Institute  
The Blood Center of Wisconsin  
Milwaukee, Wisconsin

**Mark R. Nicolls, M.D.**

Associate Professor of Medicine  
Pulmonary and Critical Care Medicine Division  
University of Colorado at Denver and Health Sciences  
Center  
Denver, Colorado

**Anne Nicholson-Weller, M.D.**

Professor of Medicine  
Harvard Medical School  
Divisions of Allergy/Inflammation and Infectious  
Diseases  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Max Nieuwdorp, Ph.D.**

Department of Vascular Medicine  
Cardiovascular Research Institute Amsterdam  
Academic Medical Center and University  
of Amsterdam  
Amsterdam, The Netherlands

**Niaobh O'Donoghue, Ph.D.**

Department of Molecular Medicine  
Conway Institute, University College Dublin  
Dublin, Ireland

**Dessy Nikova, Ph.D.**

Institute of Physiology  
Westfalia Wilhelms University  
Muenster, Germany

**Peter Oettgen, M.D.**

Associate Professor of Medicine  
Harvard Medical School  
Division of Cardiology  
Division of Molecular and Vascular Medicine, and  
Center for Vascular Biology Research  
Beth Israel Deaconess Medical Center, Boston

**Kenneth R. Olson, Ph.D.**

Professor of Physiology, Indiana University School of  
Medicine – South Bend, South Bend, Indiana

**Arne Östman, Ph.D.**

Professor of Molecular Oncology, Cancer Centrum  
Karolinska  
Department of Oncology-Pathology, Karolinska  
Institutet  
Stockholm, Sweden

**Sareh Parangi, M.D.**

Assistant Professor of Surgery  
Harvard Medical School  
Department of Surgery, Beth Israel Deaconess Medical  
Center  
Boston, Massachusetts

**Kye Won Park, Ph.D.**

Department of Oncological Sciences  
Program in Human Molecular Biology and Genetics  
University of Utah  
Salt Lake City, Utah

**John D. Parker, M.D., F.R.C.P.(C)**

Professor of Medicine and Pharmacology, University of  
Toronto  
Head, Division of Cardiology, Department  
of Medicine  
University Health Network and Mount Sinai Hospital  
Toronto, Ontario, Canada

**Michael J. Parker, M.D.**

Assistant Professor of Medicine, Harvard Medical School  
Division of Pulmonary and Critical Care Medicine  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Renata Pasqualini, Ph.D., M.D.**

Anderson Cancer Center, University of Texas  
Houston, Texas

**Michael J. Passineau, Ph.D.**

Division of Human Gene Therapy  
Departments of Medicine, Obstetrics and Gynecology,  
Pathology, Surgery, and the Gene Therapy Center  
University of Alabama at Birmingham  
Birmingham, Alabama

**Roger Patient, Ph.D.**

M.R.C. Molecular Haematology Unit  
The Weatherall Institute of Molecular Medicine  
University of Oxford  
John Radcliffe Hospital  
Headington, United Kingdom

**Cam Patterson, M.D., F.A.C.C.**

Professor of Medicine (Cardiology), Pharmacology, and  
Cell and Developmental Biology  
The University of North Carolina at Chapel Hill  
Chief, Division of Cardiology  
Director, Carolina Cardiovascular Biology Center  
North Carolina

**Knut Pettersson, Ph.D.**

Athera Biotechnologies, Fogdevreten 2b, SE-171 77  
Stockholm  
Sweden

**Peter Petzelbauer, M.D.**

Department of Dermatology  
Division of General Dermatology Medical University  
Vienna  
Vienna, Austria

**Jorge Plutzky, M.D.**

Cardiovascular Division  
Associate Professor of Medicine  
Harvard Medical School  
Brigham and Women's Hospital  
Boston, Massachusetts

**Jordan S. Pober, M.D., Ph.D.**

Professor of Immunobiology, Pathology and  
Dermatology  
Vice-Chair of Immunobiology for Human and  
Translational Immunology  
Yale University School of Medicine  
New Haven, Connecticut

**Thomas J. Poole, Ph.D.**

Department of Cell and Developmental Biology  
SUNY Upstate Medical University  
Syracuse, New York

**Sonja Praprotnik, Ph.D.**

University Clinical Center  
Ljubljana, Slovenia

**Dexter Pratt**

VP Knowledge Modeling, Genstruct Inc.  
Cambridge, Massachusetts

**Ralph E. Purdy, Ph.D.**

Department of Pharmacology University of California,  
Irvine  
Irvine, California

**Anthony E. Pusateri, Ph.D.**

Associate Director, Novo Nordisk Research U.S.  
North Brunswick, New Jersey

**Susan E. Quaggin, M.D.**

Associate Professor of Medicine, University of Toronto  
Mt. Sinai Hospital, University of Toronto, Toronto  
Ontario, Canada

**Deborah A. Quinn, M.D.**

Assistant Professor of Medicine  
Harvard Medical School  
Pulmonary and Critical Care Unit  
Department of Medicine, Massachusetts General  
Hospital  
Boston, Massachusetts

**Jacob H. Rand, M.D.**

Hematology Laboratory, Montefiore Medical Center  
Bronx, New York

**Arshad Rahman, Ph.D.**

Associate Professor of Pediatrics, Division of  
Neonatology  
Department of Pediatrics, School of Medicine and  
Dentistry  
University of Rochester  
Rochester, New York

**May J. Reed, M.D.**

Associate Professor, Department of Medicine  
Division of Gerontology and Geriatric Medicine  
University of Washington  
Seattle, Washington

**Wende R. Reenstra, M.D.**

Research Associate Professor, New England  
Inflammation and Tissue Protection Institute  
Northeastern University  
Boston, Massachusetts

**Carl L. Reiber, Ph.D.**

Associate Dean, College of Sciences  
Professor, School of Life Sciences  
University of Nevada  
Las Vegas, Nevada

**John M. Rhodes, Ph.D.**

Angiogenesis Research Center & Section of Cardiology  
Dartmouth Medical School, Dartmouth Hitchcock  
Medical Center  
Hanover, New Hampshire

**Simon C. Robson, M.D.**

Professor of Medicine  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Sharon Rounds, M.D.**

Pulmonary Vascular Research Laboratory, Providence VA  
Medical Center  
Professor of Medicine and of Pathology and Laboratory  
Medicine  
The Warren Alpert Medical School of Brown University  
Providence, Rhode Island

**Jonathan Rubin, Ph.D.**

Department of Mathematics, University of Pittsburgh,  
Pittsburgh  
Pennsylvania Center for Inflammation and Regenerative  
Modeling  
University of Pittsburgh  
Pittsburgh, Pennsylvania

**John E. Rush, D.V.M., M.S.**

Department of Clinical Sciences, Cummings School of  
Veterinary Medicine at Tufts University  
North Grafton, Massachusetts

**Stefan W. Ryter, Ph.D.**

Division of Pulmonary, Allergy, and Critical Care  
Medicine  
The University of Pittsburgh School  
of Medicine  
Pittsburgh, Pennsylvania

**Paul W. Sanders, M.D.**

Nephrology Research and Training Center,  
Comprehensive Cancer Center, and Cell Adhesion  
and Matrix Research Center  
Division of Nephrology, Professor of Medicine and  
Physiology & Biophysics and AM Chief  
VA Renal Section, Department of Medicine, and  
Department of Physiology & Biophysics  
University of Alabama at Birmingham  
Birmingham, and Department of Veterans Affairs  
Medical Center  
Birmingham, Alabama

**Gernot Schabbauer, Ph.D.**

Departments of Immunology and Cell Biology  
The Scripps Research Institute  
La Jolla, California

**Herrmann Schillers, Ph.D.**

Institute of Physiology, Westfalia Wilhelms University  
Muenster, Germany

**Ann Marie Schmidt, M.D.**

College of Physicians and Surgeons, Columbia  
University, New York  
New York

**Hans-Joachim Schnittler, M.D.**

Institut für Physiologie  
Technische Universität, Medizinische Fakultät;  
Fetzerstraße 74  
Dresden, Germany

**Jan E. Schnitzer, M.D.**

Scientific Director, Professor of Cellular & Molecular  
Biology Director of Vascular Biology & Angiogenesis  
Program  
Sidney Kimmel Cancer Center  
San Diego, California

**Daniel L. Schodek, Ph.D.**

Professor of Architectural Technology  
Department of Architecture, Harvard Design School  
Cambridge, Massachusetts

**Anthony Sebastian, M.D.**

Department of Medicine, Division of Nephrology  
Clinical and Translational Science Institute  
University of California – San Francisco  
San Francisco, California

**Jochen Seebach, Ph.D.**

Institute of Physiology, Technical University  
Dresden, Germany

**Chantal Sguin, M.D., C.M., B.Sc. (N), F.R.C.P.C.**

Assistant Professor of Medicine, Montreal General  
Hospital, Division of Hematology  
McGill University Health Centre, Montreal  
Quebec, Canada

**Frank W. Sellke, M.D.**

Johnson & Johnson Professor of Surgery  
Harvard Medical School; Division of Cardiothoracic  
Surgery  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**David Semela, Ph.D.**

GI Research Unit, Division of Gastroenterology and  
Hepatology, Mayo Clinic  
Rochester, Minnesota

**Gregg L. Semenza, M.D., Ph.D.**

Professor, Departments of Pediatrics  
Medicine, Oncology, Radiation Oncology,  
and the McKusick-Nathans Institute of  
Genetic Medicine  
Director, Vascular Biology Program, Institute for Cell  
Engineering  
The Johns Hopkins University School of Medicine  
Baltimore, Maryland

**Haruki Senoo, Ph.D.**

Department of Cell Biology and Histology  
Akita University School of Medicine  
Akita, Japan

**Solange M.T. Serrano, Ph.D.**

Laboratório Especial de Toxinologia  
Aplicada/CAT-CEPID  
Instituto Butantan  
São Paulo, Brazil

**William C. Sessa, Ph.D.**

Professor of Pharmacology  
Director, Vascular Cell Signaling and  
Therapeutics Program  
Yale University School of Medicine, Boyer Center for  
Molecular Medicine  
New Haven, Connecticut

**Vijay Shah, M.D.**

GI Research Unit, Division of Gastroenterology and  
Hepatology, Mayo Clinic  
Rochester, Minnesota

**Carrie J. Shawber, Ph.D.**

Department of Obstetrics and Gynecology; Institute of  
Cancer Genetics  
Columbia University Medical Center  
New York, New York

**Ichiro Shiojima, M.D., Ph.D.**

Molecular Cardiology/Whitaker Cardiovascular  
Institute, Boston University School  
of Medicine  
Boston, Massachusetts

**Sruti Shiva, Ph.D.**

Vascular Medicine Branch, National Heart Lung and  
Blood Institute  
Critical Care Medicine Department, Clinical Center,  
National Institutes of Health  
Bethesda, Maryland

**Yehuda Shoenfeld, M.D.**

Head, Department of Medicine B and Center for  
Autoimmune Diseases, Sheba Medical Center  
Tel-Hashomer  
Tel-Aviv University, Israel

**Eric V. Shusta, Ph.D.**

Assistant Professor, Department of Chemical and  
Biological Engineering  
University of Wisconsin-Madison  
Madison, Wisconsin

**Nicholas W. Shworak, M.D., Ph.D.**

Associate Professor of Medicine  
Director, Ultrasound Biomicrometry Core  
Section of Cardiology  
Angiogenesis Research Center; Dartmouth  
Medical School  
Hanover, New Hampshire

**Christopher C. Silliman, M.D., Ph.D.**

Professor of Pediatrics and Surgery  
University of Colorado at Denver School of Medicine  
Associate Medical Director, Bonfils Blood Center  
Denver, Colorado

**Robert D. Simari, M.D.**

Professor of Medicine, Chair of Cardiovascular Research,  
Mayo Clinic  
Rochester, Minnesota

**Michael Simons, M.D.**

A.G. Huber Professor of Medicine and Pharmacology  
and Toxicology  
Chief, Section of Cardiology; Director, Angiogenesis  
Research Center, Dartmouth Medical School  
Dartmouth Hitchcock Medical Center  
Hanover, New Hampshire

**Rashmi Sood, Ph.D.**

Blood Center of Wisconsin  
Blood Research Institute  
Milwaukee, Wisconsin

**Elmar Spuentrup, M.D.**

Associate Professor of Radiology  
Technical University of Aachen, Department of  
Diagnostic Radiology  
Aachen, Germany

**Radu V. Stan, M.D.**

Assistant Professor, Departments of Pathology and of  
Microbiology and Immunology  
Angiogenesis Research Center, Dartmouth  
Medical School  
Hanover, New Hampshire

**Elliot J. Stephenson, Ph.D.**

Department of Medicine, Division of Hematology,  
Oncology and Transplantation  
University of Minnesota Medical School  
Minneapolis, Minnesota

**Troy Stevens, Ph.D.**

Professor, Department of Molecular and Cellular  
Pharmacology Director  
Center for Lung Biology  
University of South Alabama College of Medicine  
Mobile, Alabama

**Duncan J. Stewart, M.D.**

Dexter Hung-Cho Man Chair and Director  
Division of Cardiology, University of Toronto  
St. Michael's Hospital, Toronto  
Ontario, Canada

**Erik Stroes, Ph.D.**

Vascular Medicine, Cardiovascular Research Institute  
Amsterdam  
Academic Medical Center and University  
of Amsterdam  
Amsterdam, The Netherlands

**Ute Stroher, Ph.D.**

Special Pathogens Program, National Microbiology  
Laboratory, Public Health Agency of Canada  
Department of Medical Microbiology and  
Infectious Diseases  
University of Manitoba, Winnipeg  
Manitoba, Canada

**Heidi Stuhlmann, Ph.D.**

Professor, Department of Cell and Developmental  
Biology Weill Medical College of Cornell University,  
New York  
New York

**Laimute Taraseviciene-Stewart, Ph.D.**

Assistant Professor of Medicine, Pulmonary and  
Critical Care Medicine Division  
University of Colorado at Denver and  
Health Sciences Center  
Denver, Colorado

**Glenn J. Tattersall, Ph.D.**

Department of Biological Sciences, Brock University  
St. Catharines  
Ontario, Canada

**Eugene Tkachenko, Ph.D.**

Angiogenesis Research Center; Dartmouth  
Medical School  
Dartmouth Hitchcock Medical Center  
Hanover, New Hampshire

**Alex Toker, Ph.D.**

Associate Professor of Pathology, Harvard Medical School  
Department of Pathology, Beth Israel Deaconess  
Medical Center  
Boston, Massachusetts

**Mourad Toporsian, Ph.D.**

Molecular Structure and Function, Hospital for  
Sick Children  
University of Toronto, Toronto  
Ontario, Canada

**Kevin J. Tracey, M.D.**

Director and Chief Executive, Feinstein Institute for  
Medical Research  
North Shore-LIJ Health System  
Manhasset, New York

**Lisa D. Urness, Ph.D.**

University of Utah, Division of Cardiology, School of  
Medicine, University of Utah  
Salt Lake City, Utah

**Bernard M. van den Berg, Ph.D.**

Division of Molecular and Vascular Medicine and  
Center for Vascular Biology Research  
Beth Israel Deaconess Medical Center  
Boston, Massachusetts

**Marlies Van de Wouwer, Ph.D.**

VIB Department of Transgene Technology and Gene  
Therapy, K.U. Leuven  
Leuven, Belgium

**Alexander D. Verin, Ph.D.**

Professor, Vascular Biology Center and Department of  
Medicine, Medical College of Georgia  
Augusta, Georgia

**Alan S. Verkman, M.D., Ph.D.**

Departments of Medicine and Physiology  
Cardiovascular Research Institute, University of  
California  
San Francisco, California

**Aristides Veves, M.D., D.Sc.**

Research Director, Microcirculation Lab and Joslin-Beth  
Israel Deaconess Foot Center  
Associate Professor of Surgery, Harvard Medical School  
Boston, Massachusetts

**Volker Vielhauer, Ph.D.**

Department of Pathology, Center for Excellence in  
Vascular Biology  
Brigham and Women's Hospital  
Boston, Massachusetts

**Hans Vink, Ph.D.**

Department of Medical Physics, Cardiovascular Research  
Institute Amsterdam  
Academic Medical Center and University of Amsterdam  
Amsterdam, The Netherlands

**Yoram Vodovotz, Ph.D.**

Director, Center for Inflammation and Regenerative  
Modeling  
Associate Professor of Surgery, Immunology, and  
Communication Science and Disorders  
University of Pittsburgh  
Pittsburgh, Pennsylvania

**Norbert F. Voelkel, M.D.**

The Hart Professor of Emphysema Research, Pulmonary and Critical Care Medicine Division  
University of Colorado at Denver and Health Sciences Center  
Denver, Colorado

**Ulrich H. von Andrian, M.D.**

Mallinckrodt Professor of Immunopathology,  
Department of Pathology  
Harvard Medical School, Senior Investigator, The Immune Disease Institute  
Boston, Massachusetts

**Elizabeth M. Wagner, Ph.D.**

Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Johns Hopkins Asthma and Allergy Center  
Johns Hopkins University  
Baltimore, Maryland

**Victoria Wahl-Jensen, Ph.D.**

Special Pathogens Program, National Microbiology Laboratory, Public Health Agency of Canada  
Department of Medical Microbiology and Infectious Diseases  
University of Manitoba, Winnipeg  
Manitoba, Canada

**Kenneth Walsh, Ph.D.**

Molecular Cardiology/Whitaker Cardiovascular Institute  
Boston University School of Medicine  
Boston, Massachusetts

**Qing K. Wang, Ph.D., M.B.A.**

Director Center for Cardiovascular Genetics  
Department of Molecular Cardiology  
Lerner Research Institute, Cleveland Clinic  
Cleveland, Ohio

**Wan-Chao Wang, M.D.**

Department of Immunology, Roswell Park Cancer Institute  
Buffalo, New York

**Xue Wang, Ph.D.**

Division of Pulmonary, Allergy, and Critical Care Medicine  
The University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania

**Michael R. Ward**

The Terrence Donnelly Vascular Biology Laboratories  
St. Michael's Hospital, and The McLaughlin Centre for Molecular Medicine and the Department of Medicine  
University of Toronto, Toronto  
Ontario, Canada

**Peter A. Ward, M.D.**

Stobbe Professor of Pathology  
University of Michigan Health Systems, Department of Pathology  
Ann Arbor, Michigan

**Theodore E. Warkentin, M.D.**

Professor, Department of Pathology and Molecular Medicine, and Department of Medicine,  
McMaster University, Hamilton  
Ontario, Canada

**Jean-Luc Wautier, M.D., Ph.D.**

University Lariboisiere-Saint Louis and Institut National de la Transfusion Sanguine  
Paris, France

**David J. Webb, M.D., D.Sc., F.R.C.P., F.R.S.E., F.Med.Sci.**

Christison Professor of Clinical Therapeutics and Pharmacology, Centre for Cardiovascular Science, Queen's Medical Research Institute  
University of Edinburgh, Edinburgh  
United Kingdom

**Alan B. Weder, M.D.**

Professor, Department of Internal Medicine  
Division of Cardiovascular Medicine  
University of Michigan  
Ann Arbor, Michigan

**Christian Weidenfeller, Ph.D.**

Department of Neurology  
University of Wuerzburg  
Wuerzburg, Germany

**Hartmut Weiler, Ph.D.**

Investigator, Blood Center of Wisconsin  
Blood Research Institute, Milwaukee, Wisconsin

**Andrea J. Wiethoff, Ph.D.**

Philips Medical Systems, Best  
The Netherlands

**Stuart K. Williams, Ph.D.**

Professor, Department of Surgery, University of Louisville  
Scientific Director, Cardiovascular Innovation Institute  
Louisville, Kentucky

**Ulrik Wisløff, Ph.D.**

Department of Circulation and Medical Imaging  
Norwegian University of Science and Technology  
Trondheim, Norway

**Kenneth K. Wu, M.D., Ph.D.**

Professor and Director, Center for Vascular Biology  
Associate Director, The Brown Foundation Institute of Molecular Medicine  
Division of Hematology  
The University of Texas Health Science Center at Houston, Houston, Texas  
and Distinguished Investigator and President  
National Health Research Institutes  
Zhunan, Taiwan

**Xiao-Xuan Wu, M.D.**

Hematology Laboratory, Montefiore Medical Center  
Bronx, New York

**Quansheng Xi, Ph.D.**

Center for Cardiovascular Genetics  
Department of Molecular Cardiology, Lerner Research Institute, Cleveland Clinic  
Cleveland, Ohio

**Munekazu Yamakuchi, Ph.D.**

Departments of Medicine and Pathology  
The Johns Hopkins University School  
of Medicine  
Baltimore, Maryland

**Xiaoqiang Yao, Ph.D.**

Professor, Li Ka Shing Institute of Health Science and  
Department of Physiology  
Chinese University of Hong Kong

**Susan Bok Yeon, M.D., J.D.**

Assistant Professor of Medicine, Harvard  
Medical School  
Associate Director, Noninvasive Cardiac Imaging,  
Cardiovascular Division  
Beth Israel Deaconess Medical Center

# Preface

---

This volume was born out of a yearning to develop a synthesis of the field of endothelial biology from bench to bedside. The book has several important – and complementary – goals. These are discussed in turn:

## **CELEBRATE THE HISTORY OF THE FIELD**

William Harvey's discovery of the circulation of blood in 1628 is considered to be one of the greatest achievements in the annals of science and medicine. Another 200 years would pass before Wilhelm His, a Swiss anatomist, "discovered" the endothelium. In the late 19th century and the first half of the 20th century, most investigators employed physiological tools to study the role of the endothelium in inflammation and permeability. In the 1960s, electron microscopy opened a new window into the endothelium, providing a fascinating glimpse into the structure (and, by inference, the function) of this cell layer. The successful *in vitro* culture of endothelial cells (ECs) in the 1970s marked the beginning of a new era in endothelial biology, spawning some 100,000 articles in peer-reviewed journals over the next 40 years. More recently, there has been an increased awareness of the need to study the endothelium in the context of its native environment. To that end, investigators have made remarkable progress in integrating *in vitro* and *in vivo* model systems. An important goal of this book is to highlight the rich historical foundation upon which today's field is built. The first chapter charts the history of vascular and endothelial biology. Subsequent chapters integrate – wherever possible – relevant historical considerations.

## **APPROACH THE ENDOTHELIAL CELL AS AN INPUT-OUTPUT DEVICE**

Part II of the book is centered on the analogy of the EC as a miniature adaptive input-output device. Input includes biochemical and biomechanical stimuli. The various input signals are covered in separate chapters. Output (or cell phenotype) includes changes in gene and protein expression, leukocyte

trafficking, permeability, hemostasis, and antigen presentation, to name just a few. Again, these topics are covered in individual chapters. Input is coupled to output through a large array of nonlinear signaling pathways that typically begin at the cell surface and end at the level of post-transcriptional modification or gene expression. Thus, other chapters focus on important signaling pathways and transcription factors involved in transducing signal input. One drawback in emphasizing the theme of the EC as an input-output device is that the system (input, output, and coupling) is reduced to a series of component parts, and the principal unit of investigation is the cell. Thus, there is a risk of overlooking *interactions* between the parts, and ignoring higher levels of organization. To minimize this risk, we have emphasized, wherever possible, relevant *in vivo* data. In addition, we have included selected overview chapters (for example, on hemostasis, barrier function and leukocyte trafficking). Finally, each section begins with an introductory essay with the goal of weaving together and providing context to the ensuing chapters.

## **ENGAGE DIVERSE FIELDS AND CREATE NEW KNOWLEDGE**

Although the current volume is anchored on a solid foundation of cellular and molecular biology, it integrates a number of areas not typically associated with endothelial biology. Examples include history of medicine, evolutionary biology, comparative biology, metaphors, complexity theory, education, and public health. Some of the authors have little background in endothelial research. In writing their chapters, they have, for the first time, applied their unique perspective (and research tools) to the endothelium and, in doing so, offer new and exciting insights that are not otherwise available in the existing literature.

## **INCORPORATE BROAD TIME AND SPACE SCALES**

All too often, biomedical sciences are approached on limited time and space scales. Little consideration is given to the

rich historical foundations upon which current discoveries are based. Moreover, there is a tendency to focus on a single level of investigation. In this volume, we consider multiple time scales—evolution, history of medicine, the present and future—and a broad spectrum of space scales, from molecules to cells, blood vessels, organs, organisms, and populations.

### CREATE A VIRTUAL COMMUNITY

The endothelium traverses every organ and is involved in virtually every disease state, either as a primary determinant of pathophysiology or as a victim of collateral damage. Many organ-specific disciplines have initiated efforts to study ECs in their respective fields. In some cases, such as cardiology (coronary arteries), pulmonary medicine (pulmonary and bronchial circulations), and neurology (blood–brain barrier), there is a long tradition of vascular biology, whereas in other cases (e.g., nephrology), the field of endothelial biology is in its infancy. However, owing to the current infrastructure of biomedicine, EC biologists are far more likely to interact with their departmental colleagues than they are with like-minded endothelial biologists from other organ-specific disciplines. At present, few venues exist for cross-fertilization between diverse investigators. This book represents an early effort to establish a virtual community of EC biologists.

### BRIDGE THE BENCH-TO-BEDSIDE GAP

A large gap exists between the bench and bedside in endothelial biomedicine. Although no shortage exists of published articles pertaining to ECs and the endothelium, there is a virtual absence of appreciation for this cell layer at the bedside. The endothelium has enormous, as yet untapped, diagnostic and therapeutic potential. An important goal of this book is to bridge the gap and promote an increased awareness of the endothelium in human health and disease.

*William C. Aird, M.D.*

### ACKNOWLEDGMENTS

This book would not have been possible without the help of many, many individuals. I am particularly indebted to the authors responsible for writing the chapters. I thank them for their efforts, timeliness, and patience with the editor, and most importantly for their excellent contributions. I had invaluable input from a group of Associate Editors (Helmut Augustin, Ary Goldberger, Mansoor Husain, Manfred Laubichler, Jane Maienschein, Jan Schnitzer, and Michael Simons) who helped with the design and editing of the book and who contributed thoughtful, integrative essays to help weave together the various chapters. In particular, I wish to acknowledge Manfred Laubichler and Jane Maienschein for their courageous foray into a field in which they had no prior experience. It took some coaxing to get them involved, but once they were on board, they provided me with endless inspiration and wisdom. The book is so much better for their involvement. I have worked for years with Steve Moskowitz, a medical artist. Although he has no formal training in endothelial or vascular biology, he has an uncanny ability to take words and concepts and bring them to life with his drawings. Steve played an important role in designing the layout of the book. In addition, he has spent countless hours editing and advising on the artwork, not an easy task with so many individualized chapters. I also thank Susan Glueck for her assistance in the early stages of the editing process, and Dena Groutsis for her administrative support. I would like to thank Joann (Annie) Woy for her immense efforts in copyediting, and Navdeep Singh for his work in typesetting. I am indebted to many individuals who provided support, guidance and encouragement in one way or another during the preparation of this volume, including (but by no means limited to) Robert Rosenberg, Jeffrey Flier, Peter Weller, Robert Moellering, Mark Zeidel, Alan Rigby, Kate Spokes, David Beeler, and members of my immediate and extended family. Finally, I would like to acknowledge the support of the National Institutes of Health (HL076540), the American Heart Association (Established Investigator Award), and the Mount Desert Island Biological Laboratory.

We hope that this edition is the first of many. I invite readers to e-mail me ([waird@bidmc.harvard.edu](mailto:waird@bidmc.harvard.edu)) with their comments. What aspects of the book did you like? What didn't you like? How would you organize the book differently? What suggestions do you have for new topics? The value of this book – not only as a resource to, but also as a product of, the endothelial community – will depend on your continued critical feedback.

# History of Medicine

# The Endothelium in History

---

Manfred D. Laubichler\*, William C. Aird†, and Jane Maienschein\*

\*Center for Biology and Society, Arizona State University, Tempe; †Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

The endothelium is only now beginning to gain acceptance as a physiologically relevant organ with potential clinical significance. Yet the cell layer called the endothelium was first identified well over a century ago. In this chapter, we explore the circumstances leading to the slow recognition of the endothelium as a system with untapped diagnostic and therapeutic potential. We trace historically important steps toward increased interest in the endothelium, beginning with ancient discussions of the heart and blood vessels, and the conviction that blood derives from nutrition and is continually used up by the body. We see that, in Western medicine, the dominant culture of the Catholic Church impeded new discovery and instead emphasized reliance on accepted ideas for nearly 1,500 years. Only in the context of the Scientific Revolution of the seventeenth century could anatomists such as William Harvey challenge prevailing dogma and reach the conclusion that blood circulates and that it does so through a system of connected vascular vessels.

In this chapter, we examine those contributions and the developments that followed, slowly and gradually, the rise of new technologies for observation and the framing of new questions. We ask what caused researchers to focus on cells and tissues, and then, during the last part of the nineteenth century, to identify endothelial cells (ECs) as a unique structure, distinguishable structurally, physiologically, and developmentally from the epithelium that researchers initially had seen as closely connected to it. Then, we explore what implications the identification and naming of this particular set of cells had for the biomedical sciences.

The potential for applying principles of endothelial biology to the clinic has been much less well developed, and one goal of this book is to help change that. We return to the current research situation and to the medical potential of EC research in the final chapter (see Chapter 196).

## PRE-ENDOTHELIAL HISTORY

Medical researchers often blame the second-century physician Galen for holding back progress in understanding the vascular

system. These same researchers point to seventeenth-century physician William Harvey as the heroic founder of modern medical research. Galen certainly did maintain a theory-driven interpretation of arteries and veins as conduits for all manner of things. Inhaled air, expended air, nutriment, and blood all flow through the same blood vessels, according to Galen, responding to the needs of the body as a whole (Figure 1.1, *left side*).

Almost inevitably, medical researchers and textbooks refer to Galen as “in error.” Of course, from our twenty-first century perspective of accumulated knowledge, he *was* wrong. However, such a clear-cut judgment ignores the context of the times, Galen’s reasoning, and his potentially positive contributions. As surgeon and historian Sherwin B. Nuland explains, what really matters to historical judgment is whether Galen should have known better (1). Given that he did not dissect humans, but relied on animal studies alone, we can excuse some of his descriptions, which deviate from what he would have seen had he been able to look as carefully at humans as we can today. And, given that he could not see the microscopic capillaries and that what he *could* see showed differently colored and textured arteries and veins, we can understand his descriptions of the arterial and venous networks as two largely separate vascular systems. After all, the two systems do look different. Arteries are thick, pulsate, lie deep within tissues and carry red-colored (as we now know oxygenated) blood; veins have thin walls, do not pulsate, are often superficial (such as those on the back of the hand), and contain bluish (deoxygenated) blood.

But later studies, often praised as exemplary (notably William Harvey’s), did not differ significantly from Galen’s in the physical observations that they were based on; these studies also relied on animal models and naked-eye observation. The difference lay in the questions asked, the assumptions made, and in the nature of the search for additional new information. Harvey drew on a diverse mix of experimentation, observation, and calculation in a way that Galen only argued that researchers should do. When Nuland calls Galen “The Paradox of Pergamon,” he emphasizes the irony that, during

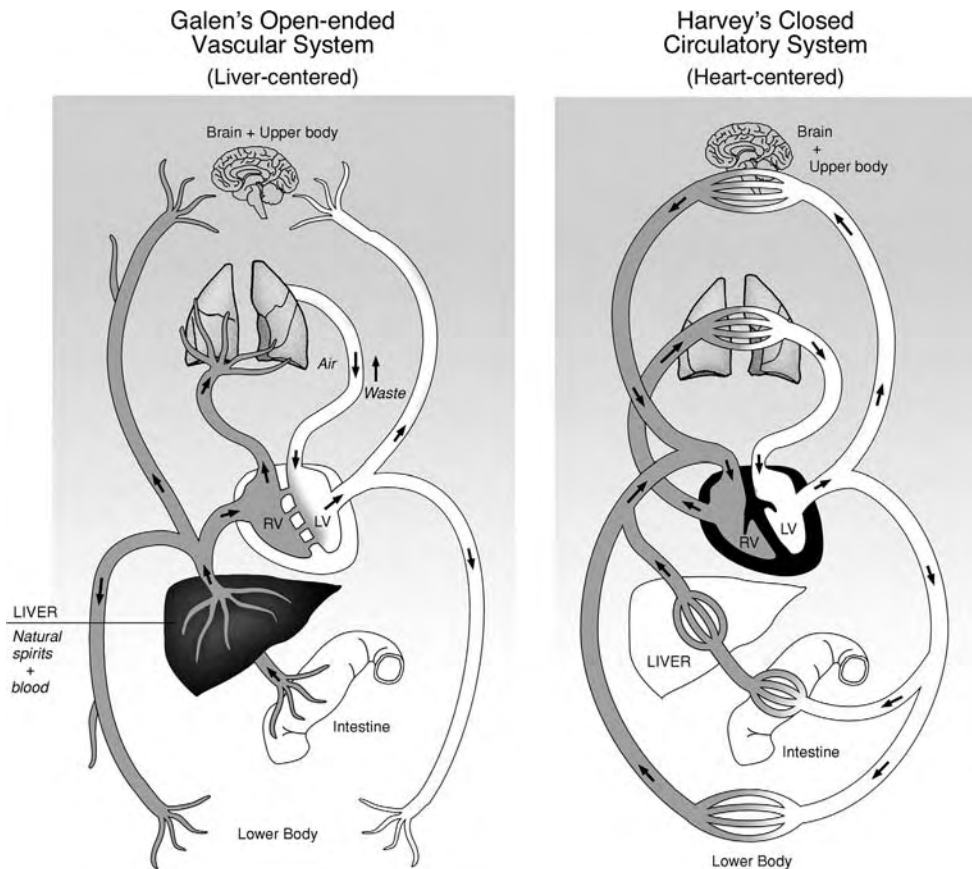

Figure 1.1. Schematic of the vasculature system as viewed by Galen (*left*) and Harvey (*right*). Galen did not recognize blood as circulating. He believed that arteries and veins functioned as distinct, open-ended systems, with veins carrying blood (synthesized in the liver), and arteries carrying both blood (derived from venous blood through invisible interventricular holes) and pneuma (derived from the lungs). Harvey employed simple yet elegant physiological experiments, including ligating arteries and veins, to prove his hypothesis that blood circulates.

his lifetime, this physician, noted for his progressive demand for evidence based on experience and for his questioning the authority of others, did not allow similar questioning of his own authority and did not question his own experiences and interpretations further. Thus, Galen was “wrong,” both at the time and in retrospect, in his inconsistent application of his own evidence-based epistemology.

These faults had a lasting effect. It is no exaggeration to say that Galen’s ideas, his insistence on adhering to them, and their unquestioning acceptance and promulgation by Catholic Church–run medieval universities effectively held back Western biomedical discovery for about 1,500 years. The universities adopted the ancient learning of Galen, Aristotle, and others *ex cathedra*, to be taught through rote lecture and memorization and without question. Medical students did not carry out their own dissections, nor did they question existing knowledge or add new discoveries. Although Galen did not create this climate of uncritical acceptance of dogmatic ideas, his own attitudes and writings did not discourage such blind acceptance – as long as it was acceptance of his own ideas.

What, then, was the impact of Galen’s interpretation? We can ask whether his “mistakes” actually captured something worth noting, and whether they were reasonable in the context in which he worked. In his insistence that the arteries and veins allowed blood, air, and nutriment all to flow in the same vessels and in both directions, as needed by the body for nutritive reasons, he actually assigned the blood vessels an active role in helping to determine which direction and at what rate the flow would occur. In this, he saw something that those “moderns” missed who viewed the system as passive plumbing that merely allowed fluids to pass through the body.

For Galen, as for the already legendary Hippocrates of the fifth century B.C., the arteries and veins both play important regulatory roles in maintaining function in a balanced, healthy body. Although we know little about Hippocrates the individual, or even about Hippocratic ideas about blood and vessels, we do know that the Hippocratic ideal retained its attraction well into the twentieth century. With its system of interacting humors and responses to the environment, the Hippocratic body was active, with an observable structure, a function that

responded to environmental conditions, and developed over the life of the individual as the baby grew into the adult. Structure, function, and developmental responses to environment are all parts of the Hippocratic body, and Galen largely adopted that set of assumptions. This ancient model, which dominated medicine for nearly 2,000 years, was internally active and reactive within its environment in ways often ignored in later times.

## CIRCULATION

Galen insisted that the heart has invisible pores that allow the movement of blood through the thick walls of the septum (see Figure 1.1, *left*). This must be the case, he surmised, because he could not see how fluids could travel from the arterial to the venous system otherwise, as they surely do. Generations of medical students absorbed this lesson as their professors read from the Galenic texts. When they looked at bodies, it was to read off the lessons of the texts: “See, here we observe exactly what the great Galen tells us that we must see.”

Only in the early sixteenth century did Andreas Vesalius join a small number of anatomists who were beginning, especially in Padua, to actually look at the body with their own eyes and to ask questions that went beyond Galen’s doctrines. At first, these questions focused mainly on filling in details and correcting small errors. Vesalius began by asking how it is that the blood can pass through the presumably small pores that Galen had described in the heart’s septum. In 1541, Vesalius contributed to a new edition of Galen. Two years later, in 1543, *De Fabrica* appeared under his name. There he wrote that:

The septum is formed from the very densest substance of the heart. It abounds on both sides with pits. Of these none, so far as the senses can perceived, penetrate from the right to the left ventricle. We wonder at the art of the Creator which causes blood to pass from right to left ventricle through invisible pores (2).

Although Vesalius had made many new observations that disagreed with Galen, he did not challenge Galen’s interpretation of the blood’s movement. If Galen said that the blood passes through pores in the heart’s septum, even if those pores are invisible, then it must be so.

Vesalius continued looking and continued thinking, however. By the second edition of his book, he concluded that he had not seen what Galen said he should see and that, therefore, the pores through the septum are simply not there. Galen was simply wrong about this. As Vesalius wrote in his 1555 edition:

Not long ago I would not have dared to turn even a hair’s breadth from Galen. But it seems to me that the septum of the heart is as thick, dense and compact as the rest of the heart. I do not see, therefore, how even the smallest particle can be transferred from the right to the left ventricle through the septum (2).

This was a tremendous breakthrough. Despite the attacks he received for the impertinence and even perceived sacrilege in challenging Galenic authority, Vesalius and his contemporaries had opened the door for further questioning of anatomical and physiological details. They also laid the groundwork for the basic methods of biomedical science: Start with one’s own observations rather than blindly accepting established doctrine. In particular, Vesalius opened the way for the study of the blood system of heart and vessels, and this focused attention on the anatomical structures that seemed important for physiological function. Medicine moved away from the idea of Hippocratic humors that run throughout the body and serve as a unifying holistic tie. Instead, a new emphasis on blood began a trend toward breaking the body into smaller and smaller units, looking for localization of function within defined structures and, eventually, localization of disease within specific structures and functions.

William Harvey carried the investigation further. Building on Vesalius’s work (and his questioning the existence of pores in the septum) and on the observations of Hieronymus Fabricius of Aquapendente (who had discovered valves in the veins but not the arteries and had asked why), Harvey found the Galenic interpretation of the movement of blood through the heart and vessels unsupportable. As he noted in the opening section of *De motu cordis* in 1628:

When they say that the left ventricle draws material, namely air and blood, from the lungs and the right sinus of the heart for the formation of spirits, and likewise distributes spirituous blood into the aorta; that sooty vapours are sent back to the lungs through the vein-like artery and spirit forwards into the aorta; what is it that keeps the two streams apart? And how do the spirits and the sooty vapours pass in opposite directions without mixing or getting into disorder (3)?

And so on to the point that they “would have it that the mitral valves should hinder its return. Good God! How do the mitral valves hinder the return of air, and not of blood?” (3). The fact that, in the same introduction, Harvey also apologized for having to challenge Galen’s authority almost 1,500 years later shows just how long Galen’s grip on medical theory lasted during the Middle Ages and the Early Modern Period. But that grip was loosening as Vesalius, Harvey, and others opened their own eyes and trusted their own senses.

Harvey famously went on to outline his arguments that blood must circulate through the body, moving out through the arteries and back through the veins after having passed through the tiny anastomoses that connected the two systems. Even though these connections and the passage of blood through them was not yet visible, for Harvey, the overwhelming accumulation of evidence compelled him to the conclusion that blood must move from one system to the other and that, therefore, the connections must exist (Figure 1.1, *right*).

The overpowering logic, the diversity of converging types of empirical evidence relating to blood's quantity and movement, and the accumulated anatomical evidence eventually carried the day in favor of Harvey's interpretation, although not without a fight. Gradually, after 1628, blood was accepted as circulating through an essentially closed system of blood vessels. In connection with interpretations from mechanical philosophers such as René Descartes in 1632, the heart came to be seen as a pump or a furnace, pushing blood out into the arteries by the action of contraction (4,5). For the mechanists, blood flows along its constrained path until it finally reaches the heart again, and it flows in from the veins to fill the void left by yet another contraction that has sent out yet more blood into the arteries.

The weight of argument in favor of the circulation model was overwhelming, even though Harvey himself could not actually see the connections between the arterial and venous systems. They must be there, but it would take new technology to see them. Sure enough, when Italian anatomist Marcello Malpighi used the newly available compound microscope to look at blood flow in the lungs of frogs in 1661, he directly observed the connecting capillaries (6). His reports drew on the direct, meticulous observation of diverse tissues and experimental manipulations to enhance observation—for example, injecting colored fluids into the vessels to observe their paths. Malpighi's capillaries were so small and so important in allowing the blood to circulate that they naturally became a focal point for understanding how the transmission of blood from arteries to veins works. With Antoni van Leeuwenhoek's confirmation using his higher-powered single-lens microscopes in the 1670s, the circulation of blood was largely accepted.

By the mid-seventeenth century, then, a very neat anatomical picture formed that was clearly "right" in the sense of accurately describing the physical phenomena of blood flow. But it largely missed the physiological action and life of the system, and it also lacked any sense of how the system develops or whether it simply exists, already connected from the very earliest stages of any individual. The focus remained primarily on structure: Harvey's followers had turned Galen's active and reactive system into a machine, with arteries and veins serving as mere passive plumbing. That Harvey himself did not hold such a mechanistic view is evident from his vision of the blood as the body's revitalizing agent. For Harvey, the circulation of blood brings renewal, similar to the cycle of evaporation and spring rains that renew the soil, or like the heavenly bodies orbiting and returning every year. Circulation brings life, and the parallels between circulation in the macrocosm of the heavens and in the microcosm of man stamped a sort of confirmation on the circulation hypothesis.

Yet Harvey's vitalistic picture had given way to a largely mechanistic world view in medicine. The mechanistic conceptions of the body also resonated with the emergence and increasing popularity and importance of sophisticated mechanical contraptions, such as clocks or pumps (7). Indeed, it can be argued that the prevailing images and metaphors of

the organism during the seventeenth and eighteenth century were all derived from the technologies of these times, which provided both the instruments for studying biological phenomena as well as the interpretative framework for its understanding. The best known and one of the more far-reaching analyses is Julian Offray de la Mettrie's "Man a Machine." Although he did not focus on anatomy as such, La Mettrie (8) saw a close connection between the fluids circulating in the vessels and the maintenance of the "elasticity of the blood vessels on which their own circulation depends."

The emerging new world order of early globalization and increased trade also contributed to the prevailing view of the importance of circulation and well-defined channels of transport. Here, as in most instances of the development of scientific ideas, the exchange of metaphors went both ways: On the one hand, the existing social and economic order shaped ideas about the organism (including concepts of pathology), while on the other hand, the biological conception of the organism also became a model for ideas about the organization of the state and the economy (9,10).

The mechanistic conception of the organism, together with the increased understanding of anatomy, also contributed to the development of a new conception of disease as a localized deficiency in a particular part of the body. Not unlike a broken machine, a sick body was considered to have a broken part. Pathology emerged in the nineteenth century as a scientific discipline that investigated both the symptoms and causes of disease within this framework of machine-like organisms (11).

## SPECIALIZATION IN BIOMEDICAL RESEARCH

The nineteenth century brought a new view of the circulatory system and its blood vessels, in terms of tissues and then cells. Rather than seeing vessels as long, essentially unstructured pipes through which the blood passively flows, researchers began to see the vessels as structured and constructed of parts. In particular, cells came to be seen as making function possible and developing over time.

The new view arose partially because of increased knowledge. Improved achromatic microscopes and microscopic techniques made it possible to observe smaller and smaller parts of the organism. Technology and inquiry reinforced each other: The desire to see more stimulated the push to develop new technologies and, simultaneously, new technologies stimulated new questions. At the same time, biology was emerging as a field of study, with an emphasis on examining structure (through anatomy and cytology), function (through physiology), and development (focused on cells and organisms). Although "biology" as a field by that name only emerged in the nineteenth century, and only fully developed in the early twentieth century, already the study of life was beginning to be differentiated into specialized subfields of study, localized in different specialties within medical schools and research institutes.

## Development

Early in the nineteenth century, Karl Ernst von Baer and others had carefully examined eggs and discovered that mammals have eggs too (first seen in a family dog sacrificed for the cause of science) (12). Observing the processes of development, they saw an emergence of form from what appeared to be unformed matter. That is, they saw form coming into being only gradually (or epigenetically), with the egg developing layers and only then differentiating into organs and systems.

Von Baer joined fellow embryologist Christian Heinrich Pander in noticing that the process of development forms “germ layers” (13). These connected but distinct layers of matter then become the various parts of the differentiating organism. Perhaps the embryo was always divided into the outer ectoderm, inner endoderm, and middle mesoderm layers, or perhaps the layers arise epigenetically through the developmental process? That remained to be determined, and some researchers held each position. (It was not until the late nineteenth century that researchers understood that these layers arise only at the gastrulation stage.) In addition, the biological significance of the layers remained to be determined: Did they provide the start of differentiated body parts, and therefore have embryological significance? Did they represent tissues that would give rise to different functions, and therefore have physiological significance? Or were they just structurally different, and changing with time? These were central questions for early nineteenth-century biologists.

## Cells

Early in the nineteenth century, Matthias Schleiden and Theodor Schwann focused on cells (14,15). They saw cells as the vital units that make up organisms, and they offered a theory of cell development whereby accumulating cells make up a growing and differentiating organism. The history of ideas about the formation of new cells during the mid-nineteenth century shows how contemporary philosophical and theoretical conceptions can shape the interpretation of observations. Schwann, who was committed to a unified theory of nature, first conceived of the formation of new cells as analogous to crystallization, which was an established mode for the emergence of new forms. He thought that existing cells secrete material, and new cells emerge through a process analogous to crystallization. It took several decades of painstaking and detailed observation to establish the mechanisms of nuclear and cell division.

By mid-century, with advancing microscopic techniques, a growing community of biological researchers had generated a picture of the embryo as a fertilized egg cell that undergoes cell divisions, develops germ layers, and then differentiates into specialized types of cells and tissues (16–20).

## Cell Pathology

Cells also assumed the central role in understanding disease, with Rudolph Virchow presenting the case for *cellular pathol-*

*ogy* (21,22). Although the “morbid anatomists,” as the early pathologists were called in Paris (led by Pierre Louis, Xavier Bichat, and others), had emphasized localization of disease in organs, Virchow localized disease in the cells. Medical science needed to understand which cellular changes were associated with which diseases, he urged, and also how cells contributed to causing disease. Cells work together at times to form membranes, Virchow asserted, including that lining the capillary (21): “A capillary vessel is a simple tube, in which we have, with the aid of our present appliances, hitherto only been able to discover a simple membrane, best at intervals with flattened nuclei . . .” This is “a membrane as simple as any that is ever met with in the body.” Although he did not call this membrane the endothelium, it was, in effect, what he was describing. And, as in later contributions, he argued that the “simple membrane” results from the cells working together. For Virchow, medicine should focus on cells and how they work together to make up functional tissues and organs. Pathology should examine the failures that occur at each level, down to the cellular.

Pathologists also began to distinguish even more finely among different types of cells and tissues. For example, diseased linings of organs and parts called for identification; Viennese surgeon Theodor Billroth used the prefix *endo-* to describe as an “endothelioma” those tumors occurring in what came to be known as *endothelial cells* (23).

## Connecting the Pieces

In the dissecting rooms and in pathology labs, researchers were looking at ever finer distinctions in their search to link disease with localized material. Physiologists sought to link functions to the localized parts of organs and cells, asking how the parts cause the observed responses. Embryologists wondered how the parts and their functions arise, although they had no way to make much progress in studying human development as yet. Structure, function, and development began to hold their specialized places in medical education. Meanwhile, the clinical ideal remained largely Hippocratic, focused on the whole organism and its interactions.

William Osler exemplified the clinician’s perspective on and wish for – if not the reality of – holism and integration. He did not look inside vessels for an endothelial lining, but instead emphasized the whole system and its actions and failures. As he wrote in *Diseases of the Arteries*, the arteries reflect the whole of life, with its “wear and tear.” For “Among organs, the bloodvessels (sic) alone enjoy no rest . . . like other organs, they live under three great laws – use maintains and in a measure sustains structure; overuse leads to degeneration; in time they grow old, in threescore or in fourscore years the limit of their endurance is reached and they wear out (24).” Osler’s remained largely a structural view, but one that saw the organism as an organic whole:

The stability of tubing of any sort depends on the structure and on the sort of material used; and so it is with the human tubing. With a poor variety of elastic and

muscular fibers in the bloodvessels, some are unable to resist the wear and tear of everyday life, and have at forty years of age arteries as old as those of others at sixty . . . not only are there individuals, but whole families with “shoddy” bloodvessels. Hence the truth to the old saying attributed to Cazalis, “a man is as old as his arteries.” In the building of the human body, as of chaises, there is, as Autocrat says, “always somewhere a weakest spot,” and too frequently this is in the circulatory system. The conditions of modern life favor arteriosclerosis, as a man is apt to work his body machine at high pressure . . . Living quieter lives and with less stress and strain, women are not so frequently the subject of arterial changes, and in consequence they last longer (24).

## THE ENDOTHELIUM

The Swiss anatomist Wilhelm His introduced the term *endothelium* in 1865, in a programmatic essay titled “Die Häute und Höhlen des Körpers (The membranes and cavities of the body)” (Figure 1.2). Halfway into his tenure as professor of anatomy and physiology in Basel (from 1857 to 1872) His introduced an academic research program that became the foundation for his work in developmental mechanics. It was based on the conviction of a “tight connection between histological embryology and the most fundamental problems of general physiology” (see Ref. 25, p. 33). Programmatically, His continued the work of Xavier Bichat, who began his short but extremely productive career with a monograph on the membranes of the human body (26). Following Bichat, His’s program was to identify the embryological origins and further developmental differentiation of tissues that have structural and functional meaning for the organism.

Nobody doubts, as was first recognized by Bichat, that all the capacities of the living body can, in the end, be explained by the coordinated interactions of the capacities of its tissues. These capacities of the tissues are, however, a direct consequence of their organization . . . A cell, even though it is endowed with rich internal capacities, only develops in closest dependency of its external conditions, it even responds promptly to the most fleeting external cause, either through changes in its vegetative state, or through other changes in its vital functions. . . . These phenomena will be revealed by means of pathological–anatomical and experimental as well as embryological analysis (25, p. 34).

During the following decades, His constantly refined his initial program, always ready to adopt new technologies. After the mid-1880s, these included advanced apochromatic microscopes and microtomes (that His helped to refine) that allowed meticulous serial sectioning as well as new methods for the three-dimensional representation of anatomical

structures. As a result, anatomical details became observable both in adult and in embryonic specimens. His’s program sought theoretical generality, but was based on observed particulars in both human and vertebrate (mostly chick) specimens.

His triggered an immediate and at times rather heated debate about the appropriateness of this new concept of endothelium. His’s specific focus was on the cavities and membranes of the third germ layer, the mesoderm, which include the vascular system, pleural spaces, and the pericardium and peritoneum. He focused especially on the importance of developmental history (*Entwicklungsgeschichte* or descriptive embryology) in understanding histology and anatomy. During that time, the respective contributions of different germ layers to various organs systems were still debated, as were the actual mechanisms of organogenesis. His’s own program emphasized the movements and foldings of germ layers as a strictly mechanical and material cause for differentiation, development, and function. His’s focus remained on early developmental stages, rather than on the later anatomical results and their biological and medical implications. In the context of increasing specialization, this mattered, because many medical researchers did not yet hold the early developmental stages as important. Researchers questioned his claims about the developmental process, about observations based on manipulative techniques that necessarily destroyed the organism being studied, and about the claims that these cells and tissues were really distinct and deserving of special consideration.

One of the peculiar features of the mesoderm, which His and other embryologists clearly recognized, is the formation of inner cavities within the differentiating mesodermal tissues (e.g., the vascular system, the lymphatic system, or the pleural spaces) and the histological differentiations associated with these structures. Among the differentiated structures connected to these cavities were so-called inner membranes, which show a remarkable diversity and thus proved to be a serious challenge for microscopic anatomists and histologists.

One problem was conceptual. How should one refer to those cell layers that line these inner cavities of the mesoderm? Common practice at that time was to refer to them as an epithelium, in strict analogy to the epithelia covering the outer surfaces of organs (e.g., the keratinocytes that cover the skin or epithelial cells that form the inner lining of the digestive system) and protecting these organ systems from their environment. In this case, the generic term *epithelium* simply meant a layer of cells serving as a lining. But, as His pointed out, the cells that line the cavities of the inner germ layer (mesoderm) exhibit certain characteristics that differentiate them from those epithelial cells that originate from the two outer germ layers (endoderm and ectoderm). Therefore, these structures should be identified by their own designation.

One alternative was to call them “false epithelia.” His found that unsatisfactory and instead introduced a new term, *endothelia*:

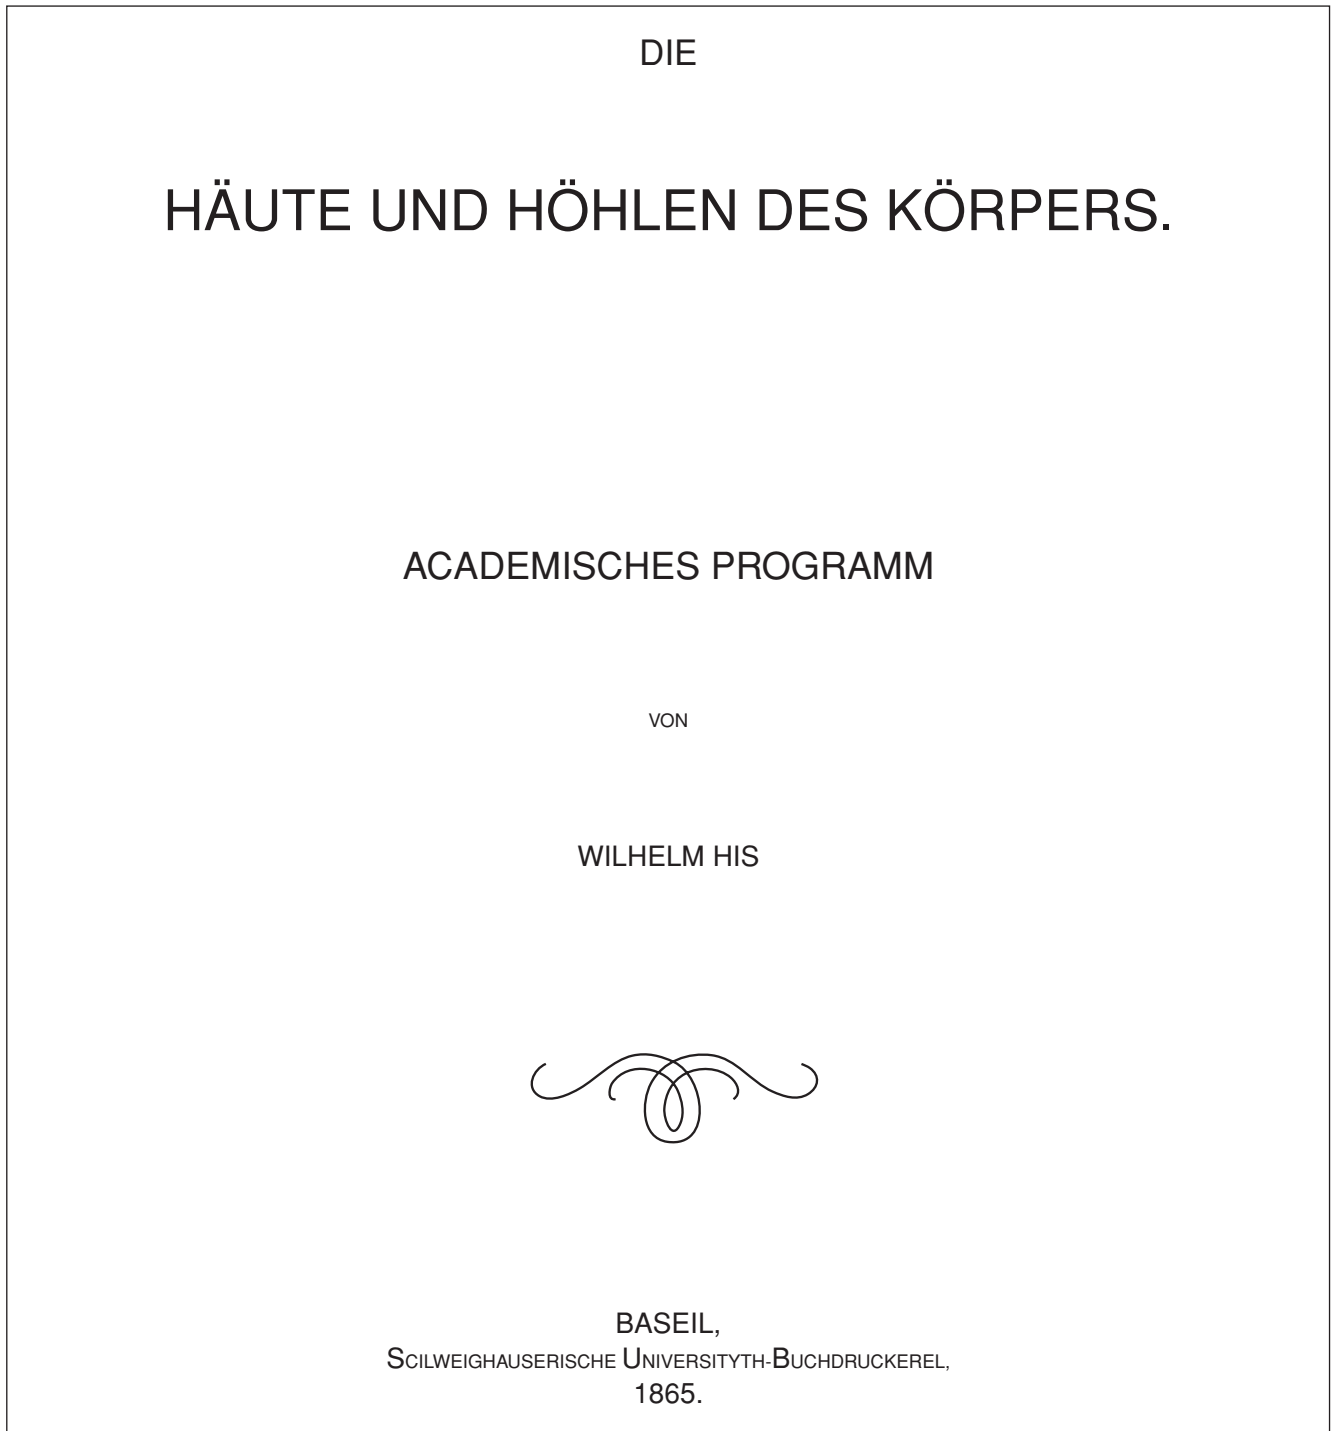

Figure 1.2. Frontispiece of Wilhelm His: *Die Häute und Höhlen des Körpers*, published in 1865. In this publication, an outline of His's research program, he first defined the endothelium as the lining of the vasculature and the lymphatic system.

It is customary to refer to the cell layer that lines the vascular and inner cavities as an epithelium. The same designation is also used for the inner cellular linings of the joint cavities and those on the back of the cornea. However, all these cellular layers that line the cavities of the inner germ layer [mesoderm] display such a large number of similarities and, from their first appearance during development, they differ from those cellular la-

yers that have their origin in one of the outer layers [endoderm and ectoderm] to such a degree that it is well justified, especially with respect to understanding their physiological functions, to identify those by means of a special designation, either referring to them as "false" epithelia in opposition to the "true" epithelia, or by calling them endothelia [sic], thus reflecting linguistically their relationship to inner membranes (25, p. 18).

His went on to describe the differences between endothelial and epithelial cells:

Beginning with early development, the contrast between serous and vascular endothelia on the one hand and true epithelia on the other hand is already visible. The former develop, as we have seen, from lymphoid cells, the least differentiated cell type that the inner germ layer [mesoderm] can produce and which are also the precursor (Mutterform) for all others. Soon they take on their characteristic flattened shape and become transparent and after reaching this stage they barely change anymore nor do they participate in any significant way in growth processes within the body (25, p. 18).

From these statements, it is clear that, by 1865, His did not recognize the participation of ECs in blood vessel formation. The perceived passivity of ECs in development is also in stark contrast to the activity of epithelial cells, which were already recognized to continue to grow and participate in changes during development.

A second, physiological difference between endothelial and epithelial cells was recognized by His. Whereas epithelial cells produce all those substances that form the secretions of the various glands in the body, in contrast, ECs were not seen to produce any form of secretions. As His emphasized, “we have no reason to ascribe to endothelia any secretory functions” (25, p. 18). The final difference between endothelial and epithelial cells that His mentioned relates to their function as barriers: Although blood serum can pass freely through ECs, which therefore do not provide a clear separation between the blood in the vessel and the surrounding intercellular substrate, epithelial cells act as a much stronger barrier, especially with regard to larger molecules:

There is another aspect in which true epithelia and endothelia are in stark contrast to each other; serum can freely pass through the latter at any place; sometimes serum filters through the endothelia and leaves the blood vessels in order to nourish the surrounding tissues; sometimes it passes from the tissues into the lymphatic system or the serous cavities, following a simple pressure gradient. This implies that endothelia do not provide a strict boundary between cavities and intercellular substances of the inner germ layer [mesoderm]; therefore physiologically these have to be seen as a whole, as they equally contribute to the function of containing the general nutritional fluids. The situation is different with true epithelia (25, p. 19).

Summarizing His’s arguments, which we present here at some length because of their historical significance, we see that the concept of the endothelium as a separate and clearly distinguishable part of the body arose as a consequence of

three different considerations. First, the endothelium can be distinguished because of its embryological origin from the mesoderm, becoming a layer of cells that covers the cavities of the inner germ layer (mesoderm). Second, ECs have a clearly recognizable structure, with the endothelial layer clearly identified as a connected layer of flattened cells. And third, ECs were not considered to be active in physiological secretion. Instead of having an active role that would have been considered physiological at the time, the endothelial layer was seen as providing a somewhat porous lining for the vascular system and related mesodermal cavities. Endothelium was more a matter of providing structure to support the vascular plumbing system, rather than as anything more active.

### The New-Found Endothelium

In the years following His’s introduction of the term, not everyone immediately adopted his proposal to identify the endothelium as a separate entity. Arguments continued about the usefulness of separating the endothelium from epithelium. Was there really something different here and, if so, did it deserve its own name? A survey of textbooks and published articles from the later nineteenth century suggests that leading anatomists such as Joseph Hyrtl, Carl Gegenbaur, and Philipp Stöhr – who all argued against the separateness of the endothelium – seemed to have the upper hand. For them, the epithelium and presumed endothelium had fundamental similarities in function and in morphology. If it was important to make distinctions of type, they preferred using additional descriptive terms to specify the origin of these “thelia,” such as mesenchymal epithelium. This interpretation was codified in some histology textbooks, which typically defined an epithelium as a connected layer of cells covering the surface of the body, an organ, or an inner cavity. Under this definition, endothelium was simply a specific form of epithelium consisting of flattened cells (*Platteneithelium*) that lined the blood vessels.

### Narrowing the Endothelium to Blood and Lymphatic Cells

Increasingly, however, others did take seriously the differences, because the term *endothelium* had its uses. Increasing acceptance that something specialized called the endothelium existed was reinforced after the 1880s and 1890s because of the advanced microscopic and histological techniques and improved equipment that made possible a much more detailed and wider range of observations. Specifically, researchers began to reliably distinguish the endothelium as a layer of cells that together serves as a membrane lining blood vessels, the lymphatic system, and (for some) parts of the nervous or other systems. The influential Heinrich Wilhelm Gottfried von Waldeyer, for example, suggested restricting the term to those cells that make up the innermost layer of blood and lymph vessels and the posterior lining of the cornea. He thus excluded some of the other “thelia” also derived from the mesoderm and that His had included in his definition of the endothelium

(27). Waldeyer's approach, based on detailed observations, provided considerable clarification about what should be included as endothelium.

The types of observations on which Waldeyer drew illuminated fine anatomical structure, and discussion of function followed. If this layer of cells is truly differentiated from others, then why? What function does it serve? Also, questions arose about how ECs develop and whether that developmental history might provide clues to their identity and use.

By 1908, knowledge about the endothelium and its use had already begun to achieve standardization and become accepted within the body of established scientific knowledge. Even such a general standard source as *Gray's Anatomy* reflected the new understanding about an endothelial lining for the vascular system. What had been called the epithelial layer was now the endothelium, and the capillaries, in particular, were seen as "very small endothelial tubes which connect the venous system with the arterial system." "The nucleated endothelial cells which constitute the wall of a capillary are flat, irregular in outline, and are united by a cement material." This passage reflects the state of knowledge: Endothelium is connection, the cells together make up the vessel walls, and they are united by some unknown material. Furthermore, they make up vast connected networks or systems of "endothelial tubes throughout the entire blood-vascular system. The heart is a great muscular thickening around a portion of the system of endothelial tubes" (28, pp. 586–587).

In 1910, A. A. Böhm and colleagues' textbook was one of many specialized texts to appear on the study of histology, which had become a standard field in medical education. For these authors, the message was clear about what types of cells constituted ECs and the significance of their embryonic origins from the mesodermal germ layer: "*Endothelial* cells are differentiated mesenchymal cells. They line the blood- and lymph-vessels and lymph-spaces." It was also important to describe them: "Endothelial cells are in structure like those of the mesothelium. In blood- and lymph-vessels they are of irregular, oblong shape, with serrated borders" (29). By the beginning of the twentieth century, although debate might continue about the existence or importance of the serrations or about the ways in which the cells connected into tissue, histologists largely followed His's initial characterization. They saw endothelial tissue as lining vessels and providing more nuance to the structural plumbing system for blood circulation.

Thus, the beginning of the twentieth century brought a growing awareness of the complexity of what had once looked like such simple tissues and cell structure. Now, it was seen that capillaries consisted of a complex coating, including ECs that themselves seemed to be connected. The understanding of structure had changed dramatically, and it remained for others to interpret what this meant for function. It now seemed that vessels do more than passively carry blood or lymphatic fluid around the body: They play some more active functional role as well. But how? Most importantly, are the vessels made of permeable cells, or do they have porous passages to allow fluids to pass from the vessels to the body? If so, how? To answer

such questions, researchers studied both the fine structure and the related function of the ECs under both normal and pathological conditions.

### Physiology and Pathology: The Endothelium in Action

With accepted structure came ascribed function. Pathologists and physiologists each worked to understand endothelial function. Already in 1884, pathologist G. Hare Philipson discussed, in his Bradshaw Lecture "On the Pathological Relations of the Absorbent System," the endothelium, which he defined as the lymphatic and circulatory vessels. As he put it, "Alterations in the amount of transudation may thus be referable, not to disturbance of the circulation, but to changes in the vessel wall, and especially in their endothelial lining" (30). The vessel wall is not a passive or essentially dead membrane, but is living and active. It helps regulate the flow of fluids either along the vessels or perhaps even through the vascular walls. But how?

Physiological studies undertaken during the first half of the twentieth century supported the concept that, in addition to the visible flow of blood through capillaries, there existed an "invisible flow of water and dissolved materials back and forth through the capillary walls," and that this "invisible component of the circulation takes place at a rate which is many times greater than that of the entire cardiac output" (31). In 1927, Eugene M. Landis demonstrated that flow through the capillary wall is directly proportional to the difference between hydrostatic and osmotic forces acting across the membrane (32). Other investigators compared the flow of graded-size molecules through artificial porous membranes and capillaries and used mathematical formulas to calculate capillary filtration coefficients and pore dimensions.

These studies gave rise to a pore theory of capillary permeability, which predicted the presence of two distinct pathways across capillaries: a small pore system for the passage of small hydrophilic solutes through water-filled channels, and a large pore system for the passage of macromolecules. Proof for the existence of these structures would have to wait for the development of higher-resolution microscopy; the advent of new microscopic techniques clarified the structure of individual cells and, especially, how cells interact.

### More than a Layer Lining Blood Vessels: Form and Function Together

The discussions about the very existence and then the nature and role of the endothelium during the first decades of the twentieth century reflect epistemological and methodological discussions within medicine and biology more generally. A developmental approach reflected the belief that biological understanding required knowledge of the origin and genesis of structures. A morphological/histological approach argued for the comparative evaluation of the internal configuration and external appearances of structures, whereas a functional/pathological approach emphasized the role that certain structures have in the orderly operations of the body.

In the endothelium, we see all three at work, as researchers sought to discover whether, what, and why endothelia exist. Even though the picture became much clearer as research moved into the early twentieth century and the endothelium was accepted as a specific entity, continuing debates about its structure and role reveal the competing underlying assumptions of the researchers involved. These debates also reveal the tendency of researchers in different specialty areas to work at different levels of analysis.

Ramon y Cajal's histology textbook in Spanish, revised and translated in 1933, provides an example. Ramon y Cajal emphasized the structural flatness of the endothelial layer of cells. Those flat cells that form a thin, pavement-like layer over a surface are endothelial, he maintained, wherever we find them and whatever their origin. The metaphor of the pavement not only conveyed that this was a flat covering, but also that it contained a sort of cement that held the individual cells together to do their job of providing a solid lining (33). This raised the question of how the cells adhere. Histologists, especially in the 1920s and 1930s, used silver nitrate preparations to discover detailed cell appearance. In the blood vessels, ECs were seen as being connected by a "resistant cement," but in the corneal surface they seemed to have connecting filaments holding the individual cells together. Details of these phenomena were laid out in textbook after textbook, each recognizing that the meaning and role of these cells remained largely unknown, and each emphasizing different aspects of what was known.

Edmund Cowdry's widely used textbook of the next year (1934) sought to bring the structure and function closer together, looking at the "functional significance of cells and intercellular substances." Cowdry pointed to a debate about the importance of ECs with respect to red blood cells. Florence Sabin and others believed that red blood cells must be produced intravascularly, because the endothelium forms a tight barrier to control the movement of cells. Alternatively, if blood cells form outside vessels, then this requires movement across the endothelial layer into the vessels. Cowdry felt that the issue was not resolved but that, in either case, the endothelium played a central role (34).

In his discussion, Cowdry recognized that it was crucial to understand the nature and extent of the endothelial layer's permeability as well as what regulates movement across that layer. Are the individual cells penetrable, or are there pores between cells that either allow, enable, or restrict movement? And how? As details about the structure became clearer, these functional questions came more sharply into focus as well.

A few years later, in Cowdry's 1938 edition, he noted that the endothelium of capillaries in the brain "holds back protein quite effectively; for the cerebrospinal fluid – a special tissue fluid – is remarkably free from protein. Permeability naturally increases with the inevitable thinning of the endothelium in capillary dilatation or stretching. This happens when the liver swells on receipt of absorbed substances from the digestive tract after meals; but the brain cannot expand to anything

like the same degree because it is limited by a bony case" (35, pp. 125–126). By the end of the 1930s, questions about the extent, nature, and effects of endothelial permeability assumed increasing importance.

Leading histologist Alfred Kohn and others argued that, especially for the vascular and lymphatic system, the notion of the endothelium as a cover and barrier facing a hollow space is misguided. Rather, because these vessels are always filled with blood and other internal substances, the vascular system is actually a complex unit composed of moving mesenchymal elements (blood and lymphatic fluids), a layer of cells (endothelium), and the vascular wall. Functionally, these cells all interact; furthermore, the ECs mediate important exchanges between the blood and other tissues (36).

According to Kohn, the functional role of the endothelium to mediate the important material exchanges within the body also accounts for the differentiation among ECs. "Fatter" ECs will be found in those areas of the body where a more intensive exchange occurs, whereas more flattened cells will occur in areas of less functional importance. Some authors referred to this as the reticulo–endothelial system, whereas others rejected the idea and continued to look at individual cells as the mechanism of control. The seeming clarity of the twentieth-century's early decades was once again giving way to debates and alternative interpretations, and evolving and expanding questions. Different levels of analysis and new techniques would bring new information, new insights, new questions, and new debates, as new technologies allowed new observations.

## TECHNOLOGY AND ITS IMPACTS AND IMPLICATIONS

Modern science is characterized by a close connection between the development of scientific concepts and theories and the available technologies and methods. Indeed, we find this connection at the birth of modern science during the so-called Scientific Revolution, which was greatly aided by telescopes, microscopes, and shortly thereafter by clocks and the pendulum. These instruments and their associated new methodologies not only allowed for increased precision in measurement, they also carried with them (or in a sense embodied, as the modern historiography of science would have it) a specific conceptual structure. Instruments and research methods are therefore not just a more precise extension of our senses. Rather, through their interactions and intervention with "nature," they constitute – or in a very real sense create – scientific objects. And these scientific objects are not just material objects "out there in nature" with specific physical properties; they are simultaneously conceptual abstractions that also have theoretical significance.

The history of endothelial biomedicine is a good illustration of these patterns. We have already seen how early ideas of the circulatory system and the introduction of the concept of the endothelium reflected larger scientific trends of the times.

The innovations included contributions of then-prevalent research methodologies and technologies. His's recognition of the endothelium as a separate and distinct entity of the body drew both on his theoretical ideas about the role of germ layers during embryogenesis and also on the newly available microscopes, microtomes, and histological techniques that revealed the morphological characteristics of ECs and their mesodermal origins. The interactions of ideas, questions, and technologies accelerated during the course of the twentieth century (37–39). As we discuss below, physiological approaches gave way to ultrastructural studies; electron microscopy, in turn, was largely supplanted by cell culture.

### **New Technologies, New Discoveries: Electron Microscopy**

Electron microscopy brought great advances in understanding structure. In doing so, however, it also moved away from an appreciation for development and dynamic interactions of the cells and their surroundings. Much of the initial excitement generated by electron microscopy was due to its ability to reveal details about the internal structures of cells and resolve some of the long-enduring arguments over whether these were artifacts. Many of the crucial techniques for employing electron microscopy in the study of cells were developed to advance the understanding of cytoplasmic structures. But electron microscopy also helped reveal some of the distinctive features of ECs.

Although a number of new procedures for improving the resolution of the light microscope were developed during the 1940s (e.g., phase contrast and ultraviolet microscopy [40,41]), the electron microscope offered the greatest promise for generating images at finer resolutions that could reveal structures in cell cytoplasm. The electron microscope depended on the idea that electrons have wave properties, with wavelength inversely proportional to electron velocity, advanced by Louis de Broglie in 1924. Several investigators began to develop electron microscopes in the 1930s, and the first commercial microscopes were introduced by Siemens in 1939. Over the ensuing years, advances in microtome sectioning, embedding protocols, and fixation techniques set the stage for a new generation of investigators who employed electron microscopy to generate new information about the structure of cells. Discoveries included George Palade's description of mitochondrial cristae and endoplasmic reticulum-associated ribosomes (42,43).

At the meetings of the Electron Microscope Society of America in 1953, Palade presented a paper entitled "Fine Structure of Blood Capillaries," in which he presented micrographs of capillaries in different organs such as skeletal muscle, heart, intestine, and pancreas. He reported that, in these organs, "the endothelial cells form a continuous lining," and that the cells contained a "large number of vesicles concentrated immediately under the cell membranes facing both the capillary lumen and the pericapillary spaces." Surprisingly, electron microscopy studies failed to reveal pores of the dimen-

sions postulated by physiologists. Palade proposed that the vesicles "may represent a system for transporting fluids across the capillary wall and may account for the high permeability rate of the capillaries." In a subsequent study employing ferritin as a molecular tracer, Palade concluded that "endothelial cell vesicles are the structural equivalent of the large pore system postulated in the pore theory of capillary permeability" (42,43).

A major result of the early electron micrographic studies of ECs was the discovery, in 1964, of Weibel-Palade bodies, which are unique to ECs. These organelles, now known to store and secrete von Willebrand factor and P-selectin, were described by George Palade and Ewald Weibel as "hitherto unknown rod-shaped cytoplasmic component which consists of a bundle of fine tubules, enveloped by a tightly fitted membrane." They concluded that, due to the regularity of its appearance in ECs, the rod-shaped bodies must have "functional significance which for the moment remains obscure" but suggested that they figure in vascular or blood physiology (44).

Another important consequence of electron microscopic studies during the 1950s was the finding of structural differences between capillaries in different organs. As noted by Hibbs and colleagues in 1958, "some variation in the structure of capillaries and arterioles normally occurs from one organ to another, and even among vessels of the same organ" (45). In the 1960s, electron microscopy was used to confirm the functional relevance of structural heterogeneity, demonstrating, for example, that the tight junctions between ECs in the brain form a highly functional blood-brain barrier, whereas the loose, somewhat disorganized junctions of post-capillary venular endothelium correspond to their predilection for solute and leukocyte trafficking during inflammation.

### **Cell Culture**

It may be argued that physiological and morphological studies – in and of themselves – were beginning to yield diminishing returns. That would change in the early 1970s, when Eric Jaffe and Michael Gimbrone independently reported the first successful isolation and primary culture of human ECs from the umbilical vein (46,47). The cells, which were obtained by collagenase digestion, could be maintained in culture for weeks to months, and were identified as endothelium by the presence of Weibel-Palade bodies and von Willebrand factor (VIII-associated antigen). The capacity to culture ECs provided researchers with a new and powerful tool to dissect cell structure and function under controlled (albeit artificial) conditions. These studies have addressed every conceivable *in vitro* property of ECs including – but certainly not limited to – subcellular organelles (e.g., Weibel-Palade bodies, mitochondria, Golgi apparatus, and endoplasmic reticulum); membrane microdomains such as caveolae or lipid rafts; cell signaling (from cell surface receptor to the level of gene transcription and posttranscriptional regulation); and the cytoskeleton.

While the cultured EC became a focal point for research in vascular biology, increasing evidence pointed to the highly complex topology of the intact endothelium. In the 1980s, several groups carried out systematic immunohistochemical analyses of the endothelium in various organs (48–50). These studies, which built on the earlier results of electron microscopy, revealed differential expression of lectins and antigens in the intact endothelium. In other words, the endothelium displayed *molecular* heterogeneity. Implicit in these observations is a critical – though largely overlooked – message which was articulated by Robert Auerbach in 1985:

The concept that vascular endothelial cells are not all alike is not a new one to either morphologists or physiologists. Yet laboratory experiments almost always employ endothelial cells from large vessels such as the human umbilical vein or the bovine dorsal aorta, since these are easy to obtain and can be readily isolated and grown in culture. The tacit assumption has been that the basic properties of all endothelial cells are similar enough to warrant the use of the cells as *in vitro* correlates of endothelial cell activities *in vivo* (51).

According to Auerbach, a key to understanding structural and functional heterogeneity was to isolate and study microvascular ECs from different organs. This approach makes the most sense if site-specific phenotypes are retained in culture. However, as we will see throughout this book, this assumption is only partially correct. For example, many site-specific properties of ECs depend on extracellular signals. Thus, when ECs are removed from their native microenvironment and cultured *in vitro*, they undergo phenotypic drift and lose many of their original properties.

### Beyond Electron Microscopy and Cell Culture

Although electron microscopy and cell cultures largely contributed to the structural and functional characterization of the endothelium, other techniques have provided new insights into the endothelium. For example, during the past few years, investigators have employed novel genomic and proteomic techniques to uncover an enormous array of site-specific properties (so-called vascular addresses or zip codes) of the endothelium. Together, these studies suggest that “far from being a giant monopoly of homogenous cells, the endothelium represents a consortium of smaller enterprises of cells located within blood vessels of different tissues . . . while united in certain common functions, each enterprise is uniquely adapted to meet the demands of the underlying tissues” (52). The modern techniques of fate mapping emphasize their developmental perspective. Again, differences in methods matter, enabling researchers to highlight different aspects of development. Similarly, the availability of new model organisms for research in endothelial biology, such as genetically modified mice and

zebrafish, have had a profound impact on theoretical conceptions of the endothelium.

One consequence of science’s dependence on methods and technologies is that knowledge accumulation is rarely continuous. We see this in the gap existing between the availability of a large number of empirical details about ECs and our limited understanding of the endothelium as a functional whole with clinical importance. We lack relevant theoretical models in systems biology that could help illuminate this bigger and more complex system in which ECs reside. As a result of the specialized thinking within separated lines of study, the dominant view of the endothelium is still rooted more in the conceptual structure of isolated cell cultures, which has implications for the clinical applications of endothelial biology.

### ENDOTHELIUM IN DISEASE

The first evidence of a potential role for the endothelium in disease (as victim, if not perpetrator) is found in published reports from late nineteenth century, which describe the abnormal morphology of ECs in a number of disease states, including tuberculosis and malaria. In the 1870s, Julius Cohnheim studied the frog tongue to demonstrate that leukocytes adhere to the blood vessel wall of venules (so-called pavementing of leukocytes), many of which passed through the wall into the extravascular tissues (leukocyte emigration). These observations were later confirmed in mammalian species. Studies in an ear chamber model demonstrated that leukocytes adhere to the damaged side of a blood vessel, suggesting that the blood vessel wall – as distinct from the leukocyte – is primarily responsible for mediating adhesion (53). However, the mechanisms underlying inflammation-induced leukocyte adhesion remained elusive for decades. According to one theory, the endothelium secreted a gelatinous substance that trapped leukocytes (54). Others claimed that electrostatic forces were responsible for mediating the endothelial–leukocyte interactions (55).

As with so many other aspects of EC biology, the elucidation of the role for endothelium in inflammation and the molecular basis of leukocyte trafficking would wait for the successful culture of ECs. In the 1980s, several investigators demonstrated that treatment of cultured ECs with inflammatory mediators resulted in phenotypic changes that included increased expression of cell adhesion molecules, leukocyte adhesion, antigen presentation, and procoagulant activities. These changes, many of which were subsequently shown to occur *in vivo*, were termed *endothelial activation*.

Another term that came into favor in the late twentieth century was *endothelial dysfunction*. In the 1970s, subsequent to Russell Ross’s response-to-injury hypothesis to explain the mechanisms of atherosclerosis, there was a growing appreciation that the *intact* endothelium may actively contribute to disease initiation and/or progression (56). Although the term *endothelial cell dysfunction* was first coined in 1980 to describe

the hyperadhesiveness of the endothelium to platelets, it was quickly adopted by the field of cardiology to describe abnormal endothelial vasodilator function (57). Indeed, it is not uncommon today to find full-length publications on endothelial dysfunction that refer exclusively to altered vasomotor tone in coronary arteries. Of course, the endothelium has many functions beyond the control of vasomotor tone, and it is distributed widely throughout the body. Thus, endothelial dysfunction is not restricted anatomically to the heart, nor is it limited in disease scope to atherosclerosis.

## CONCLUSION

Since Galen, we have determined that a layer called the endothelium exists, and that it is made up of cells called *endothelial cells*. The structure is derived from the mesodermal germ layer, is widely distributed throughout the body, is highly active with multiple functions, and is remarkably heterogeneous in structure and function. New techniques have illuminated more detail while simultaneously raising questions about the earlier simple assumptions.

Despite breathtaking advances in EC biology and a growing appreciation for its role in disease states, endothelial biomedicine has made little progress as a field. There are several possible reasons for this. First, overspecialization in medicine hampers cross-disciplinary approaches to the endothelium and keeps researchers in one area from learning about the ideas and approaches of another. Second, because the endothelium displays emergent properties and is so highly adapted to its microenvironment, it must be approached in the context of the whole organism. As long as cell culture studies are sufficient for publication and funding, there is little incentive to study endothelial biomedicine as a whole, or to look at the diverse and dispersed roles of endothelium in the body. Finally, it may be argued that by figuratively stripping the endothelium from the blood vessel and employing it as a frame of reference (i.e., “endothelial biomedicine”) we are “inventing” a field with little clinical value.

Some might argue that the endothelium should not be considered outside the context of the blood vessel. They might point out, for example, that endothelial–smooth muscle cell interactions are essential and should constitute the minimal unit of investigation and inquiry. Admittedly, this argument stands for conduit and resistance blood vessels. Alternatively, it may be argued that the functional unit of capillaries (which comprise the vast majority of the surface area of the vasculature) is the endothelial–pericyte–extracellular matrix interaction. An investigator in an organ-specific discipline may make a case for studying the endothelium in the context of the whole tissue – for example, the nephrologist, who wishes to understand the role that the glomerular endothelium plays in urinary excretion.

We are beginning to appreciate previously hidden levels of communication between ECs and other cell types and systems.

For example, increasing evidence suggests a tight developmental, structural, and functional link between the endothelium and the nervous system. Perhaps, one day, these endothelial–neural connections will define the term *vascular*.

So, it is really a matter of perspective. In choosing the endothelium as our frame of reference, we acknowledge the importance of the endothelial–mural cell interaction and the unique value of each and every vascular bed/organ (including the heart), but treat them as one of many configurations of the endothelium.

This book provides collective knowledge about the endothelium. It strives to answer the following questions:

- What do we know about the biology of the endothelium – for humans as well as other animals?
- What do we know about its structure, function, and development, including evolutionary development?
- What do we know about the clinical implications of endothelial function and the foundations on which those rest?
- How do we go about interpreting what we know, through metaphors, models, and methods?

This volume examines all these issues. In the final chapter, we return to reflect on the knowledge provided by the whole and on what it means for endothelial biomedicine.

## ACKNOWLEDGMENTS

Special thanks to William Bechtel, who added tremendously to the chapter with his advice and knowledge about electron microscopy and its impacts. We recommend his *Discovering Cell Mechanisms: The Creation of Modern Cell Biology* (Cambridge University Press, 2005) for further information on that topic.

### WHY STUDY EVOLUTION?

An understanding of the evolutionary origins of the endothelium has important implications for human health and disease.<sup>1</sup> As discussed by Nesse and Weder (Chapter 15), when approaching mechanisms of structure and function, evolutionary explanations (“why”) complement proximate considerations (“how”). They provide important insights into the design constraints, path dependence, trade-offs, and selective pressures that underlie endothelial function and vulnerability to disease. Another critical and often underappreciated consideration is that, in the course of human evolution, our body (including the endothelium) has evolved to maximize fitness in a far earlier era, perhaps tens of thousands of years ago, which is the time it takes for the gene pool to be filtered by natural selection. In Chapter 16, Eaton and his colleagues write about the environment and lifestyle of the hunter-gatherer, and remind us about the importance of cultural (as distinct from genetic) evolution in mediating the modern-day predisposition to atherosclerosis. As another example of how evolutionary theory may be applied to an understanding of human disease, Haig discusses how evolutionary conflicts between maternal and fetal genes may underlie the pathophysiology of preeclampsia (Chapter 17).

Piecing together the evolutionary origins of the endothelium is challenging and necessarily speculative. Because the human endothelium does not fossilize, interpretations rely on a combination of molecular phylogeny and comparative biology/physiology, with the assumption that what works for extant organisms may have worked for ancestral species. In Chapter 14, McVey demonstrates how molecular phylogenetic

approaches may be used to gain insights into the evolutionary history of the endothelium. In Chapter 3, Burggren and Reiber provide a comprehensive overview of the comparative biology of cardiovascular systems. Based on these data, they offer possible explanations for the evolutionary origins of a vascular lining. However, as they readily acknowledge, the selective pressures underlying the transition from an epithelial-like cell layer in invertebrates to a true endothelium in vertebrates remain enigmatic.

Endothelial cells (ECs) are absent in invertebrates, cephalochordates, and tunicates, but present in the three major groups of extant vertebrates: hagfish (myxinooids), lampreys, and jawed vertebrates (gnathostomes). The last common ancestor of hagfish and gnathostomes was also the last common ancestor of all extant vertebrates, which lived at some time more than 500 million years ago. As discussed by Aird in Chapter 6, the fact that the endothelium is shared by jawless and jawed vertebrates is evidence that the endothelium was present in this ancestral vertebrate. The absence of endothelium in amphioxus indicates that this structure was not present in the common ancestor of cephalochordates and vertebrates, and must have evolved following the divergence of amphioxus from vertebrates, between 550 and 510 million years ago (Figure 2.1).

### WHY STUDY COMPARATIVE ENDOTHELIAL BIOLOGY?

In addition to providing insights into the evolutionary origin of the endothelium, comparative studies also provide powerful conceptual frameworks for approaching the physiology and pathophysiology of the human vascular system. From the standpoint of oxygen (O<sub>2</sub>) transport, the body plan of vertebrates (and many invertebrates) may be simplified according to the scheme shown in Figure 2.2. According to this model, O<sub>2</sub> delivery (hence consumption) is governed by two principal forces: diffusion and convection. Diffusion takes

<sup>1</sup> The application of evolutionary principles to an understanding of human health and disease represents the foundation of a fledgling field termed Darwinian medicine, as reviewed in Nesse RM, Williams GC. Evolution and the origins of disease. *Sci Am.* 1998;279:86–93. See also Nesse RM, Williams GC. *Why We Get Sick. The New Science of Darwinian Medicine.* New York: Crown, 1995.

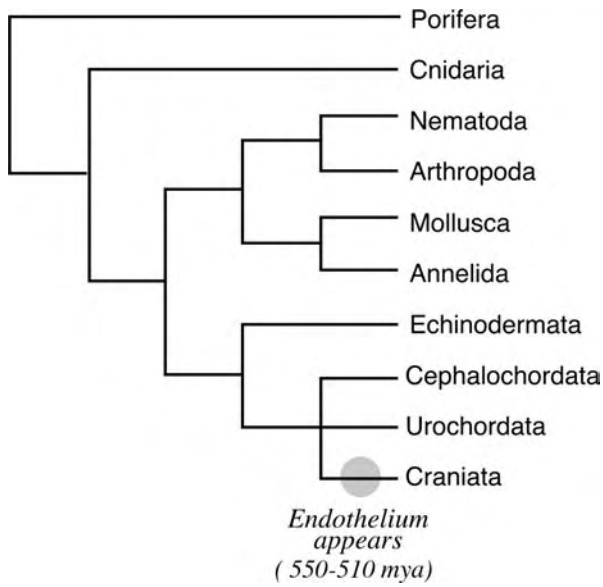

Figure 2.1. Phylogenetic tree.

place between the external environment and a highly vascularized surface and internally between blood and underlying tissue. Convection provides bulk flow delivery of  $O_2$  from the external environment and bulk flow delivery of oxygenated blood throughout the body.

As evidenced by the examples presented in the following chapters, many ways exist to “solve” the fundamental challenge of  $O_2$  delivery. Importantly, each variation conforms to the laws of physics. In fish, diffusion of  $O_2$  occurs in the gills; in terrestrial vertebrates, diffusion of  $O_2$  occurs at the level of alveoli. In both cases, a dedicated pump is present to deliver  $O_2$  by bulk flow. In Chapter 9, Tattersall discusses an interesting exception to the gill/lung paradigm, namely the obligate skin-breathing amphibian. As predicted by Fick’s law of diffusion, the skin of these animals is extremely thin, displays high surface area (by way of skin folds), and comprises a dense capillary network within the epidermis. To compensate for

the lack of a dedicated ventilatory pump, these animals have evolved voluntarily movements (e.g., bobbing) as a means of replenishing  $O_2$  at their skin surface.

Another fascinating exception to the general body plan is the Antarctic icefish, which is discussed by Detrich in Chapter 7. These fish are unique among vertebrates in that they completely lack circulating red blood cells and hemoglobin. As a result, their  $O_2$ -carrying capacity is extraordinarily low. To meet their  $O_2$  requirements, these icefish display several adaptations, including increased cardiac output, mitochondrial density, and capillary density. Detrich offers an interesting hypothesis to explain how the evolutionary loss of hemoglobin (and myoglobin) was physiologically coupled to adaptive changes in capillary and mitochondrial density.

The giraffe, the tallest living land animal on the planet, experiences unparalleled gravitational forces and requires special adaptations to prevent gravity-dependent edema in the legs. As discussed by Hargens and his colleagues (Chapter 12), a consideration of these adaptations illuminates the importance of the Starling-Landis law, and provides potential insight into mechanisms underlying autonomic dysfunction and postural hypotension in humans, as occurs in the elderly.

Icardo’s chapter on fish endocardium demonstrates not only that endothelial heterogeneity exists in early vertebrates (teleosts), but also that certain homeostatic mechanisms (e.g., secretory function, scavenger function) may be carried out by distinct organs and/or vascular beds across species, again pointing to different solutions to similar problems and challenges (Chapter 8).

The shrew is the smallest mammal on the planet. The physiology of the shrew, which is reviewed by Jürgens in Chapter 13, emphasizes the importance of scaling. Scaling is the structural and function consequences of a change in size (or in scale) among similarly organized animals. When considering mammals, certain properties scale in direct proportion (exponent 1.0) to body size. For example, although the heart size is larger in an elephant than a mouse, the heart represents 0.6% of the total body mass in each animal. Other properties

Figure 2.2. Body plan of vertebrates. This schematic simplifies oxygen transport according to four steps: (1) convection of oxygenated air or water from environment to a highly vascularized surface (skin, gills, or lungs); (2) diffusion of  $O_2$  across the gas exchanger into the blood; (3) convection of oxygenated blood around to the various tissues of the body; and (4) diffusion of oxygen to the individual cells of the tissues. (Adapted with permission from Weibel ER. *The Pathway for Oxygen: Structure and Function in the Mammalian Respiratory System*. Cambridge: Harvard University Press, 1984.)

that scale in simple proportion to body weight are lung volume, tidal volume, and blood volume. In contrast, some features exist that do not scale proportionately with weight. The most widely studied of these is basal metabolic rate or  $O_2$  consumption (hence,  $O_2$  delivery). Consider for example an elephant and a mouse. Although the elephant weighs 1 million times the mouse, each gram of mouse tissue consumes more than 100 times the amount of  $O_2$  compared with each gram of elephant tissue. In other words, the rate of  $O_2$  consumption per gram decreases with increasing body size. It has been hypothesized that the high surface area:volume ratios of smaller animals result in greater evaporation, thus necessitating higher rates of  $O_2$  consumption (metabolic heat) to maintain body temperature. Arguing against this supposition (as the sole explanation) is the observation that “cold-blooded” invertebrates also demonstrate regression lines with similar slopes.

### WHY STUDY DEVELOPMENT?

The circulatory system is the first functional organ to develop in the embryo. This is intuitive, because all other organs depend on bulk flow delivery of  $O_2$  and nutrients. Moreover, as mentioned below and covered in more detail by Lamert (Chapter 22), ECs provide important cues for the development of other tissues and organs. Many human diseases involve abnormalities in blood vessels. Signaling mechanisms are likely to be conserved between adult and developmental blood vessel formation. An important goal in regenerative medicine is to induce the formation of new blood vessels in certain ischemic diseases. Blood vessel growth is an important therapeutic target in diseases associated with excessive angiogenesis, including tumors, retinopathy, and rheumatoid arthritis.

Vasculogenesis, the process that describes the in situ differentiation of endothelial precursor cells (angioblasts) from embryonic mesoderm, results in the formation of the earliest vascular plexus (also termed *primary capillary plexus*) in the embryo proper. In a process common to all vertebrates, these angioblasts, once differentiated, migrate to the trunk midline and coalesce to form the primary axial vessels – the dorsal aorta and cardinal vein. In some cases, angioblasts differentiate directly from mesodermal cells, whereas in other cases they differentiate from an intermediate cell type, the hemangioblast. As discussed in several of the chapters in this section, the molecular basis of mesoderm-to-angioblast and mesoderm-to-hemangioblast-to-angioblast differentiation is an area of intense research interest. Among the mediators implicated are fibroblast growth factor, Indian hedgehog, and vascular endothelial growth factor (VEGF)-A.

Later development of the mature vessel system involves angiogenesis, with proliferation and sprouting of new vessels from existing ones. Sprouting angiogenesis<sup>2</sup> is controlled

by gradients of extracellular matrix-bound growth factors interacting with specialized cells at the growing edge of the vessel, termed tip cells. These latter cells express growth factor receptors and possess filopodia for “exploring” the microenvironment. Programmed branching, or stereotypic patterning, of new blood vessels is governed by a delicate balance of attractive and repellent guidance cues. Increasing evidence suggests that these cues (e.g., ephrins, semaphorins-neuropilins, netrins, and Robo-Slit) play a common role in mediating the patterning of both blood vessels and nerves (these mechanisms are covered in Part II of this volume).

Arterial-venous (A-V) identity is determined before the onset of blood flow. Several markers of arterial versus venous endothelium exist. Based on studies in zebrafish and mice, some of these markers have been shown to play a role in determining venous-arterial identity, including notochord-derived sonic hedgehog, somite-derived VEGF-A, and endothelial-derived Notch, gridlock, EphB4, and ephrinB2. The prevailing view is that Notch induces arterial fate by suppressing venous phenotype. Stabilization or maturation involves the recruitment of mural cells, a process that involves transforming growth factor (TGF)- $\beta$ , TGF- $\beta$  RI and RII receptors, platelet-derived growth factor (PDGF)-B, PDGF-R $\beta$ , and angiopoietin-Tie2 interactions (these mechanisms are covered in Part II of this volume).

Advances in the field of vascular development are based on complementary approaches. Some investigators focus on mice, others on fish (zebrafish), amphibians (*Xenopus*), or birds. Mice have the advantage in that they are closer to humans and are amenable to knockout and overexpression studies (see Chapter 20). As discussed by Chopra and Zhong in Chapter 19, fish develop externally from the mother, are optically clear, receive their  $O_2$  via passive diffusion (and can thus survive in absence of blood vessels), and are amenable to unbiased forward genetic analysis. In Chapter 18, Patient and his colleagues review the benefits of studying vascular and endothelial ontogeny in *Xenopus*. Like zebrafish, aquatic frogs are easy to maintain and develop externally. Moreover, frog embryos lend themselves to microinjection and microdissection. An advantage of the bird as a research tool is that it is amenable to transplantation studies (reviewed by Poole in Chapter 10). Certain labs focus on a signaling pathway, for example VEGF/FLK-1, throughout development and even into the postnatal and adult periods. Others place their investigative lens on a certain developmental process, such as A-V identity, which requires an understanding of multiple ligand-receptor pairs.

Two important caveats must be stated. First, while much attention is being paid to genetic predeterminants of arterial and venous fate, increasing evidence suggests that many of these properties are plastic and are in fact critically dependent on the microenvironment (particularly blood flow). Second, vasculogenesis is not confined to early stages of embryogenesis, but continues to play an important role throughout development and into adulthood.

2 Another form of angiogenesis is termed *intussusceptive angiogenesis*.

## THE ENDOTHELIUM SEEN FROM THE PERSPECTIVE OF EVOLUTIONARY DEVELOPMENTAL BIOLOGY

As we have said before, establishing the exact evolutionary history of the endothelium involves a lot of conjectures. We can readily establish the molecular phylogeny of certain crucial genes, such as VEGF (Chapter 14), or provide an argument as to why an endothelial lining of the vascular system is a beneficial, or even crucial, adaptation of larger organisms, and why we would expect that natural selection favored these structures (Chapter 3). All these studies and associated ideas contribute to our understanding of the evolution of the endothelium. But they do not yet provide us with a detailed mechanistic understanding of the origin and evolutionary history of the endothelium. For this, we must realize that at one point the endothelium had to originate within an ancestral condition; in other words, at one point in the course of evolution the endothelium emerged as an evolutionary novelty. In all likelihood, the emergence of the endothelium was a gradual process – we do not expect such a complex structure to come into being all at once – but nevertheless, the specific developmental changes and differentiations leading to the formation of what His called the “membranes of the inner cavities” (see Chapter 1) began at some point in evolutionary history. From what we have said so far, it is clear that any explanation of evolutionary novelties necessarily involves an account of how these structures develop ontogenetically in the first place, as well as how they were subsequently modified in the course of evolution. Such explanations – involving both developmental (i.e., proximate) and evolutionary mechanisms – are the purview of the relatively new discipline of evolutionary developmental biology (also termed *Evo Devo*).<sup>3</sup> The endothelium as a crucial innovation in the evolution of higher organisms and a rather diverse structure, both ontogenetically and phylogenetically, is thus a prime candidate for an *Evo Devo* analysis (Figure 2.3).

Methodologically, evolutionary developmental biology combines approaches from developmental and evolutionary biology to explain the patterns and processes of phenotypic evolution. Besides the notion of evolutionary novelties, one of the central concepts in *Evo Devo* is the idea of constraints as a limiting factor on phenotypic variation. All the chapters in this section, especially Burggren and Reiber’s overview of the comparative and evolutionary biology of vascular systems (Chapter 3), point out that the circulation of gases and nutrients is one of the central problems of animal physiology. In many organisms, especially those of a particular size

3 All evolutionary transformations, although they manifest themselves on a population level, must materialize within the constraints and possibilities of a functioning developmental system of individual organisms. Although developmental biology focuses on individual developmental sequences describing the transformation from simple (a fertilized egg) to complex (an adult organism) through the differentiation of cells and the emergence of anatomical and histological structures, *Evo Devo* tries to understand how in the course of evolution something new can emerge within these regulated developmental sequences.

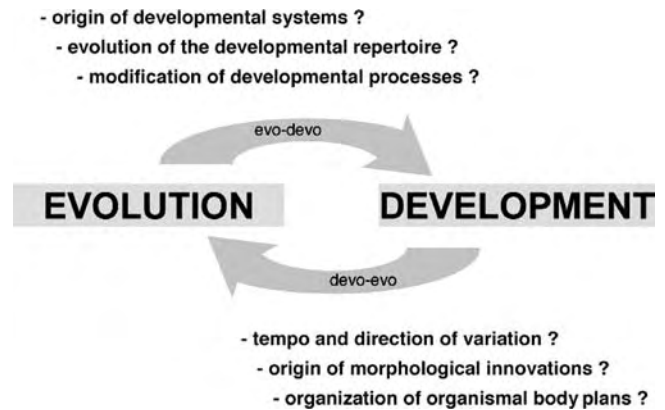

Figure 2.3. The dualistic structure of *Evo Devo* questions. The two subagendas, *evo-devo* and *devo-evo*, address different kinds of questions. For the study of the endothelium these involve: (a) the developmental origins of the endothelium; (b) the evolution of the developmental trajectories of the endothelium; and (c) their modification; (d) the phylogenetic differentiations of vascular systems and their lining; (e) the endothelium as an evolutionary novelty; and (f) the organization of a generalized vascular system (body plan).

and activity level, a circulatory system is an essential component of organismal design and, given the limitations set by the physics of gas exchange and diffusion, a closed system with a vascular lining provides an optimal solution to these challenges. This engineering perspective on organismal design can be combined with evidence from the evolutionary history and developmental mechanisms to arrive at a better understanding of the origin of vascular systems. In the course of evolution, several different types of circulatory systems emerged in different lineages, in part as independent evolutionary events or novelties, in part as modifications of existing ancestral designs. All these circulatory systems represent a way to overcome the functional limitations imposed by the basic physical laws of diffusion.

Changes in organismal design are limited by certain functional and physical constraints. Moreover, the patterns, mechanisms, and historical contingencies of individual development also constrain what kind of phenotypic variations are possible (so-called developmental constraints).<sup>4</sup> The structure of the vascular system and the endothelium is no exception. Comparative studies of the structure and formation of the

4 The concept of constraint has received a lot of attention in evolutionary biology, and a variety of different types of constraints have been proposed. Constraints are seen to have two different effects on the patterns of phenotypic evolution: (a) *limiting*, in the sense that certain phenotypes are not possible for a variety of different reasons, such as architectural constraints – when certain shell shapes in bivalves are geometrically not possible; functional constraints – in cases where the diameter of a vessel is too large, so that the pressure is too low to assure blood flow; or developmental constraints – when certain phenotypes cannot be realized within the existing developmental systems of certain lineages; and (b) *enabling*, in the sense that preexisting aspects of developmental systems facilitate certain types of novel phenotypic variants. See Maynard Smith J, et al. Developmental Constraints and Evolution. *Q Rev Biol* 1985;60:265–287 for a discussion of developmental constraints and Kirschner M, Gerhart J. *The Plausibility of Life*. New Haven: Yale University Press, 2005, for a discussion of the idea of facilitated variation.

vasculature, and more specifically the endothelium, reveal these trends and illustrate exactly what kind of phenotypes are possible based on certain invariant properties of vascular architecture and vascular development. An example of an architectural constraint is the closed-loop geometry and branching pattern of the vascular tree, which of necessity engender microdomains of disturbed flow at curvatures and bifurcations, respectively. Previous studies have established that ECs in these regions are primed for activation and vulnerable to disease (see Chapter 28). There is simply no way around this constraint. As another example, the differentiation of mesoderm-derived angioblasts into ECs, which is common to all vertebrates, must involve certain core processes whose disruption would compromise the very development of this cell layer. These core mechanisms, then, place a boundary on the nature and degree of phenotypic variation. A less theoretical and more practical consequence of these phenomena can be seen in the maternal–fetal conflict, described by David Haig (Chapter 17). Haig’s analysis also makes it clear that many solutions to functional challenges represent compromises between different functional demands and are therefore not optimal for any one given task.

Developmental constraints, however, do not just limit the phenotypic possibilities of organismal design. Quite the contrary, they also enable phenotypic evolution in the first place. Indeed, the very regulatory programs that mediate core biological processes also serve as an important substrate for modification and natural selection. Françoise Jacob once described phenotypes as the result of *bricolage*, an opportunistic assembly of contingent properties of biological systems.<sup>5</sup> But this process is far from being random, as the term *bricolage* might suggest. Rather, the historical and developmental constraints of biological systems, while limiting the range of possible phenotypes in one sense, are also the foundation for the future evolution (evolvability) of these systems in the first place. Marc Kirschner and John Gerhart have recently called this property of biological systems *facilitated variation*.<sup>6</sup> Facilitated variation is a consequence of the constraints of developing systems, and mediates between random mutations and the more structured expressions of observable phenotypic variation. We can see how the evolutionary history of the vascular system and the endothelium (as described in the chapters of this section) is a case of facilitated variation that enables certain evolutionary modifications, while at the same time ruling out alternative solutions (see Figure 2.3).

The last topic of interest in the evolution of the vascular system and the endothelium that we want to discuss here are the mechanisms that largely make evolution of the endothelium possible. Recent studies in comparative genomics have shown that only a small number of often highly conserved genes are responsible for the observed diversity in phenotypes. It has

thus become clear that phenotypic evolution is mostly a consequence of changes in regulatory gene networks and/or epigenetic control mechanisms, rather than downstream effector genes. This emphasis on regulatory evolution provides an important interpretative framework for the evolution of the endothelium. For example, it is likely that the mutation and selection of a small number of pre-existing regulatory genes (e.g., transcriptional control circuits) permitted the evolution of the endothelium. It is far less likely that the appearance of a completely novel gene, or the simultaneous mutation of multiple functional genes (e.g., those involved in mediating vasomotor tone, hemostasis, and leukocyte trafficking), was responsible for this event.

Regulatory changes, both ontogenetically and phylogenetically, operate through a complex web of signaling, gene activation, and cell-to-cell communication events based on complex signaling pathways and regulatory networks. As Mikawa shows in Chapter 21, fate mapping studies have revealed some of the details of the timing and location of vascular cell commitment and differentiation. Detailed studies of ECs throughout the vascular system of individual organisms have shown high degrees of localized specialization, as is evidenced by the variations in their functional properties and their molecular signatures and gene expression profiles (reviewed in Part II). Although some site-specific phenotypes are epigenetically programmed (i.e., rendered mitotically heritable), others are maintained through spatial and temporal differences in the extracellular microenvironment.

Kirschner and Gerhart argue that phenotypic diversification in multicellular organisms has evolved in the context of relatively fixed, basic body plans.<sup>7</sup> They propose a series of mechanisms by which the inherent constraints of core biological processes are reduced and allow for evolvability. Among these mechanisms for deconstraining evolutionary change is exploratory behavior, as exhibited by the genesis of neuronal connections and angiogenesis. Exploratory mechanisms are flexible and robust, and these are the very properties that are highly conserved.

Angiogenesis is a well established example of functional selection. Although large vessels are probably placed by instructive processes, moderate and small vessels are not, as indicated by bilateral differences in pattern. In the vascular system (and in the analogous tracheal system in insects), local oxygen deprivation may play a role in controlling the growth and branching of moderate and small vessels.<sup>8</sup>

These principles may be more broadly applied to the endothelium. The endothelium evolved in the common ancestor of vertebrates, presumably through one or a series of mutations in regulatory genes involved in mesoderm function.

5 F. Jacob. Evolution and tinkering. *Science*. 1977;196:1161–1166.

6 Kirschner M, Gerhart J. Evolvability. *PNAS*. 1998;95:8420–8427, and M. Kirschner M, Gerhart J. *The Plausibility of Life*. New Haven: Yale University Press, 2005.

7 Viewed from this perspective, the endothelium was an “add-on” structure to the basic body plan of chordates, the so-called *pharyngula*.

8 Kirschner M, Gerhart J. Evolvability. *PNAS*. 1998;95:8420–8427.

Such changes did not compromise the basic body plan, but rather built upon that plan. The endothelium evolved as an exploratory system, meaning that, although its requirements for effective function are minimal, it has a remarkable capacity to sense and respond to extracellular signals and is thus able to adapt to the diverse needs of the local microenvironment.

The actual state or differentiation of individual cells is thus a consequence of rather complex regulatory contexts

that often involve genetic, epigenetic, and environmental factors. In some cases, these decisions can be reversed, at least to some degree, whereas in others differentiation is irreversible. The diversity of ECs is thus a consequence of context-specific effects. Understanding these properties of ECs and their differentiation has enormous therapeutic implication, because clinical interventions often must be tailored to rather specific locations.

## Evolution of Cardiovascular Systems and Their Endothelial Linings

The evolution of large, multicellular, complex metazoans from their simple unicellular animal ancestors comprises a rich history covering many hundreds of millions of years. Pieced together from fossil remains, DNA analysis, and comparative morphological studies of extant animals, biologists have described a staggering array of adaptations that have arisen (and in some cases been lost and arisen again) through the course of animal evolution. Describing the specific evolutionary pathways from unicellular organisms to human is, of course, well beyond the scope of this chapter. Rather, in this chapter, we focus specifically on the general evolutionary pathway leading to the cardiovascular systems of extant animals, especially highlighting the general principles that continue to shape cardiovascular form and function to this day. In doing so, we intend to create a backdrop and context for other chapters in this book that present more specific information on the vascular endothelium in specific groups of animals (e.g., fish, amphibians, reptiles, birds, and mammals).

Before delving into cardiovascular systems and their evolution, we first must address a semantic issue regarding our use of the term *endothelium*. The invertebrate literature is replete with discussions of “endothelium” – whether it exists, whether it is discontinuous or continuous, what functions it serves, and the like. Much less often, the vascular lining of blood spaces (where it occurs) in invertebrates is described more generically as a “vascular cellular lining.” Of note, the position taken in this book is that “true” endothelium is found only in vertebrates, and it has distinguishing characteristics, such as being derived from a lateral plate mesoderm, possessing caveolae and Weibel-Palade bodies, and more. Although the vascular cellular linings in some invertebrates are analogous to the endothelium of vertebrates, these linings are not necessarily homologous. Consequently, in this chapter we carefully distinguish between the two tissues, although in fact their functions may overlap extensively. Future research directed specifically at a comparison and contrast of the cells that line vascular spaces is much anticipated.

Now, let us consider why animals have cardiovascular systems – lined or unlined.

### WHY DID CARDIOVASCULAR SYSTEMS EVOLVE?

A key feature of almost all complex metazoans is that they have an internal system for the convection of body fluids – a cardiovascular system. Although enormous species diversity exists in cardiovascular form and function, fundamental components include a fluid pump (or pumps) that propel often specialized body fluids into a series of distribution, exchange, and collection vessels. Numerous variations occur on this basic circulatory plan of heart and vessels, ranging from the relatively low pressure, “open” circulation of many invertebrates to the typically higher pressure, closed system of vertebrates. Yet, the almost ubiquitous presence of a circulatory pumping of fluid through vessels begs the following questions: “*Why did cardiovascular systems evolve?*” The answer, as is often the case in biology, is to be found in chemistry and physics.

A feature common to both the earliest single-celled animals and today’s 100-metric ton blue whale is that they both ultimately depend on diffusion to supply oxygen (O<sub>2</sub>) and nutrients to, and remove carbon dioxide (CO<sub>2</sub>) and wastes from, their intracellular sites for oxidative metabolism. Perhaps because physiologists often study diffusion over the ultrathin boundaries between blood and gas in the alveolus, or blood and tubular fluid in the nephron, we tend to attribute near-magical properties to the process of diffusion. In reality, diffusion is a highly imperfect physico-chemical process for the bulk movement of material. Although energetically inexpensive, diffusion is also a very slow process; a diffusing molecule takes a very long time to move by diffusion alone. Indeed, it is precisely because diffusion is so slow that the ultrathin boundaries of the alveolus, nephron, and other structures have evolved to reduce transmembranous diffusion times and thus maximize the bulk diffusion of molecules, ions, and other particles.

The transmembranous diffusion of molecules depends on several factors including the pathway length for diffusion, surface area across which diffusion occurs, molecular weight of the diffusion molecule, solubility of the substrate

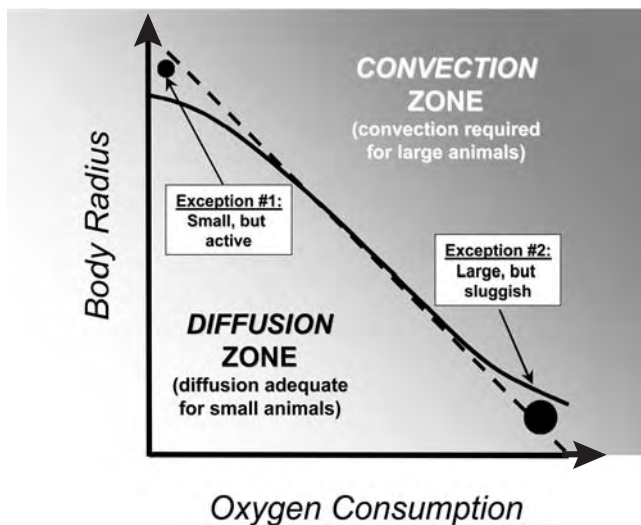

Figure 3.1. The role of diffusion and convection in the  $O_2$  consumption of animals of different body size. Generally, small animals can thrive on diffusion alone, because the diffusion distances are small. The larger an animal's body radius, the more it depends on convection to support its  $O_2$  consumption. However, very small yet active animals may require internal convection for delivery of  $O_2$ , whereas large but inactive animals may exist on diffusion alone.

for the diffusion molecule and, of course, the partial pressure or concentration gradient for the diffusion molecule. As a general rule of thumb, a hypothetical animal with a cylindrical shape, expressing a modest metabolic rate of about  $100 \mu\text{mol } O_2/\text{sec}$  in a fully oxygenated environment, could survive on diffusion alone for its transport until it grew beyond a radius of about 2 mm (Figure 3.1) (1). Beyond this radius, diffusion alone cannot provide for substrate delivery and byproduct removal.<sup>1</sup> Some animals without internal circulations considerably exceed this size by having a very low metabolic rate, especially when combined with a large surface area-to-volume ratio—for example, the large, pancake-like marine Polyclads (Platyhelminthes) – as well as a modest internal convection system created by the muscular contractions of the animal's body wall during locomotion. Conversely, some animals with high metabolic rates, although near microscopic and thus possessing short diffusion distances, have evolved circulations for the internal transport of nutrients, wastes, and respiratory gases (e.g., small crustaceans) (see Figure 3.1).

Thus, the physico-chemical limitations of diffusive  $O_2$  supply (together with the attendant limitations on the diffusion of  $CO_2$ , metabolic substrates, and nitrogenous and other wastes) have likely served as a strong selection pressure for the evolution of internal cardiovascular systems. Let us now consider the diversity of cardiovascular systems, beginning with relatively simple invertebrate systems and moving to the high-

pressure systems used to perfuse large, complex vertebrate homeotherms.

### CONVECTION OF INTERNAL BODY FLUIDS: DIVERSITY OF EVOLUTIONARY ADAPTATIONS

The mechanisms by which fluids are moved through a circulatory system evolved in loose association with both the complexity of the conduit system and particular species' metabolic demands. The advent of a "true" centralized muscular pump—that is, a heart that generates the pressure gradients used to move fluids (hemolymph or blood) through the circulatory system—is common in a variety of forms and to a broad array of animal taxa. Importantly, the evolutionary lineages of these pumps and their associated circulatory systems have multiple phylogenetic origins. Consequently, identifying homologous structures that cross phyla is difficult at best. It is, however, possible to identify analogous components that have arisen independently due to common selective pressures. Thus, distributed throughout the body and evident in a number of phyla are a variety of less familiar systems used to generate fluid pressures to facilitate blood movement and thus gas exchange.

### INVERTEBRATE CIRCULATIONS

The evolution of the invertebrate cardiovascular system is not a continuum of homologous structures seen from taxa to taxa, but rather appears to have evolved independently in several phyla in response to limitations in diffusional gas exchange and high metabolic rates (for a thorough review of invertebrate cardiovascular systems see reference 2). Most invertebrates that have evolved a circulatory system do not show "vertebrate-like" circulatory complexity and lack sophisticated regulatory mechanisms. They also typically generate relatively low flows and pressure (Figure 3.2). Nonetheless, several examples occur in which invertebrates have evolved highly efficient, high-pressure, high-flow systems. These high-performance invertebrate cardiovascular systems show a number of convergent evolutionary<sup>2</sup> traits that are comparable to vertebrate taxa: muscular pumps capable of developing appropriate driving pressures and flows, cardiac regulatory mechanisms, a complex branching circulatory system and, of particular significance, a cell-lined vasculature, to list a few. A current misperception holds that the invertebrate cardiovascular system is sluggish, poorly regulated, and "open," wherein blood bathes the tissues directly as it moves through a system of ill-defined sinuses and/or lacunae, without an endothelial boundary (thus, in part explaining the use of the term *hemolymph* or a blood-lymph mixture versus "true" blood, which is

1 Interestingly, these same principles also apply to the sizes that tumors can achieve without additional circulation.

2 *Convergent evolution* is the evolution of similar characteristics by taxonomically different organisms.

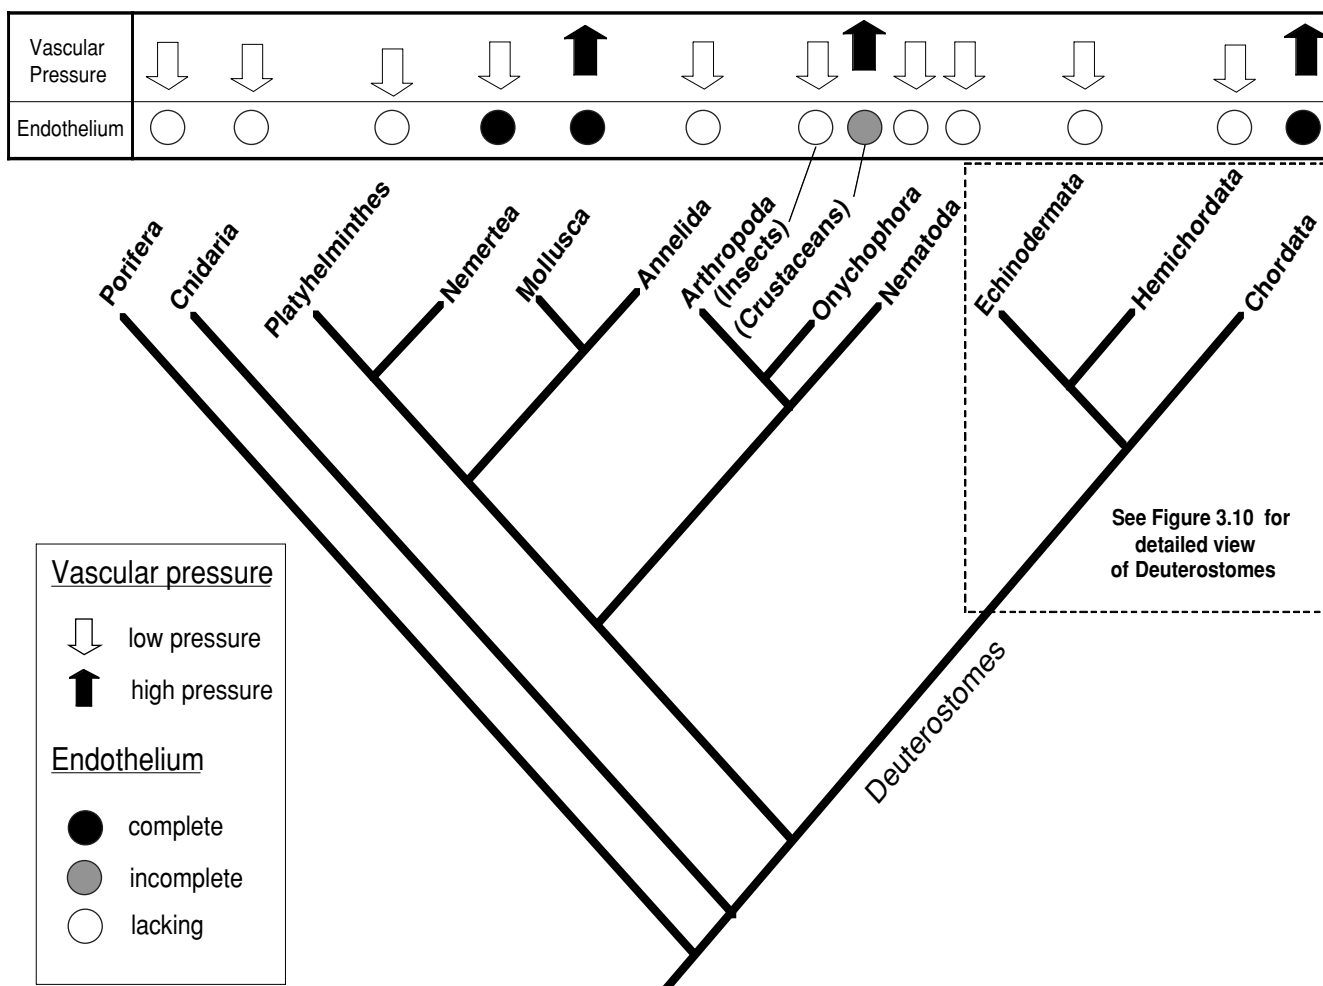

Figure 3.2. An evolutionary tree for showing the origins of the major invertebrate groupings and the appearance of the vertebrates. Also indicated is the presence of a complete or incomplete endothelial vascular lining. The arrows (*down* for low blood pressure, *up* for high pressure) indicate the taxon's blood pressure. (For comparison with vertebrates, see Figure 3.10).

typically contained within defined vessels and capillaries) (3). To the contrary, many invertebrates have evolved partially complete or even continuously cell-lined vessels (as revealed below). Why have both invertebrates and vertebrates coevolved these structures? What are the selective pressures behind the development of such systems? Several corollaries must be investigated, the most interesting being that animals having highly active lifestyles require an efficient pump and delivery system to maintain  $O_2$  delivery (metabolic demand) and thus also require high-pressure, high-flow cardiovascular systems. In most examples of a high-pressure system, the vessels in that system are lined with an "endothelium." Why? The high vasculature pressures observed are the result of a well-developed muscular pump, with fluid contained within a robust arterial system followed by a capillary-like vascular bed to support gas exchange. Does a high-pressure cardiovascular system require the development of a cell-lined vasculature? A review of the literature in the area of invertebrate cardiovascular physiology, followed by a survey of the vertebrates, follows with a specific view toward supporting this hypothesis.

### The Sponges: Internal Circulation of Seawater

One of the simplest yet more interesting pressure-generating systems is that of the phylum Porifera.<sup>3</sup> Sponges have circulatory systems for distributing seawater internally, the architecture of which incorporates a diffuse yet highly efficient pumping and circulatory system (4–5). A brief description of this circulatory system begins where seawater enters the sponge through in-current dermal pores (ostia) spaced throughout the exterior covering of epithelial-like flattened cells (the pinacoderm) (Figure 3.3). Internally, seawater then moves through the in-current canals and into a series of interconnected flagellated or radial chambers (the spongocoel or atrium), then

3 Porifera, a phylum within the kingdom Animalia, consists of approximately 5,000 species of sponges. Sponges are among the simplest animals. It is believed that they evolved from the first multicellular organisms. Sponges are filter feeders and have no true digestive tract; instead, they digest food within cells. They lack the gastrula stage during development, and the three cell layers present are not homologous to the body layers of most animals.

Figure 3.3. Circulatory system in sponges. The sponges are one of the simplest of multicellular animals, yet they have developed an internal circulatory system for the distribution of seawater. (A) The general architecture and cell types are illustrated in a simple Asconoid sponge, shown with arrows indicating the flow pattern of water into and out of the sponge. (B) The more complex pattern of water flow through a Leuconoid-type sponge. (Reproduced with permission from Ruppert EE, Barnes RD. *Invertebrate Zoology*, 6th ed. Fort Worth: Saunders, 1991.)

into major ex-current canals, and ultimately out of the sponge through the osculum (6–7).

Convective water movement through the sponge is generated by the beating action of the flagellated choanocytes that line the spongocoel or flagellated chambers. This noncentralized pump generates sufficient pressure differentials to move a substantial volume of water through the sponge, which facilitates not only filter feeding but also the more “typical” cardiovascular functions of O<sub>2</sub> uptake and waste removal (8–9). Although the historical view of sponge circulation was thought to be both simple and unregulated, it now appears that its pressure–flow dynamics are regulated through simple yet effective mechanisms. Pressures generated by flagellar beating may be started and stopped on a diurnal basis in some species (e.g., Demospongiae, Halichondria) and, in many sponges, changes in ambient water conditions may influence choanocyte flagellar activity. Moreover, flows and pressures can be regulated throughout the various chambers of the sponge by either opening or closing the in-current ostia or by increasing or decreasing the size of the osculum. This regulatory activity is accomplished through the action of specialized mesohyl cells (myocytes), which surround the osculum and act much like vascular smooth muscle cells with regard to contractility. Modulation of osculum radius has a tremendous effect on flow and pressure (10–12), just as modulation of arteriole diameter has profound effects in vertebrate cardiovascular systems.

### The Cnidarian Gastrovascular Cavity

In many invertebrate phyla, “circulatory systems” consisting of muscular pumps generate pressure for the primary purpose of digestion, yet these invertebrates can and do use these systems

secondarily for gas transport and waste removal (13–14). The internal pressure-generating systems of other invertebrates are used primarily for locomotion and are only secondarily adapted to generate pressures for the movement of internal body fluids or ingested food materials. Examples include the radial canals and gastrovascular cavity of the cnidarians<sup>4</sup> (Figure 3.4) and the highly convoluted gut of the Platyhelminthes (discussed in the next section). The primary function of these structures is to provide a large surface area for food digestion and absorption, as well as provide the structural elements for the animal’s hydraulic skeleton. However, the disruption of internal boundary layers to maintain internal diffusion gradients could be an important positive functional consequence of internal convective fluid movement. In the cnidarians, the complex network of gastric pouches and blind-ending cavities of the gastrovascular system allows nutrient uptake by cells located some distance from the pharynx and “stomach” (14). Pressures in the gastrovascular cavity are generated to move food and fluids into and out of the gastrovascular system by the contraction of the locomotory muscles of the velum in more primitive species, by coronal muscles of the subumbrella in jellyfish and, in the more complex sea anemones, via the

4 Cnidaria, a phylum within kingdom Animalia, consists of hydras, jellyfish, sea anemones, and corals. This group has two key characteristics: The first is that all Cnidaria possess stinging or adhesive structures called *cnidae*, and each *cnida* resides in a cell called a *cnidocyte*; the most common example of which belongs to the nematocysts. The second characteristic most directly related to this chapter is that the mouth leads directly into the gastrovascular cavity (a digestive cavity). Because no anus is present, excess food and waste products must exit through the mouth; thus, the digestive system is considered incomplete. This gastrovascular cavity is filled with fluid that services internal cells, provides body support, and helps maintain structure.

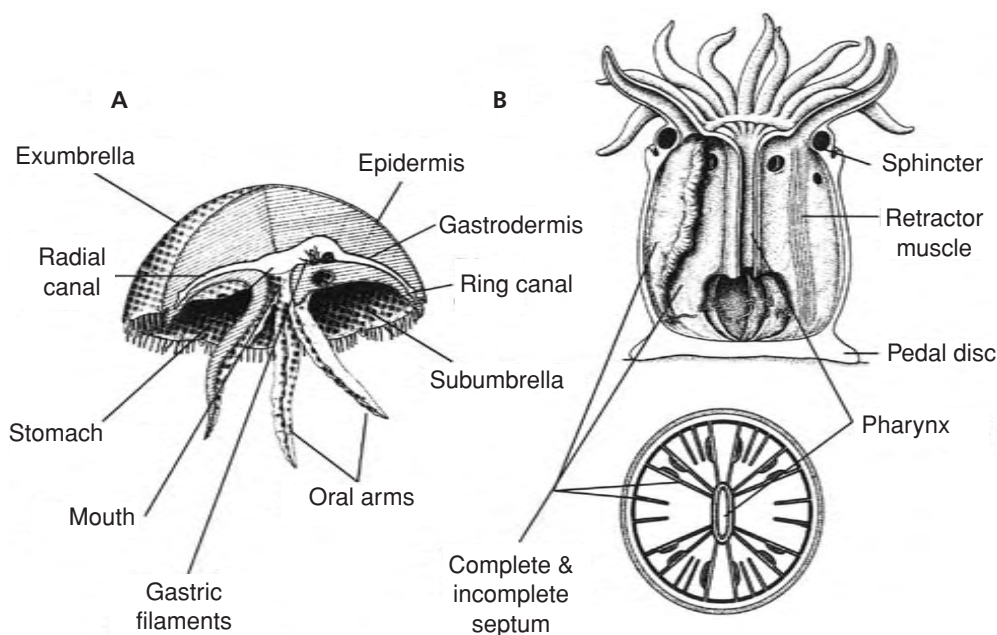

Figure 3.4. Circulatory system in cnidaria. The cnidaria are able to make dual use of their mouth, stomach, and gastrointestinal track for both ingestion and digestion but also to generate internal pressures and circulate fluids. (A) This panel illustrates an Aurelia jellyfish showing the mouth, stomach, gastrodermis, and radial canal. (B) The internal structure of a sea anemone shows a more complex series of internal compartments that are used to both increase the internal surface area for nutrient absorption as well as an internal pressure-generating system. (Reproduced with permission from Ruppert EE, Barnes RD. *Invertebrate Zoology*, 6th ed. Fort Worth: Saunders, 1991.)

digestive septal retractor muscles and pharynx (15–16). Given the size of some of the cnidarians and the complexity of the gastrovascular cavity, gas exchange is likely also facilitated by the pressure-driven movement of fluid throughout the body of these animals.

### The Platyhelminth Gut

The phylum Platyhelminthes (flatworms),<sup>5</sup> and specifically the marine polyclads of the class Turbellaria, exhibit similarities to the cnidarians with the potential for their highly convoluted gut to facilitate both digestion and nutrient/gas exchange (Figure 3.5). Platyhelminths can be active predators that can grow to several centimeters in width and length. The larger size and active nature of these animals requires not only a well-developed gastrovascular system (gut) but also some form of internal fluid circulation to support nutrient, waste, and gas exchange, which may be seen in the pseudocoel of

some turbellarians (17–20). It would appear that both the larger size of these animals and their more active behavior are in part possible because of their highly convoluted gut, which provides a very large surface area for the exchange of nutrients and other fluids.

### Nemerteans: The First Cell-Lined Circulatory System

The first true cell-lined “circulatory system” is seen in the nemerteans or ribbon worms (21–22). The relatively large body size and robust muscular body wall of ribbon worms presents a significant barrier to diffusion and thus requires internal convective fluid flow through the action of a blood circulatory system that facilitates gas exchange, nutrient cycling, and waste removal (23). Additionally, a second, rhynchocoel circulatory system is used to perfuse the head and proboscis and also functions as a hydrostat to evert the proboscis for feeding (24–26). In its simplest form, the nemertean circulation consists of two lateral vessels that parallel the gut and anastomose at the anterior and posterior ends of the animal. More complex nemertean circulatory systems (e.g., as in *Tubulanus* and *Amphiporus*) have an additional dorsal vessel with multiple connecting transverse vessels (Figure 3.6) (27).

The vessels of this system are surprisingly complex, with a complete vascular cell lining that, in some species, consists of myo-epithelial cells with cilia facing into the vessel lumen (26–27). The vessels are surrounded by both circular and longitudinal muscle to facilitate vascular contractions that, in combination

5 The phylum Platyhelminthes includes all flatworms in the kingdom Animalia. Platyhelminthes are bilaterally symmetrical, having an anterior, posterior, dorsal, and ventral end and two seemingly identical lateral surfaces. However, flatworms lack any type of body cavity or fluid-filled space located between the digestive tract and the body wall. In flatworms, this area is filled with tissue. Flatworms have primitive brains, comprised of clusters of nervous tissue and two long nerve cords that run the length of the body. These cords branch to form small nerves running throughout the body. Another hallmark of flatworms is the lack of a complete digestive tract. Flatworms take in food and excrete waste from one single opening.

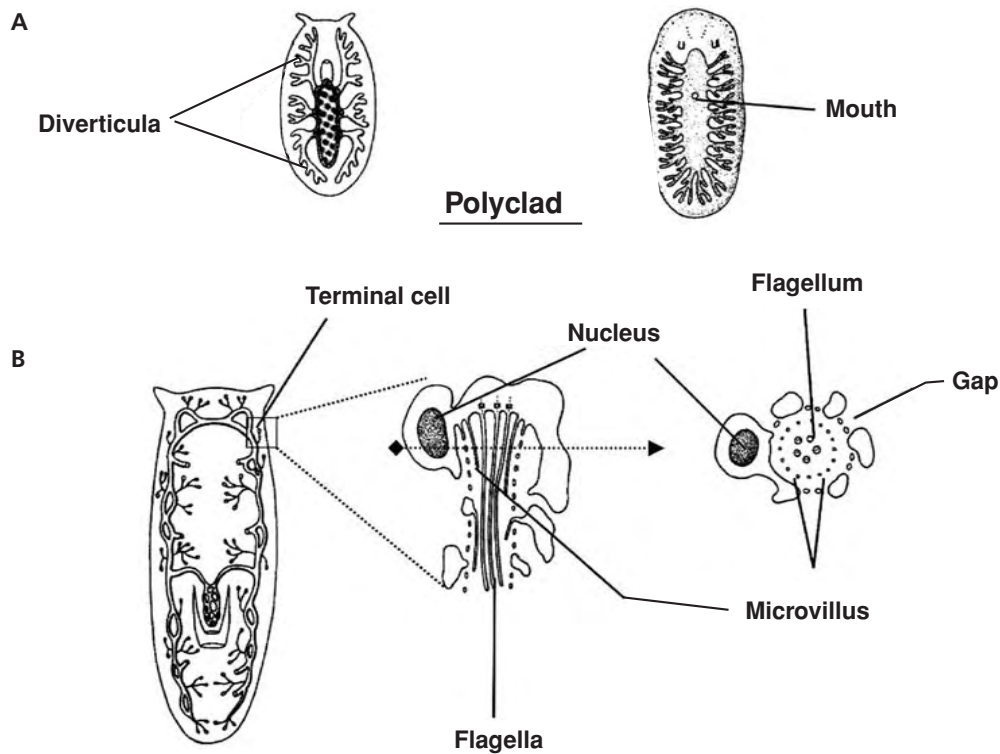

Figure 3.5. Circulatory system in platyhelminthes. The gut of the platyhelminths can show extensive diverticula, as is the case in the polyclads. These diverticula, which are small and vessel-like, serve to increase the absorptive surface area and distribute nutrients throughout the animal (A). An extensive network of complex anastomosing ducts interconnect the protonephridia (primitive renal structures) of the Turbellaria. The terminal cells of the protonephridia end within the tissues, where nitrogenous waste as well as other fluids are accumulated and then transported to exterior pores via ciliary action (B). (Reproduced with permission from Ruppert EE, Barnes RD. *Invertebrate Zoology*, 6th ed. Fort Worth: Saunders, 1991.)

with contractions of the body wall, provide the pressures to move blood within the circulatory system. The presence of a vascular cell lining is unique at this phylogenetic level and complexity within invertebrates, and it closely resembles the coelomic lining of other coelomate invertebrates. Thus, the nemertean circulatory system is proposed to have its evolutionary origins as specialized coelomic channels that have become secondarily adapted to perform circulatory functions. The myoepithelial differentiation of these coelomic cells has given rise to the endothelial lining (23,28–29). Debate exists as to the functional role of this “endothelium” or, more correctly stated, “vascular cell lining” with regard to its permeability, diffusional characteristics, and functional impact on hemodynamics, none of which has been investigated (29). Equally interesting is the tight integration between the nemertean circulatory system and the protonephridia of their excretory system. It would appear that, in some species, the protonephridia take advantage of significant circulatory pressures to aid in nephridial filtration for purposes of osmoregulation, and potentially, nitrogen excretion (29). An analogous situation exists in some platyhelminths, in which a proteonephridial system is integrated with the fluid-filled spaces of the pseudocoel. In the nemerteans, however, these two systems appear to be more functionally linked, with circulatory pressures driving filtration.

### The Molluscan Cardiovascular System: High Efficiency Muscular Pumps

With the exception of a fluid circulation within the pseudocoel of a variety of coelomate worms (four minor phyla comprising fewer than 600 species – the Sipuncula, Echiura, Pogonophora, and Vestimentifera) and the lacunar system found in the epidermis of the acanthocephalans, which are not cell-lined systems and do not appear to take on a significant circulatory role in terms of pressure development or flow, few examples of circulatory systems and no examples of centralized pumps (“hearts”) are seen until the advent of the molluscs<sup>6</sup> (23,30). Members of this phylum have developed extensive circulatory networks, with highly efficient centralized pumps (true hearts,

6 The phylum Mollusca is made up of over 150,000 diverse species. All molluscs have a muscular foot used for locomotion, as well as a mantle, an outgrowth that covers the animal. Molluscs have a coelom, which is developed from solid cell masses. Thus, all species in this phylum are protosomes. All organs are suspended in mesentery tissue within this mesodermic coelom, between the outer covering (ectoderm) and the digestive tube (endoderm) of the animal. The phylum Mollusca includes the following classes: Aplousophora (solenogasters), Monoplousophora, Polyplousophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams and oysters), Scaphopoda (tusk shells), and Cephalopoda (nautilus, squids, cuttlefish, and octopi).

Figure 3.6. Circulatory system in nemerteans. The nemerteans show the first endothelial-lined circulatory system (A), which not only facilitates the movement of blood to promote gas exchange but also is integrated tightly with the excretory systems (B), which are pressure-dependent. (Reproduced with permission from Ruppert EE, Barnes RD. *Invertebrate Zoology*, 6th ed. Fort Worth: Saunders, 1991; and Turbeville JM. Nemertinea. In: Harrison FW, Bogitsh BJ, eds. *Microscopic Anatomy of Invertebrates*. New York: Wiley-Liss, 1991.)

composed of cardiomyocytes and capable of generating pressures and flows comparable to some lower vertebrates); these hearts function in an integrated fashion with a variety of other physiological systems (Figure 3.7). Moreover, the most complex molluscs (the highly active cephalopods) have evolved a cell-lined vascular system able to generate pressures and generally perform at a level comparable to some of the simpler vertebrates (3,22,29).

The generalized molluscan body plan has been extensively modified in both form and function to allow this group of animals great adaptive radiation (23,31–33). With specific regard to the heart and circulatory system, the typical mollusc (monoplacophorans and cephalopoda) has evolved a robust muscular heart consisting of a ventricle supplied by two atria or auricles, which drain the gills and sit within the coelomic cavity (the pericardial chamber) (34). The circulatory system is functionally integrated with both the respiratory structures (gills) and the metanephridial systems (kidneys) through both direct vascular connections and blood-pressure-dependent filtration, respectively. Arterial  $O_2$ -rich hemolymph (blood) is pumped anteriorly through a major aortic vessel by the contractile action of the muscular ventricle. This aortic vessel then branches into smaller vessels to supply defined tissues through hemolymph sinuses (32). Deoxygenated venous hemolymph then moves from the tissue sinuses into the gills via afferent vessels and the hemocoel. Hemolymph flow through the gills

(branchial circulation) is countercurrent to mantle water flow, which, as in fish gills, maximizes gas exchange. Hemolymph then exits the gills through an efferent vessel and enters the atria or auricles for recirculation (3,35). Metanephridial, or renal, function depends on vascular pressures generated by the heart, with hemolymph filtration occurring through the walls of the atria (auricles) and their associated podocytes, which serve a similar function as podocytes of the visceral layer of the mammalian glomerular capsule. Pressure-driven filtrate moves through the walls of the atria (auricles) and into the pericardial cavity (renopericardial cavity), where it moves into the nephrostome and on into the kidney tubules. Excretion ultimately occurs via the nephridiopore in the mantle cavity (36).

The fundamental design of the molluscan cardiovascular system has been functionally modified to meet a variety of demands, as is seen in the diversity of molluscan classes. The cephalopods show the most extensive evolution and specialization of the cardiovascular system, with blood driven at high pressures by the heart through an endothelial-lined (i.e., more closed than open) circulatory system that contributes to the maintenance of metabolic rates almost equivalent to some vertebrates (3,37). To sustain such high  $O_2$  uptake rates, paired branchial hearts have evolved to pump blood through the gills, after which the now-oxygenated blood flows to the ventricle, where it is pumped into the systemic circuit. Functionally, the

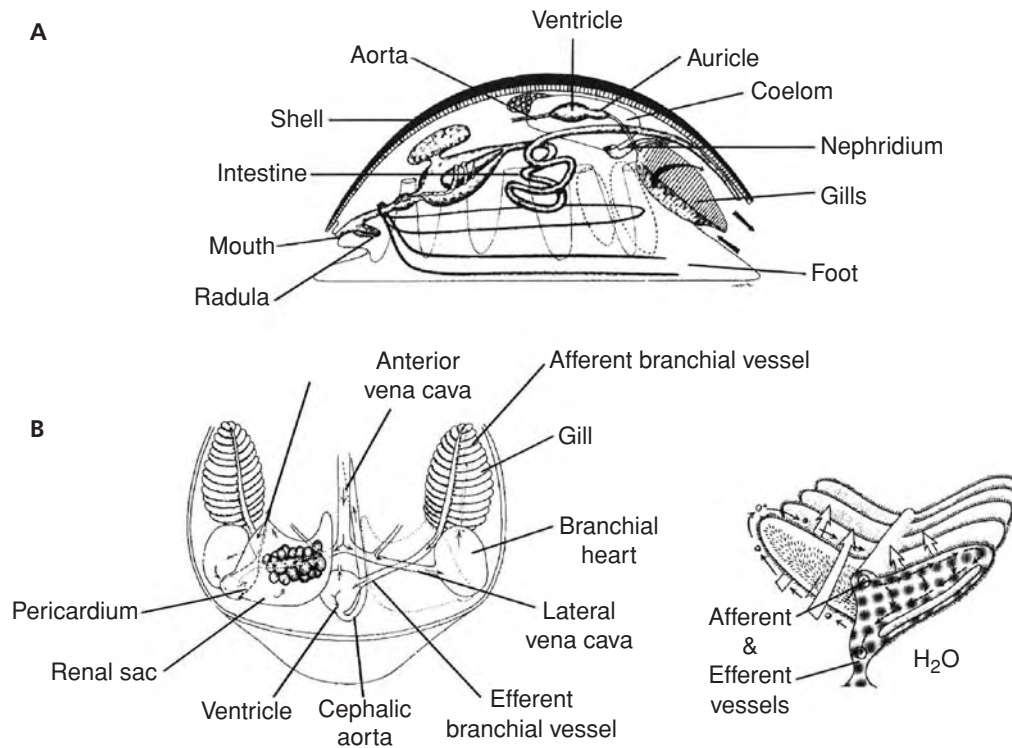

Figure 3.7. Circulatory system in molluscs. The generalized molluscs (A) have a well developed heart and circulatory system. The cephalopods have evolved highly efficient hearts, pumping blood at high pressure through both a branchial and systemic circuit (B). The inset illustrates the complex branchial circulation. The vessels of the cephalopods are lined with endothelium. (Panel A reproduced with permission from Ruppert EE, Barnes RD. *Invertebrate Zoology*, 6th ed. Fort Worth: Saunders Press, 1991; panel B reproduced with permission from Packard A. Cephalopods and fish: The limits of convergence. *Biol Rev.* 1972;47:241–307.)

cephalopods have evolved a multichambered heart capable of maintaining separation between venous and arterial blood and regulating branchial and systemic circulations. Additionally, this group of animals has developed the cardiorespiratory regulatory mechanisms needed to integrate cardiovascular and ventilatory performance with metabolic demands (38). The anatomical complexity of the cardiovascular system, along with the development of cell-lined, thin-walled, capillary-like exchange vessels and the appropriate regulatory mechanisms, appears to have been selected for in this group by increased activity patterns associated with predatory behavior, swimming, and jet propulsion (37).

The larger and more active cephalopods, such as the nautilus and the squid (the giant squid being the largest of any invertebrates), swim using jet propulsion. The use of this system does have some significant cardiorespiratory implications, in that a large volume of water must be moved through the funnel at some minimal acceleration to propel the animal. This results in excess O<sub>2</sub>-carrying capacity in the ventilatory stream or more water flowing over the gills than is necessary for purely ventilatory purposes. O<sub>2</sub> uptake must be independent of jet volume to prevent postexercise mismatches in ventilatory volume and the repayment of an O<sub>2</sub> debt (39). The nature of the jet propulsion system requires that blood delivery to both the

gills and tissues be at relatively high rates of flow and pressure. Ultrastructural examination of the vasculature of these very active cephalopods reveals a complete endothelial vascular lining, with highly branched “capillary-like” vessels that perfuse metabolically active tissues (3,40,41). Octopi are less active than squid, because they have reverted secondarily to a more benthic (i.e., bottom dwelling) existence. Octopi are restricted in the use of jet propulsion because the mantle edges have fused dorsally and laterally to the head, which limits water movement into the mantle cavity. Thus, their primary means of locomotion is crawling, through the use of their arms; they use their jet propulsion system only for shorter distances and when startled (23). The cardiovascular systems of these two cephalopods with different activity levels are similar, but discrepancies arise in reports as to the nature of the endothelia lining the vessels and the degree of tissue perfusion.

The inner cell lining of the cephalopod vasculature (like that of the nemerteans) appears quite permeable. It may not serve as a selectively permeable barrier, as it does in the vertebrates, which would make the cephalopod vascular system more “open” than “closed” (3,30,40,41). This leads to the question: Why have cephalopods evolved a cell-lined vascular system? It can be hypothesized that the invertebrate endothelia has evolved for reasons more to do with hemodynamics and

the maintenance of laminar flow than with the array of functions ascribed to the vertebrate vascular endothelia. It appears the embryonic origin of the invertebrate vascular system and the associated vascular cell lining found in some taxa is derived from the coelom. Those taxa that have evolved such a vascular cell lining appear to be more active, with higher metabolic demands, and also have well-developed centralized pumps, an extensively branched vasculature with “capillary-like” vessels, and relatively high blood pressures (see the section on crustacean circulatory system for further details).

Laminar flow is required to minimize the energy needed to move blood through these complex vascular systems. Laminar flow through a cylindrical tube can be predicted based on vessel diameter, mean blood velocity, and blood density and viscosity (Reynold’s number).<sup>7</sup> However, turbulent flow can result if sudden spatial variations occur in vessel diameter or irregularities appear along the vessels walls. In turbulent flow, a significantly greater pressure is required to move a fluid through the vessels, as compared to laminar flow. This is best exemplified by the fact that, in turbulent flow, the pressure drop is approximately proportional to the square of the flow rate, as opposed to laminar flow, in which the pressure drop is proportional to the first power of the flow rate (42–43). It would require a more robust heart and would be energetically inefficient to move blood in a turbulent pattern through a vasculature that changes shape abruptly and where the interiors of the vessels are not smooth, as seen in many lacunar systems. Thus, a vascular cell lining may have evolved to facilitate laminar flow to minimize the energy required to move blood through the cephalopod circulatory system.

### The Annelid Blood–Vascular System

Members of the phylum Annelida<sup>8</sup> contain some of the largest examples of wormlike invertebrates. Thus, in many ways, these animals should be comparable to the molluscs with regard to cardiovascular development. However, because annelids tend to be sluggish, with relatively low metabolic rates, the high rates of flow and pressure characteristic of molluscs, for example, generally are not seen in annelids (Oligochaeta are an exception, as discussed in later paragraphs) (44–46). The segmented annelids have evolved several mechanisms by which to enhance internal transport between compartments, the most primitive being the development of a coelom and coelomic circulation. They also have evolved intracellular, iron-based O<sub>2</sub>-

binding pigment (hemoglobins). The most advanced annelid system is a fairly well-developed blood–vascular system (47–48). In the smaller annelids, few cardiorespiratory adaptations exist, however; in the larger more active worms (Oligochaeta), such as the giant Australian earthworm, the heart and vasculature are well developed (49).

The general pattern of circulation through an annelid is best seen in the polychaete worms, and starts with a dorsal vessel that runs just above the digestive tract. Blood moves anteriorly at the point where the dorsal vessel anastomoses with a ventral vessel either directly or by several parallel connecting vessels. The ventral vessel runs under the digestive tract and moves blood posteriorly. Each segment of the animal receives a pair of parapodial blood vessels that arise from the ventral vessel. The segmental parapodial vessels supply the parapodia, the body wall (integument), and the nephridia, and give rise to intestinal vessels that supply the gut. Blood moves from the ventral vessel through the parapodial system, and it returns to the dorsal vessel through a corresponding segmental pair of dorsal parapodial vessels (Figure 3.8). When gills are present and integrated with the blood vascular system (as apposed to being perfused with coelomic fluid), they contain both afferent and efferent vessels (23). Pressures are generated by contractile peristaltic waves through the dorsal vessels. These blood vessels and their associated blood sinuses lack an endothelium and are lined by only the basal lamina of overlying cells (33).

Although many of the anatomical variations observed in the cardiovascular system of annelids appear to have evolved due to activity patterns, feeding behaviors, and environment, the most complex systems are seen in the class Oligochaeta. The basic anatomical pattern seen in polychaetes is maintained: segmental vessels providing blood flow to well-developed integumental capillary beds, to support gas exchange across the skin. The pressure-generating system of oligochaetes is better developed than that in the polychaetes, with primary pressure generation coming from the contractile dorsal vessel. The “hearts” of the oligochaetes are actually robust contractile vessels that connect the major dorsal and ventral blood vessels and act as accessory organs to aid in blood movement. These hearts, along with the other major blood vessels, contain folds in their walls that act as one-way rectifier valves for blood flow. The number of accessory hearts varies among Oligochaeta species, with *Lumbricus* having five pairs of hearts and *Tubifex* only one (23).

The blood vascular system of the annelids is complex in its architecture, yet has not evolved to the level seen in the cephalopod molluscs. The cardiovascular physiology of annelids is one of low pressures and flows designed to support the relatively low metabolic rates of slow-moving or benthic animals. With the exception of the capillary bed in the integument, oligochaetes lack the high degree of tissue perfusion seen in more active animals. The vasculature lacks any cell lining, which may reflect the generally low flows and pressures observed in these systems and the animals’ relatively low metabolic rates and activity patterns.

7  $N_R = 7745.8 u d_h / \nu$ , where,  $N_R$  = Reynolds number (nondimensional)  $u$  = velocity (ft/s);  $d_h$  = hydraulic diameter (in);  $\nu$  = kinematic viscosity (cSt) (1 cSt =  $10^{-6}$  m<sup>2</sup>/s). The Reynold’s number ( $N_R$ ) is used to predict the occurrence of turbulent versus laminar flow based on the ratio of inertial to viscous forces.

8 The phylum Annelida is made up of approximately 15,000 species of segmented worms. Body segmentation, a key characteristic of annelids, was a major step in the evolution of animals. Classes include Polychaeta (sand-, tube-, and clamworms), Oligochaeta (earth- and freshwater worms), Myzostomida (flattened, oval, and/or aberrant annelids), and Hirudinida (leeches).

Figure 3.8. Circulatory system in annelids. The annelid circulatory system, although extensive, is a low-pressure system with contractile vessels for pumps. It lacks an endothelial lining. ### The Arthropod Cardiovascular System

The arthropods<sup>9</sup> are by far the largest animal phylum, and they exhibit tremendous adaptive diversity. Of the major arthropod subphyla – Chelicerata, Crustacea, and Uniramia – only the crustaceans have evolved a complex cardiovascular system. The chelicerates have a relatively undifferentiated cardiovascular system when compared with the general arthropod model. The class Merostomata is best exemplified by the horseshoe crab (*Limulus*), which has a tubal heart, segmentally arranged ostia, and segmental vessels that are blind ending and supply large sinuses. The Arachnids are also part of this subphylum, and they have a similar cardiovascular system, with a tubal

heart that supplies major vessels to the anterior and posterior of the animal. A unique structure found in this class is the *book lung*, which is a modified gill open to air via spiracles. This structure is perfused with hemolymph through the ventral sinus, which then returns to the heart by way of the pericardial sinus.

The insects (Uniramia) are an incredibly diverse group of arthropods, yet this diversity has apparently come without major evolutionary advances in the heart or circulatory system, which shows very little change from the Chelicerata. The success of the insects in part can be attributed to the development of the tracheal system. The trachea are a series of tubes that open to the environment through spiracles located on the lateral edges of the abdomen. The trachea then branch repeatedly, allowing for the diffusion of O<sub>2</sub> and CO<sub>2</sub> between the environment and cells that can be augmented by convective mechanisms using muscular abdominal compressions. Thus, instead of a circulatory system carrying O<sub>2</sub> to the cells, a tracheal system replaces capillaries to meet gas exchange demands (23,33,50).

The arthropods exhibit a segmental structure similar to that of the annelids and, in the Crustacea, vestiges of segmentation can be seen in the anatomy of the heart and circulatory system. The heart (primary pressure pump) of the crustacean in its primitive form is an elongated tube and, in the more highly evolved examples, is a globular, box-like structure.

9 The phylum Arthropoda is by far the largest, with estimates of over 50 million species in existence. Arthropods range in size from less than 1 mm in length to over 4 m (the Japanese spider crabs), and show tremendous diversity in body form. Primary characteristics include bilateral symmetry; a tough, regularly shed chitinous exoskeleton; a coelom reduced to portions of the reproductive and excretory systems and the main body cavity an open hemocoel; a muscular dorsal heart with lateral ostia for blood return; and a complete gut with a well-developed nervous system. Major extant subphyla include Cheliceriformes, with classes including Merostomata (horseshoe crabs) and Arachnida (spiders, scorpions, mites, and ticks); Uniramia, with classes including the Myriapoda (centipedes, millipedes, insects) and Insecta (insects); Crustacea, with classes including the Branchiopoda (fairy, brine, and tadpole shrimp and cladocerans) and Malacostraca (true crabs: crabs, shrimp, lobster, crayfish, and pillbugs).

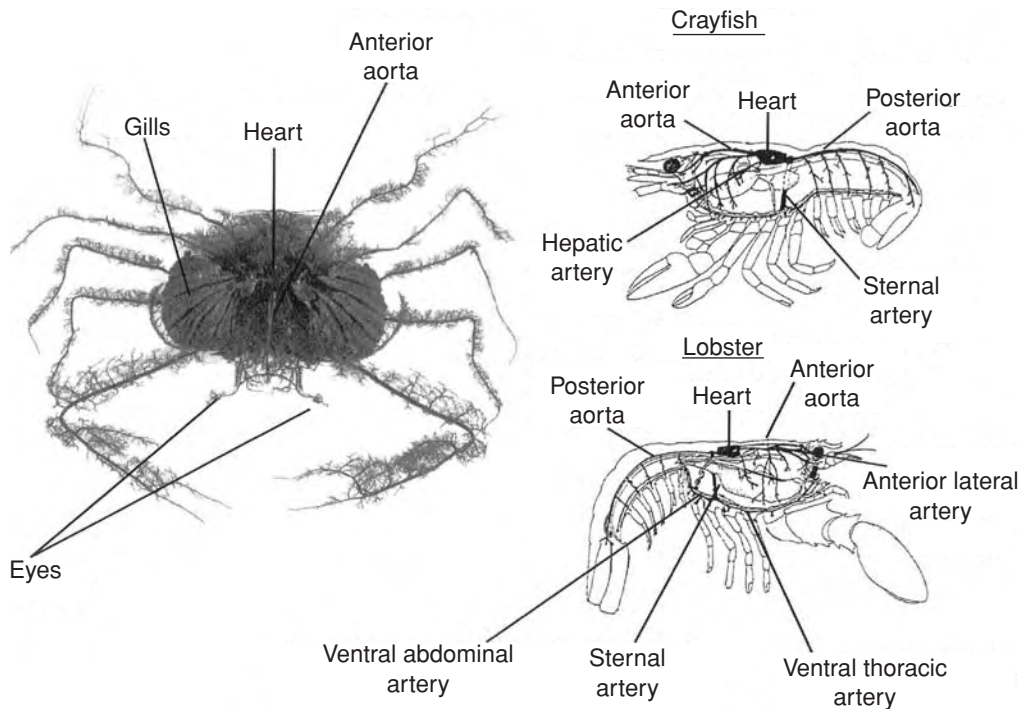

Figure 3.9. Circulatory system in crustaceans. The cardiovascular system of decapod crustaceans is highly developed, with a globular heart capable of delivering hemolymph at relatively high pressures and capillary-like vessel flows supplying metabolically active tissues. This distribution system is dramatically illustrated (*left*) in a corrosion cast of the blue crab's circulatory system and in the schematics of the crayfish and lobster. (Blue crab circulatory system reproduced with permission from McGaw IJ, Reiber CL. Cardiovascular system of the blue crab (*Callinectes sapidus*). *J Morph.* 2002;251:1–21; crayfish and lobster schematic reproduced with permission from Reiber CL, McMahon BR, Burggren WW. Cardiovascular functions in two macruran decapod crustaceans (*Procambarus clarkii* and *Homarus americanus*) during periods of inactivity, tail flexion and cardiorespiratory pauses. *J Exp Biol.* 1997;200:1103–1113.)

The ventricle is located within a pericardial sinus, where it receives hemolymph directly from the hemocoel through three paired ostia (51). In the more primitive tubal heart, the ostia appear to be segmentally arranged; in the globular hearts, however, these ostia have migrated, as the cardiac muscle has folded upon itself to form a box-like structure (52). Additionally, in the more primitive crustaceans, segmental arteries are seen branching from the anterior and posterior vessels. In the more advanced decapods, the development of the cephalothorax hides external evidence of segmentation, yet the vasculature specific to the posterior aorta in the abdomen has collateral arteries that branch off the main artery at each segment (Figure 3.9).

Typically, seven arteries leave the heart of a decapod crustacean. Arterial flow into each vessel is controlled by a single cardioarterial valve. The seven arteries consist of an anterior aorta, paired lateral arteries, paired hepatic arteries, a sternal artery, and a posterior aorta, each supplying a defined region or tissue. These vessels branch up to three times before ending in either a hemolymph sinus or in what appears to be true capillary beds (53) (see Fig. 3.9A). In the specific case of the anterior aorta, which supplies the esophageal ganglia, mouth parts, antenna, and eyes, an accessory hemolymph pump is present,

the cor frontale. This structure is composed of muscle surrounding the anterior aorta, and aids in maintaining pressure and flow through the complex series of capillary-like blood vessels in the anterior regions of the animal. Hemolymph passes through the sinuses and capillaries, where gas exchange occurs, then follows well-defined venous pathways to major inferior sinuses that supply the gills or the branchiostegal tissue (used by terrestrial crabs as a lung) (54). Once hemolymph has moved through the gills or the branchiostegal sinus, it flows into the pericardial sinus and back into the heart for recirculation (53).

Hemolymph flows and pressures are relatively low in many of the lower crustaceans (55). However, in the highly active shrimps, crabs, lobster, and crayfish, metabolic demands are met through high hemolymph flow rates and relatively high driving pressures (55–57). Intracardiac pressure has been measured previously in a number of decapod crustaceans, with mean pressures ranging from 36.3 to 6.1 mm Hg during systole to 16.2 to 1.2 mm Hg during diastole (57,60,61). The hearts of these animals are able to generate considerable pressures and flows during periods of both brief and long-term exercise (swimming). In many ways, the decapods are analogous to the cephalopods in their development of an extensive vasculature

and heart. The decapod cardiovascular system has been shown to be highly regulated through both intrinsic and extrinsic mechanisms, and it responds to a variety of internal and external stresses (56–59). The similarities with cephalopods continue at the level of the fine vessels. Although these vessels are larger than those of their vertebrate counterparts, they appear to serve the same function (53). Many examinations have been performed of the fine structure of decapod vessels, but few conclusions have been reached as to the nature of the cells that line the vasculature. Several authors have observed an endothelial-like lining of both capillaries and hemolymph sinuses. Clearly, the walls of decapod vessels do not contain muscle; thus, vasodilatation and contraction cannot be used to regulate hemolymph flow. A systematic examination of the vasculature for the presence of a cellular lining in sedentary versus very active decapod crustaceans would be interesting, and could support the hypothesis that active high-pressure systems will develop a vascular endothelia. Additionally, the nature of this “endothelium” must be examined to determine the permeability of the vasculature. In other words, is this system “open” as previously thought, or is it more appropriately viewed as “closed”?

## VERTEBRATE CIRCULATIONS

Vertebrate circulations generally are characterized by having:

- A single muscular pump for propelling body fluids at relatively high arterial pressures
- A series of closed vessels leading from arteries to arterioles to capillaries to venules to veins
- Vasculature with a complete endothelial lining and walls invested with both smooth muscle and sympathetic and parasympathetic innervation
- Blood with both a fluid matrix and a cellular component consisting of several different cell types

A few fascinating discrepancies exist, either because they represent extremely primitive lineages (e.g., hagfish with multiple hearts) or they represent extreme adaptations in more advanced groups (e.g., lack of red blood cells in the Antarctic icefish). Despite some common design features, great variation occurs in vertebrate cardiovascular systems. Consequently, it would be inaccurate to leave the reader with the sense that a heart structure or vascular layout is common to all vertebrates. With that in mind, let us now consider the taxonomic variation in vertebrate cardiovascular systems.

### Protochordates

The Protochordates (Hemichordates, Urochordates, Cephalochordates) are an informal grouping of marine animals that are pelagic (i.e., free swimming) as larvae and largely benthic as adults. They are best described as occupying an evolutionary position between the ancestral invertebrates leading

to the vertebrates and the true vertebrates (see Figure 3.2) (62–64).

The phylum Hemichordata (acorn worms) are worm-like filter feeders. Their blood contains amebocytes (leukocyte-like cells showing amoeboid motion) and hemoglobin in solution, which is synthesized from epithelial tissue lining the coelomic cavity (64). Blood is pumped by the peristaltic actions of a dorsal and ventral blood vessel through a combination of distinct vessels and large, open sinuses (65). The dorsal vessel, having a dilation often referred to as the “heart,” pumps blood into the glomerulus, presumably for the excretion of wastes through filtration. Blood draining the glomerulus flows into the ventral vessel and on to the digestive tract and other organs. A cell lining is lacking in both vessels and sinuses.

The phylum Urochordata (tunicates) comprises three classes best recognized by the class Ascidiacea or sea squirts. The cardiovascular system of ascidians has been examined fairly carefully because of the pivotal position held by the Urochordates on the proposed evolutionary pathway from echinoderms through hemichordates to urochordates and cephalochordates to vertebrates (Figure 3.10). Most recent research has taken a cellular or molecular approach toward the differentiation of cardiac mesoderm, with a view to identifying homologies with vertebrate hearts (see, for example, 66–67). Previous anatomical and physiological studies reveal a defined heart, formed of a single layer of muscle cells, that lies within a fluid-filled pericardium (68). Major aortas convey blood from both cephalic and caudal ends of the heart into a series of interconnected sinuses. Like the hemichordates, no recognizable endothelial linings are present in the heart, vessels, or sinuses of urochordates (69–72).

The phylum Cephalochordata or lancelets more closely resembles the primitive living fishes, in part because they are free-living and have a very clear bilateral symmetry, with distinct head and tail regions. Their developmental biology has been investigated extensively (see 70). Much less is known about the cardiovascular morphology and physiology of cephalochordates, but several general accounts of their cardiovascular layout have been offered (62,68,70,72). Briefly, one of the main distinguishing features of *Amphioxus* (*Branchiostoma*) is that it lacks a heart. Instead, blood is propelled through the branchial and systemic circulations by three contractile vessels. Superficially, the circulation resembles that of fishes, in that a distinct branchial circulation serves some 50 gill bars used in filter feeding, and a systemic circulation receives blood from the efferent branchial arteries and distributes it via vascular spaces and sinuses to the body tissues. However, the circulation of cephalochordates lacks a complete cellular lining (22,69,73), although an incomplete (discontinuous) lining has been described recently (74). Moreover, the gill bars comprise only 4% of the animal’s total gas-exchange surface, compared to 84% for the lining of the coelomic cavity in which the gills reside. Thus, the function of the gills appears to be almost entirely as mechanical structures for feeding, and the circulation of blood has little gas-exchange function (74–76). Circulation times are approximately 1 minute, as is the interval

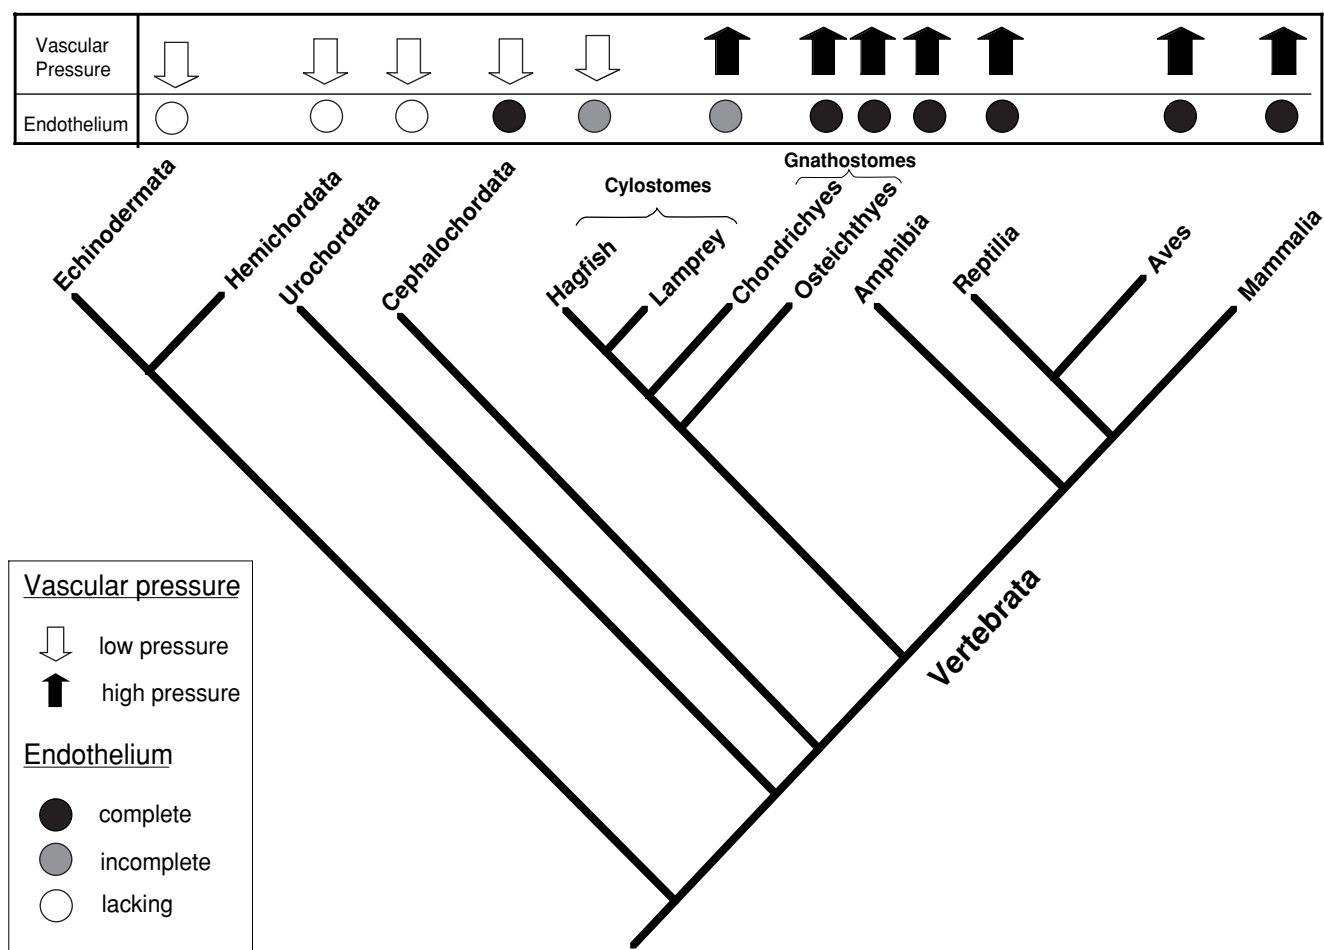

Figure 3.10. An evolutionary scheme for the protovertebrates and vertebrates. Also indicated is the presence of a complete or incomplete endothelial vascular lining. The arrows (*down* for low blood pressure, *up* for high pressure) indicate the taxon's blood pressure. The hatched perpendicular bar indicates the ancestral onset of endothelium, whereas the solid perpendicular bar indicates the ancestral onset of higher blood pressures.

between pulsatile vessel contractions (68). Intravascular pressures are thus presumed to be very low, although they have yet to be measured.

### Cyclostomes (The Agnathan Fishes, Hagfish, and Lampreys)

The most primitive fishes are the Cyclostomes, represented today by the suborders Myxinoidea (hagfishes) and Petromyzontia (lampreys). The hagfish (*Myxine*) exhibits a cardiovascular system that, in many respects, resembles that of elasmobranch and teleost fishes (see Chapter 6). A heart homologous with that of more highly evolved fishes sits centrally and ventrally, and propels blood into a ventral aorta that carries blood to the gills via the branchial vasculature. From there, a dorsal aorta carries blood to the systemic tissues. However, this heart has several unusual features, including a lack of autonomic innervation and a relative insensitivity to extracellular calcium ( $\text{Ca}^{2+}$ ) (see 77–78). Supplementing the “systemic heart” is a series of “accessory hearts” serving the posterior of the

body (caudal heart), the abdominal cavity (portal heart), and the anterior region of the body (cardinal heart). Entrance into each of these hearts, which pump venous blood, is guarded by one-way valves. Although the peripheral circulation of the hagfish superficially resembles that of gnathostome fishes, it has large open sinuses devoid of a continuous endothelial lining (77–79). Mean blood pressures in the hagfishes *Myxine* and *Eptatretus* are on the order of 5 to 10 mm Hg, placing them among the lowest recorded for any vertebrate (see 80 for references).

The lampreys appear to occupy a morphological and functional position intermediate between hagfishes and the gnathostome fishes (78,83). The lamprey cardiorespiratory physiology has been extensively investigated (see 81–85). Unlike the hagfishes, lampreys have only a single ventrally located heart. Although the heart is innervated, vagal stimulation and acetylcholine enhance rather than inhibit cardiac performance (86). Mean arterial blood pressure is about 25 to 35 mm Hg, well within the range of many gnathostome fishes. Endothelium lines their capillaries (22,87–88).

### Gnathostome Fishes (Cartilaginous and Bony Fishes)

The cartilaginous fishes (Chondrichthians) and bony fishes (Osteichthyans) generally show a common piscine cardiovascular layout, characterized by a single heart and a series of completely endothelial-lined blood vessels comprising the typical vertebrate vascular bed: arteries, arterioles, capillaries, venules, veins (see reviews 78,89–92) (also see Chapter 5). Deoxygenated blood returning from the systemic tissues enters into a large atrial chamber. Deoxygenated blood pumped from the atrium enters the single ventricle. Subsequent ventricular contraction creates mean arterial pressures typically in the 15 to 30 mm Hg range, although tunas and other similarly highly active fishes may exhibit mean pressures as high as 50 to 100 mm Hg and, remarkably, may generate peak systolic pressures in excess of 150 mm Hg (for references, see 78,93). Deoxygenated blood ejected from the heart traverses a short ventral aorta, then enters the branchial circulation and perfuses the lamellae of the gill arches. After gaining O<sub>2</sub> and losing CO<sub>2</sub> and ammonia, oxygenated blood enters the dorsal aorta for distribution to the systemic tissues. The branchial capillary network represents a significant resistance to blood flow; consequently, blood pressure in the dorsal aorta may be reduced by 20% to 50% compared with that in the ventral aorta.

Air breathing has independently evolved several times in fishes (for review see 62,81,94–95). Because the circulation plays a fundamental role in gas exchange, whether aquatic or aerial, it is thus not surprising that the introduction of an additional gas-exchange organ in the form of a gas bladder (e.g., *Lepisosteus*, the gar pike) or a true lung (the lungfishes, *Lepidosiren*, *Protopterus*, and *Neoceratodus*) has resulted in major modifications to the basic piscine circulatory pattern. To operate at highest efficiency with maximal air-to-blood O<sub>2</sub> diffusion gradients, an air-breathing organ must preferentially receive deoxygenated blood from the tissues via a newly evolved, dedicated arterial pathway, while oxygenated blood draining the air-breathing organ must be preferentially directed towards the tissues. Because most air-breathing fishes retain reasonably well developed gills (even if just for osmoregulation), the dilemma exists that O<sub>2</sub> picked up during air breathing might actually be lost from the gill surfaces into hypoxic water surrounding the gills. Thus, in many air breathing fishes, some or all of the gill arches are modified to present a much reduced surface area to the water flowing over them. This is particularly true in the lungfishes, in which oxygenated blood leaving the air-breathing organ enters the left atrium by a single pathway – the pulmonary artery (78). Concurrently, oxygenated blood from the systemic veins enters a right atrium. Although the left and right atria empty into a single, muscular ventricle, the trabecular nature of the ventricular lining, as well as the hemodynamic blood flow patterns through the ventricle, results in partially maintained separation of these two streams of arterial blood as they are ejected into the ventral aorta. A spiral valve that runs longitudinally down the internal length of the ventral aorta rotates the streams of blood such

that deoxygenated blood is primarily directed into the last two pairs of gill arches (from which are derived the pulmonary arteries), while oxygenated blood is preferentially directed into the first pair of gill arches (from which arises the dorsal aorta leading to the main systemic circulation). The anterior-most arches tend to be small and poorly developed, with lower surface area. These arches act more as shunt vessels that allow oxygenated blood to transit the branchial circulation without diffusing back out into the potentially hypoxic water irrigating the gills.

Although the lungfish has evolved a relatively specialized circulation, fishes using nonpulmonary bladders, labyrinth organs, or modified guts for air breathing tend to be plumbed into the circulation in ways broadly similar to those described for lungfishes (62,81,89,96). However, only the lungfishes have evolved a pulmonary artery leading to a distinct left atrium (62,81). Consequently, oxygenated blood from a nonpulmonary air-breathing organ typically re-enters the general systemic venous drainage. Thus, the presence of an air-breathing organ that is not homologous to a lung leads to a general elevation of blood O<sub>2</sub> levels in the fish, but does not lead to the peak efficiencies of gas exchange to be found in the lungfishes.

It is tempting to view the three living genera of lungfishes as on a direct evolutionary pathway to more terrestrial amphibians, simply because they have functional cardiorespiratory features intermediate between fish and tetrapods. However, the modern-day tetrapods, beginning with the amphibians, emerged from a vertebrate ancestor, which the lungfishes share with tetrapods. Not surprisingly, then, the amphibian circulation has its own evolutionary innovations – and limitations – as we will now explore.

### Amphibians

Amphibians typically have two distinct atria but only a single, muscular ventricle generating mean arterial pressures generally in the range of 10 to 30 mm Hg (see 78,97–98 for reviews). Like the lungfishes, amphibians have a well-developed spiral valve in the single larger arterial outflow tract leaving from the heart. This valve maintains partial separation of oxygenated and deoxygenated blood streams derived from left and right atrium, respectively. In anuran amphibians (frogs and toads), oxygenated blood preferentially enters the systemic arches, while deoxygenated blood is directed primarily into paired “pulmocutaneous” arches. Each pulmocutaneous arch immediately splits into a pulmonary artery serving the simple, non-alveolar lungs, and a cutaneous artery, which perfuses the thin, highly vascularized skin (Figure 3.11). Amphibians are skin as well as lung breathers, often deriving more than 50% of their O<sub>2</sub> from cutaneous O<sub>2</sub> uptake under resting, normoxic conditions (99–100) (see Chapter 9). Noteworthy, however, is that the skin also receives a blood supply from the normal systemic circulation. Thus, any given patch of skin is likely to receive both deoxygenated blood via the cutaneous artery and oxygenated blood via the systemic circulation. Oxygenated

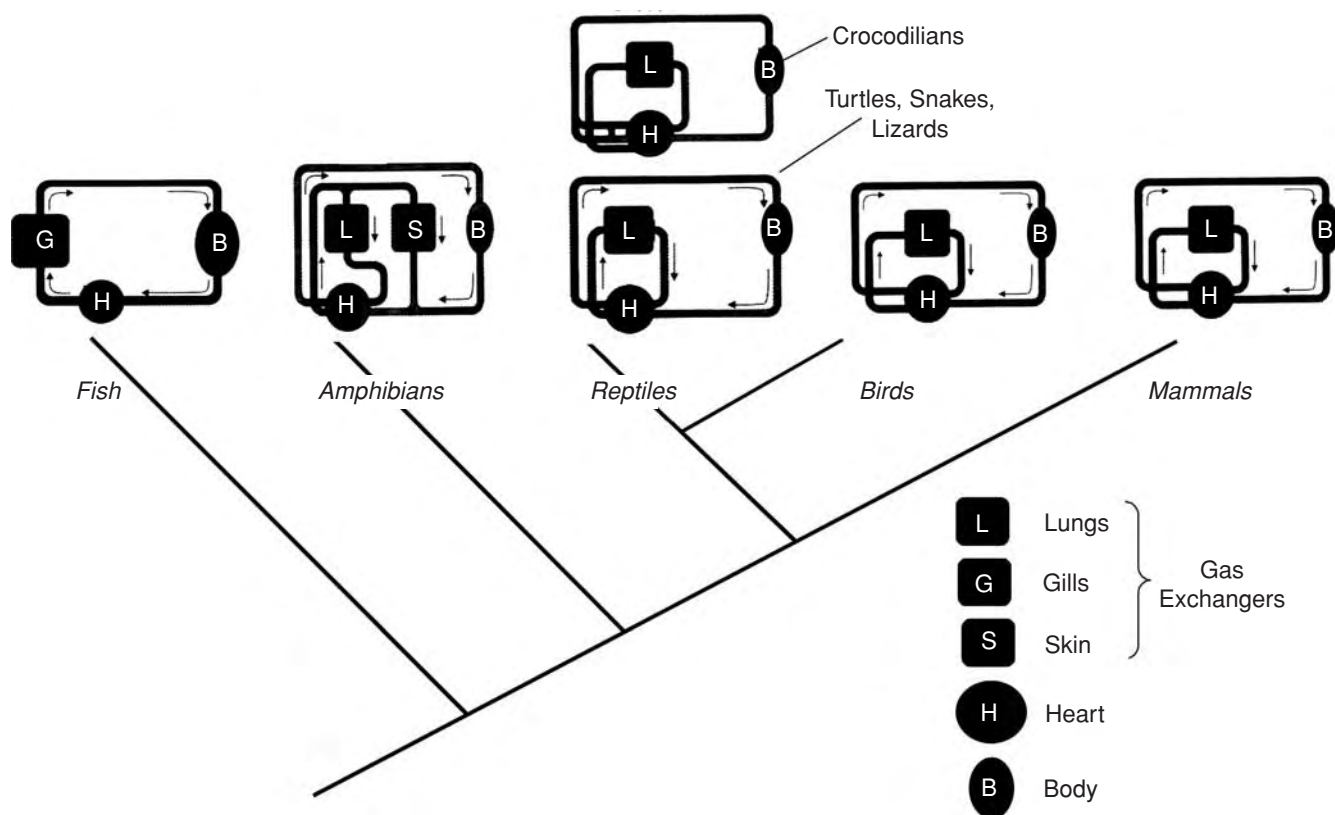

Figure 3.11. A schematic of vertebrate phylogenetic relationships and the basic cardiovascular layout of the vertebrate classes. Note that no smooth continuum of evolutionary improvement exists. Rather, each cardiovascular system is well designed to provide gas exchange at rates and in patterns appropriate for each group's environment and lifestyle. See text for further description. (Modified with permission from Hicks JW. The physiological and evolutionary significance of cardiovascular shunting patterns in reptiles. *News Physiol Sci.* 2002;17:241–245.)

blood draining the lungs returns to the distinct left atrium via pulmonary arteries. Oxygenated blood draining the skin, however, enters the general systemic venous circulation and eventually enters the right atrium.

Salamanders (Urodeles) differ from anurans in that they lack the distinct cutaneous artery of anurans, with the skin being served only by the systemic circulation typical of other vertebrates. Nonetheless, the skin still provides a significant boost to  $O_2$  uptake. An interesting evolutionary oddity in the urodeles are the terrestrial Plethodontid salamanders, which have secondarily lost their lungs and subsist entirely on cutaneous gas exchange (100). These animals also have lost pulmonary arteries and veins, and retain only a vestigial left atrium. Some salamander groups have evolved a partially divided ventricle (e.g., *Siren*, 101). Although the physiological performance of these unusual amphibians has not been evaluated, improved separation of deoxygenated and deoxygenated blood would be expected on a purely morphological basis.

### Reptiles

Reptiles are a highly polyphyletic group (that is, the group includes various distantly related taxa) and so, not surpris-

ingly, as a vertebrate class, they show three highly distinctive patterns, each characterized by profound differences in heart structure and vascular layout (62). The reptiles show some of the most complex cardiovascular patterns of all vertebrates. Indeed, the notion that the “reptile heart” is a three-chambered heart somehow awaiting evolutionary repair to strive for the heights of the superior avian or mammalian heart is now a historical view that has been replaced by a considerable appreciation of the sophistication of the various patterns that evolved in the reptiles.

Chelonians (turtles and tortoises) and squamates (snakes and lizards) have two distinct atria that pump blood into a complex ventricle that – rather than being viewed as a single ventricle, as in amphibians – is best regarded as containing three distinct chambers (see 102–103 for reviews). The left atrium pumps oxygenated blood into a cavum arteriosum, which has no direct arterial outlet. The right ventricle empties deoxygenated blood into a large cavum venosum, separating the cava arteriosum and pulmonale. The major systemic arches arise from the cavum venosum. Clearly, the function of this heart depends on highly complex patterns of flow through this partially but complexly divided ventricle. The hemodynamics and, especially, the patterns of blood flow of the chelonian heart are highly complex and involve both spatial and

temporal separation. Their description is beyond the scope of this chapter. Suffice it to say that the anatomically distinct chambers are functionally interconnected and, with each systole, blood traverses prominent intraventricular muscular ridges separating the cava. Mean arterial pressures are generally in the range of 25 to 40 mm Hg in chelonians (78), with a single pressure measured throughout the ventricle during systole despite the anatomical complexity of chambers within the ventricle.

One of the key features of chelonians is that they are typically intermittent breathers (breathing is of course suspended during diving in aquatic turtles, but breath-holding is also characteristic of terrestrial tortoises). Gas  $PO_2$  and  $PCO_2$  levels in the modestly alveolar and subdivided turtle lungs vary with the breathing–diving cycle; so too does the gas exchange performance of the lungs (see numerous authors in 98,104–105). To match ventilation to perfusion, chelonian reptiles are able to control potentially large intraventricular blood shunts by creating large changes in relative resistance between the systemic and pulmonary circulation (see 78,102–103,106 for reviews). Thus, during breath-holding, pulmonary resistance increases greatly due to constriction of a sphincter at the base of the pulmonary artery and vasoconstriction in the pulmonary vasculature. Because blood leaving the heart ultimately follows literally the path of least resistance, pulmonary vasoconstriction creates a large net right-to-left shunt leading to reduced pulmonary blood flow that, in extreme situations, is nearly eliminated, even as systemic blood flow continues. At the termination of the dive, the right-to-left shunt is reversed, and a modest left-to-right shunt appears to facilitate not only rapid reoxygenation of arterial blood, but also an elimination of  $CO_2$  sequestered in tissues during the breath-holding event (102–103). Thus, turtles and tortoises have evolved a highly flexible circulation that is admirably adapted to a lifestyle characterized by breath-holding and low metabolic rates.

Squamate reptiles (lizards and snakes) tend to show cardiovascular morphology and performance similar to chelonians. However, fascinating exceptions exist that show that pressure separation within the complex ventricle of reptiles has independently evolved several times within the reptile group. The varanid lizards (probably best known by the Komodo dragon, *Varanus komodoensis*, although numerous smaller and less frightening species inhabit this genus), are capable of high levels of metabolism and brief periods of great activity, such as predation (107). Supporting this atypical reptilian performance is a modified ventricular structure (108). Although the three ventricular chambers – cava arteriosum, venosum, and pulmonale – are still in evidence, their relative sizes and interrelationships have been modified to allow pressure separation during ventricular systole. The net effect is that the pulmonary circulation of varanids is perfused at a mean pressure of about 10 to 15 mm Hg, while the systemic circulation is perfused at mean pressures that can exceed 60 to 70 mm Hg. This decidedly mammalian-appearing separation of the circulation into a high-pressure systemic and low-pressure pulmonary circula-

tion represents an intermediary position on a functional continuum between the heart of lower vertebrates and mammals (109). The snake, *Python molurus*, also is capable of producing a functional separation of ventricular chambers during systole, leading to markedly different systemic and pulmonary perfusion pressures (110). However, it bears emphasis that the varanid lizards and pythons are, in an evolutionary sense, cardiovascular oddities that are in no way on the main pathway to the endothermic vertebrates (birds and mammals). However, that such circulations *can* evolve serves as evidence of an “evolutionary feasibility study” (111). The existence of these circulatory patterns has potentially profound implications as we ponder cardiovascular performance, metabolic rates, and attendant behaviors of those reptiles that do represent a more mainstream evolutionary pathway – the dinosaurs (112–113).

The Crocodylia – crocodiles and reptiles – exhibit a third pattern, representing a highly adapted cardiovascular performance that permits great efficiency (for reviews see 78,102–103,106,114,115). With respect to their heart structure, crocodylians have the same completely divided, highly muscular left ventricle and somewhat less muscular right ventricle as do birds and mammals. The fascinating adaptation in crocodylians comes from the numbers and positions of arterial arches. Crocodylians have a left arch that arises from the left ventricle and carries blood to the descending aorta, as in the homeotherms. However, crocodylians have retained a right aortic arch that derives from the right ventricle, as does the pulmonary arch. The bases of these two aortic arches are connected by a very short foramen of Panizza. How does this apparent oddity, which at first glance conjures up images of congenital pathologies in human patients, actually function? During active air breathing, high systolic pressures on the left side of the heart not only provide high driving pressures for systemic perfusion, but also transmit high pressure through the foramen of Panizza into the base of the right aorta, keeping shut the valve at the base of the right aortic arch. During air breathing, the low pressures generated by the right ventricle are enough to open the valve at the base of the pulmonary artery and perfuse the lungs, but not high enough to allow blood from the right ventricle to enter the base of the right aorta. Thus, during active air breathing, the crocodylian circulation is functionally indistinguishable from the circulation of homeotherms, sending equivalent amounts of blood under low pressure to the lungs and, under high pressure, to the systemic circulation. During what can be extended periods of breath-holding during diving, however, the same physiological degradation of pulmonary gas-exchange efficiency that occurs in diving turtles also occurs in crocodylians. Pressures generated by the left ventricle (which had been in the range of 60 to 80 mm Hg or higher), decrease greatly due to an as-yet poorly understood mechanism involving a decrease in left ventricular contractility. No longer held closed by high left aortic arch pressures, the valve at the base of the right aortic arch opens with each systole, and a proportion of right ventricular blood potentially bound for the lungs actually is

diverted back into the systemic circulation via the right aortic arch. By virtue of this extraventricular right-to-left shunt via the right aortic arch, crocodylians, like turtles, can bypass the lungs and save the considerable energy that would have been expended on their continuing perfusion during a dive. Diving physiologists, in many respects, view the crocodylian circulation as the pinnacle of efficiency for an intermittent breather.

### Birds and Mammals

The circulation of birds and mammals has been extensively investigated for literally centuries, and it is not our intent to repeat the efforts of the many authors who have recently reviewed the circulation of homeothermic vertebrates. Suffice it to say that, although we often lump the avian and mammalian circulation together, actually fairly major quantitative differences are present in their structure (e.g., relative size and wall thickness of the ventricles show considerable species diversity) (see Chapter 10). Another difference involves the developmental physiology of avian and mammalian cardiovascular systems. Unlike the placental arrangement supporting the mammalian fetus, the avian embryo develops its own extraembryonic chorioallantoic membrane (CAM). These anatomical distinctions in early development lead to both qualitative and quantitative differences in cardiovascular performance at all developmental stages, and especially during the transition from pulmonary breathing associated with hatching or birth. (For reviews of avian embryonic circulations, see 116.)

### EVOLUTION OF CELLULAR LININGS IN INVERTEBRATE AND VERTEBRATE HIGH-PRESSURE CIRCULATIONS

As evident from the earlier discussions, cardiovascular systems have followed a series of complex and diverse pathways during their evolution. Against this backdrop of cardiovascular evolution, it is interesting to speculate on *why* endothelial linings evolved in cardiovascular systems. These speculations can be formed as a series of hypotheses.

#### The “Endothelium as Barrier” Hypothesis

Although our observations are simply correlative rather than causative at this point, it is interesting to note that, in the invertebrates, most of the cardiovascular systems that generate and experience relatively high pressures have evolved a continuous cellular vascular lining, as have all the high-pressure systems in vertebrates (see Figure 3.10). Of course, relatively high pressures generated by a heart or hearts in a circulation provide a hydrostatic gradient for moving blood longitudinally through the vessels. However, the generation of pressures within a vessel also generates a hydrostatic pressure gradient *across* the vas-

cular walls. Whereas in some structures (nephridia of invertebrates, nephrons of vertebrates), this is a useful – indeed, necessary – phenomenon, another by-product of high intravascular pressure is the ultrafiltration of fluid from vascular into nonvascular fluid compartments in nonexcretory body tissues. Thus, this particular hypothesis holds, a cellular vascular lining may have evolved to provide some degree of control over the loss of fluids from across the vascular walls, presumably by decreasing the filtration coefficient,  $K_f$ , in the Starling equation for transcapillary fluid flux. Once endothelium as a physical barrier had evolved, secondary functions of endothelium could have evolved subsequently.

Morphological support for this thesis comes from an examination of the few but very significant appearances of cellular vascular lining in invertebrates. Shigei and colleagues (22) propose that a cellular vascular lining (endothelium or otherwise) is essentially a vertebrate adaptation. In citing numerous examples of studies that have failed to find a cellular vascular lining, these authors acknowledge but pay little attention to the fact that a cellular lining for the vasculature has indeed evolved independently from vertebrates in the Nemertea, cephalopods, and crustaceans. That these three groups of invertebrates also have a high blood pressure lends credence to the notion that the appearance of a vascular lining is in some way associated with higher sustained blood pressures. Additional evidence comes from the lack of continuous endothelium in *Amphioxus*. Although physiological examinations of this species are largely lacking, at least the morphological arrangement of the cardiovascular systems suggests a low-pressure circulation – certainly in comparison to even the most primitive of fishes. Then, in the hagfishes (with atypically low blood pressures for a vertebrate), the endothelial lining of the circulation is incomplete, being interrupted by unlined sinuses. However, speaking against the notion that endothelium serves as some form of barrier in high-pressure systems, Chapter 5 of this volume describes how the endothelium in fishes is generally a poor barrier against ultrafiltration (except in the gills and brain, where vascular permeability is much reduced).

#### Alternative Hypotheses for Evolution of Cellular Vascular Linings

Other equally valid hypotheses for the evolution of a cellular vascular lining, if not outright endothelium, relate to the many demonstrated functions of endothelium, including hormone secretion, leukocyte trafficking, control of blood clotting, and control of vascular tone. It is beyond the scope of this chapter on cardiovascular evolution to delve into these hypotheses. However, one bears consideration as an example. Muñoz-Chápuli and colleagues (29) present a “nonhemodynamic” hypothesis for the evolution of endothelium. They suggest that the epithelium may have first evolved as a system for immunological cooperation of “protoendothelial cells” and, in a good example of an “evo–devo” approach, these authors present both ontogenetic and evolutionary evidence.

Although presenting a useful summary of the cell lineages lining the coelom of various invertebrates, these researchers (29) do not recognize the existence of cellular vascular lining in some cephalopods. Thus, their hypothesis focuses more narrowly on the invertebrate–vertebrate transition of the cardiovascular system. In so doing, they suggest a more hypothetical linear transition from invertebrate to higher vertebrate evolution than the widely accepted messy, nonlinear transition with numerous false-starts. Indeed, the presence of a cellular vascular lining in the cephalopods and other invertebrates remains a stumbling block to attributing the evolution of such linings strictly to the invertebrate–vertebrate transition.

The search for *the* hypothesis to explain all data for the evolution of vascular cellular linings is likely to be frustrated by the fact that such linings have so many critical functions, and these functions are highly likely to have evolved concurrently rather than in sequence.

### Future Directions

Although the general anatomical layout of the cardiovascular system of most extant phyla is well documented, we know very little about the cardiovascular performance of the vast majority of invertebrates. In fact, we estimate that not even a single species in more than half of the phyla possessing internal circulatory systems has been assessed for blood pressure, blood flow, or even whether the circulation functions in respiration. We are discovering more and more evidence for sophisticated physiological regulation in “open” circulations (formerly viewed as inferior by physiologists, incidentally) and in lower vertebrates. Thus, we also should outline experiments that look at these same higher vertebrate-like functions that occur in invertebrate and protochordate vasculature. We also should explore how endothelial linings – wherever they exist – contribute to the regulation of blood or hemolymph flow at the tissue level, and whether this involves autoregulatory mechanisms, nitric oxide, adenosine, adenosine diphosphate, adenosine monophosphate, and the like.

We also know very little about even basic processes in the cardiovascular development of most invertebrates (e.g., the relative roles of vasculogenesis and angiogenesis in formation of the circulation), and even a surprising number of chordates. This leaves the currently popular and effective evo–devo approach to understanding physiology (117–118) waiting on the sidelines for want of even basic data for analysis. Not until we have a more comprehensive understanding of how cardiovascular systems develop and perform across development and taxa can we begin to piece together the selection pressures leading to particular suites of cardiovascular characteristics (e.g., regulated distribution of blood to selective vascular beds, efficient matching of blood or hemolymph perfusion to gas-exchanger ventilation).

In summary, taking a broad evolutionary perspective, we have learned a great deal about the cardiovascular systems of only a very small number of extant animals. A more sophisti-

cated understanding of internal body-fluid circulation system evolution will require a more synthetic, integrative, “systems biology” approach that spans the fascinating diversity of living animals.

### KEY POINTS

- Cardiovascular systems evolved when the combination of increasing animal size and increasing metabolic rate necessitated the internal convection of body fluids for gas exchange, metabolic substrate delivery, and waste removal.
- Many invertebrates have relatively low-pressure systems that slowly direct either ambient water or hemolymph through vascular spaces rather than through the endothelium-lined vessels characteristic of vertebrates. Contrary to historical perspectives, however, certain invertebrates (e.g., cephalopods and some crustaceans) have relatively high-pressure cardiovascular systems capable of the regulated preferential direction of hemolymph through cell-lined vessels.
- Evolution has led to a wide variety of cardiovascular patterns in nonmammalian vertebrates.
  - The relatively simple system of aquatic fishes becomes more complicated when the capability for air-breathing evolves, whether by appearance of a bladder-like, air-breathing organ or a true lung.
  - Amphibians have developed a dual atrial system and, in some taxa, possess specialized circulation for cutaneous respiration.
  - Reptiles show three distinct cardiovascular patterns. Chelonian circulations are well adapted to intermittent breathing by creating pulmonary bypass shunts during diving, when pulmonary respiration is less effective. Varanid lizards, with their functionally separated ventricle and high-system/low-pulmonary pressures, represent an evolutionary side track but an interesting indication that an ancestral intermediate step between typical reptiles and birds could occur. Crocodilian reptiles represent the most highly evolved reptilian system, allowing mammalian-like performance during air breathing, but the energy-saving performance of chelonians during diving.
- A correlation exists between the evolution of relatively high pressures and the presence of a cellular vascular lining. Importantly, a cellular vascular lining associated with elevated vascular pressures appears to have evolved independently multiple times (e.g., cephalopod molluscs, crustaceans, vertebrates). One (of many) possible hypotheses is that ECs might have

evolved as a barrier to the ultrafiltration of plasma in systems with high transmural vascular pressures. However, no single hypothesis is likely to account for the evolution of cellular vascular lining.

# The Evolution and Comparative Biology of Vascular Development and the Endothelium

---

J. Douglas Coffin

*University of Montana, Missoula*

One of the least considered aspects of vascular biology is vascular evolution and the clues it may hold to understanding endothelial function and pathology. Comparative problems between species are encountered on a regular basis when using laboratory animals and cultured endothelial cells (ECs) to model human conditions. Further complicating these problems is the endothelial heterogeneity found within those animal models and within humans. The evolutionary process underlies the marvelous diversities among vascular systems both within an organism and across the animal kingdom. But that same evolutionary process has generated the abundance of technical problems and complexities that are necessary to resolve as practical matters in research and medicine. The resolution of these problems lies in understanding the fundamental physiological and biochemical nature of comparative vascular biology and the subsequent application of that knowledge to human pathologies. Thus, understanding the origins of the vascular system is a vital component for the resolution of human vasculopathies.

Evolution is a biological fact; much the same as gravity or electromagnetism are physical facts. Fundamental evolutionary forces, such as mutagenesis and natural selection, are scientifically, qualitatively observed and quantitatively measured on a regular basis. The application of those evolutionary forces to the endothelium and vascular development provides a model (Figure 4.1) that correlates vascular specialization and complexity with larger or more complex organisms. Further consideration of these evolutionary trends in a developmental context leads to “Evo Devo” constructions. These reveal tissue perfusion as a basic need leading to the adaptations in vascular evolution. The need for tissue perfusion is evident for both the evolution of a heterogeneous, specialized vascular system in large, complex organisms and for the precocious neovascularization that occurs during the rapid growth and differentiation phases in embryogenesis. This need for perfusion supplies the impetus for the evolution of a specialized EC that is capable of rapid growth, and the specialized

physiological needs required to line and regulate the vascular system.

A comparison of the endothelium between evolution and development may appear to invoke “recapitulationist” arguments. Farrell (1) provides a good, short critique of Haeckel’s recapitulation theory, relative to the cardiovascular system, and how current perspectives on developmental evolution suggest that developmental processes, similar to most other evolutionary trends, are conserved or adapt without teleological or recapitulation implications. The model presented here simply suggests that tissue hypoxia can occur during two biological circumstances: Evolution of large, complex organisms and in utero development of complex, specialized embryos. The biological response in both cases is evolution, or the development of an endothelial-lined vascular system concomitant with the size and complexity of either the organism or the embryo. No teleological or recapitulationist interpretation for the events in this model are necessary – it is simply based on a common occurrence (hypoxia) with a similar response (neovascularization) in both circumstances.

## CARDIOVASCULAR AND DEVELOPMENTAL EVOLUTION

Chapter 3 provides an elegant discussion of cardiovascular evolution. The descriptions in that chapter provide an essential conclusion for the arguments in this chapter: The evolution of cardiovascular systems correlates with increasing animal size. It also provides an abundance of phylogenetic examples for the evolving endothelium in a variety of species. This chapter relates vascular morphogenesis and the developmental adaptations that have led to the more complex vascular systems in an evolution of development or “Evo Devo” context similar to other discussions on vascular evolution (2). The adaptations apparent during the evolution of the human/mammalian endothelium include gastrulation and mesodermal

Figure 4.1. Proposed model for evolution of the simplest to the most specialized vascular systems. The upper axis represents adaptations (*left to right*) from smaller, simple organisms to larger, more complex organisms with more organ systems. The lower axis represents a homogeneous, simple endothelium evolving (*left to right*) to a more heterogeneous, specialized endothelium. In this model, the more specialized vessels serve the more complex organs and organ systems present in larger animals. Examples of increasingly specialized animals are listed from left to right. Below each animal is a short description of its respective circulatory system, which also increases in complexity. The asterisk for *Amphioxus* represents some debate over whether they have a true endothelial layer, and this analysis assumes the affirmative. Note that intima (tunica intima) and endothelium are often interchangeable, but not necessarily in this case. An organism may have an inner lining layer (intima) that is not a true endothelium. The terms *smooth muscle* and *media* (tunica media) are considered interchangeable here; note that adventitial layers are not represented. The first major adaptation is acquisition of an intima, between echinoderms and urochordates. The next adaptation, from a single-chambered to a multichambered heart, represents another major endothelial specialization distinguishing arteries and veins. In *Ciona*, the endothelium already has begun a transition, completed by *Amphioxus*, to the microvascular form. Amphibians then have medial layers for smooth muscle control of blood pressure, which is regulated through the endothelium by nitric oxide (NO). Further specializations that are present in some amphibia continue in mammals. BBB, blood–brain barrier; HEV, high endothelial venule.

differentiation, the “hemangioblast,” the heart, an open circulatory system, and then a closed circulatory system. The selective forces that integrate these adaptations to form a closed vascular system correlate with the specializations found in terrestrial vertebrates.

Phylogenetic trends show that the smaller, less complex or the least-specialized organisms have fewer organs or organ systems and, therefore, they have the least need for perfusion and subsequently the least-developed circulatory systems (3). The least-developed circulatory systems have epithelial-, or perhaps endothelial-lined circulations without the medial or adventitial layers found in mammals. Essentially, in the simplest vascular systems, the intimal layer is the vasculature. It is unclear whether the intimal layer is always an “endothelium.”

The most specialized organisms in evolutionary terms have ten different organ systems. These systems have evolved to serve specialized, interdependent functions including digestion, mobility (muscular), support (skeletal), sensory and control (nervous), gas exchange (respiratory), circulation, plasma salt and protein balance (urinary), reproduction, protection and thermoregulation (integumentary), and endocrine regulation of physiological functions (4). These specializations, typically occurring in larger terrestrial mammals, are associated with more the complex vascular systems concomitant with EC heterogeneity.

The circulatory system is among the first functioning organ systems to form during development (5). In chordates, the first vessels form in midgastrulation, and the heart begins

pumping blood through these vessels during the transition from late gastrulation to early organogenesis (6). The key feature requiring circulation for the embryo is increased size and complexity. As the embryo grows larger and becomes regionalized, with a noticeable head, trunk, and hind, the increased size and complexity demand perfusion of those regions for the provision of nutrients and oxygen ( $O_2$ ) and also the removal of respiratory waste. Based on size alone, simple diffusion is no longer adequate to provide all cells and tissues with  $O_2$ , and a vascular system expands to meet the demand.

Developmental trends from midgastrulation through organogenesis also reveal that the endothelium forms the morphological base for the vascular system both in utero (7) and in ovo (8). The evolutionary and developmental demands for a pump/heart, contractility, immunology, and other functions come at later stages. The evolutionary conservation of developmental systems is similar to the conservation of anatomical structures and physiological systems: They are conserved because no advantage accrues from change. A consideration of developmental stages from conception through midgastrulation, when the endothelium begins to develop, suggests that the evolution of developmental mechanisms and processes in chordates has been conservative by building on the most basic developmental requirements of the simplest organisms (9). Preservation of the branchial arches and pharyngeal pouches in the embryo is likely the best example of that conservation. They are conserved in earlier, aquatic adult organisms (i.e., fishes and amphibians), but remodeled in adult terrapods. Perhaps this adaptation reflects the demand for gas exchange between the atmosphere and a liquid circulatory system on land.

The evolution of vascular development is quite similar. It appears that the most basic elements of a simple circulatory system are conserved, then adaptations occur at later stages. For example, evolution of cardinal veins and a dorsal aorta precede the heart in some aquatic cephalochordates such as *Amphioxus* (10). The evolution of lungs in terrapods results in a reduction in the size of the dorsal body space commensurate with an increased ventral body space. Relative to the vasculature, these changes are commensurate with a reduction of the posterior cardinal veins and evolution of the caval system for anterior venous drainage (11). Yet, the posterior cardinal veins still are evident in the early stages of the vascular development of more specialized chordates, including *Homo sapiens*. However, like the gill system, they are remodeled during organogenesis, relatively late in development. In essence, the evolutionary trend for vascular biology is to conserve the most basic processes early in development and allow remodeling during late gastrulation and organogenesis for the development of specializations.

Comparisons of vascular development among chordates show the same evolutionary conservation, in which vasculogenesis and angiogenic processes develop very similar vascular patterns. Most chordates have dorsal and ventral aortae, a cardinal system, and a primitive single-chambered heart.

These structures are conserved in simpler chordate adults such as lampreys, but remodeled in larger more specialized mammalian terrapods such as mice (see Figure 4.1) (10). Most of that remodeling occurs in organogenesis, during those stages of development when most of the specialization occurs; the earlier developmental stages are conserved. The basic, primitive vasculature develops during gastrulation; later, during organogenesis, remodeling of the basic, primitive system occurs, thereby generating specializations for each individual organ and subsequent endothelial heterogeneity.

Overall, for tissues to survive in increasingly larger, complex organisms, they must circulate fluids. Thus, as the organism becomes larger during evolution or the embryo becomes larger during development, circulation becomes a primary requirement. First, the perfusion demand is met by a simple vasculature composed mostly of a homogeneous endothelium. Later, as the organism or embryo becomes more specialized, a more specialized vasculature develops with the addition of a heart, smooth muscle, and a regionalized heterogeneous endothelium.

## BIRTH, DEATH, AND GASTRULATION

“It is not birth, marriage, or death, but gastrulation, which is truly the most important time in your life” according to a classical description provided by Louis Wolpert (5). Perhaps an exaggeration, the emphasis must not be lost regarding gastrulation that entails the formation of germ layers with specific fates and, regarding mesoderm, in reference to the circulatory system. Gastrulation is the major developmental specialization in evolution. It sets the stage for the physiological specializations occurring when organisms increase in size and complexity. Only with the evolution of gastrulation came evolution of the circulatory system, commensurate with the perfusion of tissues with  $O_2$  and nutrients and the disposal of carbon dioxide and nitrogenous wastes. Concurrent with these specializations came enhanced locomotion through extended use of the musculature and advanced neurological functions for sensory and motor control. It is not long into gastrulation that the first pluripotent mesoderm begins differentiation into angioblasts, at the start of vascular development (12,13). In this developmental scheme, hemangioblasts, first observed nearly a century ago (14–16) are the pluripotent precursors for hematopoietic cells and ECs.

## THE HEMANGIOBLAST

Hemangioblasts were purposed as the most primitive or undifferentiated prevascular cell because they were first observed on blood islands in the yolk sac and the periphery of the embryo before the embryonic vasculature developed. The early models for vascular development held that the hemangioblast (17) gave rise to blood cells and angioblasts from yolk sac precursors that migrate into the embryo proper to form the vascular

anlagen.<sup>1</sup> These are later remodeled into the embryonic circulatory system and hematopoietically formed elements (15,16). However, for many years, the hemangioblast was a theoretical concept because it had never been characterized, isolated, and proven pluripotent for both the blood and endothelium. Recent advances using differentiation markers such as FLT-1, TAL1/SLC, and platelet-endothelial cell adhesion molecule (PECAM)-1 (18–20) applied to in vitro stem-cell technology have characterized the hemangioblast a pluripotent cell upstream from both the angioblast and hematoblast (21,22). The hemangioblast offspring are freely differentiating, proliferating, and migrating angioblasts that form the basis for the “vasculogenesis” mode of vascular development (23). These new data have not only confirmed the existence of the hemangioblast, but they also have provided insights into differentiation pathways that regulate the mesoderm to hemangioblast differentiation and the subsequent hemangioblast to angioblast differentiation. The models include familiar endothelial regulatory genes such as TAL1/SLC and bone morphogenetic protein (BMP)-4 (20), hypoxia-inducible factor (HIF)-1 $\alpha$  (21), and HoxB5 (22). These are required for mesodermal differentiation into hemangioblasts; then, vascular endothelial growth factor (VEGF) and its receptor, FLK-1, are required for hemangioblast-to-angioblast differentiation (24–26).

In evolutionary terms, hemangioblasts have been described in invertebrates, aves, amphibians, and mammals (7,27). Across species, they represent a common, pluripotent stem cell capable of differentiating to either formed blood elements or the endothelium. However, a consideration of echinoderms, which have circulatory channels but no endothelium, and cephalochordates, with a primitive endothelium but no formed elements, suggests that the angioblast and endothelium may have evolved independently or before the hematopoietic precursors. Several models show that angioblasts differentiate directly from mesoderm without hematopoietic potential (12,28–30). This revives an enduring question regarding the pluripotency of mesodermal derivatives: If an angioblast arises from lateral plate mesoderm and forms a blood vessel, does it have hematopoietic potential in the interim? This problem, represented in Figure 4.2, does reveal a scenario in which redundancy for the sake of evolutionary fortitude may allow both processes to occur simultaneously in the same embryo. This type of diversity in vascular development would certainly confer the greatest evolutionary advantage.

## COMPARATIVE EMBRYOLOGY OF VASCULAR DEVELOPMENT

The first and best descriptions of vascular development published in peer-reviewed scientific journals came in the early twentieth century by Evans (14) and Sabin (15,16). Sabin, in

Figure 4.2. In evolutionary and phylogenetic terms, vasculogenesis is the precursor to angiogenesis, and the same holds true for embryonic vascular development. Current models hold that hemangioblasts and angioblasts both can arise from mesoderm. No current data suggest that either cell can be derived from endoderm or ectoderm. The central question is whether all angioblasts arise from hemangioblasts, or whether angioblasts that have no hematopoietic potential arise independently, directly from mesoderm. Perhaps both are true. Angioblasts then form vascular primordia de novo through vasculogenesis. Further neovascularization then occurs by angiogenesis or vascular sprouting from existing vessels. Several models show that circulating or free angioblasts can contribute to vascular sprouts as an alternative form of vasculogenesis, thus adding more diversity to the developmental system.

particular, described two fundamentally different modes of blood vessel development in de novo and branching terms (16). Subsequent descriptions of vascular and lymphatic development (31,32) predominantly described the branching morphogenesis aspects vascular development, because that represented the technical limits for observation through compound microscopes of ink-injected embryos.

Increasing interest in tumor angiogenesis during the 1970s, led by Folkman (33,34), generated advancements in understanding vascular development during the 1980s, when use of the QH-1 monoclonal antibody for immunofluorescence microscopy and immunoelectron microscopy led to more detailed descriptions of the de novo process for vascular development and its relationship to branching vascular morphogenesis or angiogenesis (12,13,35). The commonly used nomenclature, “vasculogenesis” for de novo vascular development and “angiogenesis” for branching vascular morphogenesis were then applied to in vitro (36) and in vivo (37,38) developmental systems.

A consideration of how these two modes of vascular development evolved provides insight into how the endothelium may have evolved. Primitive vascular systems in arthropods and insects are “open” circulatory systems, in which hemolymph is pumped in a directed, consistent manner to provide circulation of molecules and cells. In these organisms, body fluids that are separate from the feeding process are circulated within a body cavity enclosed by an exoskeleton that provides increased perfusion of organs and immune protection. The addition of a muscular pump or heart is a specialization that increases perfusion. Subsequent advancement to the closed system observed in invertebrate annelids and chordate tunicates provides even more protection, better perfusion, and thermoregulation.

<sup>1</sup> Anlagen is synonymous with morphological precursor.

The initial evolution of an open circulatory system appears to occur through a vasculogenesis mechanism. Condensations of differentiating mesodermal cells in the embryos form the anlagen of the initial, open channels that later acquire musculature (heart or smooth muscle) in organisms such as *Drosophila* (39). This is also true in developing birds and mammals, in which the first vessels form through vasculogenesis (40–42). Evolutionary conservation of the vasculogenic mechanism as the first means to develop the embryonic circulation is noteworthy. First, it demonstrates the importance of gastrulation and mesoderm as adaptations that allow formation of a circulatory system. Second, it shows a consistent, conserved function for blood vessel growth and development in ontogeny (i.e., the perfusion of rapidly growing, enlarging embryonic tissues that become ischemic without circulating blood).

Angiogenesis, in terms of sprouting or branching vascular morphogenesis from the existing vasculature, is a logical adaptation from vasculogenesis as the organism enlarges in size during development, and hypoxic regions require perfusion. Intuitively, it seems to be a more efficient process than vasculogenesis. As shown in Figure 4.2, the existing endothelium generally is considered the source of cells for this extension of the existing vessel. In angiogenesis, the new vessels are simply produced by mitotic expansion, in contrast to vasculogenesis, which requires recruitment, differentiation, adhesion, and maturation of surrounding, pluripotent mesoderm that may not be readily available. However, several studies have shown that circulating angioblasts are capable of homing to a sprouting vessel and undergoing incorporation into the endothelium (43,44). Thus, the source of ECs for embryonic angiogenesis is not necessarily limited to the existing endothelium. Blocking experiments in embryos conducted during fate mapping experiments (37), and the relative difficulty encountered in effectively blocking angiogenesis during tumor neovascularization, suggest that the evolution of neovascularization has provided a robust, opportunistic angiogenic process.

Perhaps the best means to distinguish the two modes of vascular development relative to function and evolutionary significance is to survey where and when either vasculogenesis or angiogenesis occur. Overall, vasculogenesis is mostly a developmental process that initially establishes the embryonic vascular pattern during gastrulation. Then, during organogenesis and in the adult, the angiogenic process dominates to perfuse organs and limbs. Finer resolution of the processes at work during vascular development reveals that both modes are at work in the earliest stages. Based on avian and mammalian data (12,13,42), the first vascular tissues form through vasculogenesis as capillary strands on the hypoblast or splanchnopleure during midgastrulation, when the first somites appear. Within a few hours, these structures, including the primitive dorsal aortae, have expanded to the length of the embryo and begin to sprout between the somites as intersomitic arteries. Later, the cardinal veins on the dorsal surface form likewise, and the same combination of vasculogenesis and angiogenesis forms the pattern for the endocardium that connects the

aortic arches. Once the aortic and cardiac circulations fuse, the embryo begins to circulate blood; then the transition from vasculogenesis to angiogenesis begins. Angiogenesis becomes the favored mode of vascular development and predominates into the adult stages to maintain vascular homeostasis in processes such as wound healing and in pathological processes such as tumor angiogenesis.

A comparison of the events occurring in vascular development during ontogeny with phylogenetic adaptations reveals a similar basic function for expanded, specialized vascular systems: meeting the perfusion demands of larger, more complex body forms. The earliest circulatory systems in marine invertebrates and insects appear to develop through initial condensations of mesoderm. This may be followed by some sprouting, but the latter is very limited, if occurring at all. The earliest vascular systems circulate water through marine invertebrates such as echinoderms for feeding and ambulation (ambulacral systems). These organisms have vascular channels with an intimal layer, but this is not considered an endothelium proper (3). However, echinoderms are deuterostomes and, therefore, they are distantly related to vertebrates and humans. This suggests that the echinoderm circulatory systems may be the evolutionary precursors for the closed systems of chordates.

A comparison of vascular systems in the chordates is revealing. Within the urochordates some species lack a circulatory system; others have a closed fluid, noncellular system; and then sea squirts and tunicates, for example, have both a closed circulatory system with an “endothelium” and a cellularized circulatory fluid (3,10). A comprehensive comparison suggests that several independent evolutionary pathways result in the most specialized form of a circulatory system. The simplest forms manifest an open circulation of noncellular fluids within a cellular tube with a nonseptate muscular band that serves a pump. The most specialized forms contain an endothelium, smooth muscle, a four-chambered heart that serves serial pulmonary and systemic circulations, and a urogenital system (see Figure 4.1).

The common element in the independent, convergent evolution of the endothelium and advanced circulatory systems is gastrulation and the subsequent formation of mesodermal tissue. No phylogenetic or ontogenic evidence suggests that endothelium arises from any embryonic tissue except mesoderm. Mesoderm is a product of gastrulation; consequently, the principal means for the initial formation of blood vessels in all developmental systems across all species is vasculogenesis—mesodermal differentiation and the subsequent aggregation of the angioblast products.

## EVOLUTION OF ENDOTHELIAL HETEROGENEITY

Once vasculogenesis has occurred, however, the angiogenic process takes over and drives the vascularization of many organ rudiments and organs (40,41,45). The fact that the greatest

Figure 4.3. The evolution of developmental processes is represented by the application of fundamental processes, such as induction and progressive determination, that are utilized in cleavage and gastrulation of simpler organisms. In more complex, specialized organisms, induction and progressive determination are again found in vascular morphogenesis, exemplifying a more specialized developmental and physiological system. Note the key element of progressive determination, in which pluripotency decreases as differentiation and specialization progress. Application to the hemangioblast model suggests that a point is reached in differentiation at which an angioblast is fated toward a specific endothelium and no longer capable of forming a hematopoietic cell. HEV, high endothelial venules; BBB, blood–brain barrier.

bulk organ perfusion occurs in organogenesis, the developmental phase following gastrulation, once again reveals the necessity of regional, vascular specialization within larger, more complex organisms (Figure 4.3). This also leads the specialization of the endothelium and the reiteration of endothelial heterogeneity in larger vertebrates. In short, the question arises: If we are discussing the evolution of the endothelium, and the endothelium in advanced organisms is heterogeneous, which endothelium are we discussing during “evolution of the endothelium”? A comparison of the various types of endothelium is discussed in other chapters, but in evolutionary terms the discussion of heterogeneity itself and how it arises is important. At what point in development, and at what point in evolution, does the heterogeneity arise? Transplants and fate mapping in embryos suggest that the endothelium undergoes induction and progressive determination (30,37,38,46,47).

The most important developmental concepts applying to evolution and the development of endothelial heterogeneity are embryonic induction and progressive determination. First conceived by Spemann and Mangold (48), an application of the induction principle to vascular development suggests that the surrounding tissues provide cues for local angioblast differentiation. The progressive determination of the endothelium implies that the mesoderm, in the earliest stages of vascular development, is pluripotent. Pluripotency suggests that earlier angioblasts, which have experienced little differentiation, have the ability to adapt to different regions early in development (i.e., the transplanted angioblasts incorporate into the existing vessels and assume the host phenotype or specialization). The transplant data in avian systems support this principle, in which heterogeneous transplants conducted during early gastrulation show no phenotypic differences (30,43,49). According to progressive determination, however, at later stages of development, the angioblasts become more differentiated, losing their pluripotency and their ability to adapt new phenotypes as they develop into more specialized endothelium. The avian transplant data also support this concept, exemplified by results showing that trunk angioblasts transplanted into

the head generally fail to incorporate into brain endothelium (38). Overall, the application of progressive determination appears to be valid based on the results from fate mapping and transplants in experimental embryology and in clinical human organ transplants, in which vascularization of the transplanted organs is often one of the major problems in rejection (50,51). However, relative to other adult tissues, the vasculature still retains considerable pluripotency (witness the “arterialization” of saphenous vein grafts in coronary artery bypass grafts).

An application of the developmental concepts to evolution and phylogeny suggest that smaller, simpler organisms without complex organ systems will have relatively more endothelial homogeneity. It follows then, that larger organisms with complex organ systems will have less endothelial homogeneity and a more heterogeneous endothelium organ-to-organ or region-to-region. (However, as discussed in Chapter 6, the endothelium of hagfish is heterogeneous, suggesting that EC heterogeneity arose as an early feature of this cell layer in the ancestral vertebrate.) In evolutionary terms, the simplest form of vascular heterogeneity is arterial versus venous endothelium. This was acquired as the simplest heart evolved atria and ventricular regions.

Lymphoid endothelium and vascular endothelium have an evolutionary branching point separate from venous and arterial vessels. It is unclear exactly when the lymphoid system evolved and whether it arose separately from the vascular endothelium. Did the lymphoid system exist previous to the vascular system, with the latter evolving from the primitive lymphatics to circulate blood? Or perhaps the lymphatics arose separately following the paradigm of Figure 4.1, when increasing size necessitated drainage of the interstitium to supplement the existing circulatory system. Gene expression profiles suggest that lymphatics represent a specialized endothelium derived from the vascular system early in the evolutionary process (52–56).

Examples for the comparison of regionally different vascular endothelia include the blood–brain barrier (BBB) in the brain, the high endothelial venules of the lymph nodes, microvascular and large vessel endothelium, and the glomerular endothelium. Differences in microvascular and large-vessel endothelium are discussed elsewhere in this volume and are described extensively in the literature. Based on the earlier discussion, the evolution of these differences is likely a function of size and specialization, working from a model in which the phylogenically simplest endothelium in smaller organisms resembles the microvasculature of larger, more complex organisms (see Figure 4.3). In smaller organisms, such as the sea squirt and annelids, no associated smooth muscle cells, internal or external elastic laminae are present. The endothelium in the phylogenically simplest forms resembles an open capillary in complex mammalian organs, such as the spleen. An extension of this discussion for deuterostome vascular evolution suggests that closure of the circulatory system and commensurate increases in size and complexity of the organism correlates with the acquisition of the smooth muscle cells and

elastic fibers in the medial layer that are key morphological features of large-animal endothelium. Whether the pericytes of the microvasculature are the precursors for smooth muscle, as some in the smooth muscle field suspect, is an argument for another venue. For the purpose of discussing EC evolution, changes in gene expression, EC kinetics, and cell adhesion by the large vessels during progressive determination occur as the vessel becomes functional during organogenesis. Similar changes occur phylogenically as the organisms become highly specialized. This suggests that, aside from recapitulation arguments, vascular specialization in the embryo is an adaptation resulting from increased specialization that is conserved during developmental evolution.

The correlation between increasing size and complexity noted for the evolution of specialized large-vessel endothelium can be said for the acquisition of a BBB. This feature is found in large, specialized organisms that have both a closed circulatory system and a closed central nervous system containing cerebrospinal fluid, with the two closed fluid systems in anatomical apposition. In simpler organisms, such as annelids, the smaller, less-complex central nervous system does not require a specialized vasculature for cerebral perfusion. However, as the brain becomes large and more complex with increased size and folding of the cortex, increased cerebral perfusion is required. The acquisition and evolutionary advantage of the cerebrospinal system, although still requiring perfusion from the systemic circulatory system, suggests a need for the evolution of a specialized endothelium at the interdigitation of the two tissues.

The kidney and acquisition of the highly specialized glomerular endothelium is yet another, very well studied system in vascular development. Elegant experiments using explants from the chick metanephros onto chorioallantoic membranes reported that the developing kidney became vascularized through an angiogenic mechanism (41). As the metanephron became larger and more differentiated, the ECs migrated in from the exterior to first provide perfusion, and then subsequently differentiated into glomerular endothelium. Biochemical signals from morphogenic growth factors such as fibroblast growth factor (FGF) and transforming growth factor (TGF)- $\beta$  are associated with both the initial neovascularization and the subsequent differentiation into glomerular endothelium. Later studies reported that relatively undifferentiated kidney mesoderm associated with VEGF regulation is capable of differentiating into glomerular endothelium (57). These data provide some doubt that the neovascularization of the developing kidney is strictly an angiogenic mechanism with a sole, external source of endothelial precursors. The current model (57) suggests that both angiogenic and vasculogenic modes of development are at work, with the early and predominant neovascularization occurring through angiogenesis. The perfusion of more specialized structures, such as the glomerulus, occurs through a vasculogenic mode that requires tissue induction at the site of the developing glomerulus. In evolutionary terms, this scenario demonstrates

considerable developmental specialization. The evolutionary need to acquire a renal organ and urinary system during the transition from aquatic to land animals once again correlates with a demand for perfusion of those specialized organs from the systemic circulation.

The development of a complex, specialized immune system also provides an excellent example of endothelial specialization in both evolution and development. Two striking examples exist of specialized endothelium associated with the interaction of the systemic circulatory system and the immune system: lymphatic endothelium and the high endothelial venules in lymph nodes. The question of whether the lymphatic circulation or the systemic circulation evolved first has been deferred. The simplest deuterostomes, echinoderms, have a closed circulatory system with a specialized fluid that bears a resemblance to lymph. Lymphatic endothelium has unique characteristics that suggest it appeared early in evolutionary terms. The evolutionary need for separate lymph and circulatory systems follows the common theme of increased size and specialization of the organism. The primitive, open circulatory systems of insects contain "hemolymph," containing cells in a lymphatic fluid that circulates under the exoskeleton. Insects and deuterostomes are not on the same phylogenetic branch, so it is difficult to determine whether convergent or divergent evolution allows any association in the evolution of the lymphatics. Some lower deuterostomes have a systemic circulation but lack lymphatics, suggesting they either had lymphatics that were later lost in favor of a circulatory system, or never had lymphatics at all. In organisms with lymphatics, the need to transfer lymphoid cells between the lymphatic and systemic circulations has been met through the evolution of the very specialized high endothelial venules (HEVs), which not only allow the transfer of cells but also participate in the differentiation of T cells. Much like the BBB, evolution of HEVs is another example showing the concomitant evolution of specialized body systems in larger, complex organisms requiring the protection of an immune system and perfusion through a circulatory system.

## CONCLUSION

Two common themes emerge when considering the evolution of the vasculature and the evolution of vascular development. First, terrestrial adaptation and/or the increasing size and complexity of organisms is commensurate with the evolution of specialized organ systems. Thereafter, specialized organs are consistent with vascular specializations for improved perfusion of organs, distribution of nutrients and O<sub>2</sub>, and disposal of nitrogenous wastes. Likewise, a larger, more complex embryo is commensurate with a more specialized embryonic vascular system. Second, the embryonic vascular system develops through both vasculogenic and angiogenic modes of vascular development, with vasculogenesis occurring first and angiogenesis second. These processes also are found in the

evolution of more complex organisms, with vasculogenesis evolving first, then angiogenesis second. As the embryos of organisms become larger and more complex, vasculogenesis and then angiogenesis are integrated into vascular development. This suggests that these developmental processes are adaptations to fulfill the need for increased perfusion, and that they are conserved in evolutionary terms. Furthermore, the perfusion of specialized organs during embryonic organogenesis results in a specialized, heterogeneous vasculature within those organs in adults. The evolution of ECs that are capable of both precocious growth to meet perfusion demands and physiological specializations for immunity, renal physiology, and the like are the focal point of vascular evolution.

### KEY POINTS

- The evolution of a specialized vasculature and the evolution of vascular development are both adaptations based on the demand for perfusion of the more specialized organs found in increasingly larger, complex organisms and embryos.
- The EC has evolved as an adaptation to perfuse tissues.
- Adaptations such as gastrulation and the heman-gioblast preceded the EC.
- Two modes of embryonic vascular development—vasculogenesis and angiogenesis—have evolved to perfuse embryos. During embryonic development, vasculogenesis occurs first, then angiogenesis expands and remodels the embryonic vasculature.
- Vasculogenesis precedes angiogenesis in endothelial evolution. These two evolved, developmental processes are conserved in embryogenesis.
- The specialization of the vascular system in organisms is consistent with the size, complexity, and the need for perfusion, of the organs within.
- The increased size and complexity of an organism is concomitant with increased endothelial heterogeneity.

### Future Goals

- To define the molecular basis for evolution of the EC, vasculogenesis, angiogenesis, and endothelial heterogeneity
- To characterize the evolutionary processes that led to the developmental, cellular and molecular heterogeneity of the vascular system, and the endothelium
- To transfer knowledge about endothelial evolution to biomedical applications for newer, advanced treatment of cardiovascular diseases

## Fish Endothelium

Kenneth R. Olson

*Indiana University School of Medicine, South Bend*

Fishes are the most phylogenetically ancient vertebrates, and their cardiovascular system presumably resembles the ancestral prototype. Nearly half of all vertebrate species are fishes, and they are also the most physiologically diverse. For example, hagfish have the highest plasma sodium and chloride concentration of any vertebrate (>400 mM), elasmobranchs (sharks skates and rays) adjust plasma osmolarity with 300 mM urea, and bony fishes maintain plasma osmolarity ~300 mOsm in either saltwater (1,000 mOsm) or freshwater (<1 mOsm). Body temperature varies with the environment and can range from supercooled  $-1.8^{\circ}\text{C}$  in Antarctic icefish to  $40^{\circ}\text{C}$  for desert pupfish. Ambient oxygen ( $\text{O}_2$ ) varies diurnally, seasonally, and with strata from supersaturation to anoxia, and various mechanisms have evolved to deal with hypoxia; the crucian carp is unaffected by up to 5 days in anoxic water, and many fishes breathe air, either using modified gills or as lungfish with a primitive lung. Hagfish have the lowest blood pressure yet measured in any vertebrate (7 to 10 mm Hg), whereas ventral aortic pressure approaches 90 mm Hg in tuna, similar to mammals. The gill and systemic circulations of fishes are arranged in series thus, unlike most other vertebrates, delicate respiratory tissues are exposed to the highest blood pressures. Also unique to fishes is the apparent lack of a lymphatic system; the impact of this on transcapillary fluid balance is largely unknown.

Despite this variability, the general features of cardiovascular systems in all extant vertebrates are surprisingly similar (1). Thus, it seems likely that the piscine cardiovascular system can provide clues into the factors that shaped the evolution of the vertebrate cardiovascular system and defined its plasticity.

The endothelium is the least understood component of the fish cardiovascular system. The intent of this chapter is to highlight some of its unique physiological aspects. Evolution of the endothelium, the role of the endothelium in vasculogenesis, and the specialized attributes of the piscine endocardial endothelium are described elsewhere in this volume.

### ANATOMY

Relatively few attempts have been made to systematically characterize endothelial cell (EC) anatomy in fishes, either

along the vascular tree, among organ systems, or between species. In general, ECs forming systemic capillaries are fairly typical, 4 to 10  $\mu\text{m}$  diameter and 500 to 1,000  $\mu\text{m}$  long. They are surrounded by a basement membrane (2). Although most endothelia are continuous, they are discontinuous in the liver and spleen and fenestrated in renal glomeruli (2). Endothelia in the swim bladder, gill, and secondary circulations are the most extensively studied and appear to be the most specialized.

### SWIM BLADDER

The swim bladder, or gas bladder, is a gas-filled sack present in most fishes. It is used to regulate buoyancy and occasionally to sense vibrations in the water. Many fishes actively secrete  $\text{O}_2$  into the swim bladder with aid of a gas gland that consists of a countercurrent system of long arterial and venous capillaries called a *rete mirabile* (3–7). This countercurrent system short-circuits hydrogen ( $\text{H}^+$ ), which unloads  $\text{O}_2$  from incoming blood and sustains an  $\text{O}_2$  gradient into the bladder. Retial ECs contain large vacuoles, and they have a tubular network that, in some instances, has been shown to be continuous with both plasma (luminal) and interstitial (abluminal) spaces. Water and  $\text{O}_2$  traverse the entire cellular surface, whereas intercellular junctions are the primary pathway for small solutes, and plasma proteins appear to traverse the capillary via the tubules. Arterial capillary ECs are thicker and have more intracellular organelles than do venous capillaries. Stimuli that increase intracellular calcium, such as cyclic adenosine monophosphate (cAMP), increase the permeability of the paracellular (and perhaps tubular) route, and decrease water and  $\text{O}_2$  permeability (7).

### GILL VESSELS

The fish gill is the primary organ of respiration, osmoregulation, nitrogen excretion, acid–base balance, and a major factor in regulating many blood-borne biomolecules. Three vascular pathways are present in the gill: respiratory, nutrient,

Figure 5.1. Fish gill vasculature. Schematic of a single gill arch (GA) and associated vessels is shown in (A). A 300-g rainbow trout (*Oncorhynchus mykiss*) has eight gill arches, each arch has two rows of ~200 paired filaments (F), and each filament has ~200 respiratory lamellae (L) on each side (~400/filament). Nutrient capillaries (NC) and interlamellar vessels (IL) are present between lamellae on each side of filament (enlarged diagram on right). The plane depicts a cross-section through L, IL, and NC as described in (B) and (C), and in Figure 5.2. The respiratory lamella is shown schematically in (B) and the transmission electron micrograph in (C). Pillar cells (PC) are sandwiched between two sheets of pavement epithelial cells (PE) and underlying basement membranes (BM). Flanges (PF) of adjacent PC interdigitate and delimit the vascular space. Collagen columns (C) connect the two BM and are enveloped by the PC membrane (PM), forming a seam (S) on the PC. Axial microfilaments (MF) in PC appear to be contractile. The only true EC (E) is found in the outer margin of the lamellar sinus. N, cell nucleus; RBC, red blood cell; \*, interstitial space. Dotted inset shows cross-section of PM enveloping C. (A, B are modified with permission from Olson KR. Vasculature of the fish gill: anatomical correlates of physiological function. *J Electron Microscop Technique*. 1991;19:389–405 and Olson KR. Vascular anatomy of the fish gill. *J Exp Zool*. 2002;293:214–241. Micrograph is courtesy of J. Mallatt and R. McCall.)

and interlamellar (Figure 5.1). These form the most complex circulatory network in vertebrates (8,9). The respiratory lamellae are thin, parallel, plate-like sinusoids. Each lamella consists of two parallel sheets of pavement epithelium, with underlying basement membranes, sandwiched over spool-like

pillar cells (see Figure 5.1). Typical ECs are found only in the outer lamellar margin, and these are the only cells to contain classical Weibel-Palade bodies (WPBs) (10). Pillar cells line over 95% of the lamellar vascular space but lack WPBs. Cytoplasmic flanges at each end of the pillar cell flare out to attach to neighboring pillar cells, thereby delimiting the vascular space. Each pillar cell envelops four to ten columns of collagen strands, the latter connecting the two apposed sheets of basement membrane (11). The collagen columns presumably provide structural support against the distending intravascular pressure, and their thrombogenicity is minimized by the surrounding pillar cell membrane (11). It is intuitively easy to visualize how the pillar cell plasma membrane could wrap around the collagen strands in the middle of the pillar cell (see Figure 5.1B); however, this also implies that the pillar cell flange is not continuous but rather consists of a number of broad spokes, each interrupted by a central column of collagen. Axially oriented immunoreactive filaments of actin, myosin, and 5.5 LIM protein 5 also have been observed in the pillar cell body surrounding the collagenous columns (12,13). These may provide additional structural support, and they appear to have contractile activity (14). Pillar cells are not innervated (15). Communicating (gap) junctions have been reported in pillar cells from the hagfish (16), but they have not yet been reported in teleosts. Pillar cells have been shown to actively participate in regulating plasma hormones and other blood-borne biomolecules (see below). Perhaps one of the most significant questions that remains unanswered is the degree of pillar cell involvement in actively regulating lamellar perfusion.

Interlamellar and nutrient circulations originate from postlamellar vessels in the body of the gill filament and are often apposed closely to each other (9). Although both are technically systemic circulations, their anatomy is strikingly distinct (Figures 5.2). Interlamellar capillaries contain few or no red cells, and the plasma appears to contain relatively little protein. Interlamellar ECs are thin, the cytoplasm contains few organelles, and the junctions between adjacent cells often overlap. Interlamellar vessels appear very distensible. When deflated, their EC nuclei bulge into the lumen (see Figure 5.2); when distended, they form a voluminous network that may nearly completely envelop an adjacent nutrient vessel (see Figure 5.2). Although fishes lack a lymphatic system (17), the interlamellar vessels may be its antecedent, because many of the anatomical features of interlamellar vessels are reminiscent of mammalian lymphatic capillaries.

Compared to interlamellar vessels, nutrient capillaries have a more regular circumference, frequently contain red cells, and contain more protein in the plasma. Nutrient ECs are also thicker, contain an abundant tubular system and vacuoles, and cell-cell junctions do not overlap. In some fishes, the entrance to either interlamellar or nutrient circulations is lined with ECs bearing numerous, long microvilli that perhaps restrict or regulate blood cell access to these pathways. Interestingly, corneal ECs in the blowfish contain a central cilium and numerous button-like microvilli (18).

Figure 5.2. Vascular architecture of fish gills. (A–C) Transmission electron micrographs of interlamellar (IL) and nutrient capillaries (NC) in the non-respiratory gill filament of rainbow trout, *Oncorhynchus mykiss*. (A) Although IL and NC are closely associated, NC are thicker, have numerous red blood cells (RBC), and more plasma protein, vacuoles (V) and tubules (T). Rectangles are enlarged (B) and (C) showing thin, overlapping valve-like endothelia in the IL (B) and thicker endothelium in NC (C). (Adapted with permission from Olson and Kingsley, unpublished and Olson KR. Secondary circulation in fish: anatomical organization and physiological significance. *J Exp Zool.* 1996;275:172–185.) (D) Scanning electron micrograph of a methylmethacrylate vascular corrosion replica of the dogfish shark (*Squalus acanthias*) gill showing a dilated interlamellar vessel (IL) enveloping a nutrient capillary (NC). (Adapted with permission from Olson KR, Kent B. The microvasculature of the elasmobranch gill. *Cell Tiss Res.* 1980;209:49–63.)

## SECONDARY CIRCULATION

The secondary circulation of bony fishes is unique among vertebrates in that it is an additional vascular network arranged in parallel with the primary system (19–21). It is formed from numerous narrow-bore arterioles (from several hundred to thousands per mm length of primary vessel) (22) that originate from larger systemic arteries. These arterioles then repeatedly anastomose to form progressively larger arterioles and arteries that ultimately supply a secondary capillary circulation in the skin, fins, some skeletal muscle, and buccal and opercular epithelia. Entrance to the secondary system often is guarded by ECs studded with 3- to 7- $\mu\text{m}$  long microvilli, suggesting that it is similar to the interlamellar system in the gill. It has been suggested that the secondary system is involved in osmoregulation because it is usually associated with epithelial tissues;

it also has been proposed to be the progenitor of lymphatics and a volume reservoir. Little is known about the structure of secondary capillaries or their physiology.

## PHYSIOLOGICAL PROPERTIES

### Permeability

Fish capillaries in general appear far more permeable to fluid and macromolecules than do the capillaries of other vertebrates (23,24), and bulk fluid movement between intravascular and interstitial compartments can be rapid and substantial. The half-time for transcapillary fluid transfer, either following plasma injection or loss due to hemorrhage, is only 15 minutes (24). In fact, following hemorrhage, fishes can replace nearly their entire plasma volume with interstitial fluid within

a half hour (25). Because O<sub>2</sub> solubility increases as temperature decreases, many cold-water fishes, such as trout, can survive extended periods with a hematocrit of less than 5.

The whole-body transcapillary filtration coefficient has been measured recently in trout (24). At 5 mL per mm Hg filtration pressure/kg body weight/min, it is five times greater than that reported for mammals. Both capillary hydraulic and oncotic pressures in fishes are between 5 and 15 mm Hg (26). These values are considerably lower than the corresponding 20 to 30 mm Hg pressures found in mammals. Most fish capillaries are freely permeable to protein, and the whole-body reflection coefficient is essentially 0 (0 = protein permeable; 1 = protein impermeable). Permeability measurements of perfused eel rete mirabile support the whole-animal studies: albumin permeability is only slightly less than half that of the extracellular marker, inulin (6), and this difference could be attributable to size exclusion effects (26). Notable (and necessary) exceptions to this are the gill and brain, in which reflection coefficients appear very close to 1 (23). The gill is located between the heart and systemic circulations, and intravascular pressures in the respiratory lamellae can exceed 50 mm Hg. Were it not protein-impermeable, any edema would jeopardize gas exchange. The brain, which is enclosed in a rigid vault, is also edema sensitive.

The high protein permeability of fish capillaries calls into question the relevance of Starling forces (that is, the ability of protein retained in the plasma to counter capillary hydraulic pressure). If extravasated fluid could return to the capillaries with equal ease, the Starling forces would be moot, and a lymphatic system would be unnecessary. A neutrally buoyant environment (i.e., zero hydrostatic pressure) and the relatively low metabolic rate typical of ectotherms, both of which were undoubtedly present in the primordial cardiovascular system, would allow arterial blood pressure to remain relatively low. This would help keep filtration low and thereby require less reabsorption. The addition of hydrostatic pressure, attendant with a terrestrial environment, necessitated an extravascular system to return extravasated protein, a feature common in all other vertebrates. However, the prototypical lymphatic system also may be present in the gill, appearing as the interlamellar circulation, in which higher reflection coefficients and intravascular pressures necessitate an alternative route for removing extravasated protein.

### Metabolic Functions of the Endothelium

Fish ECs have the capacity to modify plasma constituents through metabolism and transmembrane transfer. To date, most information has been obtained from the heart and gill.

The gill, like the mammalian lung, is ideally suited for regulating plasma-borne molecules (27,28). The gill is in series with the systemic circulation and, because no other organ receives more than 20% of the cardiac output, the gill will have five times more capacity than any other organ with the same metabolic activity. The gill also has an extensive endothelial surface area. Calculations based on pillar cell shape and lamel-

**Table 5-1: Percent Removal (or Activation) of Biomolecules from Circulation by Perfused Gills (p) or Gills in Vivo (i)**

Biomolecule	% Removal (or Activation)

lar geometry show that the vascular surface area is 80% greater than the respiratory surface area, approximately 900 cm<sup>2</sup> for a 300 g trout. Much of the gill's metabolic capacity is likely due to pillar cells, because their surface area greatly exceeds that of other ECs.

Biomolecules can be inactivated following their physical removal from the circulation or by endothelial enzymes in contact with plasma. Table 5-1 illustrates the combined efficiency of these processes on a number of physiologically important hormones. Angiotensin converting enzyme (ACE, or kininase II) has been identified in the vascular beds of many fishes. In the gill, it activates 65% angiotensin I to angiotensin II (Ang-II) or inactivates 25% of bradykinin in a single pass. In systemic vessels, Ang-II activation is 100% (29). Gill nutrient and interlamellar pathways play a minor role in Ang-II catabolism, most of which occurs in the systemic circulation. The gill is the predominant site at which natriuretic peptides (NPs) and endothelin (ET)-1 are physically removed from the circulation. NPs are extracted by C-type clearance receptors (NPR-C), whereas the mechanism for ET-1 removal is unknown. ACE and C-type clearance receptors have been identified in gills of the most primitive fishes, hagfish (30,31), and are indicative of the long lineage of endothelial metabolism. Inactivation of biogenic amines can occur via a number of uptake mechanisms and metabolic pathways, and these have not been fully resolved in fishes. Serotonin is removed avidly by the gill and does not circulate. Norepinephrine (NE) inactivation exceeds that of epinephrine; the latter is the predominant circulating amine. Pillar cells accumulate radiolabeled NE, but most inactivation appears to be

via systemic vessels. Gill extraction of PGE<sub>2</sub> and PGI<sub>2</sub> is relatively low.

Endothelial enzymes also are involved in the metabolism of nonvasoactive biomolecules. Carbonic anhydrase, present in endothelium of the swim bladder (32), speeds CO<sub>2</sub> hydration in the process of acid-driven O<sub>2</sub> secretion. Scavenger ECs in the gills of cyclostomes and elasmobranchs and in the heart or kidney of bony fishes also remove a variety of physiological and foreign waste molecules from the circulation (33). The endothelial clearance of xenobiotics by gill pillar cells may be an important adjunct to hepatic metabolism in many fishes, and this provides a first line of defense against environmental contaminants (28,34). Cytochrome P4501A (CYP4501A), which metabolizes polycyclic and polyhalogenated aromatic hydrocarbons, has been found in gill pillar cells (35) and vascular endothelium from most organs (35,36). CYP4501A levels in many endothelia are upregulated by these hydrocarbons as a concerted response to these toxicants. Pillar cells also phagocytose particulates such as colloidal carbon and latex spheres. As an additional defense mechanism, P-glycoprotein and multidrug-resistance protein 2 in brain capillaries of elasmobranchs and teleosts secrete xenobiotics in reverse, driving them from the central nervous system into the blood (37).

### Paracrine and Endocrine Functions of the Endothelium

A definitive identification of endocrine and paracrine signaling molecules produced by fish ECs is very limited, and most evidence is rather indirect. For instance, ET-1 and C-type natriuretic peptide (CNP), both known to be synthesized by mammalian ECs, also are produced by fishes (38,39); however, the tissue of origin is unknown. Evidence for prostanoid-type endothelium-derived relaxing factors (EDRFs) has been based on the similar ability of indomethacin and de-endothelialization to prevent the vasodilatory response of elasmobranch and teleost vessels to a number of stimuli (39–44). Prostaglandin production by fish endothelium has not been measured directly, although a bradykinin-stimulated increase in plasma PGE<sub>2</sub> in intact trout (45) suggests this is a likely candidate. Whether or not nitric oxide (NO) is an EDRF in fishes is controversial. Evidence supporting NO as a vascular EDRF has been obtained only from intact or perfused preparations (46–51). Little evidence supports NO production from isolated vessels; the inhibitors of NO synthase (NOS), or the addition of the NO precursor, L-arginine, are ineffective in isolated vessel preparations, and antibodies to NOS do not react with the endothelium of either sharks or eels (41,52,53). Fritsche and colleagues (54) observed NOS immunoreactivity in the dorsal vein of 3- to 6-day-old zebrafish larva; however, it is not known if this remains in the adult. Compounds known to inhibit cytochrome P450-mediated production of endothelium-derived hyperpolarization factor in mammals generally are ineffective in isolated trout vessels (D.G. Smith and K.R. Olsen, unpublished observations). Thus, the evidence to date suggests that either nonprostanoid EDRFs first evolved in terrestrial

vertebrates or, if present in fishes, occur only in early development. The former scenario seems more likely.

### TECHNICAL ASPECTS

Detailed methods to isolate and culture ECs from capillaries of the eel swim bladder rete mirabile, swim bladder artery and vein, bulbus arteriosus, and ventricle have been described by Garrick (55). Cells can be grown to confluence in 3 to 6 weeks, and subcultures grown in 2 weeks. These methods should be valuable for detailed studies of the physiology of fish vascular endothelium.

### NOTE ADDED IN PROOF

Recent evidence obtained from developing zebrafish embryos has shown that a thin-walled vessel, termed the *thoracic duct* (56) appears between the dorsal aorta and posterior cardinal vein and possesses numerous attributes of a true lymphatic vessel – its development requires Prox1, neuropilin 2, and VEGF-C signaling; the vessels drain the interstitium; they are devoid of erythrocytes; and they are structurally similar to lymphatics of higher vertebrates. Although these studies support the hypothesis of a piscine lymphatic system, it should be noted that similar vessels have been described in a variety of adult fish, in which both arterial and venous anastomoses, characteristic of the secondary circulation, have been identified (57).

### KEY POINTS

Research on the piscine endothelium has lagged far behind mammalian efforts, yet a number of similarities and differences are becoming evident:

- Systemic ECs in fishes are anatomically similar to those of mammals, whereas gill pillar cells are unique.
- The fish endothelium is, in general, more permeable to macromolecules.
- As in their mammalian counterparts, fish ECs actively regulate circulating biomolecules via a variety of metabolic pathways and transport mechanisms.
- Fish ECs produce vasodilatory prostanoid(s) but, at this time, little evidence supports endothelial production of either NO or a hyperpolarization factor.

The physiological and ecological diversity of fishes has undoubtedly pushed the adaptability of the

cardiovascular system to limits not encountered by mammals. Although the zebrafish has been invaluable in developmental studies, the aspect of the piscine endothelium as a model system of vascular adaptability is only beginning to be explored. These studies should provide considerable insight into the forces that shaped the evolution of the vertebrate cardiovascular system and the plasticity of the endothelium.

## Hagfish

### A Model for Early Endothelium

Salisbury Cove, Maine

Evolution can be viewed as a gradual accumulation of adaptive mutations against a background of neutral change. Intraspecific diversity may be the substrate of evolution, but intraorganismal diversity – the emergence of new proteins, new cell types, and new tissue functionalities – is its exquisite product. Each organism, indeed each organ, is a complex, interlocking “bundle of adaptations.”<sup>1</sup> The endothelium is no exception. Over the last three decades, the notion that the endothelium represents an uncomplicated permeability-selective barrier between blood and interstitium has been revised considerably. Endothelial cells (ECs) are now known to regulate inflammation, hemostasis, vasomotor tone, growth and proliferation of other cells, antigen presentation, extravasation of immune cells, and metabolism of tissue- or blood-derived hormones. These functions are differentially regulated in space and time (reviewed in 1). Endothelial cell heterogeneity reflects the capacity of the endothelium to adapt and respond to the unique demands of the underlying tissue (reviewed in 2). An important goal is to dissect the complex molecular mechanisms underlying endothelial cell function and dysfunction.

#### THE CALL FOR AN EVOLUTIONARY APPROACH

Why study comparative and evolutionary vascular biology? First, evolution is at heart an historical science, and curiosity drives us to understand the narrative of biological change as well as patterns that may underlie this change. Second, the study of simple models has for centuries been an indispens-

able tool for sharpening our analysis of more complex biological systems. One is reminded of the contributions of Mendel on *Pisum sativum*, Morgan on *Drosophila melanogaster*, and Kandel on *Aplysia californica*. Third, genomic comparisons between phylogenetically distant species facilitate the identification of essential coding and noncoding regions, because a greater interval of divergence allows neutrally evolving sequences to be discriminated from functionally constrained ones. Fourth, evolutionary thinking allows us to broaden our focus from proximate functions to include evolutionary explanations of EC function. In particular, early adaptations borne of trade-offs that are no longer applicable may contribute to design flaws in a later system. The extreme path-dependence of evolutionary change – imagine trying to build a jet engine from a propeller through slight modifications of preexisting parts – might demarcate the limits of modern endothelium and account for its propensity to disease.

#### HAGFISH AS A MODEL ORGANISM

Three major groups of extant vertebrates exist: hagfish (myxinioids), lampreys, and jawed vertebrates (gnathostomes).<sup>2</sup> All these groups possess ECs. Therefore, it is probable that ECs were already present in their most recent common ancestor. Hagfish and gnathostomes are the most distantly related

1 Here we use *adaptation* in the general sense to include any character (or even loss of character), which equips an organism to better survive in its environment and reproduce, without an implied axis of progression or growth in complexity.

2 The relationships among these groups is currently controversial. Morphological data tend to favor a sister-group relationship between gnathostomes and lampreys, with hagfish more distantly related. Some molecular data favor a sister-group relationship between hagfish and lampreys, with gnathostomes more distantly related. In either case, the last common ancestor of hagfish and gnathostomes was also the last common ancestor of all extant vertebrates. Features of ECs that are shared between hagfish and gnathostomes can be inferred to have already been present in this ancestral vertebrate.

modern animals to possess ECs.<sup>3</sup> This common ancestor lived more than 500 million years ago. Modern hagfish are represented by about 43 species referred to six genera, including *Myxine*, which is discussed in this chapter. These eel-like animals burrow into sea bottoms, from which they emerge on occasion to scavenge dead or morbid offal and prey on benthic invertebrates. They inhabit the nontropical waters of the Northern and Southern Hemispheres, preferring a lifestyle of low temperatures (6°C to 10°C) and moderate depths (30 to 1,500 m).

Hagfish are well-placed in the evolutionary tree to call attention to certain heuristic difficulties that accompany the invertebrate–vertebrate divide. No modern organism, of course, is a true intermediate form. Yet several features of the hagfish body plan bridge (and blur) the morphologic transition from invertebrate to vertebrate. It shares several features common to vertebrates, including segmental architecture with repeating myomeres, closed circulation, cellular blood, an endoskeleton, and ECs. Unlike jawed vertebrates, however, hagfish lack a biting apparatus, a third semicircular canal in the inner ear, spleen, and paired appendages; conversely, they possess a large notochord that is retained into adulthood, horny teeth, and internal gills. The uniqueness of hagfish is further evidenced by the existence of an aneural systemic heart, disseminated pancreatic tissue (within the submucosa of the gut), monomeric hemoglobin, slime-gland pores, and degenerate eyes. Research in hagfish biology may spark insights regarding the most basic features required for an endothelium in the vertebrate body plan.

In this chapter we examine the gross vascular anatomy, histology of local vascular beds, and ultrastructure of ECs in the Atlantic hagfish (*Myxine glutinosa*). We conclude by speculating on evolutionary pressures that may have led the early ancestors of craniates to develop an endothelium, and posit open questions for future research in comparative endothelial biomedicine.

## CARDIOVASCULAR STRUCTURE AND FUNCTION

### Overview

Hagfish have a closed circulation (Figure 6.1). They maintain the lowest arterial blood pressures (between 3 and 8 mm Hg) and highest relative blood volumes (18%) of any vertebrate (Table 6-1). Cardiac output is a “respectable” 8 to 9 mL min<sup>-1</sup> kg<sup>-1</sup> (reviewed in 3), which approaches the values seen in

some teleosts. According to Ohm’s law, cardiac output ( $Q$ ) is a function of pressure gradient ( $\Delta P$ ) over total peripheral resistance ( $TPR$ ) (Equation 1).

$$Q = \Delta P / TPR \quad (\text{Equation 1})$$

Because the pressure gradient, but not the cardiac output, is extraordinarily low (approximately 6 mm Hg),  $TPR$  must be negligible. Indeed,  $TPR$  has been estimated to be the lowest of any vertebrate.

Like other fishes, hagfish have a double-chambered heart containing a single atrium and a single ventricle. Unlike other vertebrates, the hagfish heart lacks cardioregulatory nerves.<sup>4</sup> The heart rate ranges from 18 to 26 beats per minute. The slow heart rate is attributed to the relatively long conduction times of the cardiac action potential – in fact, hagfish seem to be the only animals for which atrial repolarization ( $P_t$ ) normally occurs prior to the onset of ventricular depolarization (QRS complex). Hagfish have a number of accessory hearts: the portal heart, two caudal hearts, and two cardinal hearts. Most notably, the portal heart – a unique adaptation not shared by teleosts, elasmobranchs, or lampreys – serves to increase blood pressure in the common portal vein. The single chamber of the portal heart beats asynchronously with the systemic heart, as it propels blood from the gut into the liver sinusoids.

Similar to the case in other fishes, the branchial (gill) circulation is found in series with the systemic circulation. The gills are unique among vertebrates in that they are internalized and organized as pouches, typically six on each side in *M. glutinosa*.

The hagfish circulation also possesses a series of blood sinuses that are in direct communication with systemic vessels, leading some to characterize the circulation as “semi-closed.”<sup>5</sup> The most prominent of these is the large subcutaneous vascular sinus located between skeletal muscles and the skin, stretching from the tentacles of the snout to the caudal fin fold. Hagfish can hold up to 30% of their blood volume within the sinus system. It is believed that the caudal and cardinal hearts function to reintroduce sinus blood into the systemic circulation.<sup>6</sup>

### Oxygen Delivery

Oxygen ( $O_2$ ) delivery is a function of cardiac output ( $CO$ ) and  $O_2$  content of the blood (Equation 2). Cardiac output is a

3 Invertebrates either have no cardiovascular system, or an open circulation with a heart and aorta, in which “blood” (hemolymph) is ejected into an open body cavity (hematocoel). The lobster and crab aorta is lined by an innermost acellular internal lamina (consisting of fibrous matrix of unbranched fibrils and fine branched filamentous material), a thick middle lamina containing fibroblasts and striated muscle cells, and an external lamina of dense connective tissue, containing granulated cells. In contrast, the whelk (snail) aorta is lined by irregularly/randomly positioned smooth muscle cells, with fibroblasts and granulated cells scattered between the smooth muscle cells.

4 The heart is said to be *aneural*, meaning that the brain lacks direct control of the heart rate. Accumulating evidence suggests that subendocardial chromaffin cells might release catecholamines constitutively to maintain heart rate *in vivo*.

5 It is interesting to speculate that the sinus system represents a vestige of the open circulatory system or the beginnings of a lymphatic system. The cellular lining of the sinuses has yet to be characterized.

6 Each caudal heart contains two skeletal muscle chambers separated by a continuous cartilaginous plate. The cardinal hearts are not hearts in the true sense of the word, because they operate by the contraction of extrinsic muscles.

Figure 6.1. Organization of the hagfish circulation. (A) Schematic representation of adult hagfish cross-section in mid-region. Several features are typical of other vertebrates, including the arrangement of myomeres, neural tube, aorta, and digestive tract. Features that are unique to hagfish include the large subcutaneous sinus between skin and skeletal muscle, the retention of the notochord in the adult, and the presence of slime glands on the ventrolateral surface. (B) Schematic of hagfish circulation. Like other fish the gills and systemic circulation are in series. Unlike other fish the gills are internalized (there are 2 rows of 6 gills in *Myxine*; only one row is shown). Blood enters the subcutaneous sinus via skeletal muscle capillaries and reenters the systemic circulation via accessory hearts (the caudal and cardinal hearts). The portal heart pumps blood from the intestinal vasculature into the systemic heart via the common portal vein.

function of stroke volume ( $SV$ ) and heart rate ( $HR$ ), whereas  $O_2$  content is determined primarily by hemoglobin ( $Hb$ ) levels and  $O_2$  saturation (Equation 3).

$$O_2 \text{ delivery} = CO \times O_2 \text{ content} \quad (\text{Equation 2})$$

$$O_2 \text{ delivery} \propto (SV \times HR) \times (Hb \times O_2 \text{ Saturation}) \quad (\text{Equation 3})$$

Although hagfish are capable of fully saturating their blood in the gills, they have unusually low  $Hb$  levels and thus low  $O_2$  content. Moreover, because the heart lacks coronary arteries, the myocardial cells derive their  $O_2$  from poorly oxygenated mixed venous blood (reviewed in 3). As a result, the myocardium depends heavily on anaerobic metabolism. The heart contains extensive glycogen stores and is believed to generate adenosine triphosphate (ATP) from glycolysis.

Hagfish spend most of their time burrowed in the floor of the ocean. However, they exhibit short bursts of activity, for example when they feed. During exertion, cardiac output is increased. Heart rate demonstrates minimal changes. Thus,

increased stroke volume must account for the change in cardiac output. Indeed, the systemic heart has been shown to be responsive to filling pressures. Body movements help to force blood from the sinus system into the circulation, resulting in elevated preload.

### Large Vessels

Similar to large arteries of other vertebrates, the ventral aorta (and presumably other large arteries) of the hagfish contains three layers: the endothelium, media, and adventitia (4,5). Unlike other vertebrates, the medial smooth muscle cells are not concentrically aligned. The adventitia contains an unusually high number of ganglion cells and nerve fibers. An important property of vertebrate arteries is that they function as elastic reservoirs. During systole, arteries inflate and store energy, which is then released in diastole. Their elastic properties provide for continuing blood flow during diastole and protect against rupture at high pressures. Vertebrate arteries typically contain a combination of elastin and collagen, and display nonlinearly elastic behavior, in that they become stiffer with

**Table 6-1: Hagfish Properties**

	<i>Properties</i>	<i>Functional Significance/Implications</i>	<i>References</i>
<b>Variables involved in oxygen delivery</b>			
Hematocrit	13.5–15% (systemic) (vs. 30% in trout); 4.3% in sinuses	Low oxygen carrying capacity	14
Oxygen content	2.3% volume (vs. 14.6% volume in trout)	High anaerobic capacity	14
Blood pressure	Lowest among vertebrates (1–8 mm Hg)	Optimizes gas counter-current exchange in gills	15
Afterload	Lowest among vertebrates	Facilitates cardiac output	15
Blood volume	Highest among vertebrates (180 ml/kg) (18%)	High filling pressures	14
Cardiac output	Comparable to some teleosts (resting 8–9 ml/kg/min; peak 24 ml/kg/min)		15
<b>Hearts</b>			
Branchial (systemic)	Large (relative to teleosts); cardiac muscle; lacks rigid pericardium; aneural; no coronary circulation; demonstrates Frank-Starling curve	Myocardium bathed by poorly oxygenated venous blood; thus heart relies on anaerobic metabolism; anoxic tolerance based on high glycogen content (glycolysis-mediated generation of ATP)	15, 16
Portal	Cardiac muscle	Believed to “boost” blood flow from mesentery to systemic heart	15
Caudal	Skeletal muscle	Provides propulsion of blood from sinus system to systemic circulation	15
Cardinal	Skeletal muscle	Provides propulsion of blood from sinus system to systemic circulation	15
<b>Blood vessels</b>			
Aorta	Thin (compared with other vertebrates) wall consisting of three layers (endothelium, media, and adventitia), but no elastin	Lack of elastin may account for low (even nonexistent) diastolic pressure; thick wall and elastin may not be needed because of low blood pressures	4, 5
Blood–brain barrier	Capillaries 9–14 $\mu$ m diameter		7
Skin	Well-developed dense capillary network in dermis	Together with lack of scales may facilitate cutaneous respiration; also serves to deliver precursors and nutrients to mucous-producing cells in epidermis	17
<b>Endothelial cells</b>			
Kidneys	Rare fenestrae; many vesicles; thick basal lamina	Filtration believed to occur via pinocytosis	12
Aorta	Simple squamous layer, membrane bound spherical granules; surface vesicles on basal side; long tubules		4,5
Skin	Lectin positive (HPA, PNA, UEA I); tubules; prominent basement membrane, coated pits		9
Brain	Functionally tight BBB; multiple vesicles; EC contain tubular invaginations	Tubular invaginations believed to be involved in calcium regulation, not in transport	10, 11

Figure 6.2. Hagfish gills. (A) Evans blue was injected into the posterior cardinal vein and appears in the ventral aorta, afferent gill artery and radial arteries of gill pouch. (B) H&E staining of a 10  $\mu\text{m}$  frozen section from the gill of hagfish, BV indicates one of several blood vessels cut in cross section, WD indicates water duct or channel. (C) Immunofluorescent staining of 10- $\mu\text{m}$  frozen section from the gill of hagfish using FITC-labeled UEA-1. Arrows point to UEA-1-positive ECs.

increased stretch. Although the aorta of hagfish (and lamprey) displays nonlinearity as evidenced by in vitro inflation experiments, these vessels do not contain elastin (4). Rather, they possess compliant elastin-like microfibrils, which are likely responsible for their capacity to function as elastic reservoirs.

In aortic ring preparations, acetylcholine (Ach), nitroprusside, and nitric oxide were shown to cause vasoconstriction, whereas prostaglandins ( $\text{PGE}_1$ ,  $\text{PGE}_2$ , and  $\text{PGI}_2$ ) resulted in vasodilation (6). The paradoxical effect of nitroprusside and nitric oxide was observed in hagfish, lamprey, and cartilaginous fishes, but not in teleosts. These findings argue against an evolutionarily conserved role for the nitric oxide system in mediating vasodilation.

### Capillaries

The capillary bed has been described in the brain, gills, muscle, and dermis of hagfish. In microvascular corrosion casts of the brain examined by scanning electron microscopy, capillaries have large diameters (9.15 to 14.35  $\mu\text{m}$ ) and are poorly demarcated from arterioles and venules (7). These data are consistent with the notion that blood–brain barrier diameter decreased during vertebrate phylogeny. A clue to the selective advantage of reduced capillary diameter may be found in Fick's law of diffusion: Smaller diameter allows for increased

vascular density, hence increased surface area ( $S$ ), and shorter distance for  $\text{O}_2$  to travel ( $t$ ) (Equation 4).<sup>7</sup>

$$\text{O}_2 \text{ diffusion} \propto S/t (\Delta P) \quad (\text{Equation 4})$$

The ventral aorta splits into one pair of afferent brachial arteries for each pair of gills. Each artery then joins an afferent ring artery at the base of the gill folds, which gives rise to afferent radial arteries (Figure 6.2). These radial arteries anastomose and fill out a *corpus cavernosum* in the lateral aspect of the gills. Both are lined with phagocytic high endothelium and smooth muscle cells. The afferent ring artery lassoes the efferent branchial duct as it leaves the gill pouch, so that gas exchange takes place against countercurrent flow with seawater. Gills are irrigated through the pumping of the velum, which draws ocean water in the nasopharyngeal duct and into the afferent branchial duct of each gill. The velum is a relatively weak muscle compared to the buccal and opercular apparatuses used by teleost fishes for tidal ventilation. Correspondingly, ventilatory inflow in *M. glutinosa* is thought to be only 15% to 25% of that observed for teleosts, although  $\text{O}_2$  extraction is just as efficient.

7 It is also possible that smaller-diameter capillaries result in increased deformation of red blood cells, resulting in increased red blood cell–EC contact, thus increased surface area for gas exchange.

In skeletal muscle, 97% of the capillaries are located next to red fibers, whereas 53% of white fibers lack adjacent capillaries (8). These findings, which are typical for most vertebrates, are in keeping with the relative O<sub>2</sub> requirements of each fiber type.

The dermis contains an extensive and elaborate network of capillaries, which are located mainly on the outer one-third of the layer (9). These capillaries are lined by ECs, overlying a prominent basement membrane that is shared by occasional pericytes. The presence of an organized capillary network in the dermis may facilitate cutaneous respiration when the hagfish is burrowed and thus less able to draw in water over the gills. Some have argued that the diffusion distance from the water to the capillary beds is too large for skin breathing to be feasible. An alternative, although not mutually exclusive, explanation is that high capillary density is required to meet the high metabolic demands of the slime-producing mucus cells, which lie in the epidermis.

### Endothelium

Electron microscopic studies of the ventral aorta demonstrate an endothelial lining whose fine structure is “similar to those described lining the walls of blood vessels in most vertebrates” (5). These cells are rounded or flattened, have irregularly shaped nuclei, and are linked to neighboring cells via junctional complexes. The cytoplasm contains endoplasmic reticulum (ER), Golgi apparatus, few mitochondria, and “variable numbers of membrane-bound spherical granules.” Surface vesicles were found predominantly on the basal side of the cell, where they formed “long tubules.” ECs in the dermal capillaries of hagfish have been shown to bind lectins, including helix pomatia agglutinin (HPA), peanut agglutinin (PNA), and *Ulex europaeus* agglutinin I (UEA I) (9). However, it is not clear whether lectins bind to the sugars of the cytoplasm, as in mammals, or to subendothelial structures (9). In electron microscopic studies, dermal ECs display highly variable thickness, flattened nuclei, and cytoplasmic smooth tubules (also termed tubular invaginations), coated pits, coated vesicles, Golgi apparatuses, mitochondria, ER, and “dense bodies” (9). These ECs were noted to display “flange-like” lateral extensions that form desmosome-like interdigitations between adjacent cells. In our own studies, we have demonstrated that dermal capillaries contain continuous endothelium, with junctional complexes typical of the adherens and tight junctions found in the endothelium of other vertebrates (Figure 6.3).

Although the blood–brain barrier of the hagfish is tight (10), the endothelial lining of the blood–brain barrier contains many more vesicles when compared with other vertebrates. Cerebral endothelium is characterized by tubular invaginations, or infoldings of the EC membrane (11). The function of these invaginations is unknown. In the kidney, endothelial cells display rare fenestrae, but contain numerous vesicles (12). Finally, recent studies have demonstrated that ECs in gill arteries function as scavengers, much like the ECs in the

endocardium of teleosts or the liver sinusoidal ECs of higher vertebrates (13).

### EVOLUTIONARY CONSIDERATIONS

Hagfish are the most distant human relatives to possess an endothelium. Thus, the study of its cardiovascular system may provide insight into the evolutionary origins of the endothelium. ECs are found in hagfish (and all other vertebrates), but are absent in invertebrates, cephalochordates (e.g., amphioxus), and tunicates. The fact that the endothelium is shared by jawless and jawed vertebrates is evidence that the endothelium was present in the ancestor of these animals. The absence of endothelium in cephalochordates and tunicates suggests that this structure evolved after the divergence of these groups from the vertebrate lineage, between 550 and 510 million years ago.

Many invertebrates, cephalochordates, and tunicates possess muscular hearts that pump hemolymph through tubes into an open cavity. Although this latter design – a so-called open circulation – is not lined by endothelium, its mere presence indicates that contractile muscle as a means of providing bulk flow to various cells of the body evolved far earlier than did the endothelium.

The hagfish cardiovascular system has several unique features, including low blood pressures, the presence of a portal heart, and a large sinus system. An interesting question is whether these properties are derived or ancestral. Consider, for example, the portal heart. All vertebrates (and many invertebrate animals) have a single heart. If the accessory portal heart of the hagfish is indeed ancestral, then it must have been lost during evolution of the jawed vertebrates. Alternatively, the portal heart may have derived in the hagfish lineage, perhaps as an adaptation to maintain adequate venous return in the face of increased O<sub>2</sub> demands. One way to address the question of derivation versus ancestry would be to compare the cardiovascular system of hagfish to lamprey. However, such an approach is rendered dubious by the ongoing controversy regarding the relationship of these two groups.

Further analysis of the hagfish endothelium may provide important information about the evolutionary history of endothelial structure and function. The endothelium of higher vertebrates is involved in many aspects of homeostasis, including regulation of vasomotor tone, leukocyte trafficking, hemostasis, antigen presentation, barrier function. For each of the above properties, one may pose the following question: Is that feature present in hagfish and thus present in a common ancestor, or is it absent in hagfish and thus derived during vertebrate evolution? For example, does endothelium in hagfish exhibit all or some properties of vasomotor tone, leukocyte trafficking, hemostasis, antigen presentation, and barrier function? The findings in the aortic ring experiments suggest that hagfish (and perhaps cartilaginous fishes) employ unique mechanisms to control vasomotor tone. If hagfish endothelium contributes to hemostatic balance, does it

Figure 6.3. Dermal microvascular endothelium. (A) EM of dermis reveals a microvessel in cross-section. Cells containing melanin granules are seen in the extravascular space on the right hand side of the microvessel. (B) Higher magnification of a similar vessel shows well-developed lateral borders of two adjacent ECs, caveolae, and basal lamina.

express the same complement of procoagulants and anticoagulants as does mammalian endothelium? Using transmission electron microscopy, we have recently observed classic Weibel-Palade bodies in ECs from hagfish (18). These observations strongly suggest that hagfish express von Willebrand factor, a highly complex molecule that is absent in invertebrates.

The endothelium is a mosaic of phenotypes, exhibiting site-specific differences in morphology and activity. Such complexity is likely to reflect the cell's ability to adapt to the varying needs of underlying tissues. We have recently demonstrated that the endothelium of hagfish displays vascular bed-specific

heterogeneity in ultrastructure, lectin binding and leukocyte adhesion. These findings suggest that structural, molecular, and functional heterogeneity evolved as an early, core feature of this cell type.

#### NOTE ADDED IN PROOF

We have recently published a study demonstrating the structural, molecular, and functional heterogeneity of hagfish endothelium (18).

## KEY POINTS

- Comparative physiology and morphology provide important insight into the evolutionary origins of endothelial structure and function.
- The fact that the endothelium is shared by hagfish and jawed vertebrates is evidence that the endothelium was present in the ancestor of these animals. The absence of endothelium in amphioxus indicates that this structure was not present in the common ancestor of cephalochordates and vertebrates, and must have evolved following the divergence of amphioxus from vertebrates, between 550 and 510 million years ago.
- Phenotypic heterogeneity is an evolutionarily conserved feature of the endothelium.

## Future Goals

- To determine extent of EC heterogeneity in hagfish and to determine whether hagfish endothelium exhibits all or some properties of vasomotor tone, leukocyte trafficking, hemostasis, antigen presentation, and barrier function

## The Unusual Cardiovascular System of the Hemoglobinless Antarctic Icefish

H. William Detrich III

*Northeastern University, Boston, Massachusetts*

The possession of erythrocytes containing hemoglobin has long been regarded as a sine qua non of the vertebrate condition. Imagine the surprise of zoologists when they read J. T. Ruud's *Nature* article on icefishes, "Vertebrates without erythrocytes and blood pigment" (1). Ruud himself was skeptical when he heard about the *blodlaus-fisk* (i.e., lacking hemoglobin-bearing erythrocytes) that whalers reported to inhabit the waters of South Georgia in the Antarctic. He explained:

I first heard about these "bloodless fish" on a visit to South Georgia in 1929; but no specimens were forthcoming, and I did not take them seriously. I was reminded about their existence, however, when Mr. D. Runstad, biologist of the *Norvegia* Expedition (1927–28), presented me with some photographs of a "white crocodile fish" caught by him at Bouvet Island, mentioning the fact that its blood was colourless (1).

When, years later (1953), he captured several specimens of the "white crocodile fish" *Chaenocephalus aceratus* (family Channichthyidae, suborder Notothenioidei; Figure 7.1) at South Georgia, Ruud measured the hematological parameters of its blood (1). He reported that fresh blood is nearly transparent, contains leukocytes at <1% by volume, is iron poor, and lacks erythrocytes and hemoglobin. Ruud also determined that the oxygen (O<sub>2</sub>)-carrying capacity of *C. aceratus* blood is ~10% that of two red-blooded Antarctic fishes that belong to a closely related family (Nototheniidae, Notothenioidei). In all other respects, hematopoiesis in icefishes appears normal and yields the full complement of teleost nonerythroid blood cell lineages: heterophils, granulocytes, lymphocytes, and thrombocytes (2). Ruud surmised that the evolutionary loss of hemoglobin and red blood cells, which are derived characteristics (i.e., synapomorphies) shared by all 16 members of the Channichthyidae, could only occur in well-aerated

and very cold waters,<sup>1</sup> which typify the Southern Ocean surrounding Antarctica (O<sub>2</sub> near saturation, temperature range -1.9°C to +2°C):

Since these fish presumably descend from ancestors with hemoglobin in their blood, one imagines that only in the cold water of the polar regions could a fish survive which had lost its blood pigment (1).

### ANTARCTIC ICEFISHES: AN EVOLUTIONARY PERSPECTIVE

Implicit in Ruud's hypothesis is the recognition that a phenotype having the absence of erythrocytes and hemoglobin, which would be deleterious or disadaptive<sup>2</sup> for fishes living at high temperature, may be selectively neutral or perhaps disadvantageous but nonlethal at low temperature. Although the icefishes may have benefited from loss of red cells due to a concomitant reduction in blood viscosity (3–5) (this possibility remains unresolved), the development of compensatory readaptations that enhance O<sub>2</sub> delivery, which include large increases in cardiac output, vascular density, and blood volume; substantial cutaneous uptake through a scaleless skin; and a modest decrease in O<sub>2</sub> consumption (6,7), indicates that the phenotype was probably maladaptive under conditions of stress.<sup>3</sup> How, then, does one explain the successful

- 1 Cold water dissolves gases, such as oxygen, to a much greater extent than does warm water.
- 2 Per Montgomery and Clements (3), I define an adaptation as an organismal trait that evolved by natural selection for a particular biological function. Disadaptations are characteristics inferior to phylogenetically antecedent characters, and readaptations are characteristics produced by natural selection that reverse, at least partially, prior disadaptations (3).
- 3 Evolution of these cardiovascular changes in the ancestral channichthyid may have occurred before, or concomitant with, loss of hemoglobin expression, but the factor(s) that would drive this alternative path in icefishes, but not other notothenioids, are not apparent.

Figure 7.1. The icefish *Chaenocephalus aceratus*. (A) A living, gravid female. The ruler measures 15 cm. (B) Lifting the gill operculum reveals the white complex of the gills.

diversification of the notothenioid fishes over the past 10 to 15 million years and the icefishes over the past 5 to 8 million years (8,9)? The answer most likely lies in the well-documented collapse in species diversity in the Southern Ocean that occurred during the mid-Tertiary (~40 million years ago) (5,10).

Whether or not the Antarctic notothenioid fishes possessed the “right stuff,” they came to dominate the fish fauna of the Southern Ocean because tectonic and oceanographic events (e.g., the opening of the Drake Passage ~25 million years ago, and formation of the Antarctic Circumpolar Current and of the Antarctic Polar Front) led to continental glaciation, ice-shelf scouring of the continental shelf, and the cooling of the Southern Ocean to freezing temperatures by 10 to 14 million years ago (10,11). The subsequent loss of habitat and changes in trophic structure caused the extinction of more metabolically active groups. In the absence of significant niche competition, the notothenioids radiated rapidly, such that this suborder makes up over 50% of the species diversity and 90% of the biomass of the Antarctic fish fauna (10). The formation of ice-free marine embayments during the periodic recession of the continental glacial ice cover provided the cold refugia that facilitated notothenioid diversification (8). Thus, icefishes evolved and diversified as selection pressure for a cellular  $O_2$  transport system was relaxed in a cold, stable, and  $O_2$ -rich marine environment. Indeed, virtually all

icefish genomes have lost the globin gene complexes of the red-blooded relatives from which they evolved (12–16).

### THE MYOGLOBIN AND MITOCHONDRIAL CONNECTIONS

The loss of  $O_2$ -binding proteins by icefishes is not restricted to hemoglobin; six of the 16 species do not possess myoglobin in the heart (17,18), the only tissue to express this hemo-protein in the group. Failure to produce cardiac myoglobin by the six species has occurred by four independent mutations and at least three distinct molecular mechanisms (18–20). Furthermore, the myoglobin-expression status of icefishes is associated with quantitative changes in mitochondrial density and morphology. The mitochondrial density of *C. aceratus*, a myoglobin nonexpresser, is dramatically expanded (36% of cardiomyocyte cell volume) compared to those of the icefish expresser *Chionodraco rastrispinosus* (20%) and the red-blooded, myoglobin-expressing notothenioid *Gobionotothen gibberifrons* (16%) (21). Moreover, the packing density of cristae within *C. aceratus* mitochondria is low compared to those found in the mitochondria of myoglobin expressers (21). Assuming myoglobin loss and mitochondrial expansion are physiologically related, what role does the latter play in  $O_2$  delivery to cells?

The expansion of mitochondrial density observed so strikingly in the myoglobinless icefish *C. aceratus* is likely to enhance  $O_2$  flux in the heart by two mechanisms (22,23). First, high densities of mitochondria reduce the mean diffusional path length for  $O_2$  transfer from capillaries to these organelles. Second, the elaboration of additional mitochondrial membrane, a necessary consequence of the organelle expansion, may provide a “lipid highway” that enhances the diffusion of  $O_2$  through the cell because  $O_2$  is more soluble in lipid than in aqueous media. These features should compensate for the absence of myoglobin-mediated intracellular  $O_2$  diffusion (24).

### THE ICEFISH CARDIOVASCULAR SYSTEM

Having examined the molecular and cellular consequences of hemoglobin and myoglobin loss, I now turn to tissue- and organ-level properties of the icefish cardiovascular system. The icefish heart is a spongy myocardium (lacking coronary arteries) (Figure 7.2) that functions as a high-volume, low-pressure pump (ventral aortic pressures are ~2 kPa [26]). Compared to red-blooded notothenioids of the same size, icefishes have very large hearts that produce a weight-normalized cardiac output that is four- to fivefold larger, blood volumes that are two- to fourfold greater, and dense beds of capillaries throughout the body (6,17). The latter point is illustrated dramatically by Figure 7.3, which shows the retinal vasculature of a red-blooded notothenioid *Pagothenia borchgrevinki* and of the icefish *C. aceratus*. Furthermore, the mean capillary diameter in icefishes

Figure 7.2. Myoarchitecture of the spongiform ventricular wall of *C. hamatus*. Scanning electron micrograph showing the myocardial trabeculae and the intratrabecular lacunae of this volume pump. Bar, 100  $\mu\text{m}$  (25). (Reprinted with permission from Pelligrino D, Palmerini CA, Tota B. No hemoglobin but NO: the icefish (*Chionodraco hamatus*) heart as a paradigm. *J Exp Biol.* 2004;207:3855–3864.)

is 1.5 times greater than in red-blooded notothenioids (29). Because the resistance for laminar flow in a tube varies inversely with the fourth power of the radius and directly with viscosity in a Newtonian flow regime, relatively small changes in capillary diameter are expected to contribute significantly to efficient cardiovascular performance.

Although flow resistance and arterial blood pressure are low, the cardiac work of *C. aceratus* and other icefishes is estimated to consume more than 22% of resting metabolic energy production (26). Nevertheless, icefishes have a substantial reserve capacity for the uptake and transport of  $\text{O}_2$  and are certainly able to perform energetic, nonresting activities such as vertical migration in the  $\text{O}_2$ -saturated water column in search of prey (7).

#### JUST SAY NO: THE SIDELL HYPOTHESIS

The roles of nitric oxide (NO), which is produced by several isoforms of NO synthase (NOS) as a modulator of vasodilation (30) and as a signal that stimulates angiogenesis (reviewed by Conway et al. [31]), are well known. Recently, NO also has been shown to stimulate mitochondrial biogenesis (32,33). Should an organism experience long-term systemic elevation of steady-state levels of NO, one might predict that two outcomes would be (a) the expansion of tissue capillary density through angiogenesis and (b) the increase of mitochondrial

densities in heart muscle and other aerobic tissues. These predicted physiological responses correspond to two of the critical adaptations found in the cardiovascular systems of Antarctic icefishes.

Relatively little is known about NO production and levels in Antarctic notothenioids, but two recent reports suggest that this molecule may play an important role in the cardiovascular adaptation in the icefishes. First, Morlà and colleagues (34) reported five icefish species that express neuronal NOS (nNOS or NOS I) constitutively in skeletal muscle at levels that are dramatically higher than those for six red-blooded notothenioids. Second, NO regulates several cardiovascular activities in the heart of the icefish *Chionodraco hamatus*, and NOS activity is present in the endocardial endothelium and cardiomyocytes (25). The NOS isoform of the endocardial endothelium is probably endothelial NOS (eNOS or NOS III), whereas the myocardial isoform is demonstrably inducible NOS (iNOS or NOS II).

We now come full circle to the hemoprotein status of the icefishes. The oxygenated forms of hemoglobin and myoglobin are recognized as the major proteins responsible for the degradation of NO to nitrate (35,36). Thus, I can paraphrase the hypothesis originally developed by Sidell and O'Brien (28): Loss of the expression of hemoproteins during evolution of the Antarctic icefishes results in increased steady-state NO levels that mediate modification of their vascular systems and expansion of mitochondrial populations in oxidative tissues.

Figure 7.3. Retinal vasculature of red- and white-blooded notothenioids. (A) *Pagothernia borchgrivinki*, a hemoglobin-expressing notothenioid (27). (B) *C. aceratus*, a hemoglobin- and erythrocyte-null icefish (28). (Reprinted with permission from Sidell BD, O'Brien KM. When bad things happen to good fish: The loss of hemoglobin and myoglobin expression in Antarctic icefishes. *J Exp Biol.* 2006;209:1791–1802.). The vasculature has been filled with Microfil latex compound. Lenses and vitreous humors have been removed.

In the cold, stable, and O<sub>2</sub>-rich Southern Ocean, the dispersive loss of hemoglobin by the icefishes (and cardiac myoglobin in a subset of the family) may have been compensated evolutionarily by a self-rectifying readaptation. Although this hypothesis may be a simplification and the causality perhaps indirect, it is nonetheless clear that the icefishes possessed the physiological tools to correct a deleterious, but nonlethal O<sub>2</sub>-transport phenotype.

#### KEY POINTS

Antarctic icefishes are a uniquely valuable system for understanding the physiology and biochemistry of cardiovascular adaptation, and the results of such study may suggest novel therapeutic approaches to endothelial diseases:

- Evolution of the erythrocyte-null condition of the Antarctic icefishes could have occurred, almost certainly, only in the Southern Ocean, which is characterized by extremely cold temperatures, high O<sub>2</sub> availability, and low niche competition.
- Loss of hemoprotein expression in icefishes has been compensated by numerous cardiovascular adaptations.
- Recent evidence suggests that at least two of these adaptations, vascular expansion and increased mitochondrial biogenesis, result from the physiological function of the NO/NOS system.

- Key to evaluating the Sidell hypothesis will be a quantitative comparison of the signaling pathways of white- and red-blooded notothenioid fishes that function downstream of NO.
- If causality is direct, the Sidell hypothesis predicts that inhibition of NOS in icefishes, particularly those species that lack both hemoglobin and myoglobin, would lead to regression of vascularity and reduced densities of mitochondria in aerobic tissues.
- The last two proposals are currently under investigation.

# The Fish Endocardium

## A Review on the Teleost Heart

---

José M. Icardo

*University of Cantabria, Santander, Spain*

Research interest in the fish heart has been focused classically on physiological activities and on gross morphological aspects (1–2). Thus, most surveys of the fish heart define the endocardium as a continuous lining formed by cells that may be squamous, cubic, or high. This simple definition summarizes the interest aroused by the endocardium in the field of fish research. However, increasing evidence suggests that the endocardium plays a crucial role in heart physiology. Moreover, the fish endocardium displays functions that are relevant for the entire organism. Most of these data are derived from studies of the teleost heart.

### STRUCTURE OF THE ENDOCARDIUM

It is true that the endocardial cells lining the different chambers of the teleost heart may be squamous, cubic (with a more or less convex surface), or high (3–6). Less recognized is the fact that the histological appearance of endocardial cells may differ in the various heart chambers. In some species, endocardial cells bulge into the lumen of the bulbus arteriosus but are extremely flattened in the ventricle (Figure 8.1). In other species, the converse pattern is found. Histological differences in the endocardium also may occur in different areas of the same heart chamber (4). The extent to which these morphological differences reflect underlying functional heterogeneity remains unknown.

Under the transmission electron microscope, endocardial cells may show rough and smooth endoplasmic reticulum, Golgi apparatus, small mitochondria, microfilaments, and surface microvilli. The cells form a continuous endothelium, and are joined primarily through tight junctions and desmosome-like plaques (6). The interdigitations are complex and may result in cells with overlapping cytoplasm. The abluminal basement membrane is poorly organized.

Some, but not all of these features are unique to the teleost endocardium. For example, extensive interdigitations

with overlapping cytoplasm occur across species, from fishes to mammals (7). Desmosome-like junctions also have been described in other classes of fishes such as in elasmobranchs (7). In mammals, desmosomes do not normally occur between endocardial cells, but their presence can be induced by the injection of proteranol (8). Furthermore, the presence of zonula adherens junctions is well documented in mammals (7).

Perhaps the most striking structural characteristic of the teleost endocardium is the presence of membrane-bounded moderately dense bodies (MDBs) (Figure 8.1). It has been suggested that the histologic appearance of the endocardial cells (high versus flattened) correlates with the presence of these granules (9). However, a more important factor contributing to the degree of endocardial cell bulging is cell density relative to the area occupied by the basal endocardial surface.

MDBs demonstrate heterogeneity in density, structural appearance, and content. In some endocardial cells, they are highly abundant and closely packed, occupying most of the cell cytoplasm. In other cases, only a small number of MDBs can be observed (see Figure 8.1). Most MDBs are rounded and regular, and are structurally similar to the atypical secretory granules, the so-called Weibel-Palade bodies, described in the endothelium of mammalian endothelial cells (ECs) (10). However, other MDBs are oval or irregular. Depending on the species, MDBs may contain homogeneous material of different electron density, fibrillar material, or tubules (3–6). MDBs may be present in only one or in all of the heart chambers. The presence and distribution of MDBs appear to be unrelated to fish size, swimming capabilities, lifestyle, or ecology (9).

MDBs are not unique to teleosts. Endocardial-specific granules also appear in primitive fishes (hagfish and lamprey) and in elasmobranchs (11). Hence, the presence of MDBs seems unrelated to the phylogenetic position of the fish species.

Figure 8.1. Differences in endocardial cell morphology across the heart chambers and across species. (A, B) Scanning electron micrographs from the Antarctic teleost *Trematomus bernacchii*. Endocardial cells in the ventricle (A) are flattened cells (arrows, surface microplacae). In the bulbus arteriosus (B), cells are prominent and show convex surfaces, bulging nucleus, and surface microvilli. Inset: Detail of a nuclear bulging. Arrowheads indicate cell surface pits. (C, D) Light microscope micrographs from the polar teleost *Arctogadus glacialis*. Endocardial cells in the ventricle (C) are tall, prominent cells that contain a limited number of rounded, dark MDBs. Arrow indicates a subendocardial macrophage. In the bulbus (D), flattening of cells is more noticeable. MDBs are not evident. (E, F) TEM micrographs. (E) Ventricular endocardial cells of the European eel are flattened and contain numerous MDBs of small size. Endocardial cell extensions contact the subjacent myocardium (M). N, endocardial nucleus. (F) Bulbus endocardial cells of the Antarctic teleost *Notothenia coriiceps* are tall cells showing numerous MDBs with contents of different electron density. Some MDBs are releasing flocculent material into the bloodstream (thick arrows); others are empty (asterisks). Note the presence of small coated vesicles (thin arrows), cisternae of rough endoplasmic reticulum, and discrete microfilament bundles (F). Bars: A–D: 0.5  $\mu\text{m}$ ; E–F, 1  $\mu\text{m}$ . Inset: 1  $\mu\text{m}$ .

### THE ENDOCARDIUM AS A SECRETORY ORGAN

MDBs represent the morphologic expression of the secretory capabilities of endocardial cells. The MDBs of many species appear to contain neutral mucopolysaccharides (3–4,9). In other species, MDBs react with histochemical probes specific for catecholamines (12). MDBs appear to be the storage site of material prior to secretion. The precise mode of MDB for-

mation is unknown. It is also unclear how the MDB content is released. Direct discharge into the heart lumen has been observed (3) (see Figure 8.1). It presently is unknown whether the content of the MDBs contributes to the formation of the subendocardial extracellular matrix, whether it contains peptides that may regulate local activities or have systemic effects, or all of the above. Because of the great morphologic MDB variability across species, any general statement would be an oversimplification.

Figure 8.2. Fluorescence micrographs from the atrium (A) and ventricle (B) of the Atlantic cod. One hour after intravenous injection of FITC-hyaluronan, labelled hyaluronan (arrows) appears in endocardial (e) cells. Note the different morphology of the endocardium. Endocardial cells are tall in the atrium and flat in the ventricle. m, myocardium. Bar: 10  $\mu$ m. (Reprinted with permission from Sorensen K, Dahl LB, Smedsrod B. Role of endocardial ECs in the turnover of hyaluronan in Atlantic cod (*Gadus morhua*). *Cell Tissue Res.* 1997;290:101–109.)

The secretory capabilities of the teleost endocardium appear to be enhanced greatly in some species. An examination of the bulbus arteriosus of the icefish *Chionodraco hamatus* (3) revealed that the endocardium invaginates into the subjacent tissue and forms solid cell cords that constitute complex secretory structures. Endocardial cells in these cords contain numerous MDBs, which appear to discharge their content directly into the bloodstream. On the basis of the structural appearance, it was suggested that these MDBs may contain mucins or mucopolysaccharides that may protect the endocardium against physical stress (such as cold), thus performing an antifreeze function.

#### THE ENDOCARDIUM AS A SCAVENGER ORGAN

Circulating blood contains a significant amount of soluble waste macromolecules resulting from the various cellular activities and connective-tissue metabolism. In terrestrial vertebrates, these macromolecules are removed from the blood by the ECs of the liver and by macrophages resident in different tissues, such as those located in the proximity of the sinusoids in liver, spleen, and bone marrow. In a broad sense, the two cell types constitute the backbone of the reticuloendothelial system.

Experimental studies in teleosts have shown that this scavenger function is performed primarily by the ECs of the kidney or by the heart endocardium (13). (Clearance and degradation of biomolecules by the gill endothelium is discussed

in Chapter 5.) In recent years, atrial and ventricular endocardial cells of several teleost species have been shown to endocytose hyaluronan (Figure 8.2) (14), collagen (15), carbon particles (16), and ferritin<sup>1</sup> (12). As a general rule, the endocardium takes up soluble material, a process mediated by receptor-mediated endocytosis (17). However, in some cases (e.g., the medaka), endocardial cells also are able to take up particulate material such as India ink (18), ferritin (12), and latex beads (14). It is formally possible that the latter findings represent an experimental artefact associated with high concentrations of injected macromolecules. This caveat notwithstanding, endocardial cells appear to be the main site for the clearance of molecules such as hyaluronan and collagen (14).<sup>2</sup> Indeed, some MDBs could correspond to secondary lysosomes, involved in the degradation of phagocytosed material.

- 1 The location of ECs with scavenger capabilities varies along the phyletic scale. In primitive fishes (hagfish and lampreys) and in elasmobranches, uptake of soluble macromolecules occurs in the gill endothelium. In teleosts, the location of the scavenger endothelium appears to be species-specific. For example, in the Atlantic cod, medaka, and plaice, it occurs in the heart endocardium; in salmonids, in the endothelium of the head and trunk kidney; in higher vertebrates, scavenging activity is carried out primarily by liver ECs. Scavenger cells also occur in the so-called pericardial cells of invertebrates. In addition, the kidney of the lamprey, the kidney and spleen of the medaka, and the kidney, spleen, and liver of the cod contribute in variable degree to the clearance of both soluble and nonsoluble macromolecules (for references, see 13, 16).
- 2 In the Atlantic cod, hyaluronan also is cleared by cells in the kidney and in the spleen. In higher vertebrates, this occurs in liver ECs (for references, see 14).

The heart of all teleosts studied contains subendocardial resident phagocytes (16) (see Figure 8.1C).<sup>3</sup> These cells are able to ingest carbon particles (16), and have been shown to contain degenerated cardiac parasites (19). Endocardial cells and subendocardial macrophages appear to have established complementary and/or cooperative functions. In the teleost medaka, macrophages with phagocytosed material aggregate to form nodules located under the endocardium (18). Direct contact often is observed between the endocardial cells and the macrophages. These aggregations are reminiscent of the melano-macrophage centers, which appear to be the precursors of the germinal centers in higher vertebrates. However, the immune function of the aggregates remains unclear.

The role of the teleost endocardium as a defence barrier may well be even more complex. In the Atlantic cod (*Gadus morhua*), the endocardium appears to be the main site of bacterial lipopolysaccharide (LPS) uptake (17). One hour following injection of radiolabeled LPS, atrial and ventricular endocardial cells are shown to contain nearly half the injected dose. LPS is taken up by endocytosis, via scavenger receptors (17). Atrial (but not ventricular) endocardial cells collaborate with the spleen and the kidney in the clearance of bacterial antigen (20). The exposure of fish to different carcinogens induces the expression of the catalytic cytochrome P450 (CYP450) in the heart endocardium (21). CYP450 localizes in microsomes and appears to be involved in the degradation of endogenous and exogenous compounds. It should be stressed that most research on the scavenger function of the endocardium has focused on the atrium and ventricle. It appears that the bulbus endocardium does not have a scavenger capacity (12–13), although subendocardial macrophages in the bulbus are able to phagocytose ferritin particles and store them in lysosomes (12).

### OTHER ENDOCARDIAL FUNCTIONS

The endocardium has been shown to bind different molecular forms of the natriuretic hormones. Experimental studies carried out on Antarctic teleosts (22) have shown that ventricular endocardial cells bind the two types of natriuretic peptides described in fishes. Understanding of the functional significance of natriuretic hormones in fishes is far from complete. However, it is likely that endocardial cells are able, through the presence of surface receptors for these hormones, to control the physiologic activity of the subjacent myocardium and to participate in the control of body homeostasis.

Nitric oxide (NO) modulates cardiac performance in the teleost *Anguilla anguilla* through the activation of a protein

kinase cascade. Furthermore, NO signalling requires the presence of the endocardium (23). Although information on fishes is still very scarce, the teleost endocardium appears to be an important source of endogenous NO. Endocardial NO, probably acting through different activation pathways, appears to be involved in the regulation of fish heart function through autocrine-paracrine mechanisms (23).

### ENDOCARDIAL HETEROGENEITY AND THE SUBENDOCARDIUM

The endocardium is not a uniform cell layer, but rather demonstrates structural heterogeneity both across and within species. Most probably, the phenotypic differences are associated with functional heterogeneity (e.g., the secretory activity determined by the presence of MDBs, or the restriction of natriuretic peptide binding activity to the ventricular endocardium). These differences cannot easily be explained from an embryological point of view. Fate mapping studies have shown that endocardial progenitors originate in a very limited area of the early blastula and are incorporated into the developing heart with no evidence of chamber restriction (24). Thus, it seems likely that the structural and functional differences are determined – to a large extent – by microenvironmental cues from subjacent tissue (e.g., the myocardium in the atrium and ventricle, and smooth muscle in the bulbus arteriosus). Any such communication is certain to be bi-directional, with endocardial-derived signals influencing the form and function of underlying muscle.

### ENDOCARDIAL ADAPTATION TO THE ENVIRONMENT

The endocardium is able to perform complex secretory functions at below-zero temperatures. The case of the icefishes (3) is paradigmatic in this regard. However, it could be postulated that this is only an example of the long evolutionary adaptation to extreme cold. Experimental studies indicate that the scavenger function of the medaka endocardium is maintained over a wide range of temperatures (4°C to 23°C). Nevertheless, the ability to take up carbon particles is markedly decreased at 4°C (16), reflecting a decrease in general metabolism. Much less is known of the ability of the fish endocardium to respond to other environmental challenges. Our own unpublished studies on the endocardium of the African lungfish indicate that the endocardial cells undergo structural changes during the aestivation period,<sup>4</sup> losing both central surface microvilli and ruffling activity. This is accompanied by changes in the

3 Subendocardial cells are common in the vertebrate heart. In primitive fishes, such as hagfish and lamprey, subendocardial interstitial cells contain catecholamines, show the characteristics of chromaffin cells, and appear to represent the adrenal medulla of these animals. Macrophages probably do occur in these primitive fishes, but their presence has not been reported. Fibroblasts occur in the subendocardium of elasmobranchs, and occasional macrophages and fibroblasts also have been reported in the subendocardium of terrestrial vertebrates (for references, see 7, 11).

4 The aestivation is a state of dormancy or torpor, similar in some ways to mammalian hibernation. During the drought season, lungfish bury in the mud, secreting mucus that envelops the entire body and forms a cocoon, thus allowing them to survive for months without ingesting food or water. During the aestivation period an overall depression occurs of both the general metabolism and of the cardiovascular and renal functions.

nuclear surface and in chromatin distribution, probably reflecting modifications of the cell synthesis activity. Although the evidence indicates that the fish endocardium undergoes functional and structural adaptations during temperature and climate changes, this remains a largely unexplored field.

### Endocardium and Phylogeny

In teleosts, the presence of trabeculae and lacunary spaces in the ventricular chamber, as well as the presence of intricate folds in the bulbus arteriosus, accounts for a relatively greater endocardial mass than in that of the mammalian heart (25). Thus, the fish endocardium represents a large cellular compartment whose importance may be greater than in mammals, from both structural and functional points of view. Indeed, the teleost endocardium appears to perform activities that become restricted to other endothelia (or to other cell types) along the phyletic scale.

#### KEY POINTS

- The teleost endocardium is a complex organ with various capabilities. Most functions appear to be lost through evolution.
- The endocardium is a secretory organ of endocrine and paracrine importance.
- The endocardium acts as a scavenger organ.
- The endocardium regulates the functional activity of the subjacent myocardium.

#### Future Goals

- To identify the secretory products and functional analysis of local and systemic effects

## Skin Breathing in Amphibians

Glenn J. Tattersall

*Brock University, St. Catharines, Ontario, Canada*

Skin breathing, or cutaneous, gas exchange is an important route of respiration in many aquatic or semiaquatic vertebrates, and is particularly well developed in the amphibians. The skin of amphibians contains a unique vasculature that facilitates oxygen ( $O_2$ ) uptake and carbon dioxide ( $CO_2$ ) excretion. Cutaneous gas exchange can fulfill routinely 0% to 100% of  $O_2$  uptake and 20% to 100% of  $CO_2$  excretion (1). Amphibians pay a price for this: They require a relatively thin epidermis and, as a result, suffer from high rates of water loss. Thus, amphibians are, for the most part, tied to an aquatic or semiaquatic life. Furthermore, unlike lungs or gills, the skin lacks a dedicated ventilatory pump and, as such, has been thought to be a poorly regulated respiratory organ, with little scope for change. Research over the past couple of decades has revealed that amphibians may exhibit partial control over the cutaneous vasculature, and that such control is under both neural and possibly hormonal control. For the purposes of this chapter, most information will be taken from literature on ranid frogs (order Anura), because the majority of research has been done on this group.

### AMPHIBIAN CUTANEOUS CIRCULATION

Most amphibians possess a double circulation – the pulmonary and systemic – consisting of a right and left atrium and an undivided ventricle. A similar blood flow distribution pattern exists in reptiles and certain air-breathing fishes (2) (see Chapter 5). Primarily deoxygenated (deoxygenated systemic blood plus oxygenated blood from the skin are mixed) blood returns to the heart via the right atrium, whereas oxygenated blood from the lung only returns to the heart via the left atrium. Both atria connect to the single, undivided ventricle, although considerable flow separation of blood is achieved through the extensive system of trabeculae within the ventricle (3,4). Upon ventricular contraction, deoxygenated blood primarily travels through the spiral valve to the pulmocutaneous artery, which subsequently divides into the pulmonary and cutaneous artery. Oxygenated blood, on the other hand, travels via the aorta to supply blood to the tissues and other parts of

the skin. Thus, the skin generally receives blood from both the systemic and pulmocutaneous circuits (Figure 9.1). Specifically, at least in *Rana catesbeiana* (the American bullfrog), the dorsal skin receives blood primarily from the cutaneous artery, whereas skin surrounding the legs and, to some extent, the ventral surface receives mainly systemic blood (5). The skin circulation is drained by a pair of large cutaneous veins that feed into the subclavian veins and back to the heart. Thus, the skin receives both oxygenated and deoxygenated blood, but returns oxygenated blood to the heart, which is subsequently mixed with deoxygenated blood from the systemic circulation before returning to the right atrium.

A further aspect of import of the amphibian circulation concerns the innervation of the primary circulations to the lung and skin. The cutaneous artery is innervated by adrenergic fibers of sympathetic origin, which cause constriction. The pulmonary arteries themselves are innervated by cholinergic fibers of parasympathetic origin (i.e., the vagus) which cause constriction of the pulmonary artery and dilation of the cutaneous artery (6,7). This reciprocal autonomic innervation of the pulmonary and cutaneous arteries leads to situations in which blood can be directed to the respiratory organ that has the greatest potential for gas exchange. In most cases, this will be the lung, although in cases when the lung is hypoxic, hypercapnic, or poorly ventilated (e.g., during diving), blood flow to the lung will be decreased and blood flow to the skin will at least remain constant, if not increase (8,9).

### CUTANEOUS VASCULATURE

In many amphibians, 20% to 95% of the entire body's respiratory capillaries are in the skin (Figure 9.2) (10). Indeed, in the smaller frogs, skin capillaries can be more abundant than pulmonary capillaries (10). In Czopek's examination of amphibian skin, he observed that the epidermis is only four to seven cell layers thick. Overall, the dorsal epidermis is 10% to 20% thinner (18–24  $\mu m$ ) than the ventral epidermis (32  $\mu m$ ). Unlike in most vertebrates, the skin capillaries are located inside the epidermis rather than the dermis, making

Figure 9.1. Schematic of the generalized circulation in amphibians. Arrows indicate the direction of blood flow. Dotted arrows indicate that a portion of blood can be shunted from one side of the heart to the other side within the undivided ventricle.

the barrier to gas exchange much shorter (see Figure 9.2). The values quoted above, however, were from a rather unique amphibian. The epidermis of most frogs is two to three times thicker, although the respiratory capillaries still lie within the

Figure 9.2. The percentage of respiratory capillaries that are cutaneous in origin differs among groups of amphibians. Lungless salamanders (*open circles*) have greater than 90% of respiratory capillaries in the skin, with the remainder found in the buccal cavity. Lunged salamanders (*filled circles*) and frogs (*squares*), on the other hand, have substantial respiratory capillaries in the lungs, buccal cavity, and skin. Note the trend with increasing body size for the skin to play a decreasing role in providing a vascular network for gas exchange. (Values adopted from Szarski H. The structure of respiratory organs in relation to body size in amphibia. *Evolution*. 1964;18:118–126.)

epidermis. This barrier for gas exchange (18–60  $\mu\text{m}$ ) exceeds that of lung epithelium by one to two orders of magnitude, making the diffusive transfer of gases a relatively slow process.

The respiratory capillaries form a vast network of anastomosing vessels (Figures 9.3 and 9.4) lying within the epidermis and forming a virtual sheet for gas exchange (11). These respiratory capillaries are connected to the skin arteries via branching arterioles, and they drain into subcutaneous veins via venules that penetrate the dermis. Very few true (i.e. systemic) capillaries connect the arterioles directly to venules or the venular network. Flow within the respiratory capillaries themselves exhibits a high degree of heterogeneity (12). Furthermore, the number of capillaries perfused can significantly affect gas exchange (13), although the nature of the regulation of these flows is unknown (i.e., whether it occurs at the arteriolar level or within the capillary network itself). Some clue to this may come from studies examining microvascular permeability (14). Although the respiratory capillaries themselves lack smooth muscle cells, microfilaments within endothelial cells (ECs) have been proposed to be part of a contractile machinery within the frog skin capillaries. These ECs within the capillaries alter their shape and appearance under electrical stimulation (14). Whether they operate in this manner in vivo, respond to neural or hormonal stimulation, or respond to changes in respiratory gases is unknown.

#### SKIN AS A GAS EXCHANGER: ROLE OF DIFFUSION

As in any respiratory organ, the diffusion of gases occurs across a layer of tissue and into the nearby bloodstream. Across large distances, the molecular movement of respiratory gases, which is governed by Fick's law of diffusion is not a very efficient process<sup>1</sup>; therefore the larger the barrier between environmental concentrations of respiratory gases and the internal concentrations, the longer it takes for diffusion to occur. Some amphibians have anatomical modifications that capitalize on Fick's law of diffusion by increasing the total surface area available for gas exchange. The salamander, *Cryptobranchus* (15), and the Lake Titicaca frog, *Telmatobius* (16), have marked folds in their skin that allow for greater diffusive exchange area, and these species are thought to make very little use of their lungs for gas exchange (15). In addition, the male hairy frog, *Astylosternus*, develops epidermal "hairs" during its breeding season that may supplement the total gas exchange surface (17).

Gas exchange across the skin of amphibians is believed to occur between the skin and an "infinite pool" of gases from the direct, surrounding environment (18). However, theoretical considerations and empirical evidence show that an external

1 Fick's law of diffusion:  $= \frac{dQ_g}{dt} = D_g A \frac{dP_g}{dx}$  where  $\frac{dQ_g}{dt}$  is the rate of diffusion of gas (g),  $D_g$  is the Krogh diffusion coefficient,  $A$  is the surface area,  $dP_g$  is the partial pressure gradient, and  $dx$  is the diffusion distance.

Figure 9.3. Organization of skin microcirculation in amphibians. *Top*: Cross-sectional schematic of frog skin, showing the relative placement of blood vessels within and beneath the epidermis. *Bottom*: Schematic of the network of blood vessels within the skin. Mucous gland (M), stratum compactum (C), stratum spongiosum (S), skin arteries (A), branching arterioles (SA), subepidermal or respiratory capillary network (RC), arteriolar branches (PA), venules (DV), subcutaneous veins (V), subcutaneous venular plexus (SV), epidermis (E), lymph endothelium (LE). (Reproduced with permission from Olesen SP, De Saint-Aubain ML, Bundgaard M. Permeabilities of single arterioles and venules in the frog-skin – a functional and morphological-study. *Microvasc Res.* 1984;28:1–22.)

boundary layer of poorly mixed gases contributes to limiting cutaneous gas exchange (19,20). These diffusion-boundary layers result from decreased fluid velocity close to solid surfaces. The decreased fluid velocity prevents bulk flow from occurring close to the solid surface, resulting in a stagnant layer of fluid, through which diffusion is the only means of gas movement. The resulting diffusion-boundary layer poses a limitation to gas exchange (especially  $O_2$ ) primarily because the partial pressure of  $O_2$  at the skin–fluid medium interface

is low, and thus presents a relatively small partial pressure gradient (i.e., driving pressure) across the skin (20). Because it is the partial pressure gradient that ultimately determines the rate of diffusion of a gas across any surface, low values at the skin–water interface result in decreased rates of uptake and subsequent limitations to cutaneous gas exchange.

Amphibians have had to develop methods for coping with these diffusion boundary layers (namely, the hypoxic boundary layers). Increased water velocity acts to minimize or disrupt

Figure 9.4. Scanning electron micrograph of the respiratory capillary network of the tree frog, *Chiromantis petersi*. the boundary layer surrounding the amphibian skin; thus, increased activity or movement could be one method of alleviating boundary layers (21,22). The primarily skin-breathing Lake Titicaca frog, the exclusively aquatic salamander *Cryptobranchus*, and cold-submerged (and thus skin-breathing) bullfrogs all show behaviors described as “bobbing” or “rocking” when confronted with ambient hypoxia (15,16,23), suggesting an integrated detection of  $\text{O}_2$ . These behaviors act to disrupt the hypoxic boundary layers at the skin (18) and promote increased  $\text{O}_2$  diffusion gradients and therefore  $\text{O}_2$  uptake across the respiratory surface (24). Increased locomotory activity has been observed in response to hypoxia in frogs (23,25), and has been interpreted as a means of disrupting and minimizing hypoxic boundary layers by increasing skin ventilation (9,23). This detection of low  $\text{O}_2$  has been suggested by behavioral studies of overwintering amphibians that demonstrate a moderate ability to detect and avoid hypoxic environments (26). This is further supported by data showing that these same submerged, skin-breathing frogs exhibit a decline in preferred body temperature while in hypoxic environments, suggesting a sensory mechanism that modifies behavior (27).

Experimentally, Pinder and Feder (23) demonstrated that increased fluid velocity decreased the actual size of the hypoxic boundary layer around the skin. At high velocities ( $5.2 \text{ cm} \cdot \text{s}^{-1}$ ), hypoxic boundary layers were approximately  $200 \mu\text{m}$ , whereas at low velocities ( $0.2 \text{ cm} \cdot \text{s}^{-1}$ ) they were nearly four times as large, and increased to several millimeters when no water movement was present (23). Increasing the flow of water over the skin also results in a reduced hind limb capillary recruit-

ment, suggesting that local external hypoxia at the skin surface can serve to regulate the open probability of many capillaries. How this autoregulation of blood occurs in amphibian skin is unknown. Furthermore, when boundary layers are disturbed, the overall cutaneous  $\text{O}_2$  uptake rises in frogs (21), suggesting either a limitation of surface  $\text{PO}_2$  to gas exchange, a reflex increase in localized capillary blood flow or recruitment, or both.

#### SKIN AS A GAS EXCHANGER: REGULATION OF CUTANEOUS RESPIRATION

Because the skin lacks a dedicated ventilatory pump characteristic of gills (buccal and opercular muscles) and lungs (intercostal and diaphragmatic muscles), it often has been considered a poorly regulated respiratory organ (21), incapable of matching external medium flow with internal blood perfusion. Ample evidence suggests, however, that cutaneous blood flow can be altered in physiologically meaningful ways (28) and is most strongly affected when amphibians are removed from water; in other words, cutaneous blood flow decreases when the skin is exposed to air, presumably to minimize water loss (13,29). It is not normally the overall rate of blood flow that changes in individual capillaries, but rather the total number of capillaries through which blood flows appears to be altered (13).

The simplest and most compelling evidence that amphibians can, to a large extent, regulate cutaneous gas exchange comes from evidence of obligately skin-breathing amphibians. Lungless salamanders are capable of maintaining a constant rate of  $\text{O}_2$  uptake in hypoxic environments as low as 8%  $\text{O}_2$  ( $\sim 60 \text{ mm Hg}$ ) (30). Furthermore, numerous species of frogs that overwinter under the ice are functionally and exclusively skin breathers for up to 6 months of the year. These species show a capacity to maintain constant  $\text{O}_2$  uptake down to 5%  $\text{O}_2$  ( $\sim 40 \text{ mm Hg}$ ) (24,26). Some obligately skin-breathing amphibians are capable of elevating  $\text{O}_2$  uptake three to five times if made to exercise (31), suggesting that the skin is not 100% limited by its diffusing capacity, and also that there exists a degree of scope and regulation available that is presumably derived from vasculature adjustments and changes in the partial pressure gradients.

Recent work on frog skin suggests that some similarities may exist between the cutaneous artery circulation and the circulation to the lung. In mammals, a well-established relationship exists between alveolar  $\text{O}_2$  levels and blood flow, whereby poorly ventilated alveoli receive little blood (referred to as hypoxic pulmonary vasoconstriction). Based on experiments in which local hypoxia is created over certain regions of the skin, changes in cutaneous perfusion have been observed to occur (28). Within 1 to 1.5 minutes of regional and localized hypoxia, red cell flux velocity decreases by 50%, and the temporal heterogeneity of blood flow within capillaries increases by 30% (32). This response to hypoxia is not likely centrally driven, because the areas of skin exposed were too small to elicit changes in arterial  $\text{PO}_2$ , but is rather an autoregulatory

response brought about by the cutaneous vasculature. This suggests that the O<sub>2</sub> sensor is located within the skin, although where and how it regulates capillary flow is unknown.

Simple and definitive evidence exists, however, for some neural involvement in skin blood flow, at least in the regulation of global changes in skin blood flow. Descending influences from the brain are required for the vasodilatory response of the frog hind web, as evidenced by the fact that hind web capillaries of pithed frogs do not vasodilate under normal stimuli (33). Furthermore,  $\alpha$ -adrenergic blockade in bullfrogs increases the number of perfused capillaries (29) or, at the very least, prevents the normal “closure” of capillaries upon air exposure. Moreover, nonthermal vasodilation in frog hind web capillaries is blocked by guanylate cyclase inhibitors, suggesting that nitric oxide (NO) and calcium (Ca<sup>2+</sup>) signaling also are implicated in the responses of smooth muscles (presumably only in the arterioles or precapillary junctions) (34). However, no definitive studies have attempted to integrate and compare the various roles of circulating versus neural influences.

When examining cutaneous respiration, it also is useful to consider the association between perfusion limitation and diffusion limitation. At low blood perfusion rates, O<sub>2</sub> uptake is limited by the blood flow through the capillaries and should be theoretically directly proportional to the rate of blood, or hemoglobin, flow. At higher perfusion rates, the epidermal barrier limits the exchange of O<sub>2</sub>, due to a relatively stable diffusive conductance. In general, O<sub>2</sub> is mainly diffusion-limited across amphibian skin (35). Increasing blood flow does little to alter cutaneous respiration; plus, most of the parameters determining diffusive conductance are usually difficult to adjust in response to acute challenges (35). Such parameters include cutaneous surface area, capillary radius, distance between capillaries, thickness of the skin, and the diffusion constant of O<sub>2</sub>. Therefore, it seems reasonable to suggest that, for significant blood flow regulation of O<sub>2</sub> uptake to be possible, the overall O<sub>2</sub> requirement of the animal must be relatively low, allowing for regulation to occur within the range of blood flows that accommodate the metabolic demand.

### CUTANEOUS BREATHING: SPECIAL CIRCUMSTANCES IN NATURE

Many temperate amphibians become obligate skin-breathers for up to 6 months of the year when they overwinter under the ice of frozen lakes. Not only are they capable of movement and behavioral thermoregulation (27), but they also enter into a state of reversible metabolic suppression (36,37). Because submerged frogs are capable of regulating constant levels of O<sub>2</sub> uptake down to extremely hypoxic levels, it is possible that they are utilizing alterations in skin perfusion or arterial gases to achieve these results. When exposed to ambient hypoxia or the hypoxemia associated with diving, O<sub>2</sub> delivery to certain tissues is drastically altered. Although perfusion of muscle or other tissues can decrease, the skin must continue to be perfused at an elevated rate to maintain O<sub>2</sub> uptake (38,39),

because pulmonary O<sub>2</sub> uptake is no longer possible. Studies on lungless salamanders suggest that these skin-breathing amphibians are primarily diffusion-limited for gas exchange (13,40,41). As a result, increasing cutaneous blood flow should be an ineffective means of increasing O<sub>2</sub> uptake when required. However, most of these experiments were conducted at higher temperatures, at which skin perfusion is likely already at its maximum; therefore, extrapolating to much lower temperatures may lead to erroneous conclusions about the effectiveness of cutaneous gas exchange in overwintering frogs (24,29). For example, cold-submerged bullfrogs can regulate cutaneous O<sub>2</sub> uptake either through rocking or small movements (i.e., spontaneously ventilating the skin) that disrupt hypoxic boundary layers or by the recruitment of otherwise underperfused capillaries in the skin (24).

Early work also suggested that cutaneous CO<sub>2</sub> conductance does not change with temperature in amphibians (42, 43). These results, however, came from frogs at higher temperatures in air. It appears that the constant cutaneous CO<sub>2</sub> conductance prediction does not fit the scenario at these low temperatures in submerged frogs. Tattersall and Boutilier (44) showed that arterial P<sub>CO<sub>2</sub></sub> remains constant in submerged frogs between 0°C and 7°C, despite an incredible increase in whole animal metabolism (and thus CO<sub>2</sub> excretion), suggesting that CO<sub>2</sub> conductance increases at higher temperatures in submerged frogs, at least up to a critical point. This is quite opposite to the conclusion reached by Mackenzie and Jackson (42) when observing air-breathing frogs at higher temperatures. This is likely to be achieved by the recruitment of blood flow through otherwise underperfused capillaries, thus presenting a greater functional surface area for the exchange of CO<sub>2</sub> to the environment (13). The probable reasons why cutaneous CO<sub>2</sub> conductance changes with temperature in cold-submerged frogs are (a) because their total metabolic requirements are so much lower, and (b) these metabolic demands must be met solely through the skin. Air-breathing frogs at higher temperatures would have sufficient control of O<sub>2</sub> uptake and CO<sub>2</sub> excretion through the combined contributions of the lungs and the skin, but the skin itself will be governed by other external influences, namely that of water conservation. Because any increase in cutaneous conductance for respiratory gases is bound to accelerate the evaporation of water from the skin, air-breathing amphibians likely keep cutaneous conductance at a minimum across a wide temperature range through reductions in cutaneous blood flow, thus minimizing their water loss (45).

### KEY POINTS

- The amphibian skin is a relatively simple, yet not entirely understood respiratory organ, particularly with reference to the regulation of its circulation and the role of the endothelium.

- The amphibian skin serves numerous functions, including respiration, osmoregulation, thermoregulation, protection, reproduction, and communication; as such, it is little wonder that compromises in the efficiency of any one particular system are made to accommodate the function of another. Thus, the amphibian's skin is adaptive in the sense of its flexibility in serving multiple needs (e.g., thermal, hydric, and respiratory), even though it is not optimal for any one particular function.
- The regulation of cutaneous respiration is primarily determined by the diffusive properties of the skin and, ultimately, the boundary layer around it. Capillary recruitment, coupled with voluntary ventilation of the skin, which disrupts the boundary layer, combine to provide amphibians with a unique way of regulating respiration.

#### Future Goals

- To determine what aspects of the cutaneous vascular bed are responsible for regulating gas exchange under conditions related to potential ventilation: perfusion heterogeneities and in conditions relevant to what amphibians experience in nature (i.e., diving, overwintering)
- To determine how the skin appears to detect both external  $\text{Po}_2$  and internal  $\text{Po}_2$  and to respond with appropriate physiological adjustments; in light of recent research into putative cellular  $\text{O}_2$  sensors, the amphibian skin may become a tractable and interesting model for future exploration

## Avian Endothelium

---

Thomas J. Poole

*SUNY Upstate Medical University, Syracuse, New York*

### THE AVIAN EMBRYO

Chick and quail (*Coturnix coturnix japonica*) embryos have advantages for studying embryological events because they can be accessed through the eggshell or in whole embryo culture for microsurgery, microinjection, or electroporation (1). The monoclonal antibody QH-1 that labels quail angioblasts and endothelial cells (ECs) has been used extensively to study the origin of ECs and their assembly into the initial vascular pattern (2–5). This also allowed observation of quail angioblast migration in quail–chick chimeras (4). Although no equivalent monoclonal antibody exists for the chick embryo, fluorescent lectins have been used that bind to the endothelium when injected into the vasculature (6). Mouse tissue also has been successfully grafted into developing quail embryos. The mammalian angioblasts migrate extensively in the avian embryo and respond to host signals that pattern the vasculature (7). The accessibility in whole embryo culture, even into the later developmental stages, has made the quail embryo the ideal organism to follow nerve and blood vessel development in the limb, where antibodies and growth factors have been delivered by bead implantation to study the molecular basis of neurovascular congruence (8). In summary, the ability to manipulate the avian embryo has led to important discoveries of the relative roles of vasculogenesis (vessel formation from angioblast assembly) and angiogenesis (sprouting of new vessels from preexisting vessels) in embryonic vascular development.

### MOLECULAR MARKERS AND BLOOD FLOW

Arterial (ephrinB2, neuropilin 1) and venous (EphB4, neuropilin 2) markers are present on the endothelium of chick, mouse, and zebrafish embryos before blood flow begins (9). The chick embryo has been used to demonstrate that changes in these markers can be experimentally induced by changes in the pattern of blood flow (10). Thus, flow manipulations in the chick embryo before 11 days of incubation can transform arteries into veins and veins into arteries. This ability of arterial ECs to transform into venous ECs (and the reverse) also

is used during normal development as the yolk sac vasculature develops. Ephrins and Eph receptors have been shown to be important in establishing boundaries during both neural and vascular development. Increasingly, a number of growth factors and other signaling molecules have been shown to be important for the formation both of nerves and blood vessels. These signals appear to be the same for birds and mammals.

### THE AVIAN LUNG

The avian lung does not have the typical branching tree structure (bronchioalveolar) of the mammalian lung. Instead, it has what is termed a *parabronchial lung* that is said to be even more efficient physiologically (11,12). The structure of the avian lung, with its parallel parabronchi, is said to resemble a sponge. The extra efficiency of the bird lung is probably due both to the parallel and serial arrangement of the parabronchi and the exceptionally thin capillaries at the sites of gas exchange (11). The origins of the lung vasculature for both the chick and the mouse appear to be primarily by vasculogenesis (13,14). One difference between the chick and the mouse is the evidence for hematopoiesis in the developing chick lung. A recent study of the chick embryo combining vascular filling, serial sections, and immunohistochemistry of endothelial markers and vascular endothelial growth factor (VEGF) demonstrated that the pulmonary vasculature forms by vasculogenesis (14).

### SPECIAL ADAPTATIONS OF THE AVIAN ENDOTHELIUM

The chorioallantoic membrane (CAM) is one aspect of the avian endothelium not found in mammals. The CAM allows for efficient gas exchange through the eggshell and has been used both in the shell and in culture dishes as a model angiogenic assay for screening substances for angiogenic or antiangiogenic activity (15). The CAM is an interesting vascular bed that begins to shut down as soon as it is fully formed. Another concept that emerged from the study of the chick

CAM and the postnatal rat lung is intussusceptive microvascular growth or nonsprouting angiogenesis. This describes the process in which a capillary bed increases its complexity and vascular surface through the splitting of existing vessels by insertion of transcapillary pillars.

Birds also experience special hypoxic conditions when flying at high altitude or diving. Very little is known about any special endothelial adaptations for this purpose. Some evidence suggests changes in physiology (16,17). Avian eggs incubated in hypoxic conditions similar to high altitude are hypervascular (16). Embryos from certain species can hatch successfully at altitudes of up to 6,500 meters. Although no endothelial modifications are known for high-flying species, such as barheaded geese, they do have amino acid substitutions in their hemoglobin that cause a small increase in oxygen affinity (16).

Another interesting question is whether the avian nucleated red blood cell affects the efficiency of gas exchange across the capillary wall or otherwise makes capillary passage different from that of the mammalian red blood cell that lacks a nucleus and has the shape of a biconcave disc.

#### KEY POINTS

- The avian embryo is a useful experimental model for the study of vascular development. EC molecular markers have been well studied in birds, but little is known about special endothelial adaptations for hypoxic conditions.
- The quail embryo has been used extensively to understand the contributions of vasculogenesis and angiogenesis to the vascular pattern.
- The avian lung has a morphology that makes it more efficient than the mammalian lung.
- Future experiments might address how birds can function at high altitude or during diving, and how the nucleated red blood cell interacts with the endothelium.
- Now that the chicken genome has been sequenced, avian embryos will continue to be key model organisms for understanding the molecular mechanisms of vasculogenesis, angiogenesis, and neurovascular congruence.

# Spontaneous Cardiovascular and Endothelial Disorders in Dogs and Cats

---

John E. Rush

*Tufts University School of Veterinary Medicine, North Grafton, Massachusetts*

Cardiovascular disease is common in both dogs and cats, although few efforts have been made to identify the roles that endothelial dysfunction plays in these diseases. Although cardiovascular diseases such as myocardial, pericardial, and valvular heart diseases are a frequent cause of disability in companion animals, atherosclerotic coronary artery disease is almost nonexistent in companion animal species.<sup>1</sup> Tests commonly used to characterize cardiovascular disease in clinical veterinary medicine include history, physical examination including auscultation, direct and indirect blood pressure measurement, thoracic radiography, electrocardiography, and echocardiography. Echocardiographic techniques include two-dimensional, M-mode, spectral Doppler, and color-flow Doppler echocardiography. Specific clinical tests to evaluate endothelial function, such as flow-mediated vasodilation and venous plethysmography, commonly are not used, and normal values have yet to be published for clinical application in dogs and cats. Preliminary investigations into the biochemical markers that may reflect endothelial dysfunction in certain diseases have been reported for certain cardiovascular disorders; however, these tests are not used in clinical practice. Although the study of endothelial function in veterinary patients is still in its infancy, many investigators believe that endothelial dysfunction is associated with the common cardiovascular disorders in dogs and cats. This chapter approaches the topic from a brief review of the common cardiovascular diseases in dogs and cats with an accompanying summary of information related to endothelial function.

<sup>1</sup> Atherosclerotic heart disease is virtually nonexistent in any species that veterinary cardiologists deal with. The frequency of this disease in humans is truly the anomaly in the animal kingdom, excepting certain purpose-bred animal models (rabbits, etc.).

## COMMON SPONTANEOUS CARDIOVASCULAR AND ENDOTHELIAL DISEASE IN DOGS

### Chronic Valvular Heart Disease

Chronic valvular heart disease is the most common cardiovascular disease in dogs and is the most common cause of congestive heart failure (CHF) (1). Chronic valvular heart disease is most analogous to the floppy mitral valve syndrome in humans, and it is a progressive, degenerative disorder of the valve. Progressive thickening of the valve results from an accumulation of glycosaminoglycans and the accompanying loss of collagen and elastin from the valve and chordae tendineae. In most cases, the mitral valve is affected most severely; however, the tricuspid valve can be affected concurrently in up to one-third of dogs. Small- to medium-sized dog breeds are predisposed, and male dogs are predisposed compared to female dogs (by an approximate ratio of 1.5 to 1). This slowly progressive disease can be first apparent by 2 to 5 years of age as valvular thickening on echocardiography, sometimes with accompanying mitral valve prolapse. As valve thickening progresses, the mitral valve becomes incompetent and a cardiac murmur is readily identifiable. Disease in the chordae tendineae and progressive enlargement of the heart causes worsening valve coaptation, progressive mitral regurgitation and, eventually, CHF.

The etiology of chronic valvular heart disease is unknown; however, a genetic predisposition to develop the disease has been proven for Cavalier King Charles Spaniels and is suspected in Dachshunds (1,2). The disease is primarily a noninflammatory myxomatous degeneration of the atrioventricular valves and is commonly referred to as endocardiosis, acquired valvular heart disease, or simply mitral regurgitation.

Dogs may be identified with mild to moderate disease based on the presence of a cardiac murmur over the left apex of

the heart, with progressive disease associated with a murmur of increasing intensity. The earliest clinical signs usually are due to early CHF or progressive left atrial enlargement, and include intermittent cough, nocturnal dyspnea, exercise intolerance, altered sleep habits, or abdominal distention. In most dogs, left-sided CHF predominates with the development of cardiogenic pulmonary edema. Syncope also may be the initial sign of chronic valvular disease and can occur secondary to vasovagal (neurocardiogenic) syncope, supraventricular arrhythmias, low cardiac output, or as a result of paroxysmal coughing (e.g., tussive syncope). CHF can often be managed through a combination of exercise restriction, dietary sodium restriction, furosemide or other diuretics, angiotensin-converting enzyme (ACE) inhibitors, digoxin,  $\beta$ -blockers, and antiarrhythmics as required. Common clinical endpoints include severe and refractory CHF, sudden death due to arrhythmia or left atrial rupture with cardiac tamponade, and euthanasia due to poor quality of life, side effect of cardiac medications, anorexia, or worsening clinical signs.

In recent years, significant enthusiasm has been generated for the role that endothelial dysfunction may play in dogs with chronic valvular heart disease. Peripheral arterial disease has been reported in Cavalier King Charles Spaniels, a breed recognized to develop chronic valvular heart disease at a very early age. The peripheral arterial disease is identified first by either a lack of femoral arterial pulse or weakening of femoral arterial pulse.<sup>2</sup> One study noted a unilateral or bilateral weakened arterial pulse in 26% of dogs with compensated chronic valvular heart disease, and the pulse was absent in 2% of dogs (3). A weak arterial pulse was found to be caused by reduced femoral artery diameter, with histopathological findings including intimal thickening with breaks in the internal elastic lamina in occluded segments and organized thrombus (3,4). Because of excellent collateral circulation, these femoral arterial findings rarely result in overt clinical signs; however, they are believed to be a marker of more widespread endothelial dysfunction. In addition, several investigators have reported that small- to medium-sized coronary arteries have evidence of intramural (nonatherogenic) arteriosclerosis in dogs with chronic valvular disease, and that these lesions can lead to reduced left ventricular systolic function (5,6).<sup>3</sup> These arteriosclerotic lesions can result in focal myocardial necrosis or infarction, with the latter lesions (seen in severely affected dogs) having been referred to as *multifocal intramural myocardial infarction*. It is presumed that the mural coronary arteriosclerotic lesions in these cases result from endothelial disease and contribute to reduced systolic function and eventually CHF.

2 This is not a result of emboli from the valves, and it is not seen in any of the other countless breeds that get this form of heart disease. The peripheral arterial disease seems to be fairly unique to the CKCS breed, and the relationship, if any, to valvular heart disease is not well understood.

3 Although arteriosclerosis also has been documented as a histopathological finding in dogs with dilated cardiomyopathy and in cats with various forms of cardiomyopathy, these lesions have only been clearly documented to cause small vessel occlusion and microscopic infarction in dogs with chronic valvular disease.

A limited number of studies have examined biomarkers that may indirectly support a role for endothelial dysfunction in dogs with chronic valvular disease. Two studies have investigated the role that activation of nitric oxide (NO) systems may play in dogs with chronic valvular heart disease. One study identified an increase in serum nitrite/nitrate concentrations in dogs with chronic valvular disease (7), whereas another study failed to identify any increase in serum nitrite/nitrate in affected Cavalier King Charles Spaniels (8). Another study looked at nicotinamide adenine dinucleotide phosphate-oxidase diaphorase (NADPH-d) activity in canine myxomatous mitral valves and identified the role that nitric oxide formation may play in the pathogenesis of chronic valvular heart disease based on increased NADPH-d activity in the valve (9). Although the canine mitral valve does not appear to stain heavily for renin-angiotensin system activity in either normal dogs or affected dogs, endothelin (ET)-1 receptor density was found to be increased in parallel with the severity of disease in dogs with chronic valvular heart disease (10). Finally, scanning electron microscopy has identified a variety of endothelial alterations on the surface of the mitral valve from dogs with chronic valvular disease, including denudation of endothelial cells (ECs) with exposure of the basement membrane and subendothelial collagen matrix, as well as loss of orderly arrangement of ECs and increased EC plasmalemmal microappendages compared to cells on unaffected valves (1,11). These findings suggest that endothelial disease is present in dogs with chronic valvular disease and that alterations of the endothelium may contribute to the pathogenesis of chronic valvular heart disease or the accompanying peripheral or coronary arterial disorders.

### Dilated Cardiomyopathy

Dilated cardiomyopathy is the second most common heart disease in dogs. Large and giant breed dogs are predisposed, and the disease is particularly common in certain breeds of dogs such as Doberman Pinschers, Great Danes, Boxers, Newfoundlanders, and Irish Wolfhounds. It has been estimated that up to 50% to 60% of all Doberman Pinschers will develop dilated cardiomyopathy. A genetic origin for the disease has been described in certain breeds based on pedigree analysis; however, a specific molecular cause has not yet been determined for any breed. With the exception of Portuguese Water Dogs, dilated cardiomyopathy is an adult-onset disease with clinical signs developing in middle-aged or older dogs. Each breed appears to have specific features that are characteristic of cardiomyopathy in that breed. For example, serious ventricular arrhythmias leading to syncope or sudden death are common in both Doberman Pinschers and Boxers with dilated cardiomyopathy. The histologic finding of attenuated wavy fibers is typical for Newfoundlanders and other giant-breed dogs, whereas cardiomyopathy in the Boxer appears to mimic arrhythmogenic right ventricular cardiomyopathy in humans, with fatty infiltration and loss of myocytes in the right ventricular wall (12). In most cases, canine dilated cardiomyopathy

Figure 11.1. Lateral thoracic radiograph from a Doberman Pinscher with dilated cardiomyopathy and CHF. Note the pulmonary edema in the perihilar region.

eventually results in CHF (Figure 11.1), sudden death, or euthanasia due to poor quality of life, progressive signs of heart failure, drug intolerance, or anorexia.

Less is known relative to endothelial dysfunction in dogs with dilated cardiomyopathy. Serum nitrite/nitrate concentrations are reported to be elevated in dogs with dilated cardiomyopathy (7), and plasma ET-1 immunoreactivity was reported to be elevated in dogs with dilated cardiomyopathy and CHF (13).

### Hemangiosarcoma and Pericardial Effusion in the Dog

The third most common cardiac disease in dogs is pericardial effusion, leading to cardiac tamponade. Pericardial effusion in dogs can result from a number of neoplastic disorders as well as idiopathic causes. Neoplasia is the most common cause and, of the neoplasms that cause pericardial effusion, hemangiosarcoma of the right atrium and right auricular appendage is the most common. The cause of hemangiosarcoma in the dog is unclear; however, it is known to originate from ECs.

Hemangiosarcoma often is associated with disseminated intravascular coagulation, and canine hemangiosarcoma cells express vascular endothelial growth factor (VEGF) receptors 1 and 2, CD31, and CD146, and also produce growth factors and cytokines such as VEGF, basic fibroblast growth factor, and interleukin-8 that are stimulatory to EC growth (14).

### SPONTANEOUS FELINE CARDIOVASCULAR AND ENDOTHELIAL DISEASE

The most common cause of cardiovascular disease in the cat is cardiomyopathy, and hypertrophic cardiomyopathy is the most commonly described form (Figure 11.2) (15). The

Figure 11.2. Gross pathology specimen from a cat with hypertrophic cardiomyopathy. The heart has been sectioned to demonstrate the right atrium and right ventricle (*top*), aorta (*center and extending to the right*), left ventricle, and left atrium. Note the hypertrophy of the interventricular septum and left ventricular free wall.

cause of hypertrophic cardiomyopathy in the cat is undocumented for most breeds; however, a genetic basis is suspected in the majority of cases, and a genetic mutation of myosin binding protein C has recently been documented in Maine Coon cats (16). Maine Coon cats, Himalayans, American Short Hairs, Rag Doll cats, and Norwegian Forest cats are predisposed to hypertrophic cardiomyopathy. Most surveys identified that male cats and cats of larger size also are predisposed to hypertrophic cardiomyopathy. Dilated cardiomyopathy, once a common cause of cardiovascular disease in the cat, is now rarely seen due to the discovery that dietary taurine deficiency caused this reversible form of cardiomyopathy. Various other forms of cardiomyopathy have been described, including restrictive cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and various unclassified forms of cardiomyopathy.

Hypertrophic cardiomyopathy in the cat can result in syncope or sudden death; however, the most common clinical presentations are CHF or arterial thromboembolism. CHF is thought to result from diastolic dysfunction, with progressive left atrial enlargement and eventually pulmonary edema or biventricular heart failure, leading to pulmonary edema and plural effusion. CHF often is managed with a combination of dietary sodium restriction, diuretics such as furosemide, ACE inhibitors, and either  $\beta$ -blockers (atenolol) or calcium channel blockers (diltiazem) to help reduce heart rate and improve diastolic function. Narrowing of intramural coronary arteries is identified on histopathology; however, the most impressive changes are myocardial hypertrophy with increased fibrous connective tissue and myofiber disarray in the left ventricle and interventricular septum. The role of endothelial function in the development or progression of cardiomyopathy in the cat has not been well studied. (A new study describes a test for endothelial function in the dog [17].)

## Arterial Thromboembolism

Arterial thromboembolism is a common complication of virtually all forms of feline heart disease. In most cases, the thrombus originates in the left atrium, dislodges, and is carried downstream, where embolism of the terminal aorta,<sup>4</sup> and/or iliac arteries creates severe clinical signs. In 90% of affected cats, the thrombus lodges at the aortic trifurcation, although thromboembolism to the front limb, central nervous system, kidneys, or other sites also is reported. Aortic thromboembolism results in an acute onset of severe posterior paresis and pain, with loss of femoral arterial impulses, cyanotic nail beds, and the development of cool limbs and firm gastrocnemius muscles. Aortic thromboembolism is a catastrophic complication of cardiomyopathy in the cat: only 40% to 50% of cats ever regain function of the rear limbs. Of those cats who do regain function of the rear limbs, many experience repeated episodes of arterial thromboembolism. Vascular stasis in the dilated left atrium, exposure of subendothelial collagen due to left atrial stretch, and altered coagulation are all proposed to play a role in the development of intracardiac thrombus. It appears that vasoactive factors mediate a significant component of the clinical signs, because simple ligation of the terminal aorta of the cat results in no clinical signs; however, double ligation with addition of thrombus leads to severe vasoconstriction of collateral vessels and classic clinical manifestations of arterial thromboembolism. Earlier reports indicated that serotonin may play a role in the development of this scenario; however, the exact interplay of endothelial factors that lead to the vasoconstriction is unclear at this time. One recent study identified that plasma arginine concentrations are reduced in cats with arterial thromboembolism (18), leading to the hypothesis that the lack of collateral circulation could result from reduced NO production. Manual surgical removal of the thrombus requires anesthesia and is associated with a high rate of complications. Thrombolytic drugs also have not been uniformly successful, because they can lead to bleeding complications or severe reperfusion injury with life-threatening hyperkalemia and metabolic acidosis. Most therapy is aimed at prevention of thrombus formation with use of aspirin, low-molecular-weight heparin, or Coumadin.

4 The term *saddle thrombus* often is used to describe arterial thromboembolism (ATE) of the terminal aorta. On necropsy, the thrombus itself is located in the distal aorta and extends a short distance into the iliac artery, but the thrombus typically does not extend down into the femoral artery. Simple ligation of the terminal aorta in normal cats fails to produce the clinical signs of ATE. A substance(s) is suspected to be elaborated by the thrombus that causes vasospasm and “shuts down” the collateral circulation, because a thrombus seems to be necessary to cause clinical signs of ATE. Some cats have thrombus in the terminal aorta large enough to only occlude one iliac artery, and they have single rear-limb signs, but this is less common. Clinically “silent” thromboembolism to the kidneys commonly is noted on abdominal ultrasound or necropsy of these cats, and ATE to the coronary vasculature is suspected based on focal left ventricular wall thinning and dysfunction in selected cats – this is thought to account for at least some cases of sudden death.

## KEY POINTS

- Valvular, myocardial, and pericardial cardiovascular diseases are common in dogs and cats, although atherosclerotic coronary artery disease is extremely rare in these species.
- Common cardiovascular diseases in dogs include degenerative mitral valvular disease, dilated cardiomyopathy, and pericardial effusion due to hemangiosarcoma. Hypertrophic cardiomyopathy and resulting arterial thromboembolism are the most common cardiovascular problems in cats.
- Preliminary research indicates that endothelial dysfunction contributes to the development or progression of cardiovascular disease in dogs and cats.

## Future Goals

- To determine whether therapeutic interventions to improve endothelial function can alter the development or progression of cardiovascular disease in companion animals
- To develop a reliable, minimally invasive, and clinically applicable test for endothelial function, such as flow-mediated vasodilation, to aid in the characterization of endothelial and cardiovascular disorders in dogs and cats

## Giraffe Cardiovascular Adaptations to Gravity

Alan R. Hargens\*, Knut Pettersson†, and Ronald W. Millard‡

‡University of Cincinnati College of Medicine, Ohio

### GRAVITY AND THE CARDIOVASCULAR SYSTEM

The physiological systems of animals have adapted to Earth's gravity over the past hundreds of millions of years. In general, gravitational adaptations of the cardiovascular system are more pronounced in terrestrial species with greater height and thus greater gravity-dependent gradients of blood pressure from head to feet. For example, dinosaurs (1), tree-climbing snakes (2), giraffes (3), and other tall animals have evolved mechanisms to provide adequate blood flow and nutrition to their brains while restricting blood flow and tissue swelling in their legs. Terrestrial animals of short stature and marine animals probably require much less sophisticated cardiovascular adaptive mechanisms. At the other extreme, aquatic snakes have little ability to withstand gravity out of water and rapidly "faint" when placed head above tail (2). Moreover, when gravity is absent even over short periods of time, astronauts experience orthostatic intolerance upon readaptation to gravity (see Chapter 58). Because humans are relatively tall compared to other species of animals, they too have developed extensive and sophisticated regulatory mechanisms to maintain cerebral perfusion and prevent lower extremity edema while in an upright posture. In fact, most understanding of gravitational mechanisms to date relates to observations in humans. However, taller terrestrial animals, such as the giraffe, may allow better understanding of the physiological adaptations to gravity. For example, blood pressure in giraffes is high to pump blood to their brain, but high blood pressures in their feet would theoretically cause severe dependent edema.

Cardiovascular systems generate and regulate blood pressure to provide flow to tissues. This blood flow nourishes tissues by supplying oxygen ( $O_2$ ) and other nutrients, and by removing carbon dioxide ( $CO_2$ ) and other waste products. Transmural pressures ( $P_x$ : pressure gradients from inside to outside the circulation) dictate the wall stress ( $S$ ) and degree of openness or closure (vessel radius  $r$ ) experienced by circu-

latory structures according to the Law of Laplace:  $P_x = S/r$  (4). Normally, five components determine transmural pressure in the circulation: (a) the dynamic pressure resulting from cardiac pumping against peripheral resistance to blood flow; (b) dynamic pressures due to inertial forces of blood during activity (e.g., the footward acceleration of blood in leg vessels at heel strike during locomotion); (c) pressure due to the finite compliance (volume/pressure characteristics) of the systemic vasculature, especially the veins (this pressure is commonly called the mean circulatory filling pressure); (d) extravascular pressure of tissues and interstitial fluid (e.g., total tissue pressure); and (e) an intravascular hydrostatic pressure due to gravity (gravitational pressure). Although extravascular tissues and fluid have mass, gravity affects extravascular hydrostatic pressures to a minor extent because tissue fluids are bound within cells or are discontinuous in most extravascular spaces (except for cerebrospinal fluid). Structural and contractile tissues respond dynamically, within physiological limits and over a long period of time, as adaptive structural and functional remodeling, to increased (or decreased) levels of physical stress by increasing (or decreasing) their functional capability and/or mass (5). Although physiological responses to stress occur within seconds to minutes, longer-term functional and structural compensatory adjustments to the initiation of stress are detectable within hours (6).

### TRANSCAPILLARY FLUID BALANCE

Transcapillary fluid shifts between the microcirculation and the surrounding tissues (Figure 12.1) are dictated by capillary surface area and the ability of capillary basement membrane and endothelium to retain plasma proteins. These fluid shifts are determined by hydrostatic and colloid osmotic pressures according to the Starling-Landis equation (7):

$$J_c = L_p A [(P_c - P_t) - \sigma_p (\pi_c - \pi_t)] \quad (\text{Equation 1})$$

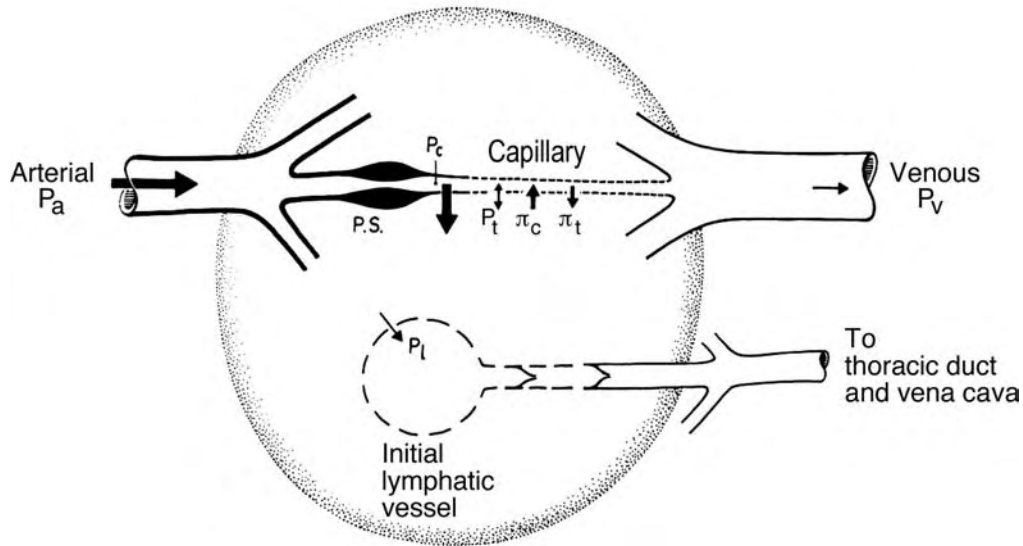

Figure 12.1. Starling pressures, which regulate transcapillary fluid balance. Pressure parameters that determine directions and magnitude of transcapillary exchange include capillary blood pressure  $P_c$ , tissue fluid pressure  $P_t$  (directed into capillary when positive or directed into tissue when negative), plasma and capillary colloid osmotic pressure  $\pi_c$ , and tissue fluid colloid osmotic pressure  $\pi_t$ . Precapillary sphincters (P.S.) regulate  $P_c$  and capillary flow. It is generally agreed that a hydrostatic pressure gradient ( $P_t >$  lymph pressure  $P_l$ ) drains off excess tissue fluid under conditions of net filtration. Relative magnitudes of pressure in resting tissues are depicted by the size of the arrows. (Reproduced with permission from Hargens AR. Interstitial Fluid Pressure and Lymph Flow. In: Skalak R, Chien S, eds. *Handbook of Bioengineering*. New York: McGraw-Hill; 1986:1–35.)

where  $J_c$  is net transcapillary fluid shift,  $L_p$  is hydraulic conductivity of capillary wall,  $A$  is capillary membrane filtration area,  $P_c$  is capillary blood pressure,  $P_t$  is tissue fluid pressure,  $\sigma_p$  is reflection coefficient for plasma proteins,  $\pi_c$  is capillary blood colloid osmotic pressure, and  $\pi_t$  is tissue fluid colloid osmotic pressure. Again, because blood has continuous columns within the body, local  $P_c$  is greatly affected by gravity. On the other hand, because tissue fluids are discontinuous in the body,  $P_t$  is relatively unaffected by gravity.

In most tissues, a net flux of fluid and plasma proteins occurs across the capillary membrane (endothelial cells [ECs] and basement membrane), through the interstitial spaces, and into the lymphatic system (see Figure 12.1). The hydraulic conductivity of capillary wall  $L_p$  is determined by endothelial function as well as capillary basement membrane thickness. Generally, the reflection coefficient for plasma proteins,  $\sigma_p$ , is determined by the permeability properties of the capillary wall. Some tissues, such as muscle and skin, have relatively high  $\sigma_p$  ( $\approx 0.9$ ) such that protein transport rates are low. In other tissues that have lower  $\sigma_p$ , such as lung and liver,  $\pi_t$  is almost equivalent to  $\pi_c$ . In these tissues,  $L_p$  and filtration rates are relatively high and lymphatic drainage is critical for tissue fluid balance. Recent evidence also indicates that lymphatic vessels have a two-valve system, with primary valves at the level of the initial lymphatic endothelium and a secondary valve system in the lumen of the transporting lymphatics that facilitates unidi-

rectional transport towards the lymphatic nodes and thoracic duct (8).

#### MICROCIRCULATORY ADAPTATION TO GRAVITY

Transcapillary ultrafiltration,  $J_c$ , in the human calf is significantly lower than that in the forearm in supine subjects (9). Although postural changes are associated with increases in precapillary resistance, altering pressure and flow characteristics within exchange vessels of the dependent limb, no changes occur in the capillary surface area available for exchange (10). The autonomic regulation of capillary hemodynamics in dependent limbs appears to involve a veno-arteriolar reflex (11). Exploration of dependent limb capillary filtration has revealed that the  $\alpha$ -adrenergic receptor-mediated vasoconstrictor response in the circulatory system of the human leg is enhanced upon standing and may represent an adaptive mechanism that limits blood pooling and transcapillary ultrafiltration in the leg during upright position (12). However, should autonomic nervous system dysfunction (i.e., dysautonomia) exist, profound hypotension will occur without the typical reflex tachycardia when standing abruptly. In such individuals, dependent limb vasoconstriction control is decreased significantly (13). In this regard, orthostatic hypotension is a common consequence of such dysfunction in elderly patients.

Because the human feet and head experience the greatest change in blood pressure with altered vectors of gravity, it is worthwhile to understand their structure and functional responses to gravitational stimuli. Previously, we found that elevation of blood pressure to the head produced by a transition from 60 degrees head-up tilt (HUT) to 6 degrees head-down tilt (HDT) increases microcirculatory blood flow in skin of the head (14). This pressure and flow increase may be expected in a tissue not commonly exposed to increased blood pressure and therefore, not able to regulate blood flow closely to prevent edema. On the other hand, moving the body from 6-degree HDT to 60-degree HUT actually reduces microcirculatory flow in the foot. This response suggests that the microcirculation of the lower body, normally adapted to upright posture on Earth, is able to regulate capillary pressure and flow adequately to prevent dependent edema. Combined with vasoconstriction and a thicker capillary basement membrane in dependent tissues to reduce hydraulic conductivity (15), other mechanisms for preventing dependent edema include lymphatic drainage (7) and skeletal-muscle venous pumps in the leg (16).

#### GRAVITATIONAL PHYSIOLOGY IN THE GIRAFFE

The giraffe, *Giraffa camelopardalis*, represents a unique mammalian model for developmental studies of tissue adaptation to increasing load bearing. Whereas fetal giraffes develop in a quasi-weightless milieu, postpartum giraffes must contend with increasing load bearing in their dependent tissues as they grow to heights of over 5 meters. Previous studies of the adult giraffe cardiovascular system (17–19) indicate that this system is certainly a unique model for investigating the physiology of being tall and adaptations to large and variable gradients of blood pressure. These early studies of blood pressures document that arterial pressure near the giraffe heart is about twice that in humans to provide more normal blood pressure and perfusion to the brain. In the context of higher systemic blood pressure and longer hydrostatic columns of blood from heart to feet, the giraffe circulatory system exhibits significant increases in vascular wall muscle thickness, capillary basement membrane thickness, and other vascular control systems in dependent blood vessels that, in concert, participate in capillary fluid dynamics and edema prevention.

During the 1985 Giraffe Physiology Expedition to Africa, our studies focused on hemodynamic adaptations and edema prevention in the legs of adult giraffes (3,20). Mean values for arterial and venous pressures for giraffes and humans qualitatively match the expected gravitation pressure gradients, using the heart as a reference for fluid discontinuity between the head and foot (Figure 12.2). Although  $P_c$  was not measured directly in the giraffe, it is probably near local venous pressure ( $P_v$ ) in the feet (150 mm Hg) and about 10 to 20 mm Hg at the top of the giraffe's neck (3). Importantly,  $\pi_c$  was identical in the giraffe and human and, therefore, contrary to

an early, unpublished theory by August Krogh. Thus,  $\pi_c$  in the giraffe foot offers no unusual resorptive pressure for preventing dependent edema. Because of rapid circulation and mixing of blood within the cardiovascular system, it is difficult to imagine how  $\pi_c$  could be significantly higher in the dependent tissues of the giraffe. Although some  $P_t$  values in the neck were negative, the average bodily  $P_t$  ranged between 1 and 6 mm Hg, except under the tight skin and fascia of the extremities, where mean  $P_t$  was 44 mm Hg. Interestingly,  $\pi_t$  in legs was very low (1 mm Hg), except in foot samples that were contaminated by blood. This finding provided evidence that giraffe capillaries are highly impermeable to plasma proteins and that  $\sigma_p$  approximates unity in lower limbs. This conclusion was supported by studies of peripheral lymph that indicated only trace amounts of protein were present and  $\pi_l$  equaled zero.

Of importance, we found that the blood and tissue fluid pressures that determine transcapillary ultrafiltration are highly variable with exercise (Figure 12.3). These pressures, combined with a tight skin and fascial "antigravity suit," move venous blood and tissue fluid upward against gravity, thus preventing pooling of blood and edema in dependent tissues. More proximally, an active skeletal-muscle pump aids venous return. The nonhydrostatic pressure gradient down the giraffe's jugular vein indicates that blood cascades down from the head, and that circulation above heart level does not depend on a siphon-like principle, as earlier proposed (21). Other edema-preventing mechanisms include dependent precapillary vasoconstriction, abundant lymphatic drainage, and very low capillary permeability to plasma proteins.

Developmental alterations are present in the load-bearing tissues of newborn compared with adult giraffes (22). For example, vascular wall thickness closely relates to local blood pressure in the developing giraffe. Tissue samples were collected from four 5- to 6-year-old, 3.5- to 4-meter, male and female giraffes during the 1985 Giraffe Physiology Expedition; and from three newborns and two 25- and 35-year-old, 5-meter adult giraffes from the Cincinnati and Cheyenne Mountain Zoos. Arterioles and other microcirculatory vessels were sampled from skin and muscle of the head, neck, thorax, legs, and feet. Although we never had the opportunity to measure blood pressures in newborn giraffes, based on comparable studies of other species, the arterial pressures of baby giraffes are probably significantly lower at heart level and in dependent tissues than are those in adult giraffes. It is apparent that dependent arteries in adults had much thicker walls than did those in newborn giraffes (Figure 12.4). In adult animals, arterial wall hypertrophy correlates directly with the degree of tissue dependency (Table 12-1). Thus, the wall thickness-to-lumen ratios of large arteries increase from head to foot (except for one "ankle" artery that didn't follow this pattern).

We believe the developing giraffe provides an excellent model for investigations of adaptive mechanisms to natural hypertension found in the adult giraffe. Arteries of the feet

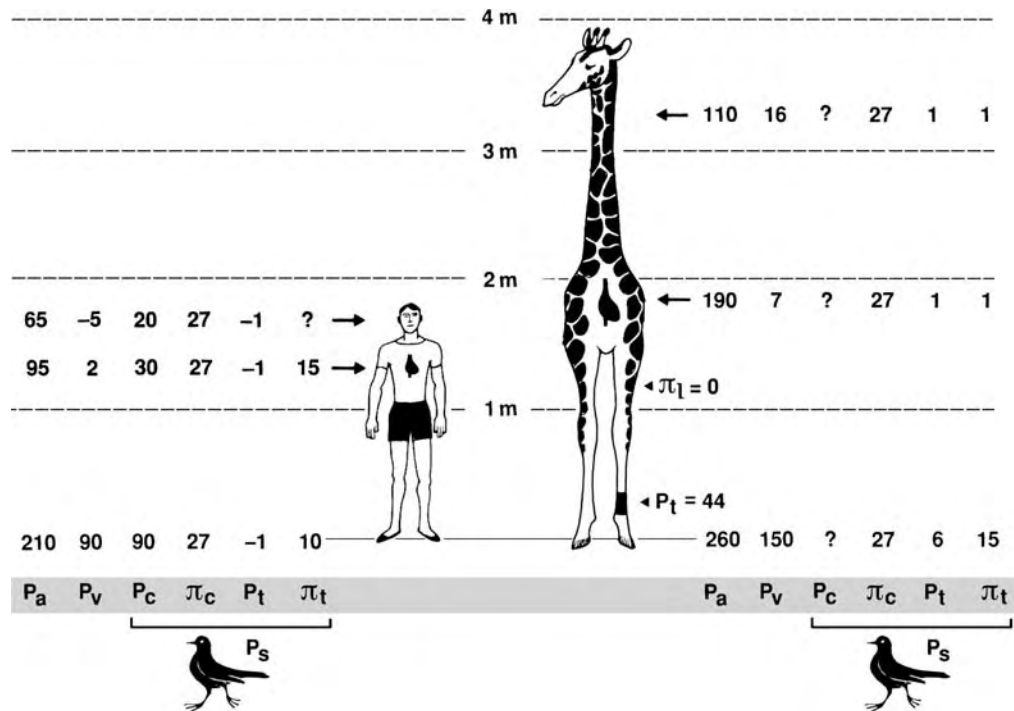

Figure 12.2. Mean arterial  $P_a$ , venous  $P_v$ , and Starling pressures ( $P_c$ ,  $\pi_c$ ,  $P_t$ , and  $\pi_t$ ) in giraffe (right) as compared to human (left) at hydrostatic levels between the head and feet. In the giraffe, lymph samples obtained from the leg had only trace amounts of protein and  $\pi_1 = 0$ . Foot samples for  $\pi_t$  often were contaminated by blood and therefore were less reliable.  $P_t$  beneath the tight skin and fascia of the legs ranged between 40 and 50 mm Hg and indicated the presence of a “natural anti-G suit” in the giraffe. Data for pressures in humans are obtained from several sources in addition to our previous studies. (Reproduced with permission from Hargens AR, Millard RW, Pettersson K, van Hoven W, Gershuni DH, Johansen K. Transcapillary Fluid Balance in the Giraffe. In: Staub ND, Hogg JC, Hargens AR eds. *Interstitial-Lymphatic Liquid and Solute Movement, Advances in Microcirculation*. Basel, Switzerland: S. Karger; 1987:195–202.)

are exposed to blood pressures greater than 400 mm Hg in adult giraffes (3). These vessels have developed pronounced smooth-muscle hypertrophy and narrow lumens to accommodate these extraordinarily high blood pressures. Our previous report of a less-than-normal arterial pressure gradient from heart to foot in the upright, stationary giraffe (3) suggests that the reduction in lumen cross-sectional area plays some role in blood pressure reduction to dependent tissues. It is interesting that the arterial wall hypertrophy apparently is confined to dependent vessels with diameters over 400  $\mu\text{m}$  microns in adults and is not observed in newborn giraffes or in vessels near the head of adult giraffes.

#### CAPILLARY BASEMENT MEMBRANE OF THE GIRAFFE VASCULAR SYSTEM

In 1971, Williamson and co-workers (15) measured the capillary basement membrane width (CBMW) in muscle obtained from human infants ( $n = 19$ , 9F/1M, 1-day to 6-month-olds), children ( $n = 4$ , 1F/3M, 3- to 5-year-olds), and adults ( $n = 17$ , 6F/11M, 36- to 75-year-olds) obtained within 6 hours post-mortem. They also evaluated muscle from one adult giraffe for

capillary basement membrane thickness. The measurements in human samples illustrate a significant age-dependent effect, with the thickest basement membrane measured in the adult capillaries. The results also illustrate increased CBMW in the lower legs of adults. CBMW in human infants ranges from 538 to 563  $\text{\AA}$  and does not vary significantly with anatomic location. In children, CBMW is significantly thicker (806 to 1,076  $\text{\AA}$ ) in all anatomical sites sampled (pectoral, abdominal, thigh, calf) than that in the same sample sites of infants. As in infants, no difference in the CBMW is noted among anatomical locations in children. In contrast, the CBMW of adults is significantly greater than that in children and infants, and shows progressive thickening in dependent tissues moving down toward the feet (pectoral = 964  $\text{\AA}$ , calf = 1,894  $\text{\AA}$ ). In giraffe, the CBMW increases from 780  $\text{\AA}$  at the neck to 1,437  $\text{\AA}$  in the front and hind legs. These data are consistent with the hypothesis that CBMW is strongly influenced by intravascular hydrostatic pressure, which is most extreme in the long hydrostatic column of the giraffe circulatory system. This increase in CBMW in the leg of giraffes may be an important contributing factor to microcirculatory fluid homeostasis in dependent tissues with high intravascular pressure.

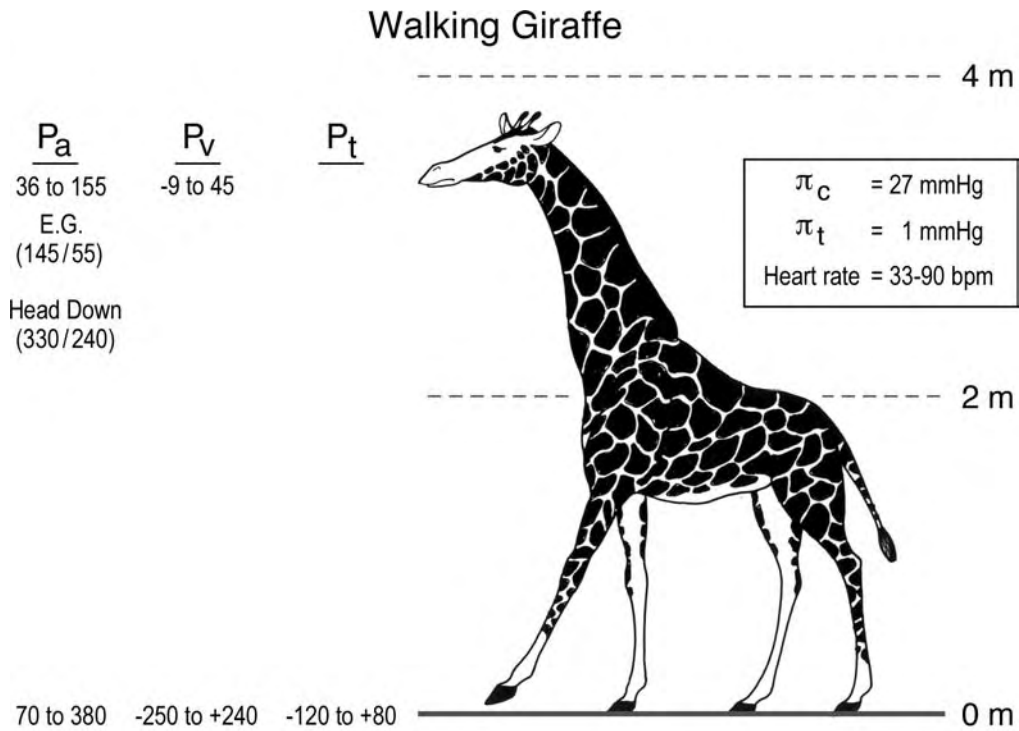

Figure 12.3. Range of averaged mean blood and tissue fluid pressures in neck and foot of walking giraffes. Negative venous and subcutaneous pressures during exercise help prevent dependent edema. With head upright, mean arterial pressure below the jaw ranged between 36 and 155 mm Hg (e.g., 145/55 mm Hg for systolic/diastolic pressures). Drinking water in head-down posture raised carotid pressures to 330/240 mm Hg. (Reproduced with permission from Hargens AR, Millard RW, Petterson K, van Hoven W, Gershuni DH, Johansen K. Transcapillary Fluid Balance in the Giraffe. In: Staub ND, Hogg JC, Hargens AR eds. *Interstitial-Lymphatic Liquid and Solute Movement, Advances in Microcirculation*. Basel, Switzerland: S. Karger; 1987:195–202.)

### INNERVATION OF THE GIRAFFE VASCULAR SYSTEM

Giraffes are tall animals, and changing posture will therefore cause major circulatory changes, including an increase of hydrostatic pressure in the head and neck during head-down drinking. However, the structure of the cardiovascular system in the giraffe is adapted gravitationally to the normal upright posture of the animal. Because short-term regulation of blood pressure and flow is determined by activity in the sympathetic nervous system, we examined and compared the innervation of different segments of the cardiovascular system (23). In general, efferent, sympathetic nerves control cardiac function, arterial resistance, and venous capacitance.

Tissue specimens were obtained from two young male giraffes killed as a part of a conservation-culling program in Africa. We used antisera against dopamine- $\beta$ -hydroxylase (D $\beta$ H, marker of adrenergic nerves), neuropeptide Y (NPY, a peptide transmitter in sympathetic nerves), as well as general markers for nerve terminals (synapsin 1) and nerve fibers/axon bundles (neurofilament, NF). With these antibodies, a network of nerve terminals and fibers was demonstrated. The distribution of nerve elements was similar using different antisera. However, although all antibodies visualized varicose nerve terminals indicative of adrenergic fibers, the NF antibody also marked nonautonomic axon bundles (Table 12-2).

In all arterial blood vessels, a network of nerve terminals with D $\beta$ H-, NPY-, and Syn1-positive fibers was found. NF-positive fibers were sparsely located at the medioadventitial border, and thick paravascular bundles were found frequently. In the medial layer of the popliteal artery, NF-positive nerve fibers also were observed; but the other antibodies used gave no labeling, indicating that the nerves were not adrenergic. In general, arteries from the extremities had a relatively sparse innervation and were usually restricted to the medioadventitial border, although some evidence for a sparse sympathetic

**Table 12-2: Innervation of Giraffe Vasculature**

Blood Vessels		Adventitial Innervation	Media Innervation
Load-bearing vessels	Tibial artery	+	–
	Popliteal artery	++	–
	Metatarsal artery	+	–
	Tarsal artery	++	+
	Saphenous vein	–	–
Central vessels	Metatarsal vein	–	–
	Ascending aorta	++	++
	Pulmonary artery	+	–
	Superior caval vein	–	–
Head and neck	Inferior caval vein	–	–
	Carotid artery	+++	+++
	Jugular vein	+	–

The density of nerve terminal (axons) near smooth muscle cells ranges from – (no nerves observed) to +++ (a dense network present). (Reproduced with permission from Nilsson O, Booj S, Dahlstrom A, et al. Sympathetic innervation of the cardiovascular system in the giraffe. *Blood Vessels*. 1988;25:299–307.)

innervation of the outermost layer of the media was found. The ascending aorta had a denser innervation, with sympathetic fibers frequently penetrating into the outer medial layers. The carotid arteries had the densest innervation of all arteries. The nerves penetrated deep into the media, with fibers reaching almost to the intima layer.

In veins, the sympathetic innervation was sparse. In fact, veins from the lower part of the body and caval veins were devoid of adrenergic innervation. However, NF-positive, paravascular axon bundles were found, and the expected adrenergic fibers at the medioadventitial border were absent. In the jugular veins, however, we observed such adrenergic fibers, although their density still appeared sparse.

These observations show that a sympathetic innervation of the vascular system exists in giraffes, but the innervation pattern is nonuniformly distributed. It is surprising that the caval and load-bearing veins apparently lack sympathetic innervation. This is in sharp contrast to man, wherein veins in the extremities, and especially capacitance veins, have a rich supply of adrenergic fibers, the activity of which is important for venous return from the legs (24). We can only speculate on why giraffes lack this type of innervation, or alternatively, use other transmitters than those for which we stained. However, the larger veins in the legs of giraffe run beneath both the tight skin and a stiff fascia. Thus, the capacitance of these veins may be limited despite their high venous pressures reported (see above), so little capacitance is present to regulate.

Sympathetic nerves were, however, found in the jugular vein. During upright posture, these veins do not need active regulation, but this could be important during head-down drinking, when the pressure gradient is reversed and jugular pressure increases. Valves also are present in the jugular

veins (25), and these could—together with sympathetic nerves—contribute to prevent blood flow in the retrograde direction and pooling of blood in the head during those short periods when giraffes lower their head below heart level to drink.

The innervation of limb arteries is similar to that found in most mammalian species, and innervation is restricted largely to the medioadventitial border. However, as the thickness of the medial layer can be extreme in these vessels, the efficiency in the spreading of excitation from the nerves must be very efficient if these nerves are to control the contractions of the entire medial sheet. The density of the innervation of large arteries increases from foot to head. In the aorta, we found fibers in the outer medial layer. In the carotid arteries, sympathetic fibers are found penetrating deep into the media, almost reaching the intima layer. The physiological significance of this dense innervation is not known. However, the pattern we observed is consistent with an adaptive pattern, with dense innervation in vessels subjected to the largest transient fluctuations during head-down drinking, and a less dense sympathetic innervation occurring in the vasculature of load-bearing tissues.

In summary, our results concerning tissue adaptations to increased load bearing in the developing giraffe, along with those of other investigators, provide intriguing findings that deserve further investigation, especially from an EC standpoint. More studies of the developmental biology of giraffes are needed to elucidate those mechanisms by which tissues adapt to increased blood pressure in the feet. Such knowledge may provide useful information for understanding structural and functional adaptations of blood vessels in human health and disease.

#### KEY POINTS

- Despite very high local blood pressures, dependent edema in the giraffe is prevented by a tight “anti-gravity suit,” muscle pumping of blood and lymph toward the heart, and vascular adaptations.
- Vascular walls and capillary basement membranes increase thickness in dependent tissues.
- Some vascular adaptations in the giraffe are developmental in nature.
- Surprisingly, arteries and veins of the lower body have sparse sympathetic innervation.

#### Future Goals

- To understand better EC structure and function and their role in the local regulation of giraffe circulations of blood and lymph
- To determine which adaptations are developmental in nature

- To investigate cerebral circulations, in order to understand adaptive mechanisms during head-down drinking behavior in giraffes

#### ACKNOWLEDGMENTS

These studies were supported by grants from NSF (DCB-8409253), NIH (HL-32703), National Geographic Society (3072–85), Department of Veterans Affairs, and NASA. We thank Professor Wouter van Hoven and the Department of Zoology, University of Pretoria, South Africa, for providing giraffes and facilities for our 1985 Giraffe Physiology Expedition. We thank Dr. D.G.A. Meltzer and Roodeplaat Research Labs, Dr. Richard Burroughs and the National Zoological Gardens in Pretoria, and Dr. Frik J. Stegmann and the University of Pretoria Veterinary School at Onderstepoort. We thank Dr. Paul Calle, the Cheyenne Mountain Zoo, and the Cincinnati Zoo for providing specimens of baby and aged giraffes.

# Energy Turnover and Oxygen Transport in the Smallest Mammal

## The Etruscan Shrew

Klaus D. Jürgens

*Zentrum Physiologie, Medizinische Hochschule, Hannover, Germany*

Life on Earth started with the formation of small organisms and, in general, larger ones evolved from smaller ones. Today, the size range of adult mammals spans eight orders of magnitude, from 1.5 to 150,000,000 g. Although all mammals have a common design principle, they are by no means geometrically similar, either in form or in function. If an elephant had the shape of a blown up shrew, its legs would not be able to carry the weight of its body. If the energy turnover rates of the elephant and shrew were directly proportional to differences in body mass, the elephant's body temperature would be at boiling point. The field of biology dealing with the scaling of the structural and functional properties of organisms is called *allometry*. Allometric tools are used not only to phenomenologically describe the body size dependence of parameters but also to investigate the underlying scaling laws. One of the most important parameters governing life is energy turnover or metabolic rate, usually measured as oxygen (O<sub>2</sub>) consumption. For terrestrial mammals, the best fit of the relationship between measured basal metabolic rate (BMR) and body mass (M) is the power function  $BMR = 3 M^{0.7}$  (BMR in watts, M in kg) (1).<sup>1</sup> On a double logarithmic scale, this function is a straight line with a slope of 0.7 (Figure 13.1). In addition to studying the biological basis for scaling laws, it is also of interest to investigate why some species deviate significantly from the allometric mean. When considering extremely small endotherms,<sup>2</sup> the following questions arise: What are the

structural and functional properties that constitute the lower end of the mammalian size range, and why do no smaller mammals exist?

The smallest extant mammalian species is the Etruscan shrew (*Suncus etruscus*, *S.e.*) (Figure 13.2). The average body mass of this species is 1.8 g (range 1.3 to 2.4 g), which is close to that of the bumblebee bat (*Craseonycteris thonglongyai*), for which a mean body mass of about 2 g has been reported (see 2). Small shrew-like animals are thought to be among the earliest species in mammalian evolution, appearing about 200 million years ago. A fossil record from the early Eocene, about 50 million years ago, of an extinct shrew weighing only 1.3 g has been described (2).

An important parameter that appears to limit the smallness of mammals is energy expenditure. Depending on geometric conditions, the relation of body surface to body mass increases with decreasing size. Therefore, heat loss through the body surface to the environment compared to heat production in the body core is larger in smaller species. Thus, the smaller the mammal, the higher is the mass specific energy turnover necessary to maintain a constant body temperature. High energy turnover requires high rates of food intake as well as high O<sub>2</sub> consumption rates; hence the need for appropriate adaptation of the O<sub>2</sub> and substrate transport systems.

Because muscles play a major role in the capture and chewing of food, in convective O<sub>2</sub> transport, and in the generation of heat, these organs must be adapted to provide the enormous mass-specific rate of energy consumption to the body. Exceptionally rapid muscle contractions, together with an enormous store of adipose tissue, serve to optimize thermogenic potential.

The O<sub>2</sub> transport properties of the Etruscan shrew, especially its cardiovascular system, have been studied extensively during the last several years. The shrew's mass specific performance is higher than that of any other studied mammal. Among other parameters, the capillary densities of heart and

1 Different mass exponents are calculated for different parameters. If the exponent is close to 0, the parameter is independent of size or mass; if it is 1, the parameter is size dependent, and it scales linearly with mass (M). Many parameters fall between these values, such as metabolism (0.7 to 0.75) or some rates (respiratory and heart approx. -0.25). For example, the stroke volume is proportional to M (i.e., exponent 1), and heart rate has a mass exponent of -0.25; thus, the product stroke volume times heart rate or cardiac output scales with 0.75, which is in accordance with metabolism. This is as it should be, because all the O<sub>2</sub> must be delivered by the circulation.

2 Warm-blooded mammal.

Figure 13.1. Allometric plot of BMR of terrestrial mammals as function of body mass. Circled triangle depicts Etruscan shrew.

skeletal muscle (3,4) and of lung are higher than in any other mammal, indicating very large diffusion capacities per unit body mass (Table 13-1).

A large vascular bed means a large endothelial surface. As yet, no studies have been carried out to determine whether the endothelia of species living under such extreme metabolic conditions show special adaptations with respect to the enormous fluxes of respiratory gases and nutrients that are required.

### OXYGEN CONSUMPTION AND METABOLISM

The shrew demonstrates the highest  $O_2$  consumptions per unit body mass (mass specific  $VO_{2max}$ ) of any endotherm studied to date. This holds for basal as well as for maximal metabolic rates. Taylor (5) measured a maximal  $O_2$  consumption of 870 mL  $O_2$ /(kg min) in the red-toothed shrew *Sorex minutus*

Content of mitochondria in muscle (Vol%)		
Heart	36	25
Diaphragm	35	12

(3 g body mass) exposed to cold in a helium/ $O_2$  atmosphere (6). This value is almost the same as that measured in a small hummingbird during hovering flight (7). For the white-toothed shrew *Suncus etruscus* (2 g body mass), values close to 1,000 mL  $O_2$ /(kg min) have been recorded during exercise (8). This value is 250 times the mass specific resting  $O_2$  consumption of humans and about 12 times their mass specific maximal  $O_2$  consumption. To make such an outstanding metabolic rate possible requires many special adaptations: (a) the food intake per day equals the animal's body mass (9); (b) the intestinal passage time is less than an hour, so an enormous transport rate of sugars, amino acids, and fatty acids takes place through

Figure 13.3. Oxygen transport cascade and transport parameters in mammals.

intestinal epithelia, blood, and lymph vessels; (c) the activities of enzymes needed for aerobic metabolism, such as citrate synthase (CS), exceed those of any other mammal; and (d) the activities of enzymes needed for anaerobic metabolism, such as lactate dehydrogenase (LDH), are lower than in any other mammal, leading to a CS:LDH activity ratio in *S. etruscus* gastrocnemius muscle that is 100 times higher than that in the muscle of a 70 kg human (10). The shrew's skeletal muscle cells consist of 35% mitochondria (human muscle cells have 10% to 20%) (11,12), which have richly folded inner membranes and, therefore, an extremely large inner respiratory surface. Moreover, remarkable adaptations of the O<sub>2</sub> transport system are seen at all levels of the O<sub>2</sub> transport cascade (Figure 13.3).

## RESPIRATORY SYSTEM

The mean maximal respiratory rate measured at 22°C was 758/min in *S. etruscus*, and the highest single value amounted to 894/min or 15/s. The shrew has a total lung volume of 80 to 130  $\mu$ l (8,13). Assuming a maximal tidal volume of 40% of the lung volume, these values are consistent with a mass-specific tidal volume of 16 to 20 mL air/kg. O<sub>2</sub> extraction per breath, which is independent of body size in mammals, is approximately 50 mL O<sub>2</sub>/L air (8). Thus, the Etruscan shrew has a calculated maximal ventilatory O<sub>2</sub> uptake rate of 720 to 970 mL O<sub>2</sub>/(kg min), which is consistent with the measured maximal O<sub>2</sub> consumption in this species. Because relative tidal vol-

umes and O<sub>2</sub> extraction are not significantly size-dependent,<sup>3</sup> the high ventilatory O<sub>2</sub> transport rate in *S. etruscus* is achieved exclusively by its high respiratory rate (8).

How well do the diffusional transport properties of the lung match this high ventilatory O<sub>2</sub> uptake rate? Gehr and colleagues (13) determined morphometrically a mean specific O<sub>2</sub> diffusion capacity of 11 mL O<sub>2</sub>/(kg min mm Hg) and a maximal value of 15 mL O<sub>2</sub>/(kg min mm Hg) for *S. etruscus* (compared with an average of 6 mL O<sub>2</sub>/(kg min mm Hg) in humans). The high diffusion capacity of the shrew lung is due to a very large alveolar surface (8.5 m<sup>2</sup>/kg body mass) and capillary surface (6.5 m<sup>2</sup>/kg body mass), compared to 1.9 and 1.7 m<sup>2</sup>/kg in man, respectively, as well as to an extremely thin diffusion barrier, 0.27  $\mu$ m, compared to 0.61  $\mu$ m in man, as determined morphometrically. In addition, the diffusion distance within red cells is relatively short in the shrew; the mean cell diameter is only 5.5  $\mu$ m (mean cell volume 28  $\mu$ m<sup>3</sup>) compared to 7.5  $\mu$ m (88  $\mu$ m<sup>3</sup>) in humans (14).

Assuming a rather large mean maximal P<sub>O<sub>2</sub></sub> difference between alveolar gas and lung capillaries of 50 to 70 mm Hg, which is appropriate for conditions of heavy work in mammals, one predicts from the maximal diffusion capacity a maximal diffusional O<sub>2</sub> flow of 750 to 1,050 mL O<sub>2</sub>/(kg min). This means that the maximal O<sub>2</sub> consumption in Etruscan shrews is limited by the structurally determined diffusional O<sub>2</sub> transport capacity as well as by the ventilatory O<sub>2</sub> transport capacity (8). This situation is in contrast to larger mammals and humans, in which the morphometrically determined diffusion capacity of the lung generally exceeds the functional diffusion capacity required for maximal aerobic performance (13).

## CARDIOVASCULAR SYSTEM

Measurements of the maximal heart rate in *S. etruscus* have yielded an average of almost 1,100/min. The maximum single value recorded, 1,511/min (25/s), is the highest heart rate ever reported in an endotherm. It exceeds the highest values reported so far for small red-toothed shrews like *Sorex minutus* (3 g, 1,091/min), small bats such as *Myotis lucifugus* (5 g, 1,370/min), and small hummingbirds like *Calliphlox amethystina* (2.4 g, 1,280/min) (8,15). Nevertheless, small mammals such as shrews have considerably lower resting and maximal heart rates than predicted from their body mass using allometric relationships. For resting conditions, 1,140 beats/min are predicted, but only 840/min were measured. In larger mammals, the resting heart rate increases up to three-fold due to exercise; in *S. etruscus*, the maximal increase is only 1.8 times the resting and 1.3 times the allometrically predicted basal heart rate. The maximal heart rate of the Etruscan shrew is only six to eight times that of man, whereas

3 Examples of parameters that are allometrically independent of body mass include blood pressure, hematocrit, or capillary diameter. Examples of mass-dependent properties include organ sizes and functional parameters, such as metabolic rate and heart rate, or life history parameters, such as maximal lifespan and gestation period.

the maximal respiratory rates such as the  $VO_{2max}$  are 12 times that of humans (see Table 13-1). This means that, unlike in the respiratory system,  $O_2$  transport by the circulatory system requires adaptation not only of heart frequency but also of stroke volume and blood  $O_2$  extraction. Indeed, the relative heart mass and the relative heart volume of *S. etruscus* is higher than that of man (14), providing a higher relative stroke volume for the shrew (estimated 3.5 mL/kg body mass compared to 2 mL/kg in trained humans). The shrew's blood is characterized by a large  $O_2$  capacity (0.24 mL  $O_2$ /mL blood), based on an increased hemoglobin concentration and a low  $O_2$  affinity or large  $O_2$  half-saturation pressure ( $P_{50}$ ), respectively ( $P_{50}$  at 37°C = 35.2 mm Hg) (humans 0.20 mL  $O_2$ /mL blood, 27 mm Hg). A mixed venous  $PO_2$  of 20 mm Hg, as may occur under conditions of maximal work in mammals, would result in an 80%  $O_2$  desaturation of the shrew's blood, thus allowing an increased  $O_2$  extraction (0.19 mL  $O_2$ /mL blood) at maximal work when compared to humans (0.15 mL  $O_2$ /mL blood). These values lead to an estimate of the maximal circulatory  $O_2$  transport rate of 760 to 1,000 mL  $O_2$ /(kg min) in the Etruscan shrew (8), thus matching the measured  $VO_{2max}$ .

Studies reveal that all three maximal  $O_2$  transport rates – ventilatory, diffusional, and circulatory – correspond fairly well with the experimentally obtained maximal  $O_2$  consumption rate. Moreover, all these transport capacities seem to match at this lowest end of the mammalian body size range; that is, the concept of symmorphosis (16) is ideally realized in the smallest mammal (see Table 13-1). The principle of symmorphosis suggests that morphogenesis is regulated in a way so that the formation of structural elements in an organism satisfies but does not exceed the functional requirements of the system.

## MUSCLE TISSUE

The heart and skeletal muscles of *S. etruscus* are functionally and structurally adapted to the requirements of an enormously high energy turnover. The tissue diffusion capacities are mainly determined by capillary surface area and intercapillary distances and, hence, capillary densities. Heart muscle of *S. etruscus* contains 7,300 capillaries/mm<sup>2</sup> (papillary muscle), compared with 2,700/mm<sup>2</sup> in human heart (3). The capillary density of M. soleus is 2,800/mm<sup>2</sup>, compared with 290/mm<sup>2</sup> in man (4). These data lead to mean maximal diffusion distances of 6.6  $\mu$ m in shrew heart muscle (compared with 10.8  $\mu$ m in humans), and 10.7  $\mu$ m in shrew soleus muscle (versus 33.1  $\mu$ m in humans).

The high metabolic rate in shrews is associated with rapid muscle contractions. At 37°C, a contraction cycle is completed within 13 msec in the extensor digitorum longus and within 18 msec in the soleus muscle, allowing these muscles to contract at extremely high contraction frequencies. Skeletal muscles of *S. etruscus* contract up to 900/min in respiratory muscles (diaphragm), up to 780/min during running, and up to 3,500/min during shivering (10). In contrast to larger mam-

malian species, in which muscles used for locomotion (fast twitch muscles) have different fiber types and different myosin heavy chain patterns compared with muscles predominantly used for supporting the weight of the body (slow twitch muscles), all skeletal muscles of the Etruscan shrew completely lack slow-twitch type I fibers and consist of only fast-twitch type IID fibers. IID fibers seem to be most appropriate when a combination of a high shortening velocity and a high aerobic capacity is required. IIB fibers show even higher shortening velocities than do IID fibers, but rely predominantly on glycolytic metabolism. IID fibers are considerably thinner in diameter than IIB fibers; they exhibit smaller distances for  $O_2$  diffusion. Therefore, IID fibers seem to be the best compromise between a high adenosine triphosphate (ATP) turnover, which is required not only for physical performance but also for the heat production needed to cope with the great heat loss of a small mammal, and a small fiber diameter which, together with a high capillary density, makes a high  $O_2$  flux into the fiber and high ATP production possible (10).

## THERMOGENESIS AND BROWN ADIPOSE TISSUE

During food shortage or at low ambient temperatures ( $T_a$ ), the Etruscan shrew can lower its body temperature ( $T_b$ ) and enter a torpid state to reduce its resting energy expenditure. During torpor, the  $T_b$  of the shrew has been shown to drop on average to 12°C at a  $T_a$  of 4°C (with levels falling to as low as 6°C in some animals) (17). Heart frequency decreased to 100/min and respiratory rate to 50/min at 12°C. A mean warm-up rate of nearly 1°C/min in the body temperature range of 12°C to 37°C was measured in *S. etruscus*, which is among the highest values measured in heterothermic mammals (17). Because active rewarming from torpor, like exercise, requires a high metabolic turnover, the mass-specific  $O_2$  transport rate is also very high under these conditions. Estimation of the mixed venous  $O_2$  partial pressure showed that, at the tissue level, the rewarming process corresponds to heavy work conditions.

Below a  $T_b$  of 17°C, shivering does not significantly contribute to rewarming, as shown by electrocardiograph/electromyograph (ECG/EMG) recordings. In this temperature range, nonshivering thermogenesis by brown adipose tissue (BAT) is responsible for heat production and rewarming. It is useful for this purpose that most of the fat mass of *S. etruscus* consists of BAT. On average, it amounts to nearly 10% of total body mass, the highest value reported for a mammal. After the onset of shivering, the rate of rewarming increases, and EMG recordings show up to 3,500 bursts per min, probably caused by asynchronous firing of several motor units. The ventilatory system is adapted to such an extent that, during rewarming from torpor, in addition to the appropriate  $O_2$  transport capacity, a capacity also exists for hyperventilation. This is necessary because, as known from other heterothermic mammals, animals in the phase of rewarming from torpor

have to compensate for acidosis caused by CO<sub>2</sub> accumulation during transit into torpor (17).

## LIFESPAN AND REPRODUCTION

Allometric investigations show that, within many mammalian orders, maximal lifespan (LS) increases with body mass (M) proportional to M<sup>0.2</sup> (1). Metabolic rates (MR) of mammals (basal [BMR], mean active, or field as well as maximal MR), scale with body mass according to M<sup>0.7</sup> to M<sup>0.8</sup>. Thus, the product LS × MR, which is the amount of energy consumed in a mammal during maximal lifespan, is roughly proportional to M, or, the mass-specific lifetime energy expenditure LEE = LS × MR/M is independent of body mass. For the LEE of mammals, a mean value of 5,000 MJ/kg is calculated (1). A possible mechanism underlying this relation is the production rate of reactive oxygen species (ROS), which increases with metabolic rate or O<sub>2</sub> consumption, respectively. ROS damage membranous and cytosolic cell components and, although antioxidants and repair mechanisms continuously fight against the processes impairing cell function, a steady accumulation of cell aging events seems to occur. Due to the shrew's extreme O<sub>2</sub> consumption rate, its LEE is used up within a short time. Despite being equipped with an outstanding antioxidant capacity, the maximal lifespan of *S. etruscus* occurring in wild-living animals is only 19 months, whereas under ideal laboratory conditions 26 months have been observed (9).

In terms of survival of the species, this short lifespan is compensated for through a very high reproduction rate. On average, 3.5 (maximal six) litters per year with a mean litter size of four newborns have been recorded. The altricial newborns are suckled until they have reached their adult body mass 3 weeks after birth (9). On average, a female shrew produces offspring equivalent to 20 times its own body mass. Thus, in addition to the energy expenditure required for maintaining its own homeostasis, a considerable amount of lifetime energy expenditure is needed for gestation and lactation – for the growth and homeostasis of offspring.

## KEY POINTS

- The smallest mammal, the shrew *S. etruscus*, exceeds all other animals with respect to its maximal O<sub>2</sub> consumption and the performance of its O<sub>2</sub> transport cascade.
- Maximal ventilatory, diffusional, and circulatory O<sub>2</sub> transport capacities are matched in a perfect way, supporting the concept of symmorphosis.
- Entrance into torpor is used to save energy. Rewarming times are very short.

- The extreme metabolic rate leads to a large production rate of ROS and a short maximal lifespan, according to the concept of a constant maximal lifetime energy expenditure.

## Future Goals

- To investigate whether the large transport rates require special properties of the endothelia

## Molecular Phylogeny

---

John H. McVey

*MRC Clinical Sciences Centre, Imperial College, London, United Kingdom*

An important challenge in studying evolutionary biology is to reconstruct the past based primarily on evidence from the present by studying the comparative biology and molecular phylogeny of present-day organisms. Studying the fossil record may help fill some of the gaps in our understanding. Unfortunately, the cardiovascular system does not fossilize; therefore, any rendition of the evolutionary history of the endothelium is at best speculative. In constructing a hierarchical pattern of evolution based on the comparative analysis of structure and function, it is assumed that two structures that look similar are closely related, however, structures also may look similar because they have evolved similar adaptations, so called *convergent evolution*. For example, the arthropod *Tachypleus tridentatus* (Japanese horseshoe crab) contains a clotting system consisting of a protease cascade of three serine protease zymogens and a clottable protein (coagulogen). The components of this cascade are stored in granules in hemocytes and released in response to foreign substances such as lipopolysaccharide (LPS). Hemolymph coagulation in the horseshoe crab shares many common features with the vertebrate-clotting system (cascade of serine protease zymogens, clottable protein, and LPS response), but the proteins involved are quite different and have arisen independently of each other. Conversely, structures that no longer look similar nor appear to share a common function may have arisen from a common ancestor through *divergent evolution*. Similar pitfalls befall the analysis of molecular sequences: Because genomes have evolved through duplication events, many coding sequences may share a degree of sequence identity with each other; however, this does not mean that they share a common function. For example, it is widely believed that large regional or whole genome duplications have contributed to the structure of vertebrate genomes (1,2). The mechanisms by which these have arisen are controversial, but it has been proposed that the evolution of the vertebrate genome involved two whole-genome duplication events that are thought to have occurred early in the vertebrate lineage, some 500 million years ago (3). However, local duplication and translocation also could account for the evolution of multigene families on separate chromosomal regions, whereas other genetic events, such as gene conver-

sion and gene loss, can further complicate our understanding of duplicate gene evolution. (To clarify certain terms used in evolutionary comparative analysis, a glossary is provided at the end of this chapter.)

Central to a discussion of molecular phylogeny is the distinction between orthologous genes (*orthologues*) and paralogous genes (*paralogues*). The degree of sequence identity may make it difficult to differentiate orthologous genes in different species, which have evolved directly from a common ancestral gene, from paralogous genes, which have evolved from a common ancestral gene through duplication and therefore share common structural features, but have since diverged from the parental copy through mutation and selection or drift and have completely diverged functions. The sequence composition of the genome of a particular organism leading to *codon usage bias* may further complicate analysis. For example, the genome of the lamprey (*Lampreria fluviatilis*) is very GC-rich: Three members of the vitamin K-dependent blood coagulation factor family, sharing the domain structure Gla-EGF1-EGF2-SP, were recently identified (4,5). Phylogenetic sequence comparisons, however, all suggested that these sequences were more related to each other (because of sequence composition bias) rather than other known mammalian coagulation factors, making it impossible to assign them to appropriate orthologous groups and thus specify function.

Evolution, while providing a solution to one problem, may also lead to a new set of challenges. For example, the development of a high-pressure cardiovascular system, although providing a means for overcoming the oxygen (O<sub>2</sub>) transport problem and thereby paving the way for the evolution of larger animals, introduced the potential life-threatening consequence of rapid exsanguination following vascular damage and the potential entry and dissemination within the organism of life-threatening pathogens. The organisms we see today reflect multiple, parallel evolutionary events that may have arisen independently but have coevolved because of their reliance on each other. Thus, all extant vertebrates have a similar vascular network, specialized blood cells that transport O<sub>2</sub> and fight infection, and a coagulation network that provides a rapid localized response at the site of vascular damage. The

endothelium in man has coevolved to provide a complex series of physiological functions that include the control of vasomotor tone, trafficking of cells and nutrients, maintenance of blood fluidity, regulation of permeability, and formation of new blood vessels, among other functions. The endothelium expresses appropriate receptors or molecules that interact with blood cells (lymphocytes, monocytes, platelets) and complex molecular systems (for example, the blood coagulation network) to maintain normal blood flow and exclude blood cells from peripheral tissues. Upon vascular injury or inflammation, this same system responds by promoting cell adhesion, extravasation, and/or controlled fibrin deposition to prevent blood loss.

The endothelium cannot, however, be regarded as a simple homogeneous cell type. Endothelial cell (EC) phenotypes are differentially regulated at any given point in time, at any given location. Endothelial heterogeneity occurs between different organs, within the vascular loop of a given organ, and even between neighboring ECs of a single vessel. Indeed, it has been suggested that it is more realistic to consider an EC as an adaptive input–output device responding to the local environment in which it is located (6). If it is so difficult even to directly compare ECs within a single organism, it is likely that comparisons across different species may be even more difficult.

At the gross anatomical level, it is clear that all extant jawed vertebrates possess a similar vascular system, which at least in part fulfils a similar role to that of man. At the molecular level, it also is clear that all jawed vertebrates share at least some of the differentiated features found in man. This chapter reviews approaches for studying molecular phylogeny and illustrates how, using molecular phylogenetic analysis of the vascular endothelial growth factor (VEGF) family, one can study the evolution of the endothelium.

## PHYLOGENETIC ANALYSIS

The starting point for the construction of a multiple-sequence alignment that optimally defines or represents a protein family is an analysis of current sequence databases (for example, NCBI's nonredundant [nr] database) using sequence analysis tools such as TBLASTN or Position-Specific-Iterated BLAST (PSI-BLAST) (<http://www.ncbi.nlm.nih.gov/BLAST/>) (7–9). Translated DNA–protein searches are capable of finding more homologues than searching by DNA–DNA comparison because of the redundancy of the genetic code. These two methods work in very different ways: TBLASTN searches by comparing the query protein sequence against a nucleotide database translated dynamically into all six reading frames. In contrast, PSI-BLAST takes a query protein sequence and compares it to a protein database; it generates a profile from the results of the search, which is then applied to subsequent searches in an iterative manner. As new sequences are added, the profile is refined. The process is repeated until no new relationships are identified. The PSI-BLAST search is an extremely

powerful tool that can identify distantly related sequences with less than 20% amino-acid sequence identity. To refine the approach, it may be useful to select a subset of the query sequences encoding a known conserved functional domain to maximize the number of significant scores. Web-based tools, such as SMART (<http://smart.embl-heidelberg.de/>) (10,11), can aid the identification of conserved functional domains within the sequence of interest. The aim is to identify distant relatives of a given sequence while minimizing the number of false positives. All BLAST-based programs assess the statistical relevance of sequence similarities through an E-value, which is defined as the number of sequences expected to have a similar or better score by chance alone. The current default threshold for the NCBI Web-based PSI-BLAST analysis is 0.005, which is a 1 in 200 chance of obtaining a false positive. Those sequences that share significant sequence identity and are thought to represent orthologous sequences or genes may then be aligned using tools for multiple sequence alignment (for example, the ClustalW program [12]) and then optimized either manually or using other tools (for example, Gblocks <http://molevol.ibmb.csic.es/Gblocks/Gblocks.html> [13]) if necessary. These multiple alignments then can be used to infer phylogenetic trees.

Two crucial steps must be taken in phylogenetic inference: the identification of *homologous characters* and tree construction. In phylogenies based on morphological data, the reliability of a phylogenetic tree depends on the quality of the assignment of homologous characters; similarly, in phylogenetic tree building, the reliability depends on the quality of the multiple sequence alignment. A high-quality alignment containing accurate and carefully chosen sequences is the single most important prerequisite for secure phylogenetic analysis.

Three reconstruction methods commonly are used for inferring phylogenies: distance-based methods, maximum parsimony, and likelihood methods. *Distance-based methods* first convert the sequence alignment into a distance matrix that represents the evolutionary distances between all pairs of sequences in the data set. The phylogenetic tree then is inferred from this distance matrix using algorithms such as neighbor joining (NJ). Pairs of sequences are compared, and those pairs with the lowest distance score (i.e., having the shortest distance) are linked to form a *node*. This pair is then treated as a single unit; the process is repeated to identify the sequence with the least distance score from this node until all sequences have been placed in the tree. In contrast, the *maximum parsimony methods* consider all possible evolutionary trees that could explain the observed sequence relationships and then select the tree that requires the minimum number of character changes. Finally, *likelihood methods* create all possible trees and then use statistical methods to evaluate the probability that a given tree could have produced the observed data. This is possible for small data sets; however, for large numbers of sequences the number of trees generated becomes so large that computational analysis becomes limiting.

No ideal method exists at present, and the best tree from any program may not represent the “true” tree. Once a tree has

been generated, the reliability of the tree can be assessed using statistical indices, such as bootstrap percentages obtained using bootstrap analysis and Bayesian posterior probabilities. The *bootstrap* procedure randomly samples the original data set to generate new pseudoreplicate data sets, which then are analyzed. Bootstrapping typically involves resampling subsets of data 1,000 times; the bootstrap value is the frequency with which a given branch occurred exactly within that topology. Branches having bootstrap values of 95% to 100% indicate a high level of confidence, but values as low as 70% often are cited as reliable.

**VASCULAR ENDOTHELIAL GROWTH FACTOR FAMILY**

In the vertebrate embryo, the development of a vascular system involves two fundamental processes: vasculogenesis and angiogenesis. VEGFs are members of a family of growth factors known as the cystine-knot super family (14). These factors are characterized by the presence of eight conserved cysteine residues essential for embryonic vasculogenesis and angiogenesis and for neovascularization in cancer and other diseases (reviewed in [15]). In mammals, VEGF-A is the prototypical member of a family of related growth factors that includes placental growth factor (PlGF), VEGF-B, VEGF-C, and VEGF-D. The biological functions of these growth factors are mediated by a family of cognate protein tyrosine kinase receptors (VEGFRs): VEGF-A binds to VEGFR1 (also known as FLT-1) and VEGFR2 (also known as FLK-1); VEGF-B and PlGF bind only to VEGFR2; and VEGF-C and VEGF-D both bind to

VEGFR2 and VEGFR3 (also known as FLT-4). VEGF-A has a critical role in vascular development as evidenced by the observation that targeted disruption of the murine gene results in impairment of angiogenesis resulting in death between embryonic day (E)11 and E12. In contrast, a biological role for VEGF-B has not been clearly established. VEGF-C and VEGF-D are strongly implicated in lymphangiogenesis. Overexpression of VEGF-C and VEGF-D in transgenic mice induces the formation of hyperplastic lymphatic vessels. Conversely, inhibition of VEGF-C and/or VEGF-D by overexpression of a soluble (nonsignaling) form of VEGFR3 leads to inhibition of lymphatic vessel growth. PlGF appears to be weakly angiogenic; mice lacking PlGF are viable and develop normally but show reduced angiogenesis in pathophysiological situations such as ischemia.

A simple text search of the Entrez database (<http://www.ncbi.nlm.nih.gov/gquery/gquery.fcgi>) identified the human VEGF amino acid reference sequences for VEGF-A, -B, -C, -D, and PlGF (GI: 76781481, 4507887, 4885653, 4758378, and 20149543, respectively). These paralogous sequences were then aligned using ClustalW. This sequence comparison identifies conserved sequence motifs essential for the structure-function of the VEGF family. The highly conserved cystine-knot domain is clearly identified (Figure 14.1). The consensus sequence for the cystine-knot motif is C<sub>1</sub>-(X)<sub>n</sub>-C<sub>2</sub>-X-G-X-C<sub>3</sub>-(X)<sub>n</sub>-C<sub>4</sub>-(X)<sub>n</sub>-C<sub>5</sub>-X-C<sub>6</sub>, in which cysteines 2, 3, 5, and 6 form a ring by disulfide bonding between C<sub>2</sub>-C<sub>5</sub> and C<sub>3</sub>-C<sub>6</sub>. The third disulfide bond formed by C<sub>1</sub>-C<sub>4</sub> penetrates the ring, forming a knot (Figure 14.2). In the VEGF family, two additional highly conserved cysteine residues exist. Each of the reference sequences (VEGF-A, -B, -C, -D, and PlGF) was then

Figure 14.1. Amino acid alignment of the human VEGF family sequences. The sequences were aligned using ClustalW multiple sequence alignment program and displayed using Bioedit (<http://www.mbio.ncsu.edu/BioEdit/bioedit.html>). White on black indicates identity with the consensus; black on gray indicates similarity with the consensus. The cystine-knot motif is boxed, and the eight conserved cysteine residues are numbered.

Figure 14.3. Neighbor-joining tree inferred from the alignment of sequences with sequence similarity to the cystine-knot of the human VEGF family, illustrating the phylogenetic relationship of sequences. The sequences were aligned using ClustalW, following a PSI-BLAST search with the boxed sequences from Figure 14.1. The figure was generated by TREEVIEW (<http://taxonomy.zoology.gla.ac.uk/rod/treeview.html>; [21]). The GI accession number for each sequence and the species of origin is given. The VEGF clades are assigned based on the annotations of the human amino acid sequences.

unambiguously assign these sequences. It also must be noted that these sequences are predicted to encode expressed proteins using automated gene prediction methods, and they may not encode a functional protein as the process of genome evolution proceeds through a process of gene duplication and gene loss.

The analysis of the additional *D. rerio* sequences demonstrates the presence in the *D. rerio* genome of at least four genes predicted to encode proteins with significant sequence identity to mammalian VEGF sequences (see Figure 14.4), with all eight cysteine residues and their spacing within the cystine-knot conserved, with the exception of 68388133, which lacks cysteine 8. Because cysteine 8 (C<sub>6</sub> in the cystine-knot consensus) forms one of the essential disulfide bonds (C<sub>3</sub>–C<sub>6</sub>; see Figure 14.2), it is highly likely that this sequence does not represent a functional VEGF molecule. The presence of multiple VEGF-like sequences in *D. rerio* suggests this gene family evolved prior to the divergence of bony fish from tetrapods over 430 million years ago. This is perhaps not surprising

given the highly conserved vascular system found in all vertebrates and the importance of the VEGF family in vascular development. However, further analysis will be required to demonstrate that these molecules have identical functions in mammals and teleosts.

Proteins with sequence identity to mammalian VEGFs also have been identified in several invertebrate species, *Drosophila melanogaster* (fruit fly; Pvf1, GI: 22832528; Pvf2, GI: 22945847; Pvf3, GI: 22945848), *Caenorhabditis elegans* (nematode; GI: 17555774), and *Podocoryne carnea* (jellyfish; GI: 45934767) (17). *D. melanogaster* has three genes predicted to encode proteins with sequence similarity to human VEGF sequences (Figure 14.5). The sequence similarity is primarily confined to the cystine-knot and is relatively low; however, all eight cysteine residues are conserved, with the exception of Pvf2 (GI: 22945847), which lacks cysteine 2. This cysteine does not contribute to the cystine-knot (see Figure 14.2) and therefore this may still represent a functional VEGF-like molecule. Molecular phylogenetic analysis fails to assign the *D. melanogaster*

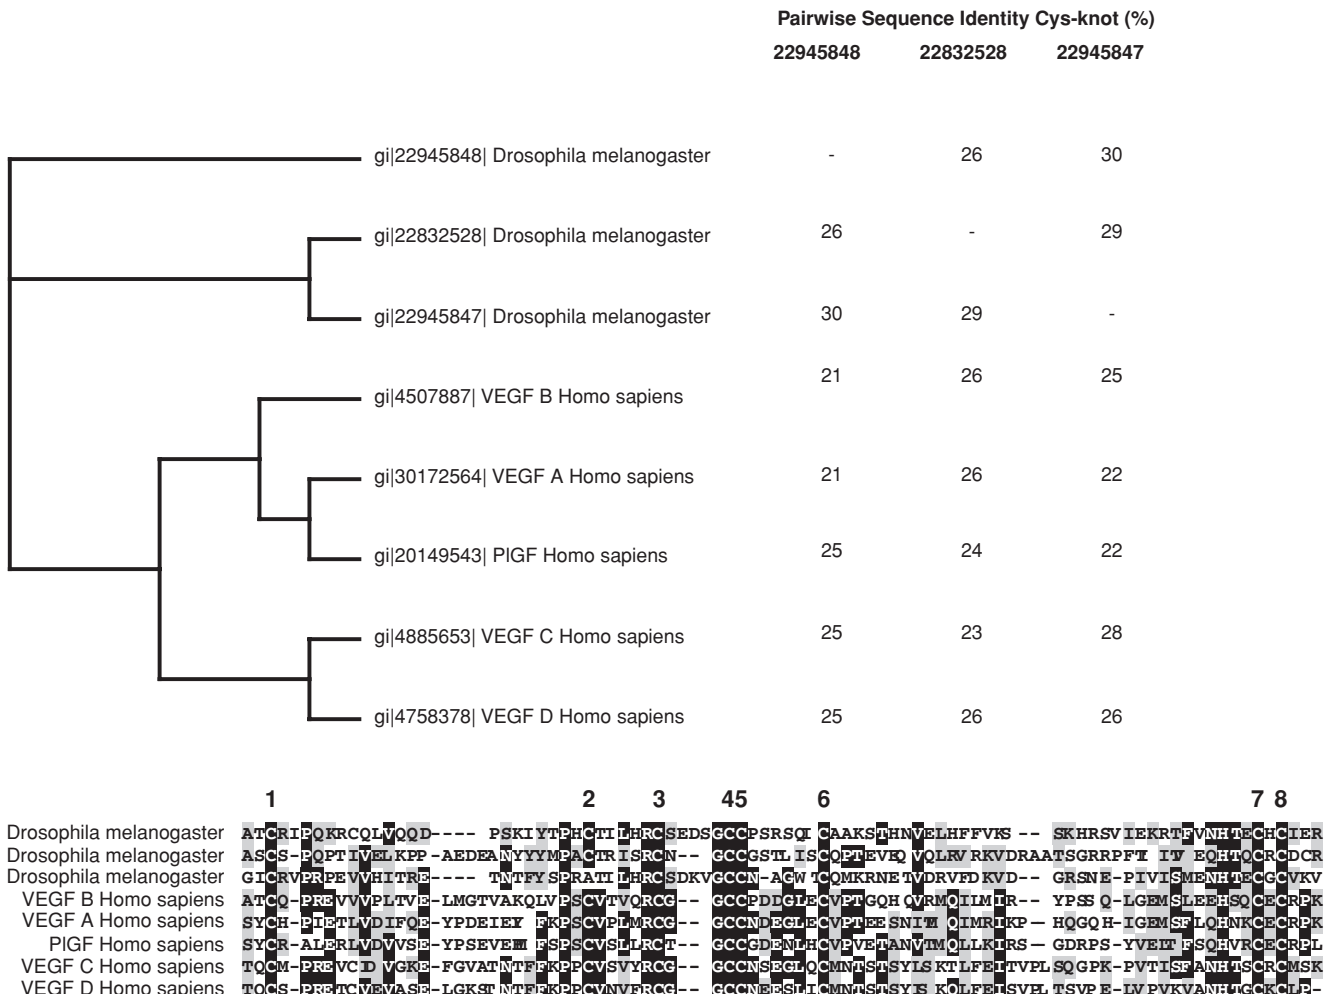

Figure 14.5. Comparative sequence analysis of human and *Drosophila melanogaster* VEGF-related sequences. The sequences were aligned using ClustalW, following a PSI-BLAST search. The GI accession number for each sequence and the species of origin is given. The amino acid alignment of the cystine-knot is shown with the conserved cysteines numbered 1–8. The sequences are displayed in the same order as presented in the tree. The pairwise sequence identity was calculated using a PAM250 scoring matrix using BioEdit.

sequences to any particular clade relative to the characterized mammalian sequences (see Figures 14.3 and 14.5), and comparison of the exon-intron structure of the genes does not provide any additional insight into any possible relationship between the *D. melanogaster* genes and the mammalian VEGF genes. Is it possible to infer a functional role for these molecules in *D. melanogaster* based on our knowledge of their function in mammals? Conversely, is it possible to infer functional roles for VEGF molecules in mammals based on experimental data obtained from *D. melanogaster*? To infer a functional role for a mammalian gene from studies of a gene in *D. melanogaster*, one must be confident about their orthologous relationships. *D. melanogaster* does not have ECs or blood vessels, but has an open circulatory system, with an aorta and heart represented by a contractile tube lined by a layer of myoepithelial vascular cells called *cardioblasts*. It is therefore intriguing that, in *D. melanogaster*, VEGF appears to play a role in blood cell migration and differentiation; recent analysis of *D. melanogaster* lymph gland development has provided evidence for a “hemangioblast”-like cell that can differentiate into heart, aorta, or blood cells (18,19). Disruption of the *Vegfr2* gene in mouse suggests a close association between endothelial and hematopoietic cells in the mouse embryo. Furthermore, human hematopoietic cells purified from cord-blood or bone marrow on the basis of CD34 and *VEGFR2* expression generate both haematopoietic and ECs in vitro.

In contrast, in *C. elegans*, an organism completely devoid of a vascular circulatory system, receptors resembling the VEGFR of vertebrates were expressed in cells of neural origin (20). Expression of VEGFR molecules in neural cells occurs in mammals but not in *D. melanogaster*. Whereas in *P. carnea*, a member of the most basal phylum of the animal kingdom having tissue organization and a complex nerve net but no blood cells or blood vessels, the VEGF and VEGFR-like genes are expressed in the tentacles and developing radial and ring canals. These structures share a common tubular formation, and the genes appear to play a role in tube formation (17). It is tempting to suggest that during evolution these molecules may have been recruited for the purposes of cell migration and cell adhesion in similar processes (for example, neurogenesis, angiogenesis, hematopoiesis) in different species. However, at present it is not possible to conclude whether these processes used genes derived from the same ancestors or different genes and, consequently, whether the sequence similarity is due to homology by descent or to convergence.

#### KEY POINTS

- Molecular phylogenetic analysis and comparative sequence analysis are powerful tools to identify and characterise molecules that may share similar function(s) in diverse organisms.

- If an orthologous relationship can be defined securely between genes in different species, then important insights may be obtained about the function of these molecules; however, it is often the case that orthologues and paralogues cannot be distinguished.
- Comparative sequence analysis can identify amino acid residues critical for the structure and function of these proteins.
- Sequence similarity shared by two proteins does not necessarily imply shared function.
- The addition of complete genome sequences of many more organisms will increase the confidence of phylogenetic analysis, in particular the discrimination between orthologues and paralogues.

#### GLOSSARY

**Convergent evolution** Convergent evolution results when unrelated species are acted on by the same selection pressure, and adaptive traits tend to resemble traits in other species without a shared evolutionary lineage. The development of flight in birds and certain insects is an example of convergent evolution.

**Divergent evolution** Selection pressure may also result in diver-

gent evolution, where related lineages evolve different traits in response to different selection pressures.

**Orthologue** Orthologues are equivalent genes in different species that evolved from a common ancestor by speciation.

**Paralogue** Homologous sequences (that is, sequences that share a common evolutionary ancestor) that diverged by gene duplication (within one organism).

**Codon usage bias** Most amino acids are specified by more than one codon. For example, the codons GCU, GCC, GCA, and GCG all code for the amino acid Alanine and are therefore described as synonymous. However, genes of many organisms use these codons with different frequencies. The bias in synonymous codon usage may be determined by the sequence composition of the organism, in particular the GC content of the genome.

**Homologue** Homologous proteins have evolved from a common ancestor, and their evolutionary relationship is evident from similarities in sequence, structure, and/or function.

**Distance-based methods** Method that takes the input data and derives from them some measure of similarity/difference and from this constructs a tree that tries to match this data.

**Parsimony methods** Method based on the principle that the simplest explanation, the one that requires the fewest hypotheses, is the one most likely to be correct and therefore the one that requires the fewest number of character transformations.

**Likelihood methods** A statistical method that calculates the probability of the observed data under varying hypotheses, in order to estimate model parameters that best explain the observed data and determine the relative strengths of alternative hypotheses.

**Bootstrap analysis** A type of statistical analysis used to test the reliability of specific branches in an evolutionary tree.

**Clade** A lineage (or family) made up of its ancestor and all its descendants (derived from *klados*, Greek for branch).

**Out-group** A closely related species that is used for comparison; for example, to infer the ancestral versus the derived state of a polymorphism.

## Darwinian Medicine

### What Evolutionary Medicine Offers to Endothelium Researchers

---

Randolph M. Nesse and Alan Weder

*The University of Michigan, Ann Arbor*

Almost all our detailed knowledge about the endothelium is proximate knowledge about its structure, development, and functioning, and how its dysfunctions lead to disease. The other, evolutionary half of endothelial biology has been neglected. Some researchers are unfamiliar with the fundamental distinction between proximate and evolutionary questions, and methods for formulating and testing evolutionary hypotheses about the endothelium remain underappreciated. This chapter offers a brief overview of the distinction between evolutionary and proximate explanations, followed by an introduction to evolutionary medicine and its applications to the endothelium.

Evolutionary, or Darwinian, medicine simply brings the power of evolutionary biology to bear on the problems of medicine. Some areas, such as pathogen evolution and population genetics, are well developed. Another aspect, emphasized in Darwinian medicine, is the enterprise of formulating and testing hypotheses about why natural selection has not shaped bodies that are more resistant to disease. The six key reasons for traits that leave bodies vulnerable to disease are reviewed below. Each is illustrated with examples from general medicine, and then with examples from a major disease of the endothelium, atherosclerosis.

#### TWO SEPARATE BIOLOGICAL QUESTIONS

Ernst Mayr passed away early in 2005 at age 100, shortly after publishing his twentieth book and the last of his 700+ scientific articles. One of his enduring contributions was his dogged emphasis on the importance of distinguishing proximate from evolutionary (sometimes called *ultimate*) biological explanations. His treatise, *The Growth of Biological Thought*, traces these two only-occasionally intersecting threads in biology: one that studies how things work (proximate), the other that

studies why organisms are the way they are (evolutionary) (1). His final book, *What Makes Biology Unique*, continues and updates the theme (2). Over and over again, he makes the point that every biological trait needs both a proximate explanation of its structure and operation, and an evolutionary explanation of why it is the way it is. For example, an explanation of the structure of chlorophyll and how it captures photons and traps their energy in chemical bonds is essential. Equally important, however, is an evolutionary explanation of the biological history of chlorophyll and how its particular form gives a selective advantage. As many will know, the story is intriguing, with the machinery for photosynthesis evolving in one-celled organisms about 3.5 billion years ago, probably in the precursors to cyanobacteria. It has been only about 1 billion years, however, since those organisms were incorporated into the eukaryotic cell as chloroplasts. A complete biological explanation of chlorophyll needs both a proximate description of how chloroplasts work, and an evolutionary explanation of the selection forces and phylogenetic pathways that gave them their current characteristics, instead of others.

The distinction between “how” and “why” questions was developed further by Tinbergen, in a seminal article describing his famous “Four Questions” (3). Here, he divides proximate questions into two subtypes: those about the structure of a trait and those about its ontogeny. He also divides evolutionary questions into those about how a trait gives a selective advantage and those about the phylogeny of a trait. Implicit in this classification is the need to address four separate questions when offering a full biological explanation for any trait. All too often, the four questions are inadequately distinguished or incorrectly taken to be alternatives. Sometimes the evolutionary questions are not taken seriously or are ignored completely.

Much of this situation is understandable because education about these aspects of evolutionary biology often is

limited, even for some biologists. It remains lamentable nonetheless. Biology would progress faster if evolutionary questions about every trait were addressed systematically. In medicine, this is of particular importance. Many physicians have naïve notions about the body, such as the belief that a normal genome exists, or that the body is designed like a machine, or that its flaws result mainly from the limited powers of natural selection. Asking evolutionary questions reveals that the body is a bundle of trade-offs, with no trait perfect, and substantial vulnerabilities persisting not just because selection is too weak, but also for several other reasons.

## DARWINIAN MEDICINE

In the past decade, rapid progress has been made in using evolutionary principles to understand why bodies are so vulnerable to disease (4–8). The obvious explanation, the limits of natural selection in the face of mutation and drift, is certainly important. However, five additional reasons must be considered in any assessment of why a trait appears suboptimal. Each of these reasons deserves separate consideration for medical conditions in general, and for aspects of the endothelium in particular.

### Novel Environments

Much, even most, of modern chronic disease arises because we live in environments far different from those our bodies were selected for (see Chapter 16). Paradoxically, our greatest threats now come from our grand success at providing ourselves with all manner of tasty food available with little effort at any time. A third of adults are overweight in many developed countries, and rates of obesity are rising quickly everywhere food is plentiful, giving rise to Syndrome X and all its complications (9). The preferences that shaped our current food supply shape our personal dietary habits. On the African savannah, tendencies to eat fat, sugar, and salt and minimize exercise were generally useful; today, they are fatal (10).

### Infection and Vulnerabilities from “Arms Races”

A second major reason why natural selection cannot make bodies that defend themselves better from disease is because natural selection is simultaneously making other organisms better able to penetrate defenses (11). Worse yet, the rate of evolution in bacteria and viruses is orders of magnitude faster than is the rate for slowly reproducing organisms such as humans.

### Limits on What Selection Can Do

This brings us to what selection can and cannot do. Some scientists attribute flaws in the organism mainly to the inevitability of mutations and the slow rate at which selection can purge them from the gene pool. Such mutations and the limited

speed of selection are indeed significant factors explaining the body’s imperfections. However, they are by no means the only or the most important factors. Furthermore, their importance often is overrated by those who hold fundamentally mistaken views, such as that the body is a well-designed machine, or that there exists a single normal genotype/phenotype. The body does work like a machine, but its origins were far different from any design shaped with the forethought of an engineer. It is cluttered with remnants of previous features that limit optimality. Consider the path of the recurrent laryngeal nerve, from the brainstem all the way down to just above the lung, where it wraps around the subclavian artery before ascending again to pass behind the thyroid gland on the way to the larynx. The vas deferens makes an equally circuitous path (12). Such “design flaws” exist because the body is profoundly path-dependent: Just like the arrangement of keys on a typewriter keyboard, once structures are in a particular conformation, changing them can be very expensive or impossible. An automobile designer can move the gasoline tank if it proves vulnerable to rupture, but natural selection can never alter the awkward and dangerous path of childbirth through the narrow ring of the pelvis.

### Trade-Offs

Trade-offs are another source of traits that seem less than perfect. Here the problem is the same as that faced by any human designer. No trait can ever be completely perfect because at some point making one trait better will make others worse. Bones could be thicker, but they would then be heavier and less mobile. Joints could be more flexible, but that would risk damage to muscles. The immune system could be more aggressive but only at the cost of constant tissue damage.

### Selection Maximizes Reproduction, Not Health

It is a common mistake to think that the body is designed for health, and all disease arises from design flaws. Actually, bodies are products of evolution, not design. They are merely phenotypes that maximize the transmission of genes (13,14). If a gene increases reproductive success, it will spread, even if it causes disease or shortens life. Aging itself may result, in part, from pleiotropic genes that cause aging but that are nonetheless selected for because they give a benefit in youth when selection is strong (15,16). Likewise, much of the increased mortality in males compared to females comes from the reproductive benefits of increased allocation of effort to competition at the expense of tissue repair (17). Increased reproduction at the expense of health does not seem to be an obvious major factor in shaping the endothelium, but men develop atherosclerotic disease more rapidly than do females, almost certainly because sexual selection has resulted in systems that allocate more effort to competition and less to tissue protection and repair in males as compared with females (17,18). In particular, traits that benefit a fetus may be selected for, even if they damage the mother.

### Defenses Are Useful Despite Their Costs

Finally, there exist the body's many protective responses such as pain, fever, vomiting, cough, and inflammation. Although they cause suffering and often bodily damage, they are useful responses, not defects. Their costs are trade-offs for the benefits they offer. It is all too easy to imagine that defenses are problems. For instance, the fever, pain, fatigue, and cough that accompany a cold do not seem to be obviously useful. This "clinician's illusion" that they are problems is bolstered because blocking them with drugs seems to cause few complications. However, this is only because the body has so many redundant defense systems, and because the systems that regulate defense expression are shaped to express defenses whenever that is worthwhile. If there is any uncertainty in when to express them, this means a normal system will have many false alarms. Many defenses, such as vomiting or panicked flight, are quite inexpensive compared to the huge cost of not responding to a real danger such as intestinal infection or an approaching tiger. The defense should be expressed whenever the average benefit is greater than the average cost, so many false alarms are normal and to be expected. This has been called "The Smoke Detector Principle," because we tolerate false alarms from burnt toast to ensure that the alarm sounds every single time even a small fire occurs (19). Disrupting defenses is not, however, completely benign; using drugs to block fever, cough, or diarrhea can lead to serious consequences (6).

### EVOLUTIONARY ANALYSIS OF ENDOTHELIAL DYSFUNCTION AND ATHEROSCLEROSIS

The healthy endothelium contributes to several processes of obvious adaptive advantage: control of hemostasis, protection of subendothelial structures from circulating blood, local modulation of hemodynamics, and defense against infection. Endothelial dysfunction, broadly defined, can be lethal, as evidenced by von Willebrand disease and endotoxic shock. Subtler endothelial dysfunction is characteristic of early atherosclerosis, an important disease of the developed world. Although we cannot know for certain, it is unlikely that atherosclerosis caused significant morbidity or mortality in the pre-agricultural era, and indeed modern hunter-gatherers are little affected by atherosclerosis (see Chapter 16). However, atherosclerosis is now epidemic in developed societies worldwide, suggesting a near universal predisposition for the disease, with some of the variation in vulnerability arising from genetic differences. Although some common vulnerability factors, such as low levels of high-density lipoprotein (HDL) cholesterol, may result from the accumulation of multiple rare alleles in a specific population, most probably they result from common allelic variants found in all populations (20). The apolipoprotein E story is particularly germane in this regard (21). Common and widely dispersed genetic patterns are of ancient origin, and thus presumably predispose all humans to disease susceptibility when they interact with

modern conditions. Indeed, even in recent historical times, transitions from relatively low to high rates of atherosclerosis have been observed to accompany cultural transitions.

At this early juncture, it is important to acknowledge explicitly that we do not propose that "genes for atherosclerosis" exist. Rather, we believe that those suites of genes, shared by most of us, that now exact a net cost were preserved because they have yielded a net benefit over evolutionary time. This may be because dietary changes interact with these genes to impose costs throughout life, or because the benefits during early life are larger for some genes than are their adverse consequences during adulthood (*antagonistic pleiotropy*). The massive amount of work constituting the bulk of the current volume provides insights about the proximate mechanisms by which atherosclerosis arises and progresses, and we draw heavily on that mechanistic knowledge. Our task is to suggest reasons why natural selection over the past hundred thousand years conserved an essentially universal vulnerability to such an important disease process.

Although early atherosclerosis usually is characterized as "endothelial dysfunction," and the progression of atherosclerosis as a "response to injury," close examination of early events shows the endothelium to be functioning in a largely normal manner, at least as regards one of its primary functions – immunity. For most of hominid history, infections have represented grave threats, whether arising from injury, peripartum infection, or endemic pathogens. The nature, although not the risk, of infectious disease changed as settled communities developed (11). Increased population density permitted human-to-human disease transmission, leading to the rise of epidemic disease, and animal domestication led to the emergence of novel zoonoses, especially evident now as avian influenza threatens. Innate and acquired immunological functions that eliminate or suppress infections are highly conserved as powerful and often apparently redundant defenses. The evolution of such systems cannot reasonably be attributed to anything other than incremental beneficial genetic changes that improved the reproductive success of those individuals who had them. The endothelium contributes very importantly to immunity, and one of its functions – the controlled transport of intravascular substances and cells to the subendothelial space – seems to predispose us to atherosclerosis. Although this could be interpreted as a simple defect, it appears much more like an adaptation that has benefits that are equal to or greater than its costs in a classic trade-off.

Atherosclerotic lesions begin as low-density lipoprotein (LDL) particles accumulate in the subintimal space (22). The concentration of LDL in the blood is an important determinant of the rate of accumulation, as is the concentration of HDL available for reverse cholesterol transport out of the tissue. However, the trafficking of lipoproteins across the endothelium is not passive. Rather, LDL and HDL cross endothelial cells (ECs) by means of *pinocytosis*, which allows the delivery of triglycerides and cholesterol for metabolic support, cell growth, and steroidogenesis.

The macrophage is another key player in atherosclerosis (22,23). Although macrophages normally resident in the subintima can handle some foreign antigens, the local response to tissue infection triggers an elaborate signaling system marshalling a defense reaction that includes the trans-endothelial migration of large numbers of monocytes and subsequent differentiation into macrophages to engulf bacteria and expose them to lysosomal enzymes. Macrophage phagocytosis and the intracellular lysosomal degradation of bacteria are efficient, but via coevolution, some organisms have derived strategies to frustrate macrophage capabilities. Thus, although bacteria that can be opsonized are cleared efficiently, many bacteria (e.g., *Listeria* and tuberculosis) have evolved resistance to the constitutive killing mechanisms used by macrophages such that they can survive, even intracellularly. *Chlamydia pneumoniae* may be of particular importance (24).

The process of the development of bacterial resistance is reminiscent of how LDL particles take up residence in the subendothelium, escape macrophage metabolism, and cause disease. Native LDL particles attach to macrophage LDL receptors and are efficiently engulfed and metabolized, just as bacteria are. As part of this normal process, macrophage LDL receptors are down regulated and, in consequence, individual macrophages do not become overloaded with LDL particles. However, under oxidizing conditions, LDL particles are transformed to oxidized LDL particles that are taken up by macrophages via alternative high-capacity scavenger receptors (CD36 and type A scavenger receptor [SR-A]) normally employed for the ingestion of bacteria. These receptors are not down-regulated by the accumulation of oxidized LDL; macrophages continue to accumulate lipoprotein moieties in a relatively unregulated manner, leading to the cellular congestion evident in foam cells (22). Note, however, that during the early stages, both ECs and macrophages are doing what they are well adapted to do: that is, prevent invasion by microscopic threats. It is probably only in our modern environment that these processes are corrupted by excess lipoprotein levels and oxidative stress that leads to disease.

While macrophage functions are being subverted, the endothelium overlying the early atherosclerotic lesion is intact and functional. Indeed, it appears that the normal vessel is able to heal the early effects of subintimal foam cell accumulation. Fetuses show foam cell lesions, termed “fatty streaks,” during early development, particularly in hyperlipidemic mothers in which the fetal blood cholesterol level correlates closely with that of the mother (25). These early fatty streaks appear to regress later in pregnancy either as fetal cholesterol demand decreases or fetal production increases; fetal cholesterol requirements become less dependent on maternal sources, and fetal blood cholesterol concentration is no longer correlated with that of the mother. The initial accumulation probably reflects an example of fetal–maternal conflict: The rapidly developing fetus requires more cholesterol than it can synthesize and is dependent on transplacental delivery, thus creating a potential conflict with the mother who could use these caloric resources for herself or a subsequent offspring.

David Haig has pioneered this line of thought (26), as exemplified in his chapter in this volume on such conflicts and their role in preeclampsia (Chapter 17). The consequences of poor fetal lipoprotein access are profound: Cholesterol deficiencies in the mother can cause severe fetal developmental defects, particularly in the lipid-rich brain. Not all the vascular changes in the fetus may be reversible, however, because postnatal atherogenesis may be accelerated in the offspring of hypercholesterolemic mothers who develop hypercholesterolemia themselves (27).

In part, the healing process itself may induce atherosclerosis. Lipoprotein(a) is an LDL-like particle with putative roles in tissue repair and inhibition of fibrinolysis that may also act as a surrogate for vitamin C in animals that have lost the ability to synthesize the vitamin *de novo*. Lipoprotein(a) is limited to a subgroup of primates (and interestingly appears to have evolved independently in the hedgehog) in which it may have evolved when injuries resulted from trauma and infection. When expressed in a modern milieu, in which endothelial dysfunction is widespread (27), the actions of lipoprotein(a) promote atherosclerosis. In fact, just as for macrophages and the endothelium, lipoprotein(a) is doing what it does best – trying to heal injury.

The aspects of the modern environment predisposing to atherosclerosis in the developed world are well known: dietary excess, sedentary lifestyle, cigarette smoking, air pollution, and diabetes, in addition to the acquired lipoprotein disorders of high LDL and low HDL concentrations. Although it is clear that the nonlipid risk factors can result in endothelial dysfunction, as evidenced by diminution of flow-mediated dilatation or responses to infused acetylcholine, it appears that atherosclerosis develops only in the face of the lipid disorders. The key player is almost certainly LDL – isolated low HDL-cholesterol or high blood pressure in knockout mice without LDL are incapable of causing atherosclerosis; high LDL cholesterol seems to be the *sine qua non* of atherosclerosis. However, native LDL-cholesterol itself does not appear to be sufficient for triggering atherosclerosis; there appears to be a requirement for oxidation. As noted above, LDL oxidation seems to be a key feature of the macrophage’s inability to regulate LDL particle uptake, and oxidation likewise plays an important role in the progression of lesions by stimulating subintimal lipoprotein retention, cytokine elaboration, and the chemoattraction of participating inflammatory cells by macrophages. Oxidized LDL uptake is one of the factors promoting the release of inflammatory mediators. The inflammatory response decreases nitric oxide (NO) production and contributes to “endothelial dysfunction” (by which is meant the vasodilator response to NO-mediated agonists) (28).

Macrophage responses may not be confined to vessels, as recently suggested by observations of macrophage infiltration into adipose tissue, where elaboration of cytokines also occurs. Lerke and Lazar (29) have recently suggested the possibility that fat cells are recognized as invaders by macrophages, triggering responses similar to those causing atherosclerosis. If so, the sequence would add credence to the idea that macrophage

activity and its attendant ill effects on the endothelium are conserved evolutionary responses of broad utility that are rendered harmful by modern environments. Although many aspects of the environment contribute to atherosclerosis, all seem to operate through LDL oxidation which, in a sense, serves to protect LDL particles from intracellular metabolism and, in that way, mimics one of the strategies followed by bacteria.

Returning to the question of why this most useful process has come to cause atherosclerosis, the most obvious factor is the level and kinds of lipids characteristic in contemporary human diets. Hunter-gather and traditional rural societies have serum cholesterol levels far below those of Westernized populations. Indeed, less than 5% of adults in the United States have a total cholesterol of less than 150 mg/dL, the average value in the more biologically “normal” populations (30). Thus, in essence, almost everyone in the United States, and in many other Westernized countries, is hypercholesterolemic, and the situation for triglycerides is similar. Undoubtedly, our societal hyperlipidemias are overwhelmingly due to diet, both its macronutrient composition and its caloric excess, particularly when such a diet is coupled with a sedentary lifestyle. The effect of modern lifestyle is Syndrome X, which in addition to promoting hyperlipidemia also increases oxidative stress, resulting in increased levels of atherogenic oxidized LDL (31).

One way of thinking about atherosclerosis is to view it as the result of an evolved adaptive response that protects against infection but that results in endothelial injury in modern environments. Because the consequences of the injury occur late in life, natural selection preserves those systems promoting atherosclerosis in preference to those suppressing them, a classic case of antagonistic pleiotropy. This is a trade-off, but not quite a classic one. Because the costs were probably minimal until the past century, and because they caused no harm until modern times, the genetic variations that increase vulnerability to atherosclerosis are not really “defects,” but are instead excellent examples of “genetic quirks” that give rise to untoward effects only when they interact with factors encountered in modern environments. These speculations about the adaptive roots of atherosclerosis give rise to a specific prediction that individuals who have a genetic predisposition to atherosclerosis may be less vulnerable to infection and more susceptible to other inflammatory diseases. In regards to the question of autoimmune diseases, data demonstrate a strong association between rheumatoid arthritis and accelerated atherosclerosis (32), although the authors of that article suggest that the chronic low-grade inflammation of arthritis activates the atherosclerotic process rather than vice versa. In truth, the relationship may be bidirectional, with each process reinforcing the other.

The adaptive significance of the systems that leave us vulnerable to atherosclerosis is only one half of a full evolutionary explanation. We also need to know the phylogeny of those systems, and particularly if path dependence has constrained them so that natural selection cannot shape a less vulnerable mechanism. Although it would conceivably be possible to develop alternative ways of preserving the func-

tions of lipoproteins necessary for blood-borne triglyceride and cholesterol delivery while preventing excessive pinocytotic delivery to subendothelial spaces, such an adaptation would probably seriously compromise cholesterol-dependent cellular and immune processes. Because immune function has such obvious selective value – whereas atherosclerotic disease, primarily manifest late in life, presumably is not a major selection force – there would seem to be little tendency to shape such an adaptation. However, too much of a good thing is dangerous, as illustrated by chronic inflammatory diseases such as rheumatoid arthritis accelerating atherosclerosis. Conversely, in situations in which innate immunity is compromised (e.g., by inactivating mutations of the Toll-like receptor 4 (TLR4) receptor, a pattern recognition receptor involved in lipopolysaccharide clearance), atherosclerosis is decreased (33). Thus, in the trade-off of immune function versus atherosclerosis, the benefits of immunity provide greater advantages early in life when selection is stronger, thus leaving us with a strong predisposition to atherosclerosis. A signal detection analysis of the costs and benefits of various regulatory settings could further illuminate the situation (19).

Are other evolutionary factors at work? A direct infectious hypothesis has been championed by Ewald, who contends that atherosclerosis is triggered by infections that have coevolved with humans (24). Of particular interest has been the relationship of *Chlamydia pneumoniae*, an organism capable of living inside inflammatory cells in blood vessel plaques. Ewald suggests that the bacterial infection, rather than being a bystander colonizing a disrupted vascular wall, is pathogenetic. He further notes that in the case of inflammatory arthritis, a higher incidence of joint-fluid *C. pneumoniae* infections are associated with a higher prevalence of the apolipoprotein  $\epsilon 4$  genotype. Because this is a risk factor for coronary disease, it is possible the mechanism mediating risk is an increased susceptibility to *C. pneumoniae* infection and vascular inflammation. Clearly, if true, the early lesions could attract macrophages, increase local oxidative activity and, in the presence of LDL particles, trigger atherosclerosis. An attempt at testing this hypothesis by treating patients with established atherosclerosis with antibiotics was negative (34), but it is still plausible to assume that the role of the bacterium is prominent in the early disease but not after atherosclerosis has progressed. *C. pneumoniae* is not the only infection thought to accelerate atherosclerosis: Many chronic subclinical infections, including periodontitis, sinusitis, bronchitis, and diverticulitis – in fact any source of chronic endotoxemia – may provoke an inflammatory response and increase the risk of atherosclerosis (35). The other major player in the atherosclerotic picture, HDL, may be a defense against atherosclerosis-promoting infectious agents by acting as a scavenger of lipopolysaccharide (36).

## CONCLUSION

The implications of an evolutionary view of the endothelium are several. First and most obviously, in the absence of

profound changes in the environment or human nature, it is unlikely that atherosclerosis can be prevented in the general population through the public health measures known to be effective – diet and exercise – although they can be effective for those individuals capable of modifying their behavior (37). The burgeoning epidemic of obesity suggests that the lifestyle causing hyperlipidemia is triumphing to the extent that reducing cholesterol values to those of hunter-gatherers by lifestyle interventions is simply unrealistic. As a society, we seem to be much more willing, even eager, to embrace antiatherosclerotic strategies that depend on the administration of costly drugs to already-ill individuals nearing the end of the natural history of atherosclerotic diseases. Given current costs, inequalities in health care delivery, and the poor public health infrastructure, such treatments, unfortunately, cannot reasonably be provided for population-wide treatment and, in any case, they are not that effective. More promising preventive approaches include modifications like statins and antioxidants, although one line of argument developed above suggests the need to be on guard for the possibility that antioxidants may increase other vulnerabilities. Epidemiological evidence supporting the benefits of dietary antioxidants is encouraging, although the effectiveness of antioxidants in intervention trials has been disappointing (23). Trials in established atherosclerosis may, however, be a case of too little, too late, as atherogenesis is already well advanced, perhaps beyond the period in which antioxidants could be effective. What is clear is that only with the development of effective preventive approaches that can be widely applied will any progress be made in preventing the complications of atherosclerosis.

One potentially beneficial feature of modern society is found in Barker's hypothesis, which implies that improved maternal nutrition may decrease the development of features described as the "thrifty phenotype" – a set of metabolic adjustments programmed to promote calorie retention but which increase the risk of late-life atherosclerosis (38,39). Unfortunately, to realize the benefits of improved maternal nutrition, the environment of the offspring throughout life would have to promote avoidance of calories and fat excess, which again seems impracticable.

Genetic engineering has been held out as a possible cure for atherosclerosis. We believe the evidence is overwhelming that only a small minority of the focus on "gene hunting" for atherosclerosis should therefore be on finding common allelic variants or haplotypes controlling "normal" homeostatic functions. This is not to say that elucidation of monogenic diseases will not lead to a better understanding of the vulnerabilities of atherosclerotic disease progression, just as a molecular understanding of the LDL receptor in familial hypercholesterolemia contributed so importantly to the development of drugs useful in preventing further progression of atherosclerosis. The identification of the Milano Apo A1 mutation (40), which exerts a powerful protective effect against atherosclerosis by markedly enhancing reverse cholesterol transport and presumably acting to heal the early atherosclerotic lesions before the sequence

of reinforcing mechanisms is recruited, may be another example of how a monogenic disease can inform the development of prevention strategies.

Just as genetic determinants are likely to be "normal" alleles, normal immune processes predispose to atherogenesis. Could atherosclerosis be prevented by the selective modulation of immune function, specifically the physiological functions of macrophages involved in atherogenesis? Similarly, perhaps endothelial transport of LDL molecules can be targeted. The endothelium has its own protective mechanisms against the transport of larger lipoproteins such as very-low density lipoprotein (VLDL). Perhaps a "vaccination" that slowed LDL-cholesterol transport could have promise for slowing atherosclerosis. Ceruloplasmin is a potential source of oxidized LDL (41); perhaps the copper-depleting drug developed for the treatment of Wilson's disease of the liver, trientine, could possibly have an antiatherosclerotic effect. Such speculations demonstrate the heuristic value of an evolutionary perspective on the endothelium. We anticipate that readers of this volume will bring a mass of sophisticated knowledge about the proximate mechanism involved in endothelial diseases. We hope that this chapter will encourage some of them to ask new evolutionary questions about why the endothelium is the way it is, and why it leaves us so vulnerable to such common and devastating diseases. If they do, progress in endothelial biomedicine will occur even faster.

#### KEY POINTS

- Posing and testing evolutionary hypotheses about characteristics of the endothelium will speed scientific progress.
- Every aspect of the endothelium needs both a proximate and an evolutionary explanation.
- The same design features that lead to vulnerability to atherosclerosis offer other substantial benefits.
- Few genes that predispose to endothelial disease are defects; most are quirks that pose risks only in the modern environment.

#### Future Goals

- To describe every aspect of the endothelium in relation to an evolutionary explanation
- To describe every disease of the endothelium in relation to an evolutionary explanation that encompasses the six reasons for vulnerability

## The Ancestral Biomedical Environment

S. Boyd Eaton\*, Loren Cordain†, and Anthony Sebastian‡

\*Emory University, Atlanta, Georgia; †Colorado State University, Fort Collins;

‡University of California, San Francisco

Behaviorally modern humans evolved in Africa perhaps as early as 100 thousand years ago (kya) (1) and, by 50 kya, they began spreading throughout Eurasia and Australia. Since that evolutionary watershed, the human genome has changed little. For millions of years, human ancestors, like all other organisms, had responded to altered environmental circumstances solely through biological evolution (Table 16-1). However, during the past 50 millennia, humans have increasingly been able to adapt to new ambient circumstances through cultural innovation, in addition to the underlying (and slower) genetic change. Since agriculture and animal husbandry first appeared, perhaps 10,000 years ago, hemoglobinopathies and adult lactose tolerance are almost the only generally acknowledged genetic modifications. On the other hand, our lifestyle has changed radically: Nutrition, physical activity, reproductive experience, psychosocial relations, microbial interactions, and toxin/allergen exposure are all vastly different now from what they were for ancestral humans and prehumans during the period when our primary genetic makeup, including those factors relevant to endothelial health and disease, was selected.

The resulting discordance or mismatch between our genes and our modern lives is a likely contributor to many common chronic diseases and probably to various forms of endothelial dysfunction, so an appreciation of its potentially pertinent elements may further our understanding of pathophysiology. Also, awareness of the ancestral human lifestyle may suggest new avenues of prevention research applicable to the endothelium.

Reconstructing the biomedical circumstances of Stone Age humans is a fascinating, if sometimes frustrating endeavor. Several categories of data exist. Human skeletal remains are amenable to gross anatomical, microscopic, and biomechanical evaluation, as well as to radioisotopic analysis. Archeological finds, mainly at living sites, include the bones of animals consumed as food, botanical remains, artifacts (such as hearths, tools, weapons), and cave or rock wall paintings.

Hunter-gatherer (forager)<sup>1</sup> groups studied in the last century (no true hunter-gatherers have survived into the twenty-first century) were the best, if imperfect, surrogates for Paleolithic humans. Their subsistence patterns, obligatory physical activity, reproductive experience, biomarkers (serum cholesterol levels, blood pressure, glucose responsiveness, etc.), and microbial interactions can be considered representative of patterns for the humans of 50 to 25 thousand years ago. Proximate analyses of the game animals and uncultivated plant foods consumed by recent hunter-gatherers provide further information regarding our ancestors' nutrient intake.

Most available evidence is thus indirect. We cannot take blood samples from, biopsy, observe, or interrogate our behaviorally modern ancestors of 25 kya. We will never have electron micrographs of their endothelium. Nevertheless, by dint of ongoing multidisciplinary efforts, a defensible and increasingly detailed picture of their life and health is emerging. It affords a view of the lifestyle for which our genes were originally selected, and it provides further understanding of the epigenetic milieu<sup>2</sup> that influenced their function.

### ANCESTRAL HUMAN BIOLOGY

#### Blood Pressure

Numerous studies in varied geographic settings have established that the blood pressure of hunter-gather populations averages 100 to 110 systolic/70 to 75 diastolic (2), somewhat below the long-accepted "normal" values for Americans

- 1 Hunter-gatherers (synonymous with foragers) subsist on hunted wild animals, gathered wild plant foods, and aquatic resources. They have no domesticated plants or animals except the dog.
- 2 The epigenome consists of proteins and chemical molecules that surround and adhere to protein-encoding DNA. By amplifying or muting genetic expression in response to bioenvironmental circumstances (e.g., nutritional changes), the epigenome provides rapid response capability—genetic flexibility independent of DNA evolution as classically understood.

**Table 16-1: The Time Scale of Human Evolution**

Million years ago (Paleolithic)	
8–6	Human and chimpanzee ancestral lines split. ( <i>Orrorin</i> , <i>Sahelanthropus</i> ). Beginnings of upright posture and bipedalism
6–4	<i>Ardipithecines</i>
4.5–2	<i>Australopithecines</i> (including “Lucy”)
~2.5	<i>H. habilis</i> (or <i>A. habilis</i> – genus disputed); initial appearance of stone tools
1.75	<i>H. erectus</i> / <i>H. ergaster</i> ; achievement of modern human height and body proportions.
1.75–1.5	<i>H. erectus</i> migrates to southern Asia; present until 30 kya or later
	Presumably ancestral to <i>H. florensis</i>
1.75–0.2	Brain enlargement with little technological innovation
Thousand years ago (Paleolithic)	
750–500	<i>H. heidelbergensis</i> ; ancestral (in Europe) to <i>H. neanderthalensis</i> and (in Africa) to <i>H. sapiens</i>
200–150	Anatomically modern <i>H. sapiens</i> appears in Africa with little or no technological advance
100–50	Behaviorally modern <i>H. sapiens</i> appears in Africa (improved linguistic capability is thought to be the key evolutionary change)
	Rapid technological innovation begins
60–5	<i>H. sapiens</i> spreads worldwide
20–10	<i>Epipaleolithic</i> ; incipient agriculture
Thousand years ago (Neolithic)	
10–2	Ice Age ends, agriculture becomes widespread
	Sedentary living with towns and states; “civilization”

and other Westerners. Furthermore, the same studies have invariably found that forager blood pressure remains low as they age. Conversely, for inhabitants of developed nations, blood pressure typically rises as the population grows older. For hunter-gatherers, hypertension is almost nonexistent (2), whereas over 25% of American adults have elevated blood pressure (3).

Several factors appear to underlie these repeatedly confirmed observations. An obvious contributor is the availability of commercial salt. Hunter-gatherers are not the only low blood pressure societies. Traditional horticulturists, agriculturists, and pastoralists<sup>3</sup> whose economies lack commercial salt are also normotensive throughout their lives (2). As for all other free-living terrestrial mammals (both carnivores and herbivores), forager diets provide far more potassium than sodium (five to ten times as much) (4).<sup>4</sup> In stark contrast,

3 Pastoralists practice animal herding as their primary economic activity (e.g., the Samburu and Maasai of East Africa).

4 The homeostatic response to chronic diet-derived net acid load includes release from bone of alkaline calcium salts (phosphates, carbonates) to buffer hydrogen (H<sup>+</sup>). The liberated calcium and phosphorus are lost in the urine without compensatory gastrointestinal absorption; thus bone mineral content gradually declines.

the foods consumed by Americans yield more sodium than potassium, a nutritional electrolytic inversion with manifold pathophysiological implications (4). Of these, acid–base balance may be most important. As for recent hunter-gatherers, a high Stone-Ager intake of fruits and vegetables (twice the present consumption) tended to drive systemic pH toward alkalinity, whereas modern consumption of cereal grain products and dairy foods is net acid-producing (5). Over a lifespan, the corrective metabolic measures required to maintain homeostasis produce urinary calcium loss and accelerated skeletal mineral depletion while increasing the risk of urolithiasis (4). Effects on endothelial function have been little investigated.

Another significant influence is body size; greater body weight increases the risk of hypertension. The body mass indices (BMI) of recently studied hunter-gatherers average 21.5 (6), whereas the American mean is 26.5 (7). It is not clear that body mass independently influences blood pressure. Probably BMI is a marker for body composition, and it may be that excess fat relative to lean tissue is the pertinent biological variable. Forager skinfold thickness measurements, which are typically half or less those of age-matched North Americans, show that their fat content, as a percentage of total body weight, is typically below 15% for men and 25% for women (2). Many Westerners with “normal” BMIs are nonetheless overfat and/or undermuscle (8). When a convenient, inexpensive, and accurate method of determining body composition becomes available, this biomarker is likely to supplant BMI as a health status indicator.

Recently studied foragers have been aerobically fit with VO<sub>2</sub> max values placing them in the good to superior range, well above the poor to average values more characteristic of age-matched Americans (9,10). This difference clearly reflects the circumstances of hunter-gatherer life: travel, subsistence activities, and recreation all entail physical work.

Walking, running, carrying, digging, and dancing are prominent features of a lifestyle without motorized equipment or draft animals. Increasing one’s aerobic power through a program of endurance exercise usually results in lower blood pressure (and a lower resting heart rate) (see Chapter 56) (11). For Stone Agers, such a program was obligatory, not elective.

### Carbohydrate Metabolism

The insulin responsiveness of five different hunter-gatherer groups, on three continents, was evaluated in the last century (12). All showed remarkable insulin sensitivity, and it seems reasonable to assume that preagricultural human ancestors shared this desirable metabolic characteristic. Insulin resistance, an increasingly common finding in Americans and other Westerners, seems rare to nonexistent among foragers (12). However, migrant studies and serial determinations among societies undergoing acculturation to Western ways in their own homelands indicate that a population with initially favorable insulin responsiveness may become transformed within a generation or two into one with highly prevalent

insulin resistance (13,14). This shows that genetic makeup, while important, is not the main driving force regarding carbohydrate metabolism.

The chief behavioral changes associated with secular increases in insulin resistance have to do with diet and body habitus. The common nutritional elements that characterize populations with desirable insulin responsiveness include a limited intake of simple carbohydrate such as sugars and goods made from refined flour. Carbohydrate consumption itself may be substantial for insulin-sensitive groups, but is derived from whole grain (for many agriculturists) or from uncultivated fruits and vegetables (for hunter-gatherers). Such foods typically exhibit low glycemic indices and, especially, low glycemic loads (15). In addition, dietary fiber intake for normoglycemic populations tends to be considerable (16). The fiber may be predominantly insoluble (nonfermentable), as from wheat and rice, or it may be largely soluble (fermentable), as from wild fruits and vegetables. Uncultivated plant foods tend to be much more fibrous (three to four times as much fiber/100 g) than are the fruits and vegetables popular in Western nations (16). Groups tending to have a low prevalence of insulin resistance generally consume much more fiber (of all sorts) than do Americans, sometimes 70 to 100 g/day (16,17). Added sugar (i.e., extraneous to basic food items themselves) contributes up to 25% of American food energy each day (18). Foragers loved honey, an equivalent foodstuff, but it was difficult to obtain and usually available only on a seasonal basis. The best current estimate is that, over the course of a year, honey generally contributed about 2% to 3% of dietary energy for hunter-gatherers (4).

As discussed earlier, recently studied foragers have been lean, with BMIs in the low-normal range; corpulence is essentially unknown. On the other hand, Venus statuettes dating from 25,000 years ago prove that at least some ancestral humans were obese. However, the mere fact that such statuettes were made suggests they represented special, high-status individuals such as religious figures (shamans) or political leaders (19). Given the exertional requirements of hunter-gatherer existence, obesity would have been impossible for rank-and-file group members. Skeletal remains from the Late Paleolithic (50 to 10 kya) indicate average muscularity similar to that of today's superior athletes (10). This finding tends to confirm that strenuous physical activity was a hallmark of the ancestral lifestyle. Although depictions of humans are uncommon elements of cave and rock wall paintings from the Paleolithic, those available show lean and muscular individuals. No painted or etched figures matching the Venus statuettes have been found.

Higher BMIs are strongly correlated with a risk for insulin resistance, and individuals whose BMI is within normal limits also have increased risk if their body composition includes excessive adipose tissue. Both these circumstances were most uncommon among Stone Agers, and it seems likely that the metabolic milieu within which the human endothelium was designed to function was one in which hyperinsulinemia was rare.

## Lipid Metabolism

During the twentieth century, the serum cholesterol values of six different hunter-gatherer groups living on four continents were determined. The mean was 123 mg/dL (3.2 mmol/L), and none of the groups had an average value exceeding 150 mg/dL (3.9 mmol/L) (2). (We have no data on the HDL:LDL partition.) The hunter-gatherer mean falls within the range observed for serum cholesterol levels in free-living higher primates –90 to 135 mg/dL (2.3 to 3.5 mmol/L) – much below those of average Americans (~200 mg/dL [5.2 mmol/L]) (2,20).

The cholesterol levels of hunter-gatherers (and other traditional peoples with originally low serum values) rise strikingly when they adopt a more Western lifestyle, whether by migration or by the introduction of new ways within their own region (21,22). This again indicates that, although genes are important, nutrition and other modifiable bioenvironmental factors are even more so for determining a population's blood lipid values.

Although foragers, horticulturists, traditional rural agriculturists, and pastoralists all have low serum cholesterol levels, their intake of dietary lipids varies substantially. Hunter-gatherers and most pastoralists (e.g., Maasai) consume a considerable amount of fat and cholesterol, whereas the diets of horticulturists and rural agriculturists typically provide relatively little of either. The common nutritional features are a low level of saturated fat and almost no harmful trans fatty acids (4), while dietary intake of cholesterol and total fat appears to be of limited importance regarding serum cholesterol levels (23).

During the Late Paleolithic (50,000 to 15,000 B.P.) our ancestors were consummate hunters, obtaining about 50% of their dietary energy from animal sources (24). Although game animals are much leaner than the commercial animals from which our supermarket meat is obtained, their cholesterol content is quite similar, so cholesterol consumption for Stone Agers averaged about 500 mg/day (versus <300 mg/day for contemporary Americans) (25). In Northeast Africa, the region where behaviorally modern humans are thought to have evolved (1), fats probably contributed about 35% of daily energy intake (26). However saturated fat consumption was only about half that of Americans (~7% versus 12% to 15%) because, during most of the year, animal fat from game is predominantly monosaturated with a far lower proportion of saturated fat than is found in commercial meat (27). Harmful trans fat intake was essentially nil (versus ~2% of total energy in the United States). Wild ruminant flesh contains 3% to 5% trans-vaccenic acid, but this is converted, after absorption, into conjugated linoleic acid (CLA) isomers for which limited evidence indicates anticarcinogenic and antiatherosclerotic activity (7). Polyunsaturated fat consumption for Paleolithic humans was nearly double that of Americans, and the  $\omega 6:\omega 3$  partition was much different, approximately 2:1 ( $\omega 6:\omega 3$ ) for ancestral humans (28); at least 10:1 currently (29).

### Micronutrient Intake

Typical Stone Agers were more physically active than are average Westerners: estimates of 5.2 MJ (1,240 kcal)/day versus 2.3 MJ (555 Kcal)/day as energy expenditure during physical activity have been proposed (9,10). Contrary to popular misconception, our remote ancestors (after the appearance of *Homo erectus* 1.7 million years ago) were about as tall as are average Americans (30). Consequently, preagricultural humans required considerable dietary energy each day – perhaps 12.1 MJ (2,900 kcal) for adult males (9,10). Uncultivated plants and wild game tend to provide high levels of micronutrients relative to their energy content, unlike today's often calorically concentrated foods. Hence, retrojected ancestral intake of vitamins, minerals (including antioxidants), and – probably – phytochemicals was high, ranging from 1.5 to 8 times current intake depending on the specific nutrient (25,31). For example, mean daily vitamin C intake for American adults is about 90 mg, whereas retrojected ancestral consumption is estimated at just over 500 mg (25).

The exception, previously noted, is sodium. Preagricultural intake is thought to have been less than 1 gram per day (25), whereas contemporary Westerners typically consume over 4 g/d because of salt added during food processing, meal preparation, and at the table (4). The key factor is commercially available salt – not latitude. Tropical Venezuelan Yanamamo consume extremely little sodium, less than 500 mg/d. Conversely, the pattern for potassium follows the general rule – much less intake now than for Stone Agers (less than 3 g/d currently versus up to 10 g/d in the past) (4).

### Tobacco Abuse

Tobacco abuse was an impossibility for the earliest behaviorally modern humans of 60 to 50 kya because they were Africans, whereas the genus *Nicotiana* is indigenous to the Americas, Australia, and certain Pacific Islands (2). By about 50 kya (or even slightly before) humans had spread as far as Australia, while Paleoindians, the ancestors of Native Americans, were in the New World by 12,000 B.P. (and perhaps earlier; this dating is contentious). However, contemporary human ancestors who came from Europe, Asia, or Africa had no experience with tobacco until the voyages of Columbus 500 years ago. This relatively brief exposure has been insufficient to develop any genetically based resistance to its adverse health effects. Indeed, Australian Aborigines and Native Americans appear similarly prone to tobacco-linked disorders, so even 50 millennia have failed to provide significant immunity.

### Microbial Interactions

In his book, *Plague Time*, biologist Paul Ewald argues that microorganisms, especially *Chlamydia pneumoniae*, but also *Porphyromonas gingivalis*, and perhaps others are the underlying, basal cause for atherosclerosis (32). He and numerous other investigators suggest that chronic vascular wall infec-

tion by such intracellular organisms produces the initial mural damage, either directly or by triggering an immunological inflammatory response. In either event, these authors maintain, such primary injury triggers the complex pathological process leading to atherosclerosis. Absent this chronic infection, atherosclerotic vascular disease fails to develop, no matter what commonly accepted risk factors are present.

Epidemic infectious diseases are thought to have been rare to nonexistent among Stone Agers because of the small group size, because their nomadic existence minimized the sanitation problems that became critical after fixed settlements appeared about 10,000 years ago, and because several important microbial illnesses are thought to have spread from animals to humans after domestication, again beginning about 10,000 years ago (33).

Conversely, endemic infectious disorders are thought to have been major killers of Paleolithic humans (34), and both *C. pneumoniae* and *P. gingivalis* are endemic conditions, at least in the contemporary Western world. If they were similarly prevalent during the Stone Age (and among those current populations largely free from atherosclerosis), their role in vascular pathogenesis would have to be considered necessary, but not sufficient. The modern epidemic of coronary, cerebral, and peripheral vascular disease may have resulted from the superimposition of tobacco abuse, hypercholesterolemia, hypertension, and other factors on an underlying infectious or inflammatory predisposition that has existed perhaps as long as there have been humans.

### POTENTIAL RESEARCH INITIATIVES

A recapitulation of selected biomedical differences between ancestral and contemporary humans, potentially pertinent to endothelial health, is shown in Table 16-2.

Their collective or individual influence on endothelial microanatomy and physiology provide many possibly rewarding opportunities, for example:

- Other factors being equal, how does the endothelium respond when total blood cholesterol is varied between 3.2 mmol/L (125 mg/dL) and 5.2 mmol/L (200 mg/dL) (35)?
- Is the endothelium affected when a typical American sodium–potassium intake pattern is changed to one in which sodium is restricted to <1,000 mg/day and potassium increased to >5,000 mg/day (36,37)?
- What is the endothelial impact of prolonged magnesium supplementation (to match retrojected Stone Age intake) (38)?
- Does a diet rich in long-chain (C20 and above) polyunsaturated fatty acids with an  $\omega 6:\omega 3$  ratio of about 2:1 protect the endothelium against some or all known harmful influences (39,40)?
- How does an elevated intake of antioxidants (to ancestral levels) affect the endothelium (41–43)?

**Table 16-2: Ancestral versus Modern Humans**

Differences	Contributing Factors	Paleolithic	Contemporary
<b>Blood Pressure</b>			
Paleolithic:			
Normotensive through life cycle	Dietary intake of electrolytes BMI	Na <sup>+</sup> << K <sup>+</sup> Lower	Na <sup>+</sup> > K <sup>+</sup> Higher
Contemporary:			
Tends to rise with age; many hypertensives	Aerobic power	Higher	Lower
<b>Insulin Responsiveness</b>			
Paleolithic:			
Nearly all insulin sensitive	BMI Body composition	Lower More muscle Less fat	Higher Less muscle More fat
Contemporary:			
Many insulin resistant	Glycemic load Fiber	Lower High intake	Higher Low intake
<b>Lipid Metabolism</b>			
Paleolithic:			
Lower serum cholesterol	Saturated fat intake Trans fat	Lower Almost nil	Higher 2% of energy intake
Contemporary:			
Higher serum cholesterol	PUFA $\omega 6:\omega 3$ Simple CHO Dietary fiber	More $\sim 2:1$ Lower Higher	Less 10:1 (or more) Higher Lower

- Over time, does a consistently low glycemic load diet affect the endothelium beneficially (44,45)?
- Does the endothelium respond differently to an alkalinizing dietary pattern compared with one that is acid-producing (46)?

More important than any single investigative lead is the integrative, theoretical framework provided by the concept that the human genome was selected through evolutionary experience for the biobehavioral circumstances of ancestral life and that contemporary chronic diseases arise, in large measure, from the discordance that has been created between our genes and our lives. Deviation from and reversion toward the original human pattern may underlie, respectively, both disease causation and prevention. Perhaps a program of research based on the evolutionary discordance paradigm could make a vital contribution to the understanding and ultimate conquest of chronic illnesses, including those involving the endothelium.

**KEY POINTS**

- We are genetic Stone Agers living in a Space Age biomedical milieu.
- Discordance between our Stone Age protein-encoding DNA and our contemporary (especially affluent) lifestyles promotes development of chronic degenerative diseases, including those affecting the endothelium.

## Putting Up Resistance

### Maternal–Fetal Conflict over the Control of Uteroplacental Blood Flow

---

David Haig

*Harvard University, Cambridge, Massachusetts*

All expenditures involve an opportunity cost. This is true in economics: Money spent on one activity is unavailable for other activities. But it is also true in evolutionary biology: Time, resources, or energy expended on one fitness-enhancing activity is unavailable for other fitness-enhancing activities. Organisms, like consumers, are faced by trade-offs. Beyond a certain level of reproductive expenditure on any particular offspring, a parent's resources are better allocated to other uses, say to fighting disease or laying down fat to survive the next winter. And these other uses, either directly or indirectly, translate into less investment in other offspring. An organism usually maximizes its expected number of surviving offspring, not by investing everything in a single offspring, but by spreading its reproductive effort across multiple offspring (1).

Trivers (2) recognized that the reproductive trade-off between continued investment in one particular offspring and investment in other offspring implied the existence of an evolutionary conflict between parents and offspring. A parent is equally related to all its offspring (a gene in the parent has a 50% chance of being transmitted to each offspring), but an offspring is more closely related to itself than to its sibs (a gene in an offspring is definitely present in that offspring but has only a probability of being present in the other offspring that compete for parental resources). Therefore, offspring will have evolved to extract more investment from parents than parents have evolved to supply. It should be emphasized that this is not a conflict in which every gain to the offspring is a loss to the parent, but one in which conflict arises over how much the parent supplies. Human parents will be familiar with the problem of “setting limits” to offspring demands. As former children, we are all familiar with how unreasonable these limits can seem.

Parturition does not mark any fundamental change in the genetic relationship between mother and offspring. Therefore, the logic of intergenerational conflict should apply to interac-

tions before, as well as after, birth. Haig (3–7) has argued that the physiological details of human pregnancy do not make sense without an appreciation of the element of conflict in maternal–fetal interactions. In this chapter, I focus on conflict over the level of maternal blood flow through the intervillous space of the placenta and how this helps to illuminate the causes of preeclampsia. The maternal endothelium emerges as a major player in fetal attempts to direct a greater proportion of maternal blood to the placenta.

#### HEMODYNAMICS OF PREGNANCY

A simple model of the maternal circulation during pregnancy is presented in Figure 17.1. Cardiac output from the left side of the heart is shared between two subcirculations arranged in parallel. The uteroplacental subcirculation (with resistance,  $R_p$ ) represents all maternal blood diverted through the intervillous space of the placenta, whereas the nonplacental subcirculation (with resistance,  $R_m$ ) represents the systemic blood supply to maternal tissues. The fetal share of maternal cardiac output is determined by the ratio of nonplacental resistance to the sum of the uteroplacental and nonplacental resistances, namely:

$$\text{Fetal share} = \frac{R_m}{R_m + R_p}.$$

The theory of parent–offspring conflict predicts that fetal genes have been selected to appropriate a greater share of maternal blood than maternal genes have been selected to supply. Therefore, placental factors are predicted to increase  $R_m$  and decrease  $R_p$ , whereas maternal factors are predicted to decrease  $R_m$  and increase  $R_p$  (7). If  $R_m$  were increased without a change in  $R_p$ , the arteriovenous pressure difference would

Figure 17.1. Schematic diagram of the maternal circulation during pregnancy. A proportion of maternal systemic blood flow is diverted through the intervillous space of the placenta. This proportion is determined by the relative values of the uteroplacental resistance ( $R_p$ ) and the nonplacental resistance ( $R_m$ ).

have to rise for nonplacental blood flow to be maintained. Uteroplacental blood flow would then increase in proportion to the rise in pressure head.

Figure 17.1 illustrates another important consequence of hemochorial placentation: The placenta can release substances directly into maternal blood. Therefore, all aspects of maternal physiology and metabolism that can be influenced by blood-borne factors come under contested control during pregnancy. The placenta is expected to release a cocktail of substances into the maternal circulation that can act at remote sites to benefit fetal fitness. From the perspective of natural selection, the mother's body becomes a somewhat unruly extension of the fetal soma. The mother lacks a comparable ability to influence fetal physiology, because maternal substances must first cross a layer of trophoblast and then the fetal endothelium before the substances gain access to the fetal circulation. These layers allow the fetus to exclude, or metabolize, unwanted maternal factors.

## UTEROPLACENTAL CIRCULATION

The endometrium is supplied with blood via spiral arteries that undergo cyclic regeneration and degeneration over the course of the menstrual cycle. A pregnancy is established when an implanted embryo releases human chorionic gonadotropin (hCG) into the maternal circulation to prevent menstruation. Extravillous trophoblast cells invade the endometrium and remodel the spiral arteries, destroying the vessels' muscular lining and greatly expanding their radius. In the process, the endothelium is, at least partially, replaced by trophoblast. The remodeled arteries open into the intervillous space of the placenta, where maternal blood bathes the large surface area of the chorionic villi. The villi and the intervillous space are lined with syncytiotrophoblast and constitute the principal site for fetal uptake of nutrients and release of wastes. Maternal blood then drains from the intervillous space via uterine veins (8–10).

Maternal blood flows through the intervillous space from at least as early as 8 weeks of gestation, although flow initially is torpid because the lumens of the remodeled arter-

ies are partially clogged by trophoblast (11,12). The oxygen tension of the placenta increases steeply from 8 to 12 weeks of gestation, as these trophoblastic obstructions are cleared to allow a more vigorous intervillous circulation (13). The trophoblast-mediated remodeling of maternal arteries continues into the second trimester of pregnancy and extends into the myometrium (14,15). This process of remodeling may continue into the third trimester in some pregnancies (16).

The uterus receives a small proportion of cardiac output in nonpregnant women, probably less than 1% (9). This proportion increases progressively during pregnancy as the fetal demand for resources escalates. The uterine share of maternal cardiac output is estimated as 9% at 20 weeks gestation, 12% at 24 weeks, 14% at 28 weeks, 15% at 32 weeks, and 16% at 36 to 38 weeks (17). This increase in fetal share must be associated with a progressive increase in the ratio of  $R_m$  to  $R_p$ . The continued invasion of trophoblasts during second trimester could contribute to this change by reducing  $R_p$ , either by extending remodeling deeper into the myometrium (for already modified arteries) or by the modification and recruitment of additional arteries as the placenta spreads laterally.

The theory of maternal–fetal conflict predicts that placental factors will act to decrease, and maternal factors act to increase,  $R_p$ . Therefore, the theory would be supported if trophoblast were principally responsible for the remodeling of spiral arteries into large-diameter, low-resistance vessels. The situation appears somewhat more complex than this simple prediction. The earliest signs of remodeling (vascular dilation) occur in the absence of trophoblasts, but the full expression of the “physiological changes” depends on the presence of trophoblasts (8,10,18). The latter changes include the loss of muscular and elastic elements from the vessel walls, thus abrogating the mother's ability to control the flow of blood to the intervillous space by vasoconstriction.

What is the evidence for maternal counteradaptations to increase  $R_p$ ? The arterioles that supply the endometrium increase rapidly in length during the first weeks after ovulation, becoming highly convoluted as they outpace the growth in thickness of the endometrium (hence their designation as spiral arteries) (19–21). The vessels' increase in length and tortuosity would, by itself, increase  $R_p$ . However, another factor also may be at work. The rapid growth of the arterioles greatly increases the size of the “target” for modification by the initially tiny embryo, potentially slowing the early invasion of trophoblasts and allowing the mother to prepare defenses in depth. The peri-implantation period also is accompanied by decidualization of the endometrial stroma. This process is initiated around spiral arteries but then spreads to the rest of the endometrium (22). Decidualization involves the deposition of a basement membrane-like pericellular matrix (23) and has been conjectured to create a barrier that limits the extent of trophoblast invasion (3,24). It is worth emphasizing that the evolutionary challenge facing mothers is to “set limits” to trophoblast invasion, not to prevent it altogether.

## NONPLACENTAL CIRCULATION

Maternal cardiovascular changes during pregnancy (increased heart rate, increased cardiac output, increased plasma volume, decreased arterial pressure, peripheral vasodilation) have been compared to the adaptive response to an arteriovenous fistula (25,26), with the low-resistance connection between spiral arteries and uterine veins playing the role of the fistula. This analogy has fallen into disfavor because the cardiovascular changes are initiated before substantial blood flow occurs through the intervillous space (27,28). The opening of the intervillous “fistula” is a predictable event, however, and thus can be *anticipated*, whereas fistulas caused by traumatic injuries are unpredictable events. In Aristotelian terms, the analogy is false from the perspective of efficient causes (physiological mechanism) but perhaps not from that of final causes (adaptive function).

The theory of maternal–fetal conflict predicts that placental factors will act to increase nonplacental resistance ( $R_m$ ), but maternal factors will act to decrease  $R_m$ . Conflict over  $R_m$  is predicted to intensify as pregnancy progresses, because the nutritional requirements of the fetus steadily increase and because growth of the placenta confers greater power on the conceptus to influence maternal physiology. Early in pregnancy, a decrease in  $R_m$  and a concomitant decrease in arterial pressure occurs (29,30). The theory interprets these changes as a maternal adaptation to reduce the fetal share of cardiac output. Arterial pressure reaches a nadir in the second trimester, before a progressive rise toward term (29). Some studies report little increase in cardiac output after 24 weeks (31). Others report a decline toward term (32,33) or find that cardiac output in the third trimester is widely divergent among subjects (34). An increase in arterial pressure without an increase in cardiac output implies that total systemic vascular resistance (a combination of  $R_m$  and  $R_p$ ) has increased. That is, the increase in arterial pressure during third trimester appears to be at least partly explained by an increase in vascular resistance. The theory of maternal–fetal conflict interprets this increase as a fetal adaptation to direct more blood to the intervillous space.

A corollary of these interpretations is that the factors responsible for the early decline in peripheral resistance should be maternal in origin (28), whereas the factors responsible for the late-pregnancy increase in resistance should be placental in origin. Placental factors that increased  $R_m$  would not increase fetal share if these factors caused a proportional rise in  $R_p$ . Therefore, placental factors are predicted to preferentially target  $R_m$ . Specificity of effects for resistance vessels of the nonplacental circulation is probably facilitated by the physiological changes to uteroplacental vessels (large diameter, lack of smooth muscle, partial replacement of endothelium by trophoblast).

## PREGNANCY-INDUCED HYPERTENSION AND PREECLAMPSIA

For a subset of pregnant women, the rise in blood pressure during the second half of gestation is sufficient for a diagnosis of

pregnancy-induced hypertension (PIH). A subset of this subset develops a far more serious condition known as preeclampsia, in which high blood pressure is accompanied by proteinuria (see Chapter 161). Bosio and colleagues (35) reported a longitudinal study of hemodynamic measures in 378 primigravidas recruited between 10 and 14 weeks of gestation. Of this cohort, 44 women (12%) developed hypertension, including 20 (5%) who developed preeclampsia. Women who subsequently developed hypertension had higher cardiac output at 10 to 14 weeks than did women who did not develop hypertension, and this difference became more pronounced as pregnancy progressed. For the women who developed hypertension but did not develop proteinuria (gestational hypertension;  $n = 24$ ), high cardiac output was maintained until term. For the women who developed hypertension with proteinuria (preeclampsia;  $n = 20$ ), a dramatic fall in cardiac output occurred with the onset of clinical disease concomitant with a dramatic increase in peripheral resistance. Thus, the progression to preeclampsia involved a crossover from a state of high cardiac output with low peripheral resistance to a state of low cardiac output with high peripheral resistance.

Preeclampsia can be associated with damage to most maternal organ systems. Its maternal pathophysiology exhibits necrosis and hemorrhage in multiple tissues, best explained by reduced perfusion secondary to vasospasm (36). Roberts and colleagues proposed that endothelial dysfunction was the common factor that united the diverse manifestations of preeclampsia and that this dysfunction was caused by factors released into the maternal circulation by the placenta (37). This model of the immediate cause of preeclamptic symptoms has attained wide acceptance, although debate continues on which circulating factors are principally responsible for endothelial dysfunction and on the causal antecedents for the release of these factors.

Fetal nutrition is compromised in many cases of preeclampsia. Numerous studies have reported that fewer spiral arteries are remodeled by trophoblasts in preeclamptic pregnancies (14). Significantly, increased uteroplacental resistance and reduced placental perfusion precedes the onset of preeclampsia. Therefore, birth weight is decreased and the incidence of preeclampsia increased for first pregnancies compared with subsequent pregnancies (38,39), for twin pregnancies compared with singleton pregnancies (39,40), and for women giving birth at high altitude compared to low altitude (41,42). Uteroplacental blood supply may improve in second and subsequent pregnancies because of permanent changes to uterine vessels that occur during the first pregnancy and may be impaired at high altitude because fewer spiral arteries are remodeled (43–45). Average birth weight is reduced in twin pregnancies, presumably because two fetuses compete for limited maternal resources.

Haig (3,7) interpreted preeclampsia as an expression of a fetal adaptation to increase uteroplacental blood flow by causing vasoconstriction of the mother’s nonplacental circulation. High peripheral resistance does not occur in all pregnancies.

Therefore, the induction of this state was proposed to be a conditional strategy of the fetus to increase blood flow to the uterus in pregnancies in which the supply of one or more nutrients is inadequate for fetal needs. The strategy is risky because of the possibility of substantial impairment of the health of the fetus's principal postnatal caregiver (its mother). For such a risk to be justified, the increased flow of nutrients to the placenta must have been associated with major increases in the probability of infant survival. From this perspective, the induction of preeclampsia may be a stereotyped response to increase placental perfusion whenever a fetus stands to gain a relatively large benefit from an increased blood supply, whereas the reasons for activating this response may be diverse. As a corollary, the release of factors that cause maternal vasoconstriction should be interpreted as evidence of normal, rather than aberrant, placental function. In this view, preeclampsia has two kinds of "causes" that should be clearly distinguished: First are the "predisposing" factors (inadequate trophoblast invasion, twin pregnancy, etc.) that cause activation of the adaptive fetal response; second are the "effectors" of the adaptive response – the placental factors responsible for maternal symptoms.

Uteroplacental blood flow can be increased either by increasing cardiac output (for given  $R_m$  and  $R_p$ ) or by increasing the ratio of  $R_m$  to  $R_p$  (for a given cardiac output). Bosio and colleagues reported that preeclampsia preferentially occurred in pregnancies with higher than average cardiac output before the onset of disease. They proposed that high cardiac output could contribute to endothelial damage and the onset of preeclampsia (35). An alternative interpretation is that high cardiac output is the fetus's "preferred" mechanism of enhancing uteroplacental blood flow, with peripheral vasoconstriction employed as a last resort if the preferred mechanism proves inadequate.

I have neither the space nor competence to adequately review the many circulating factors that are increased or decreased in preeclampsia. Instead, I will pick three factors that have attracted recent attention (sFLT-1,  $AT_1R$  autoantibodies, and leptin), and use these to illustrate the kinds of interpretation that are suggested by viewing preeclampsia as a fetal adaptation rather than as physiological malfunction. My discussion is prefaced by two general observations. First, adaptations may be complex. If preeclampsia is an expression of a fetal adaptation to increase nutrient supply, then this adaptation may involve multiple placental factors that target multiple maternal systems. These may include factors that increase the nutrient content of maternal blood as well as those that increase the volume of blood flowing through the intervillous space. Second, mothers are expected to have evolved countermeasures to limit fetal manipulation of maternal physiology and to limit the costs to maternal health. Therefore, fetal actions must be clearly distinguished from maternal responses. Both may be hyperactivated in preeclampsia: The former are predicted to exacerbate symptoms, whereas the latter are predicted to ameliorate symptoms.

Maynard and colleagues (46) identified soluble *fms-like tyrosine kinase 1* (sFLT-1) as a prime candidate to be the placental factor responsible for the endothelial dysfunction of preeclampsia. Levels of sFLT-1 were elevated fivefold in the sera of preeclamptic patients compared with normotensive controls, but these high levels declined rapidly after delivery. Moreover, sFLT-1 was shown to be responsible for the antiangiogenic properties of preeclamptic sera and to induce preeclampsia-like symptoms (hypertension, proteinuria, glomeruloendotheliosis) when administered to rats. sFLT-1 is believed to antagonize the actions of vascular endothelial growth factor (VEGF) by preventing VEGF binding to membrane-bound receptors. Several independent groups have confirmed the association of preeclampsia with elevated sFLT-1 (47–51).

The maternal–fetal conflict hypothesis sees endothelial dysfunction and vasoconstriction as the *function*, rather than as a side effect, of elevated sFLT-1. There is no need to invoke some other function for placental release of sFLT-1 in preeclampsia. The conflict hypothesis also provides a ready interpretation of why sFLT-1 and VEGF should be simultaneously elevated in preeclamptic sera (46): The former is a fetal adaptation to reduce angiogenic repair; the latter, a maternal adaptation to enhance repair.

Wallukat and colleagues (52,53) have reported that the sera of most women with preeclampsia contain antibodies that stimulate *angiotensin AT<sub>1</sub> receptors* ( $AT_1R$ s), but that such antibodies are absent from the sera of most normotensive pregnant women (54). In one woman, anti- $AT_1R$  antibodies were undetectable in serum at 21 weeks of gestation but were present at 24 weeks, after the onset of preeclampsia. Anti- $AT_1R$  antibodies disappear from the serum of preeclamptic women after delivery (52). The theory of maternal–fetal conflict suggests that anti- $AT_1R$  antibodies may be part of a fetal adaptation to increase uteroplacental blood flow, in this case by targeting maternal  $AT_1R$ s. This interpretation would be strengthened if it could be shown that anti- $AT_1R$  antibodies are a placental rather than a maternal product (or are induced by exposure of the maternal immune system to placental  $AT_1R$ s).

The human placenta is a significant source of *leptin*, most of which is released into the maternal circulation (55). Maternal plasma leptin levels are higher in preeclamptic pregnancies than in normotensive pregnancies, and this difference precedes the onset of symptoms (56). Levels of leptin mRNA are higher in placentas from preeclamptic, than from normotensive, pregnancies (57,58). A plausible function of placental leptin is to promote maternal lipolysis, thus enhancing the nutrient supply to the fetus (59). If preeclampsia results from the activation of an integrated fetal response to increased nutrient supply, then increased production of leptin may be one component of this response that specifically targets maternal adipocytes.

The hypothesis that preeclampsia is an outcome of a fetal adaptation to increase uteroplacental blood flow has a strong and a weak version. In the strong version, preeclampsia itself

has been associated during human evolution with benefits to fetuses, relative to otherwise-equivalent fetuses that did not cause preeclampsia. In the weak version, preeclampsia is the occasional nonadaptive outcome of fetal adaptations that operate in nonpreeclamptic pregnancies to increase uteroplacental blood flow.

The key prediction of the strong version of the hypothesis—that the peripheral vasoconstriction of preeclampsia increases blood flow to the placenta—has yet to be demonstrated. The ideal test would be a longitudinal study that measured uteroplacental blood flow before and after the onset of preeclampsia. The strong version predicts that the onset of preeclampsia should be associated with an *increase* in placental perfusion. Such a test would be technically challenging. Another prediction is that preeclampsia should increase fetal fitness (strictly, that preeclampsia should have increased fetal fitness in the recent evolutionary past). However, this prediction is confounded with the subsidiary prediction that preeclampsia should be preferentially induced by fetuses with lower than average expected fitness. Preeclamptic pregnancies are more likely than normotensive pregnancies to result in small-for-gestational-age babies, for both preterm and term deliveries (60). Can this be used as evidence against the prediction that preeclampsia improves fetal nutrition? Not necessarily, if the fetuses were already small-for-gestational-age before the onset of preeclampsia. It is not obvious what should be the appropriate comparison group. Preeclampsia is not always associated with impaired fetal growth, however, because the incidence of large-for-gestational-age babies is increased when preeclampsia develops near term (60,61).

Twin pregnancies provide an interesting comparison. The incidence of preeclampsia is increased presumably because two fetuses are competing for maternal resources, and the uterus contains two placentas, not because remodeling of spiral arteries is impaired in twin gestations. Thus, twins from preeclamptic pregnancies are less likely to have viability compromised for other reasons that predispose to preeclampsia in singleton pregnancies. Two studies have reported that average birth weight and gestation length are increased, and perinatal mortality is decreased, in comparisons of preeclamptic twin pregnancies to normotensive twin pregnancies (62,63).

In the weak version of the hypothesis, preeclampsia is viewed as a pathological malfunction that benefits neither mother nor fetus. This is similar to conventional views. Even so, I hope that an appreciation of the element of conflict could contribute to understanding the causes of preeclampsia in two ways. First, it could provide a set of hypotheses about the physiological functions in normotensive pregnancies of the factors that overwhelm the mother's homeostatic mechanisms in preeclamptic pregnancies. Second, it could provide an understanding of why homeostasis should be particularly unstable in pregnancy. Communication between parties with conflicting interests is more difficult than communication between parties with identical interests. If conflicts of interest are possible, messages cannot always be trusted, and untrustworthy mes-

sages are often best ignored. One consequence is that maternal physiology during pregnancy will lack many of the checks, balances, and feedback controls that are present in the non-pregnant state. Suppose, for example, that a signaling system existed whereby a mother informed the fetus whenever she found herself in situations that required a temporary reduction in fetal demands. If the fetus responded accordingly, those maternal genes would then be favored that caused mothers to send the same signal when their need was less dire. This would, in turn, favor fetal genes that gave a muted response to maternal signals. Such a signaling system is inherently unstable. In this view, preeclampsia may result from the inability of a physiologically threatened mother to credibly communicate her perilous state to a demanding fetus (5,6).

Finally, evolutionary considerations may help to explain why preeclampsia is a relatively common condition of human pregnancies, but similar conditions are rare or absent in other mammals. An important constraint on the physiological demands that a fetus can make on its mother is the offspring's dependence on a healthy mother for postnatal care. This constraint is relaxed in humans relative to other mammals because mothers who experienced difficult pregnancies would often have received support from other members of their social group. Thus, temporary incapacitation of a mother need not have been a death sentence for her newborn (indeed, human infants sometimes survive maternal death). A consequence of human social evolution may therefore have been a shift in the relative costs and benefits toward favoring greater fetal demands during pregnancy.

#### KEY POINTS

- An evolutionary conflict exists between maternal and fetal genes over the amount of maternal blood that flows through the intervillous space of the placenta. In preeclampsia, placental factors cause damage to the maternal endothelium, resulting in systemic vasoconstriction and increased blood flow to the placenta.
- Placental factors are responsible for the endothelial dysfunction observed in preeclampsia.
- sFLT-1 appears to be one of these placental factors.
- Multiple maternal systems may be targeted by multiple placental factors.

#### Future Goals

- To determine whether the vasoconstriction of preeclampsia causes an increase or decrease of maternal blood flow to the placenta
- To identify the different placental factors (and their maternal targets) responsible for the complex symptoms of preeclampsia

# *Xenopus* as a Model to Study Endothelial Development and Modulation

Aldo Ciau-Uitz, Claire Fernandez, and Roger Patient

*Weatherall Institute of Molecular Medicine, University of Oxford, United Kingdom*

The endothelial cells (ECs) of the primary vascular plexuses are among the first mesodermal derivatives to differentiate and become functional in the vertebrate embryo. Anatomically, ECs can be seen developing long before the heart initiates beating and, in gene expression studies, cells expressing endothelium-specific genes can be detected just after the end of gastrulation. In mammalian models, in embryo studies of the early events involved in the induction of ECs from their mesodermal precursors, a process termed *vasculogenesis*, are hampered by the technical difficulties inherent to the in utero development of the embryo. In addition, gene perturbations that result in impaired vasculogenesis are usually fatal and, as a consequence, the further remodeling and maturation of the vascular system, angiogenesis, cannot be investigated. Although embryonic stem cells and EC lines represent useful systems for the investigation of the signaling mechanisms involved during vasculogenesis and/or angiogenesis, due to their cell homogeneity and low anatomical complexity, these signaling mechanisms may well not be fully applicable to the embryo environment. Thus, model systems such as *Xenopus* and zebrafish, in which embryos develop externally and in a less circulation-dependent manner, offer an invaluable opportunity for the study of the early development of the vascular system. However, because the zebrafish is less amenable for transplantation and lineage-labeling experiments and, critically, because it lacks smooth muscle cells and a lymphatic system, *Xenopus* appears to be more suited for the study of some aspects of blood vessel development. Therefore, fate maps of the different blood vessels can be generated in *Xenopus*, and the importance of the interaction between ECs and smooth muscle cells during blood vessel formation can be studied.

During the last 50 years, the African clawed frog, *Xenopus laevis*, has been one of the most useful models to study early vertebrate development. After its initial worldwide intro-

duction to the laboratory as a pregnancy bioassay,<sup>1</sup> *Xenopus* became the preferred model for developmental biologists due to its easy cultivation and capacity to produce large numbers of homogeneous, nonseasonal embryos (1). Together with its external development, the large size of the *Xenopus* embryo makes it ideal for experiments involving microsurgery, tissue transplantation and, very importantly, lineage labeling and the microinjection of genetic material. The application of modern molecular techniques, combined with traditional embryological methods, has led to the discovery of numerous developmental mechanisms that later have been proven to be relevant to all vertebrates. Here, we summarize the current knowledge on the early development of vascular ECs in *Xenopus* and discuss the prospects for using the *Xenopus* embryo as a model for drug discovery and therapeutics.

## ORIGINS AND DEVELOPMENT OF VASCULAR ENDOTHELIAL CELLS

Knowledge of the origins, developmental history, and tissue interactions of the mesodermal precursor cells giving rise to ECs is essential for a better understanding of the hierarchy of signaling pathways governing vasculogenesis. Few systems are as suited as *Xenopus* to the investigation of these fundamental issues: The embryos are large and, in a small percentage of them, the cleavage planes are perfectly regular and symmetric, which allows reliable and reproducible cell labeling and fate mapping experiments (2). In fact, the contribution of single blastomeres of the 32-cell stage embryo to tissues of the

<sup>1</sup> The South African clawed frog (*Xenopus laevis*) was formerly widely used in a pregnancy test, in which female frogs were injected with an extract of urine from the women to be tested. The presence of a characteristic pregnancy hormone (gonadotropin) induces ovulation in female frogs.

tailbud-stage embryo has been determined (3–4), and some attempts have been made to investigate the origins of the major blood vessels of the tadpole (5–6). Surprisingly, one of the fate mapping efforts concluded that all blastomeres of the 32-cell stage embryo contribute to some extent to the endothelium of the major blood vessels (6). This is in clear contradiction to previous fate maps, which showed that the animal-most<sup>2</sup> blastomeres of the 32-cell stage embryo only give rise to ectodermal derivatives (3–4); therefore, the endothelium, which is a mesodermal derivative, would not derive from these blastomeres. This discrepancy may be a consequence of the use of irregularly cleaving embryos,<sup>3</sup> which have an altered fate map (2); their animal-most blastomeres do give rise to mesodermal derivatives (7). In a 32-cell stage regularly cleaving embryo, the blastomeres giving rise to the mesodermal layer are well defined (Figure 18.1A for color reproduction, see Color Plate 18.1.), and only those blastomeres would be expected to give rise to the endothelium of the blood vessels. Alternatively, the contribution of endothelium from the animal-most blastomeres may reflect a neural crest contribution to this cell lineage (8).

To familiarize the reader with the blood vessels of the *Xenopus* tadpole, we will describe the development of the embryonic vasculature before giving an account of their origins. The first anatomically distinguishable ECs in the embryo are seen a couple of hours before the initiation of heart beating, whereas the first cells expressing endothelium-specific genes are detected one day earlier (Figure 18.1B, *arrow*). A comprehensive anatomical description of embryonic vascularization can be found elsewhere (9 and references therein); here we focus on the development of the vasculature up to stage 40, just after the primary circulatory circuit is established, as visualized with molecular markers.

Using the endothelium-specific gene *Tie2* as a marker, the first ECs are observed ventral to the heart field just after the end of neurulation<sup>4</sup> (see Figure 18.1B, *arrow*). As development progresses, the ventral region of the embryo is rapidly populated by ECs that form a network of vitelline vessels (Figure 18.1C–K, *VitV*). Initially, the vitelline vessels surround the developing ventral blood island (VBI)(10), but later they extend both dorsally and ventrally. Dorsally, they extend to

cover the whole of the lateral plate and join the developing posterior cardinal veins (PCVs, see Figure 18.1C–F); ventrally, they reach the ventral midline as the red blood cells of the VBI mature and enter circulation (Figure 18.1G–K). Interestingly, a large yolky area at the posterior of the embryo is never vascularized (see Figure 18.1E–I, *star*); this yolk mass is continuously reduced through development until it disappears at around stage 40. After stage 40, the vitelline vessels further remodel to form a single major vessel in the ventral midline, the median abdominal vein, which is connected to the caudal vein by ventral commissures (9).

By stage 32 a number of vessels can be seen developing anterior to the vitelline vessels (see Figure 18.1F). The anterior end of the vitelline vessels connects to the sinus venosus (SV) via the omphalomesenteric vein (OMV). Further anterior the SV drains into an already lumenized endocardium (End). Anterior to and from the endocardium extends the developing arterial system; the ventral aorta (VA) extends toward the head, where it branches to form a pair of external carotid arteries (ECAs), one on each side of the embryo. Almost immediately, the ECAs extend dorsally and internalize to connect with the internal carotid arteries, which in turn extend posterior to the head as the paired dorsal aortae (pDA). The eyes are one of the first organs to be irrigated. To fit this demand, the hyaloid artery (HyA) develops from the anterior end of each internal carotid artery. Also at this stage of development, a complex vascular network appears to be developing around and posterior to the eyes, and later a number of cranial vessels will develop from this vascular plexus (Figure 18.1G–J). The VA is connected to the aortic arches (see Figure 18.1G, *AoArch*), which extend dorsally to join the pDA. The aortic arches develop in series from anterior to posterior and irrigate the gills of the tadpole. Six pairs of aortic arches develop in the early embryo, but they remodel constantly until only three of them remain at stage 50: the first, known as the ECAs; the third, which are the largest and known as the larval aortae; and the fourth (9). In the head, the venous system appears to develop later than the arteries, because at stage 32 only the primordia of the anterior cardinal veins (ACV) can be seen developing just anterior to the pronephric sinus (see Figure 18.1F).

The PCVs are the first of the major axial vessels to develop (see Figure 18.1D). Although anatomically they are first seen at stage 32, their precursors are seen as early as stage 26 (see Figure 18.1D), in the area dorsal and posterior to the pronephric anlagen (the dorsal lateral plate, DLP), where they are already associated with the precursors of the pronephric sinus (see Figure 18.1D, *PS*). Later, the PCV precursors extend posteriorly all along the trunk and finally, at around stage 34, they reach the tail. At the level of the tail, the two PCVs fuse in the midline to form the caudal vein (see Figure 18.1J, *CauV*). Meanwhile, the pronephric sinus grows ventrally forming the duct of Cuvier (DCuv) and later connects to the SV. As the nonvascularized yolk mass disappears, the two PCVs fuse to form the interrenal vein. Fusion initiates in the posterior at stage 35 to 36 and extends slowly anteriorly until,

2 *Xenopus* mature oocytes exhibit an animal–vegetal polarity, in which the animal hemisphere is characterized by being strongly pigmented, whereas the vegetal hemisphere is lightly or not pigmented at all. After fertilization, the animal–vegetal polarity is conserved so that, at the 32-cell stage, eight blastomeres (Tier A, Figure 18.1A) form the animal pole of the embryo; these are the animal-most blastomeres.

3 After fertilization, *Xenopus* embryos undergo a series of synchronous cell divisions that can occur both symmetrically or asymmetrically. In symmetrically dividing embryos, the animal–vegetal division planes meet at both the animal and vegetal poles (Figure 18.1A) and produce blastomeres of equal size. On the other hand, in asymmetrically dividing embryos, the animal–vegetal division planes do not meet at the vegetal pole; as a result, blastomeres produced are of different sizes (2). The former embryos are called *regular cleavers*, whereas the latter are *irregular cleavers*. Both are found in the wild and are able to develop normally.

4 The developmental stage in which the rudiment of the central nervous system is laid out in the embryo is known as *neurulation*. During this process, neural cell precursors undergo morphogenetic movements to form the brain and neural tube.

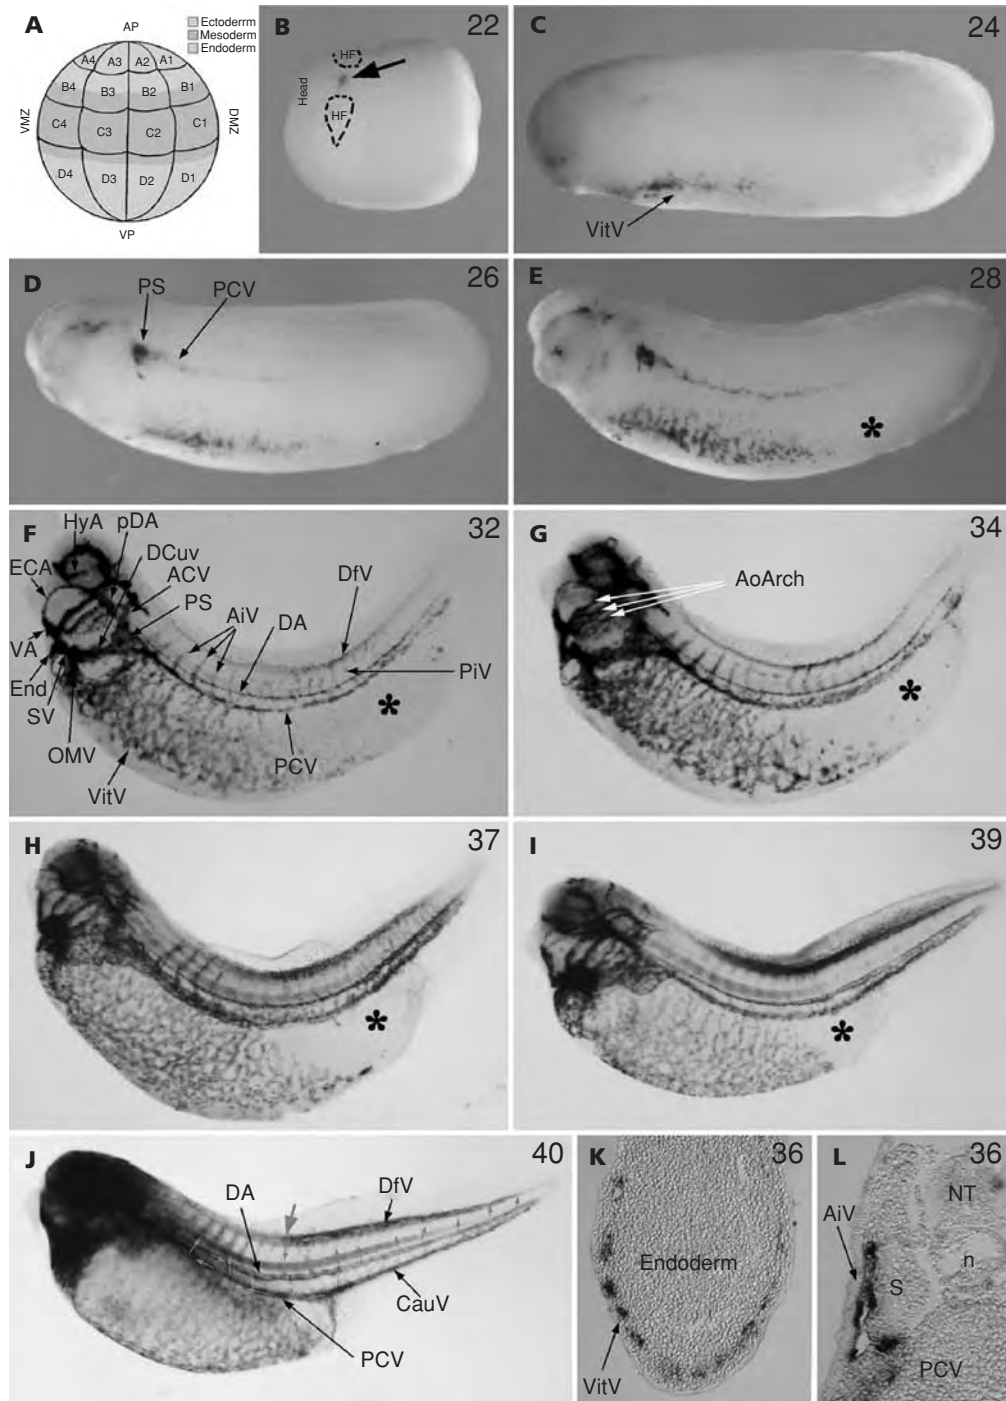

Figure 18.1. Early development of the vascular system in *Xenopus* embryos. (A) Regions of the 32-cell stage embryo contributing to the three primary germ layers. (B–L) Development of the vascular system as illustrated by the expression pattern of the angiopoietin tyrosine kinase receptor, Tie2; numbers at top right corner indicate developmental stage. B, Ventral view; C–J, lateral view, anterior to the left; K–L, transverse sections through the trunk. Asterisk (\*) indicates nonvascularized tissue in the posterior. Small arrows in J indicate direction of circulation, whereas the large arrow indicates the anterior limit of circulation through the DfV. ACV, anterior cardinal vein; AiV, anterior intersomitic vein; AoArch, aortic arches; AP, animal pole; CauV, caudal vein; DA, dorsal aorta; DCuv, duct of Cuvier; DfV, dorsal fin vein; DMZ, dorsal marginal zone; ECA, external carotid artery; End, endocardium; HF, heart field; HyA, hyaloid artery; n, notochord; NT, neural tube; OMV, omphalomesenteric vein; PCV, posterior cardinal vein; pDA, paired dorsal aortae; PiV, posterior intersomitic veins; PS, pronephric sinus; S, somite; SV, sinus venosus; VA, ventral aorta; VitV, vitelline vessels; VMZ, ventral marginal zone; VP, vegetal pole. For color reproduction, see Color Plate 18.1.

at stage 48, it reaches and joins the posterior vena cava (9). The largest artery of the embryo, the dorsal aorta (see Figure 18.1F, *DA*) extends posteriorly from the fused pDA. Anatomically, the pDAs are first seen at stage 31, at the level of the first branchial arch; by stage 33 to 34, they have reached the level of the pronephros and, by stage 35 to 36, they unite in the midline to form a median DA. The DA extends posteriorly, so that, at stage 37 to 38, it penetrates the tail as the caudal artery (9). At the molecular level, DA precursors already can be seen all along the trunk and tail by stage 32 (see Figure 18.1F, *DA*).

The development of the DA is very interesting for several reasons. First, the origins of the DA differ from that of the pDAs: Although most of the pDAs differentiate from head mesoderm, the DA and the most posterior portion of the pDA develop from the DLP mesoderm (10–11). Second, at stage 26, the precursors of the PCVs and the DA are both located in the DLP; however, from stages 28 to 30, a group of cells migrate from the DLP toward the midline; later, these migrating cells differentiate into the DA (11). Migration of the DA precursors appears to be under the control of vascular endothelial growth factor (VEGF) signaling, because the migrating cells express the VEGF receptor, Flk-1, whereas the hypochord, a structure located in the midline, expresses a diffusible form of VEGF (11–13).

As early as stage 31, intersomitic vessels can be seen developing from the axial vessels. Interestingly, in the posterior of the embryo, dorsal to the nonvascularized yolk mass, both the veins and DA produce intersomitic vessels (5,14) (see Figure 18.1E, *PiV*) whereas, more anteriorly, in the trunk, intersomitic vessels only sprout from the PCVs (Figure 18.1L, *AiV*), the significance of which is currently unknown. Also at stage 32, the dorsal ends of the *PiV* appear to coalesce to form a large dorsal fin vein (*DfV*), which only exists in the posterior of the embryo and drains into the PCVs at the level of the cloaca, through the most anterior *PiV*. Circulation initiates at stage 35, when the first red blood cells are seen in the heart; however, not until stage 39 to 40 can cells be seen in circulation throughout the embryo. After stage 40, the vasculature continues to remodel, and new vessels develop to meet the demands of the developing thoracic organs. A description of these events can be found elsewhere (9). Finally, in parallel, the rudiments of the lymphatic system are being laid out in the pronephric region, where the lymphatic heart<sup>5</sup> (Figure 18.2B, *LH*; for color reproduction, see Color Plate 18.2.) can be morphologically distinguished from stage 33 to 34 (9). Interestingly, the lymphatic heart endothelium appears to have a gene expression profile similar to that of the endothelium of the arteries and veins (A. Ciau-Uitz and R. Patient, unpublished observations). Later, after stage 40, the lymphatic heart endothelium extends both anteriorly and posteriorly to form the main lymph vessel of the larva.

<sup>5</sup> In embryos with a well-developed lymphatic system, the lymphatics drain into the most anterior end of the posterior cardinal vein. At this junction, the lymphatic vessel attached to the posterior cardinal vein appears to rhythmically pump lymph into the venous system, for which reason it has been called the *lymphatic heart*.

Our lineage-labeling of regularly cleaving embryos indicates that three areas of the early blastula give rise to the majority of the ECs of the tadpole:

- The anterior vitelline vessels, omphalomesenteric veins, endocardium, ventral aorta, and the most anterior portion of the external carotid arteries derive from blastomeres C1 and D1 of the 32-cell stage embryo (10–11).
- The posterior vitelline vessels derive from blastomere D4 (11).
- The major vessels of the trunk and tail derive from blastomere C3 (10–11) (Figure 18.2A–D).

Interestingly, blastomere C3 also gives rise to the lymphatic heart (see Figure 18.2B), indicating that the PCVs, the DA, and the lymphatic hearts all derive from the early DLP precursors. In mouse embryos, the lymphatic vessels sprout from the PCVs; therefore, it is well possible that the *Xenopus* lymphatic hearts also sprout from the PCVs. Because all arteries irrigating the future thoracic organs sprout from the DA, and most of the veins from these organs drain into the PCVs, it appears that blastomere C3 gives rise to most of the vasculature of the adult. The origins of the head vasculature and the aortic arches have not been investigated in regularly cleaving embryos; however, in irregularly cleaving embryos, the origins of the aortic arches have been assigned mainly to blastomere D2 (6).

#### HEMANGIOBLASTS, HEMOGENIC ENDOTHELIUM, AND HEMATOPOIETIC STEM CELLS

For over 80 years it has been known that the blood and ECs of the chick and mouse yolk sac differentiate from homogenous cell clusters, with the peripheral cells becoming ECs while the internal cells give rise to blood. Since then, it has been postulated that both lineages derive from a common precursor cell called the hemangioblast (15). The existence of such a cell is supported by the common origins of blood and ECs during development, as well as by their common gene expression profiles. In addition, zebrafish mutants and mouse knockout and knockin mutants further support the existence of the hemangioblast, both in embryos and adults. However, only recently has direct evidence been presented supporting the existence of hemangioblasts in differentiated mouse embryonic stem cells (16) and in the mouse yolk sac (17). In *Xenopus* embryos, we have described the existence of two hemangioblast populations (10), the first located ventral and anterior in the neurula-stage embryo (Figure 18.2E–H), and the second in the DLP of tailbud embryos (10–11) (Figure 18.2I–K). We also have demonstrated that the ventral anterior hemangioblast gives rise to vitelline vessels, OMVs, endocardium, VA, and the most anterior portion of the ECAs as well as to the red blood cells and myeloid cells of the embryonic lineage (10, A. Ciau-Uitz and R. Patient, unpublished observations). In its turn, the DLP

(I–K) Tailbud-stage embryo double-stained for blood and endothelial genes showing a population of hemangioblasts located in the dorsal lateral plate (DLP, *arrows*); later, this population gives rise to the axial vessels and adult hematopoiesis. (L) Expression of LMO2 in blood vessels. (M) Hematopoietic stem cells (*arrow*) emerging in association with the ventral wall of the dorsal aorta and expressing the blood gene, SCL. (N–P) Transgenic embryos showing expression of GFP in blood vessels. GFP expression was under control of the *Xenopus FLK-1* promoter as indicated in reference 25. LH, lymphatic heart; NF, neural fold; Pd, pronephric duct; PN, pronephros; RBC, red blood cells. For color reproduction, see Color Plate 18.2.

hemangioblast gives rise to the pronephric sinus, PCV, and DA as well as to hematopoietic stem cells (HSCs) (10–11) (Figure 18.2C and M, *arrows*). It appears that the generation of hematopoietic cells in the *Xenopus* embryo always occurs in close association with ECs; however, the opposite is not true, because the head vasculature is never seen associated with developing blood cells. Thus, according to their ontogeny, two types of ECs exist in the embryo: those deriving from hemangioblasts, and those not deriving from hemangioblasts. Interestingly, some blood genes such as *CBF $\beta$* , *MafB*, and *LMO2* are seen associated with different maturing and/or differentiated blood vessels. Between stages 32 and 40, *LMO2* is expressed in a large number of vessels (Figure 18.2L), whereas in the same period, *CBF $\beta$*  and *MafB* are mainly expressed by the vitelline vessels (data not shown). This may suggest that different hematopoietic genes have different roles during the specification and/or maturation of the vasculature.

One feature strikingly conserved through evolution is the formation of hematopoietic clusters in the ventral wall of the mature DA and other large arteries of the embryo (10,18–20) (Figure 18.2C and M). These intraaortic clusters express a number of genes later expressed in mature endothelium or blood, including *CD34*, *CD31*, *GATA2*, *LMO2*, *AML1/Runx1*, and *CD45*. Furthermore, transplantation experiments have demonstrated that the first HSCs localize to the DA and the vitelline and umbilical arteries of the developing mouse embryo (21). Taken together, it is widely accepted that the intra-aortic hematopoietic clusters represent the first emerging HSCs in the embryo. However, how these clusters are generated is still controversial (22). Several mechanisms are proposed, including: (a) transdifferentiation, in which the mature endothelium of the DA gives rise directly to the HSC; (b) dedifferentiation-differentiation, in which the mature endothelium dedifferentiates into a less mature mesodermal cell that subsequently differentiates into the HSC; (c) mesodermal differentiation, in which a mesodermal precursor localized within the endothelial lining of the DA differentiates into the HSC; and finally (d) colonization, in which a mesodermal precursor located in the surroundings of the DA differentiates into HSCs that migrate and colonize the ventral wall of the DA. By whichever mechanism, the ECs of the DA undoubtedly play a significant role during the emergence of the HSC.

## FUTURE DIRECTIONS

A body of evidence suggests that the genes and signaling mechanisms involved during the development of the vasculature are well conserved between *Xenopus* and the mouse. Key regulators of hemangioblast development, vasculogenesis and angiogenesis—such as VEGF-A and its tyrosine kinase receptor, Flk-1; the angiopoietin tyrosine kinase receptor, Tie2; and the hematopoietic transcription factors GATA-2, SCL, *LMO2*, and *AML1/Runx1*—have been described for *Xeno-*

*pus*. Also reported are genes shown to be specifically expressed by ECs and/or involved in EC physiology and/or migration; among them are *Xmsr*, members of the Eph-ephrin system, neuropilins, and the Ets transcription factors *Fli1*, *Ets-1*, *Ets-2*, and *Erg*. However, the isolation and characterization of key genetic components such as the VEGF receptor tyrosine kinases *FLT-1* and *FLT-4* is yet to be accomplished in *Xenopus*. Fortunately, several libraries of expressed sequence tags (ESTs) have been generated in the past few years and, undoubtedly, these libraries will greatly facilitate the isolation of the factors currently missing in the endothelial genetic machinery of *Xenopus*.

Collections of thousands of *Xenopus* ESTs are available commercially in the form of microarrays. The employment of such microarrays in gain- and loss-of-function experiments can be used not only to unravel the genetic cascades involved during the embryo's vascularization, but also as a powerful tool for the discovery of unknown components of the endothelial genetic machinery. Until recently, gain-of-function experiments in *Xenopus* have been achieved by mRNA injection into early embryos. Similarly, loss-of-function has been achieved by injecting the mRNA of dominant negative forms of the gene of interest. Undoubtedly, future researchers will make use of transgenic technologies (23) to achieve tissue- and temporal-specific gene perturbation. New loss-of-function technologies also are being developed, and so far the employment of modified antisense oligonucleotides, in particular morpholinos, has greatly benefited the *Xenopus* community. Thus, morpholinos can be used to perform rapid, low-cost loss-of-function studies of endothelial genes and, because *Xenopus* embryos are less dependent than their mammalian counterparts on circulation for oxygen transport during early stages of development, loss-of-function analyses can be performed at later stages of development.

The *Xenopus* animal cap induction assay also has been an informative tool for developmental biologists (24). The *Xenopus* blastula contains a large blastocoel, the roof of which is called the *animal cap* and which consists of a few layers of ectodermal cells. If the animal cap is excised and cultured for a few days in saline medium, it forms atypical epidermis with no evident structural differentiation. When the animal cap is cultured in media containing growth factors however, differentiation is induced, and tissue differentiation can be identified by morphology and/or molecular markers. Tissue-specific differentiation can be achieved by using particular growth factors at particular concentrations, and a wide range of mesodermal and endodermal derivatives, including blood, has been produced (24). The animal cap assay also can be used to investigate the roles played by individual genes in these processes. Fertilized eggs are injected in their animal poles before the first cleavage with mRNA encoding the factor of interest, the animal caps are excised at the blastula stage and cultured for a few days, and then morphological and molecular analyses are performed. The combination of single-gene animal cap assays and EST microarrays could be

used as a high throughput protocol to identify downstream genetic targets and new components of the endothelial genetic machinery.

*Xenopus laevis* is a pseudotetraploid species, and this fact has hampered genetic studies in this organism. In recent years, a close diploid relative of *X. laevis*, *X. tropicalis*, has been proposed as an alternative model for genetic studies. The developmental biology of *X. tropicalis* appears to be very similar to that of *X. laevis*, and all the technologies employed in *X. laevis* also can be applied in *X. tropicalis*. This has prompted the genomic characterization of *X. tropicalis*, and its genome is currently being sequenced. The genome sequence will facilitate not only the identification of conserved motifs in the regulatory sequences of endothelial genes, but also will provide much-needed promoters and enhancers for the generation of endothelium-specific transgenic lines. Furthermore, several large-scale mutagenesis screens currently are being carried out using *X. tropicalis* (25). The generation of mutations affecting the development of the vascular system may lead to a better understanding of the roles of currently known factors and to the discovery of new genes.

In vivo studies of gene regulation using both *X. laevis* and *X. tropicalis* can now be performed thanks to the development of a simple and reliable transgenesis protocol (23). Transgenic lines can be generated using promoters isolated from different organisms but, as its genome is becoming available in the form of clones and sequence information, more and more lines will be established using *X. tropicalis* sequences. By fusing the regulatory sequences of the gene of interest with the coding region of the green fluorescent protein (GFP), gene expression can be monitored in real time as the embryo develops (Figure 18.2N–P). Furthermore, transgenic lines have been generated using binary gene expression systems such as GAL4-UAS, tetracycline-controlled gene expression, or Cre/FLP-mediated recombination; these can be used to produce uniform and tissue-specific transgene expression. At the moment, only the promoters of *Xenopus Flk-1* (25) (see Figure 18.2N–P) and mouse *Tie2* (25) have been used to drive GFP expression in ECs in *Xenopus*. In the future, the use of hemangioblast-, vein-, artery- or lymphatic-specific promoters will greatly facilitate the identification of the mechanisms involved in the differentiation of these cell lineages. Transgenic lines also could be used as models for the identification and validation of novel drugs targeted to the vascular system. Although both zebrafish and *Xenopus* embryos are suitable for the screening of chemical libraries with the aim of discovering novel chemical modulators of angiogenesis, the absence of smooth muscle cells and lymphatic vessels in the zebrafish leaves *Xenopus* as more suited for these studies (26). In the longer term, this could assist with the identification of pharmacological agents for the treatment of numerous pathological disorders in which ECs play an important role – for example, tumor development. Importantly, screenings also will provide new tools to study the development and physiology of ECs under normal conditions.

## KEY POINTS

- The *Xenopus* system offers an exciting opportunity to study the development and genetics of ECs and their modulation. In particular, *Xenopus* should make valuable contributions to our understanding of how ECs are specified in the early embryo and the importance of their interaction with other cell lineages.
- The endothelial genetic machinery appears to be conserved between *Xenopus* and mammals, including the close association between hematopoietic and EC programming during development.
- In *Xenopus*, well-developed embryological techniques are available, such as fate mapping, tissue transplantation, and explant culture, which facilitate the study of EC development.
- The generation of transgenic lines, together with the external development of the *Xenopus* embryo, greatly facilitates the in vivo study of the embryo's vascularization.

## Future Goals

- To sequence the genome of *X. tropicalis*, together with large scale mutagenesis screens, to provide new sequences for the generation of endothelium-specific transgenic lines and new mutant lines carrying endothelium-specific mutations
- To develop EST microarrays in conjunction with animal-cap induction to facilitate the investigation of the EC genetic cascade and the discovery of new components of the genetic machinery
- To establish endothelium-specific transgenic lines for in vivo study of the development of the vascular system, as well as provide models for assessing the toxicity, effectiveness, and specificity of new drugs modulating angiogenesis, before clinical trials are implemented
- To use *Xenopus* as an ideal system for the low-cost, high-throughput screening of chemical libraries with the aim of discovering new drugs modulating particular aspects of angiogenesis

## ACKNOWLEDGMENTS

We thank Paul Krieg for providing the Flk1 promoter used for transgenesis. We apologize to those investigators whose work could not be cited because of space constraints. This work was supported by the MRC.

## Vascular Development in Zebrafish

Sameer S. Chopra and Tao P. Zhong

*Vanderbilt University School of Medicine, Nashville, Tennessee*

The use of zebrafish (*Danio rerio*) as a vertebrate model has yielded tremendous insight into the complex cellular and molecular events that underlie embryonic vascular development. Compared to more traditional model organisms such as chicks, mice, and frogs, zebrafish offer distinct advantages and have made unique contributions toward our understanding of vascular development. Recent studies in zebrafish have led to the identification of mutations and molecules that are responsible for the specification of endothelial progenitor cells (or angioblasts), differentiation of arterial and venous cells, and patterning of the dorsal aorta (DA) and intersegmental vessels. Zebrafish embryos develop externally and are optically clear, affording noninvasive and high-resolution access to nearly the entire vascular system. The ability of zebrafish embryos to survive temporarily without blood circulation (oxygen is obtained via diffusion) permits the study of defects in vascular development that would otherwise be embryonic lethal in other organisms, and without the confounding effects of hypoxia. Given their fecundity, small size, and brief generation time, zebrafish are highly amenable to genetic manipulation, including large-scale mutagenesis screens. Importantly, the zebrafish genome has been mapped and sequenced by the Sanger Center in Britain. Genomic and positional cloning reagents, such as genetic maps and libraries, are available. Forward genetic approaches,<sup>1</sup> in combination with gene mapping and positional cloning, already have been employed successfully to identify genes that disrupt the formation and patterning of embryonic vasculature and other organs (1,2). The discovery of *gridlock* (*grl*) – a *hairy*-related basic helix-loop-helix (bHLH) transcription factor involved in arterial endothelial development – demonstrates the power of mutagenesis screens to uncover novel genetic pathways and developmental mechanisms with no presupposition about the role of genes in biological processes (discussed below) (3,4).

To date, zebrafish studies have helped to clarify the cellular and molecular mechanisms underlying critical phases of embryonic vascular development including: (a) specifi-

tion of angioblasts and differentiation of arterial and venous endothelial cells (ECs); (b) organization of ECs into a primary circulatory network comprised of the DA and the cardinal vein; and (c) growth and remodeling of this primary network into intersegmental vessels. This chapter discusses some of those important events that have been analyzed mostly in zebrafish, and also compares some of these events to those in other organisms.

### HISTORICAL OVERVIEW

The earliest published studies using zebrafish date back to the 1950s, when several researchers took advantage of the transparency of zebrafish embryos to examine the effect of toxic compounds on development. George Streisinger, Charles Kimmel, and colleagues at the University of Oregon later championed the use of zebrafish in the 1980s, through a series of important publications describing its genetics and embryonic development. The zebrafish reached widespread popularity in biomedical research a decade ago, with reports of the successful conduct of two large-scale zebrafish forward genetic screens.<sup>2</sup> The power of forward genetics to uncover new pathways that govern early development and organogenesis previously only had been demonstrated in invertebrate models such as *Drosophila*. Interestingly, a number of zebrafish mutants exhibited features resembling human disease phenotypes, and the positional cloning of specific mutations often identified genes orthologous to human disease genes. The heart and fin defects in the *heartstring* mutant, for example, result from a nonsense mutation in the zebrafish orthologue to *TBX5*, a T-box transcription factor whose loss of function underlies the heart and limb abnormalities of human patients suffering from Holt-Oram syndrome (5). The otic vesicle defects in the *mariner* zebrafish mutant are caused by mutations in the myosin VIIA gene, which is disrupted in human Usher 1B deafness syndrome (6). The poor cardiac contractility and

1 Mutagenesis screens are conducted to isolate mutants with phenotypes, then genes are cloned from the mutants.

2 An entire issue of the journal *Development* was devoted to these reports (*Development*, 1996;123(1):1–461.).

perturbed sarcomeric assembly in the *pickwick* mutant result from a mutation in the gene encoding the zebrafish homolog of *titan*, a gene whose aberrant function results in human dilated cardiomyopathy (7). Zebrafish *sau* proved to be due to a defect in the erythroid aminolevulinic synthase (*ALAS-2*) gene, a critical enzyme that regulates the first step in heme biosynthesis in embryonic red blood cell (8). Mutations in *ALAS-2* gene cause human X-linked congenital sideroblastic anemia. In addition to modeling diseases with known causes, zebrafish mutants may also hold promise for identifying new disease genes in humans. Such was the case with *weissherbst*, a zebrafish mutant displaying hypochromic anemia caused by a mutation in the gene encoding the iron transporter ferroportin 1 (9,10). Later, it was discovered that patients with type 4 hemochromatosis have defects in the same transporter. In the *gridlock* mutant, the aortic bifurcation is blocked, in a manner similar to coarctation of the aorta, a human congenital cardiovascular disease of unknown etiology (3). There also exist zebrafish mutants with cystic kidneys, such as *doublebubble*, which may represent polycystic kidney disease of human (11). Both *gridlock* and *doublebubble* also one day may demonstrate

that genes discovered through zebrafish forward genetics can contribute to the discovery of novel human disease genes.

### THE ZEBRAFISH EMBRYONIC VASCULATURE

The anatomy and development of the major embryonic vascular network, the circulatory loop in the trunk, is highly conserved between zebrafish and other vertebrates. The zebrafish axial vessels, the DA and the posterior cardinal vein (PCV), form a simple circulatory loop in the trunk prior to the first heartbeat (Figure 19.1 for color reproduction, see Color Plate 19.1) (12). The rudiments of these vessels assemble through vasculogenesis, in which endothelial progenitors (angioblasts) migrate from the lateral mesoderm and coalesce first into cords and subsequently into vessels with lumens (13). Elaboration of the simple circulatory loop occurs through angiogenesis, in which new vessels sprout, grow, and remodel to form an anastomotic arterial and venous network. One key feature differentiating zebrafish from other vertebrates is the vasculature of the yolk sac. Whereas other vertebrate

Figure 19.1. Anatomy of the zebrafish embryonic vasculature. (A) Diagram of a circulatory loop at the zebrafish embryo at 30 hpf. (B) Fluorescent confocal microangiogram showing the zebrafish embryonic vasculature at 60 hpf. H, Heart; VA, ventral aorta; AA, aortic arch; PHS, primary head sinus; NCA, nasal ciliary artery; PrA, prosencephalic artery; MsV, mesencephalic vein; DLV, dorsal longitudinal vein; PCeV, posterior cardinal vein; CctA, cerebellar central artery; PHBC, primary hindbrain channel; DLAV, dorsal longitudinal anastomotic vessel; DA, dorsal aorta; Se, intersegmental vessel; CA, caudal artery; CV, caudal vein; ACV, anterior cardinal vein; PCV, posterior cardinal vein; SIV, subintestinal vein; CCV, common cardinal vein (duct of Cuvier). For color reproduction, see Color Plate 19.1.

embryos form a complex capillary plexus network that undergoes pruning and remodeling to form the vitelline artery and vitelline vein, the zebrafish yolk sac does not develop these extraembryonic vascular structures. Instead, part of the cardinal venous system extends into the yolk sac (see Figure 19.1).

### THE ORIGIN AND SPECIFICATION OF ANGIOBLASTS

Angioblasts are endothelial precursors that have certain characteristics of ECs but have not yet organized into a cord (13). In zebrafish embryos, angioblasts arise in the lateral plate mesoderm at the 5-somite stage and can be detected by their expression of vascular endothelial growth factor receptor (*VEGFR2*; *flk1*) (14–16). Cell lineage analysis indicates that angioblasts migrate to the midline and assemble into the DA and the cardinal vein (Figure 19.2; for color reproduction, see Color Plate 19.2) (4). Similarly, in avian embryos, angioblasts, which are detected by QH1 antibodies, originate from the lateral plate mesoderm (17). Angioblasts from the splanchnopleural mesoderm, a ventral compartment of the lateral plate mesoderm in contact with endoderm, populate the floor of the DA and endothelial lumens of vessels in visceral organs (18). Hematopoietic stem cells that eventually reside in the ventral side of aortic lumen also are derived from the splanchnopleural mesoderm. In contrast, angioblasts derived from the somitic paraxial mesoderm contribute to vessels in the neural tube, limb buds, and the roof of the aorta and never invade the visceral organs. The somatopleural mesoderm, a dorsal layer of the lateral plate mesoderm in contact with ectoderm, produces few angioblasts (18). Thus, angioblasts in the embryo proper originate primarily from splanchnopleural mesoderm and somitic paraxial mesoderm.

In the yolk sac of avian embryos, the earliest sign of angioblast formation is the appearance of blood islands that emerge from the extra-embryonic mesoderm in association

Figure 19.2. Assembly of the dorsal aortae and the cardinal veins in zebrafish embryos. Schematic drawing indicates the crossover section of zebrafish embryos at the trunk region, showing the neural tube, notochord, aorta, cardinal vein, and gut. Angioblasts appear to migrate and assemble into the dorsal aorta and the cardinal vein. For color reproduction, see Color Plate 19.2.

with visceral endoderm (19). The external cells of blood islands differentiate into ECs, and the internal round cells develop into hematopoietic stem cells. Based on the simultaneous emergence of angioblasts and hematopoietic cells in blood islands, it is postulated that angioblasts and hematopoietic cells originate from a common precursor termed the “hemangioblast” (20,21). Multiple lines of evidence support the existence of such progenitors with dual potential. Both angioblasts and hematopoietic progenitors express similar sets of transcription factors and surface receptors. In addition, single-gene mutations have been found to perturb the development of both angioblast and hematopoietic lineages (22).

Although numerous studies suggest that direct interactions between endoderm and mesoderm might be required for angioblast specification<sup>3</sup> in the embryo proper (23,24), more recent studies in *Xenopus* suggest the endoderm is not required for this process (25). These findings imply that signals for angioblast specification may be contained within the mesoderm, or that this process occurs by an intrinsic cellular mechanism. This suggests that interactions of mesoderm and endoderm might not be required for angioblast specification. Critical molecular insight into the specification of angioblasts has come from studies of *VEGFR2/FLK-1* and its ligand VEGF. Targeted inactivation of *FLK-1* in mouse embryos causes embryonic lethality and results in the absence of both endothelial and hematopoietic cells, indicating that *FLK-1* is essential for angioblast specification (26). In zebrafish, the *schwentine* mutation encodes a truncated *Flk-1* gene (27). Surprisingly, *schwentine* mutant embryos do not display defects in angioblast specification, although formation of both intersomitic and subintestinal vessels is disrupted. This milder phenotype in zebrafish *schwentine* mutants, compared to mice with inactivated *Flk-1*, might be explained by partial retention of VEGF signaling by the truncated *FLK-1* receptor. Alternatively, a second copy of *flk1* in the zebrafish genome may compensate for the defective *flk1* in *schwentine* mutant embryos (Len Zon, personal communication).

VEGF, the ligand for *FLK-1*, is expressed in the paraxial mesoderm and in the surrounding endoderm adjacent to angioblasts (28). In mice, inactivation of a single *VEGF* allele results in impaired yolk sac vasculogenesis and a defective DA, suggesting that a critical level of VEGF is required to sufficiently activate the *FLK-1* receptor during vasculogenesis (29). Unexpectedly, complete inactivation of VEGF activity in both zebrafish and mouse embryos does not inhibit angioblast specification. These results suggest that additional VEGF ligands (i.e., VEG-F-B and VEG-F-C) may interact with the *FLK-1* receptor during vasculogenesis to induce angioblasts (30). Alternatively, yet unidentified mesodermal-derived factors may promote angioblast specification via the *FLK-1* receptor.

Unlike *schwentine*, a second zebrafish mutant line termed *cloche* is characterized by a defect in angioblast specification (31). Similar to mouse embryos with inactivated *Flk-1*, *cloche*

3 Mesodermal cells differentiate into angioblasts.

mutants also fail to develop hematopoietic lineages (32). Transcripts of both endothelial and hematopoietic markers including *flk1*, *fli*, *scl*, *gata1*, *tie1*, and *tie2* are absent in *cloche* embryos at very early stages; at later stages, their expression is minimal and restricted to caudal regions of the embryo. Cell transplantation studies reveal that the *cloche* mutation is cell-autonomous<sup>4</sup> for the generation of endothelial lineages but non-cell-autonomous for hematopoietic lineages (32). These findings suggest that *cloche* might act as an intracellular factor for inducing angioblast formation. Improved understanding of the molecular mechanism of *cloche* in vasculogenesis will depend on the success of ongoing efforts to identify the *cloche* gene via a positional cloning approach.

Current studies using a gain-of-function approach have placed *cloche* in a putative molecular pathway. Forced expression of *scl*, a basic helix-loop-helix (bHLH) transcription factor, in *cloche* embryos restores expression of the endothelial marker *flk1* and the hematopoietic marker *gata1*, and increases the number of both endothelial and blood cells (32). These findings suggest that *cloche* acts upstream of Scl for hemangioblast specification, which in turn controls differentiation of angioblastic and hematopoietic lineages. Additional zebrafish studies suggest that Scl acts synergistically with Lmo2, a LIM domain transcription factor, in converting paraxial mesoderm into angioblasts (33). Forced expression of *scl* mRNA in zebrafish embryos induces ectopic expression of endothelial markers *flk*, *fli*, and *flt4* in somitic paraxial mesoderm. The restriction of angioblast induction to somitic paraxial mesoderm correlates with Scl-induced *lmo2* expression in this region. Consistent with these findings, misexpression of *lmo2* and *scl* mRNA induces mesodermal cells in the region of head, heart, and pronephros into ECs at the expense of myocardial and pronephros fates (33). Thus, expression of both *scl* and *lmo2* can induce angioblast specification and endothelial differentiation in paraxial mesodermal cells. Together, these data suggest that Scl and Lmo2 synergistically act downstream of *cloche* in controlling angioblast formation. Although these gain-of-function studies in zebrafish indicate an important role for Scl and Lmo2 in angioblast specification, loss-of-function studies of these genes in mice and zebrafish suggest that neither is essential for this process. Targeted inactivation of mouse Scl or Lmo2, for example, causes defects in both hematopoiesis and angiogenesis but does not affect angioblast specification (34–36). Similarly and consistent with the loss-of-function phenotype in mice, knockdown of zebrafish *scl* using antisense morpholinos results in absence of hematopoietic cells but not a loss of angioblasts or ECs (37,38).

Taken together, these results suggest that Scl and Lmo2 are required for hematopoiesis and angiogenesis but are not essential for angioblast specification. In mammals, members of fibroblast growth factor (FGF) are suggested to induce angioblast specification. However, in zebrafish, mutation in

*fgf8* does not affect the formation and differentiation of angioblasts and ECs, but causes deficiency of cardiac precursors (39), suggesting that Fgf signaling is not required for angioblast specification but is essential for induction of cardiomyocytes in zebrafish.<sup>5</sup>

In summary, angioblasts arise from the lateral plate mesoderm that associates with the endoderm. The induction and differentiation of angioblasts and ECs require molecular mechanisms that are critically dependent on *flk1* and *cloche*.

## FORMATION OF THE DORSAL AORTA AND THE CARDINAL VEIN

The assembly of angioblasts into endothelial cords and subsequently into lumens of the DA and the cardinal vein represents the next major milestone in vascular development. Although little is known about cardinal vein assembly, a number of zebrafish studies have clarified the structural and molecular requirements for formation of the DA. The zebrafish *floating head* (*flh*) mutation occurs in *Xnot*, a homeobox gene, and inhibits development not only of the notochord and hypochord, but also of the DA. *Flk-1*-expressing ECs, however, still appear to form a venous luminal structure in the region of the cardinal vein (14). The hypochord is an endodermally derived, transient structure in fish and amphibian embryos that lies ventral to the notochord and immediately dorsal to the aorta. Flh acts cell-autonomously with respect to the development of the notochord, floor plate,<sup>6</sup> and hypochord because transplanted wild-type cells give rise to all three structures in *flh* host embryos (40). In addition, the aorta can be rescued only in the region immediately beneath the cell-transplant notochord and possibly the hypochord (14). Similar to zebrafish *flh*, *no tail* (*ntl*) embryos that have a mutation in the *brachyury* gene lack a differentiated notochord and hypochord but develop one axial vessel, which appears to be the cardinal vein (14). Collectively, these observations suggest a tight correlation between presence of the notochord (and possibly hypochord) and the DA. It is not clear, however, whether signals from the notochord or hypochord directly induce formation of the aorta or of adjacent tissues, which then subsequently provide the requisite signals for aorta assembly. Nonetheless, these observations provide a novel avenue for investigating the molecular basis of DA formation.

Studies conducted in *Xenopus* suggest a putative model for DA assembly that involves both the hypochord and VEGF signaling (41). VEGF has been found to play a critical role in controlling DA development (29,42). Although VEGF is expressed in the hypochord, somites, and endoderm during frog and fish embryonic development, *VEGF-121* appears to be preferentially expressed in the hypochord relative to *VEGF-165*

4 Genes that encode proteins with roles in the intracellular rather than extracellular environment.

5 It is possible that redundancy in the *fgf* family may compensate for the loss of individual *fgf* members for angioblast formation.

6 The ventral part of the neural tube.

and *VEGF-188*. Furthermore, ectopic *VEGF-121*-expressing implants are sufficient to promote angioblast migration. Based on these findings, it may be hypothesized that a gradient of VEGF established between the hypochord and the lateral plate mesoderm directs the migration of angioblasts to the midline to form the aorta. This hypothesis would be supported by evidence that loss of *VEGF-121* in the hypochord impairs arterial angioblast migration and leads to abolishment of aorta formation in *Xenopus* embryos. It also remains to be resolved how the loss of VEGF activity in mice (which, like other mammals, lack a hypochord) results in the complete absence of DA formation. It is possible that other embryonic structures, such as somites, express VEGF and thus serve a role analogous to the hypochord in inducing angioblast migration and aorta assembly.

Recent studies on vascular tubulogenesis in zebrafish have uncovered cellular events required for reshaping endothelial cords into tubes (43). At the 22-somite stage, arterial and venous angioblasts coalesce into single cords at the midline. Thereafter, arterial and venous angioblasts gradually segregate from each other in order to occupy distinct domains and then align in the form of rudimentary tubes. A factor EGF-like domain 7 (*Egfl7*) secreted from ECs was identified and thought to regulate the cord-to-tube transition. Inactivation of *Egfl7* in zebrafish embryos results in failure of the separation of arterial angioblasts from venous angioblasts, resulting in lack of lumen formation of the aorta and cardinal vein (43). Because the secreted *Egfl7* protein remains in the vicinity of ECs and associates with the extracellular matrix, it is proposed that *Egfl7* provides a permissive substrate around angioblasts to facilitate the local movement and segregation of arterial angioblasts from venous angioblasts.

### PATTERNING OF THE INTERSEGMENTAL VESSELS

In the vertebrate vascular development, intersegmental vessels sprout from the DA and cardinal vein and grow to form the vascular system of the trunk. Taking advantage of the optical transparency of zebrafish embryos, studies have determined that this vascular network actually forms via a two-step mechanism (44). Primary sprouts emerge bilaterally from the DA and elongate dorsally, branching cranially and caudally along the dorsolateral roof of the neural tube to form paired dorsal longitudinal anastomotic vessels (DLAV) (Figure 19.3; for color reproduction, see Color Plate 19.3). Secondary sprouts grow from the PCV, with some connecting to the base of primary segments. The primary segments with patent connections to secondary segments become intersegmental veins, while the primary segments that remain connected to the DA become intersegmental arteries (44,45).<sup>7</sup> These intersegmental

Figure 19.3. Model of the construction of an intersegmental vessel in zebrafish embryos. An intersegmental vessel is composed of three types of ECs: the dorsal connection to the DLAV is a T-shaped EC; the ventral connection to the aorta is an inverted T-shaped EC; the middle connection is an elongated EC. ISV, intersegmental vessel; DLAV, dorsal longitudinal anastomotic vessel. For color reproduction, see Color Plate 19.3.

tal vessels develop via migration and growth directly from axial vessels. Each of the intersegmental vessels is comprised of three types of ECs (see Figure 19.3) (44,45). The first one has its cell body in the DA and branches dorsally, the second one connects the first one and the third one, and the third one has its cell body in the DLAV and branches ventrally. These ECs derive from the lateral plate mesoderm, incorporate into the DA and move up to become part of the intersegmental vessels.

An analysis of the molecular events underlying this phase of vascular development has been facilitated by several zebrafish mutant lines. For example, *schwentine*, *y10*, and *out of bounds* (*obd*) mutations have linked FLK-1, phospholipase C $\gamma$ -1 (*Plcg1*), and plexinD1 (*PlxnD1*), respectively, to angiogenic growth, sprouting, and patterning of intersomitic vessels (27,45,46) (MGH screen, unpublished observations). Because *Flk1* and *Plcg1* are implicated in the intracellular transduction of VEGF signaling, the phenotypes resulting from mutations in these genes are consistent with the known function of VEGF for promoting blood vessel growth. In *obd* mutants, intersegmental vessels grow but are mispatterned, sprout precociously at irregular sites, and neither elongate along the intersomitic boundaries nor form interconnected branches along the trunk (47). Reduction of *plxnD1*, a semaphorin ligand receptor, using antisense morpholinos, causes defects indistinguishable from zebrafish *obd* mutants and similar to those displayed by mice with targeted inactivation of *PlxnD1* (47). These data implicate *PlxnD1* as a gene required for proper blood vessel path-finding during angiogenesis. It is notable that, in the developing nervous system, axonal path-finding is

<sup>7</sup> The normal circulatory loop in the intersomitic vascular system is as follows: (a) blood flow into the dorsal longitudinal anastomotic vessel (DLAC) via intersomitic arteries from the dorsal aorta, (b) flow into intersomitic veins from DLAV, and (c) flow from intersomitic veins into the cardinal veins.

guided by repulsive cues from semaphorin ligands that bind to plexin receptors in migrating neuronal growth cones (48). Semaphorins possibly could serve a similar role in the embryonic vasculature by providing repulsive signals that restrict the navigation of intersegmental vessels to the intersomitic boundaries. Further support for this model comes from studies of the netrin receptor *Unc5B* and its ligand Netrin-1a, which appear to control endothelial tip-cell filopodia and branching (49). *Unc5B* is expressed selectively in endothelial tip cells, and the reduced function of this gene in mice causes excessive vessel branching in the internal carotid artery, intersegmental vessels, and vessels of the nervous system. In zebrafish embryos, reduced *Unc5B* function causes intersegmental vessels to exhibit ectopic filopodial extensions and form extra vessel branches at variable positions, resulting in aberrant anastomosis. These data thus suggest that, during angiogenesis, blood vessels are guided by repulsive mechanisms that employ the same cues and receptors that guide axons.

In summary, the optical clarity of embryonic zebrafish and their genetic and experimental accessibility have enabled the rapid imaging and analysis of the vascular “wiring” and patterning of intersegmental vessels in developing transgenic embryos, in which the expression of green fluorescent protein is driven by the *fli1* promoter. These studies represent the first comprehensive investigation into the development of angiogenic networks.

## MOLECULAR SIGNALS IN ARTERIAL AND VENOUS DIFFERENTIATION

The mechanism by which ECs assume an arterial or a venous identity has been elusive for many years. It has been hypothesized that arterial and venous EC fate is established by anatomical location and local physiological conditions in the primary vascular network. Mounting evidence suggests, however, that arterial and venous fates actually are determined *prior* to blood circulation (3,4,50–52). Since the discovery that *ephrinB2* (*efnb2*) (a transmembrane ligand) and *EphB4* (a cognate receptor for *efnb2*) expression are restricted to the arterial and venous endothelium, respectively, multiple molecules including Notch, Gridlock(*grl*)/*hey2*, and VEGF have been demonstrated to regulate arterial and venous EC differentiation (Table 19-1). Inactivation of either *ephrinB2* or *EphB4* in mice results in defects of vascular remodeling and maturation in angiogenesis. However, these mutations do not exhibit defects in arterial and venous differentiation (50). Nevertheless, this pair of transmembrane-anchored signaling molecules defines the identity of arterial and venous endothelium prior to the onset of circulation.

## DELTA-NOTCH SIGNALING

The expression of Notch receptors and ligands is observed in arterial but not venous endothelium. Furthermore, perturbed

Delta-Notch signaling results in defective arterial differentiation in mice and zebrafish. In zebrafish, *deltaC*, *notch5*, and *grl* (a component of the Notch pathway) are expressed in arterial ECs (3,51). This observation also was made for *notch1b* (T.P. Zhong, unpublished observations). Because *notch1a* and *notch1b* are duplicate copies of the *notch1* gene in the zebrafish genome (53), *notch1b* could be the counterpart of the mammalian *Notch1* gene. In mice, Notch1, Notch3, and Notch4 receptors and Jagged1, Jagged2, and Delta-like4(*dll4*) ligands are all expressed in arteries but not in veins (54,55). Among those, Notch1, Notch 4, Delta-like4 (*dll4*), Jagged1, and Jagged2 are expressed in arterial ECs and Notch3 and Jagged1 are expressed in arterial smooth muscle cells (55). Although zebrafish homologues of *jagged1* and *jagged2* have been isolated, whether they are expressed in arterial ECs is not known. Future in situ hybridization experiments are required to test their expression patterns.

Functional studies of Notch signaling in both zebrafish and mice suggest a critical role for this pathway in arterial–venous differentiation. The zebrafish *mind bomb* (*mib*) mutation occurs in a gene encoding a ubiquitin ligase that is essential for Delta-expressing cells to activate Notch receptors in neighboring cells (56). During vascular development, *mib* mutants display disorganized axial vessels and cranial hemorrhage. Some mutant embryos also have reduced DA size, arterial–venous shunts, and ectopic intersomitic sprouts (51). Characterization of *mib* demonstrates that the expression of certain arterial gene markers are absent (*efnb2*, *notch5*) or reduced (*deltaC*), whereas others are unaltered (*grl*, *tbx20*)

(51). This suggests that ECs in *mib* mutants have established arterial fate but are defective in subsequent arterial differentiation and maintenance. *Mib* mutant embryos also display ectopic expression of *flt4*—a gene whose expression is normally restricted to venous endothelium 24 hours post fertilization (hpf)—in arterial endothelium. Furthermore, perturbation of Notch signaling by misexpression of a dominant negative *Su(H)*, a transcriptional mediator of Notch signaling, results in the absence of arterial markers and, in some cases, partial loss of the DA with simultaneous expansion of a contiguous region of the cardinal vein (4,51). These data support the idea that arterial fate is specified and maintained via repressing venous fate. Because the milder phenotype of *mib* mutants potentially may be explained by the expression of the *mib*-related gene, it will be important to test whether inactivation of both genes causes more severe defects in arterial endothelial specification. Consistent with these findings in zebrafish, mice with targeted deletions in *Dll4*, *Jagged1*, *Notch1*, or *Notch1/Notch4* display marked abnormalities in vascular development, including yolk sac vascular remodeling abnormalities, a reduced DA, massive hemorrhages, and embryonic lethality (57–59).

### The Role of *grl/hey2*

The zebrafish *grl* gene is related to the recently described *Hey2/Hrt2/Hesr1/Chf1* in mouse, belonging to a novel group of the *hairy* and *E(spl)*-related bHLH family (3,60,61). The *hey* gene family consists of three members, *hey1*, *grl/hey2*, and *heyL*, in human, mouse, and zebrafish, with only a single counterpart in *Drosophila* (3,62,63). In mice, members of the *Hey* gene family show both partially overlapping and complementary expression patterns. All three members of this family, for example, are expressed in the presomitic mesoderm, somites, and aorta, but *Hey1* and *Grl/Hey2* expression are restricted to the atrium and ventricle of the heart, respectively (60,61). Zebrafish *grl/hey2*, in contrast, is the only *hey* gene expressed in the aorta and the heart. In addition, *grl/hey2* is expressed in angioblasts at the lateral plate mesoderm prior to vessel formation and subsequently becomes restricted to arterial ECs (3,63). *Grl/hey2*, therefore, is expressed at the correct time and in an appropriate region for regulating arterial endothelial differentiation in zebrafish. Furthermore, two conserved Su(H)/rbp-1-binding sites (CGTGGGAA) have been identified in the upstream regulatory region of zebrafish *grl* and its mouse homologue *Hey2*, suggesting that *grl/hey2* acts as a transcriptional target of Su(H) (4,64). Indeed, transcriptional activity of *Hey2* is regulated by Notch signaling in cultured cells, and expression of *grl/hey2* is downregulated in zebrafish and mouse embryos lacking Notch activity (4,64–66).

The functional importance of *Grl/Hey2* has been analyzed in mutant zebrafish embryos whose hypomorphic *grl* allele causes artery-specific defects, including a disruption of the aortic bifurcation (67). In addition, *EGFP* expression under control of the *flk1* promoter reveals that the aorta in *grl* mutants has a decreased lumen size. Reduction of *Grl* function using a high dose of morpholino-modified antisense oligonu-

cleotides specifically inhibits the formation of the DA, whereas a low dose of antisense morpholinos phenocopies the defects in *grl* mutant embryos (4). This suggests that, in zebrafish, *Grl* is required for arterial endothelial differentiation in a dosage-sensitive manner. Furthermore, *grl* mutant embryos express the early arterial marker *notch1b* but not the late arterial markers *deltaC*, *notch5*, *ephrinB2*, and *tbx20*, indicating that *grl* mutants (like *mib*) have acquired an initial arterial fate but are defective in subsequent arterial differentiation, maintenance, and maturation.

In mice, *Hey* genes function redundantly in vascular development because of their overlapping expression in the aorta. Targeted inactivation of *Hey2* causes fatal cardiomyopathy, ventricular septation defects, and high lethality, but the arterial endothelial system is not affected (68). However, the combined loss of *Hey1* and *Hey2* prevents arterial endothelial differentiation, reduces the size of the DA, inhibits both vasculogenesis in the placental labyrinth and vascular remodeling, and is embryonic lethal (66). Thus, the phenotype of *Hey1/Hey2* double-knockout mouse embryos is similar to that of zebrafish embryos with reduced *Grl* activity. These defects also are similar to the phenotype of mouse embryos lacking either *Notch1* or *Dll4*, suggesting that *Hey1/Hey2* function in the Notch pathway to regulate arterial endothelial differentiation and development. In humans, expression profiling has identified *grl* as part of a group of signaling genes that includes Notch receptors and is selectively expressed in human arterial ECs (HUAECs). In addition, expression of *Grl* in human umbilical venous ECs (HUVECs) induces the expression of a group of artery-specific genes (69). The apparent conservation of *Grl* signaling from zebrafish to humans underscores the potential importance of this pathway in arterial EC differentiation.

### VEGF Signaling

Among its other roles, recent studies suggest that VEGF is also important for promoting differentiation of the arterial endothelium (52,70). In cultured murine embryonic ECs, the addition of VEGF-A<sub>120</sub> or VEGF-A<sub>164</sub> induces *ephrinB2* expression in up to 50% of cells, whereas the addition of bFGF, BMP2, PDGF, IGF-1, NGF, NT-3, BDNF, or Sonic Hedgehog can only promote *EphrinB2* expression in approximately 10% (70). Importantly, both VEGF isoforms induce arterial differentiation without promoting endothelial proliferation at the low concentration of 2.5 pM (70). In zebrafish, reducing VEGF activity using antisense morpholinos causes loss of expression of the arterial markers *ephrinB2* and *notch5* and leads to ectopic expression of venous marker *flt4* (52). Conversely, misexpression of *Vegf-121* mRNA or *Vegf-165* mRNA causes ectopic *ephrinB2* expression in the cardinal vein (52). Taken together, these results suggest that VEGF is sufficient to promote arterial endothelial differentiation in vitro and in vivo. What remains unclear, however, is the manner in which VEGF influences this process. One proposed model suggests a differential effect of *Vegf* on arterial ECs in

zebrafish, in which some angioblasts that migrate medially first preferentially receive Vegf that is secreted from the somites and hypochord. These angioblasts therefore become specified as arterial angioblasts and subsequently differentiate into arterial ECs (71). Alternatively, angioblasts with prespecified arterial fate determined by an intrinsic cellular mechanism respond to Vegf induction, which triggers overt arterial differentiation. Indeed, the proportion of *ephrinB2*-expressed embryonic ECs induced by Vegf never exceeds 50%, suggesting that isolated *ephrinB2*-negative embryonic ECs contain prespecified arterial and venous angioblasts in a 1:1 ratio, respectively. Thus, Vegf only promotes prespecified arterial angioblasts to subsequently differentiate into arterial ECs.

Gain- and loss-of-function studies using VEGF as an entry point in zebrafish have led to the placement of several genes in a putative pathway that regulates arterial endothelial development. The hedgehog (Hh) signaling pathway has been shown to be important for arterial differentiation and development in zebrafish (52). The zebrafish *sonic-you* (*syu*) and *you-too* (*yot*) genes encode the orthologues of *shh* and *gli2*, a downstream effector of Hh signaling (72,73). Mutations in either *syu* or *yot* result in loss of *vegf* expression in somites, which in turn downregulate *ephrinB2* expression in the aorta and suggest that the somatic source of Vegf is important for arterial differentiation. Forced expression of *vegf-121* or *vegf-165* in *yot* mutant embryos rescues *ephrinB2* expression. Furthermore, constitutively active Notch signaling rescues expression of *ephrinB2* and *notch5* in embryos with reduced Vegf activity, whereas misexpression of *Vegf-121* cannot restore *notch5* expression in *mib* mutant embryos. These data suggest that Vegf acts downstream of Hedgehog signaling but upstream of the Notch pathway for regulating *ephrinB2* and *notch5* expression during arterial endothelial differentiation.

### Plasticity of Arterial and Venous Fate

Although multiple signaling molecules appear to regulate the identity of arterial and venous ECs prior to blood flow, studies using quail-chick transplantation have revealed that arterial and venous EC fate remains plastic until embryonic day 7 (74). Before this time, the embryonic DA or cardinal vein can colonize both arteries and veins in chick host embryos when transplanted from quail donors. These transplanted arterial and venous ECs express the avian arterial markers *ephrinB2*, *neuropilin-1* (*nrp-1*), and *tie2* when they integrate into the lining of arteries. Cells that integrate into venous endothelium, however, do not express these markers. After embryonic day 7, arterial and venous ECs gradually lose their plasticity and become committed. It is possible that the smooth muscle cell layer in the maturing vascular wall plays a role in maintaining the arterial endothelial fate. Thus, arterial and venous EC fates are prespecified but not fully committed at early embryonic stages and can be altered by the local vascular environment. Furthermore, genes such as *ephrinB2*, *nrp-1*, and *tie2* may not be involved in determining arterial and venous endothelial fates, but rather serve as markers of

arterial differentiation and/or maintenance. Indeed, *ephrinB2* is not expressed in angioblasts at the lateral plate mesoderm in zebrafish embryos.

It would be interesting to determine whether constitutive expression of Notch receptors and downstream Grl/Hey2 transcription factors leads to commitment of arterial endothelial fate. Likewise, it will be important to examine whether *notch* and *grl* are ectopically induced in venous ECs when they convert into arterial ECs after transplantation. Venous arterialization occurs when a vein segment is transposed into an arterial region in therapeutic procedures (75). The most recent evidence suggests that venous ECs can adapt to a novel vascular environment. High levels of Notch and Grl/Hey2, for example, are ectopically induced in human femoral veins when exposed to arterial flow conditions (G. Garcia-Cardena and M. Gimbrone, personal communication). This suggests that venous arterialization in humans is coincident with a molecular program similar to that required for arterial EC differentiation during embryonic development. It remains to be seen, however, whether molecular evidence of arterial transformation actually leads to structural and functional adaptation of the vascular wall.

### KEY POINTS

- Despite their relatively recent arrival as a vertebrate model system, zebrafish have already contributed much to our understanding of embryonic vascular biology. Uniquely amenable to both forward and reverse genetic approaches as well as in vivo gain-of-function analysis, the zebrafish model is primed to uncover key signaling pathways conserved among vertebrates and essential for vascular development.
- Zebrafish studies have provided novel insight into angioblast specification, differentiation of arterial and venous endothelium, assembly of the DA through vasculogenesis, and the sprouting, growth, patterning, and remodeling of vessels during through angiogenesis.

### Future Goals

- Future comparative genetic studies in zebrafish, mice, chicks, and other organisms will be necessary to decipher the tremendous complexity underlying the emergence of a vascular network and circulation during vertebrate embryogenesis.
- Benefits of this formidable effort are numerous and may include important insights for regenerative biology and novel therapeutic approaches for patients suffering from a variety of diseases involving the vascular endothelium such as atherosclerosis and cancer.

## ACKNOWLEDGMENTS

We thank all members of the Zhong laboratory, at Vanderbilt University, who have contributed to some of the ideas and work summarized here. Work in the Zhong laboratory has been supported by grants from the National Institutes of Health (NIH), the American Heart Association (AHA), March of Dimes Foundation, and the Vanderbilt Academic Venture Capital Fund.

# Endothelial Cell Differentiation and Vascular Development in Mammals

---

Cam Patterson

*Carolina Cardiovascular Biology Center, University of North Carolina, Chapel Hill*

As the developing mammalian embryo expands beyond a small mass of cells, it acquires a need to establish circulation in order to facilitate communication among different parts of the embryo. It also must establish a mechanism for nutrition and oxygenation once simple diffusion becomes a limiting mechanism. These requirements provide a rationale for why the cardiovascular system is the first to function during mammalian development. An analysis of vascular development therefore provides a paradigm for understanding the general principles of organ development in mammals. Practical reasons also exist to elucidate the mechanisms by which blood vessels form. It is clear that defective vascular development contributes to a number of congenital conditions in humans, from hereditary angiomas to more complicated developmental syndromes. In addition, we now know that many pathological events in adults follow rules that resemble developmental events, such that understanding the latter can inform how we approach the former. In this chapter, we briefly review the field of vascular development from an historical perspective, after which the key steps in mammalian endothelial differentiation will be considered, with a focus on the molecular and cellular events that underlie the principles of developmental blood vessel formation.

## HISTORICAL OVERVIEW

Consistent with its central importance in embryonic development, the history of research into vascular development is populated with seminal histologists such as Wilhelm His and Florence Sabin (see Chapter 1). Ideas about endothelial origin followed shortly after the development of histology and cell biology as fields of study. Beyond characterization of the fundamental anatomy of vascular development (in many timeless analyses that bear rediscovery by present-day investigators), the first investigators in this field participated in one of the classic debates in all of developmental biology: Where and when do endothelial cells (ECs) – and hence blood vessels – arise in the developing embryo? Because blood vessels are first observed

in the yolk sac in avian and mammalian embryos, initially it was assumed that all blood vessels arise from extraembryonic tissues. However, careful histologic analysis subsequently indicated that isolated foci of ECs also can be observed in the embryo proper, which suggested that blood vessels arise from an intraembryonic source (specifically, the mesoderm) rather than via colonization (1,2). The latter model has been successively reconfirmed by increasingly sophisticated approaches to isolate and track blood vessel development in mammalian systems.

In addition to taking advantage of advances in cell biology, and subsequently in the rich tools of the molecular biology revolution, several fundamental approaches have greatly accelerated the understanding of endothelial differentiation and vascular development. Techniques to culture embryos *in vitro* and to perform fate mapping with viruses and dyes have markedly simplified the discovery of antecedent–decendent relationships within vascular cell lineages. The ability to manipulate the mouse genome via homologous recombination has facilitated reverse genetic approaches for understanding the role of specific genes and pathways in vascular development. Simultaneously, high-throughput phenotype-driven genetic approaches in mammalian systems have permitted the identification of unanticipated molecular participants in vascular developmental pathways. Finally, the ability to manipulate embryonic stem cells in culture and to differentiate these cells down the endothelial lineage has served as a powerful tool for recapitulating the developmental process in a refined and controlled situation. These and many other approaches are the tools for discovery that have led to the understanding of endothelial development described in the remaining sections of this chapter.

## GASTRULATION AND POSTGASTRULATION EVENTS

Although considerable debate has arisen about what is a surprisingly elusive question, it is now generally accepted that the

Figure 20.1. Blood islands. Blood islands are foci of loose hematopoietic (Hp) and adjacent endothelial (En) precursors forming a thin lumen. These structures represent the initial morphological characteristic of vascular development in extraembryonic tissues in mammals.

mesoderm is the exclusive source of EC progenitors. Although efforts have been made to identify specific loci within the mesoderm that preferentially specify endothelial fates, it seems clear that precursors to endothelium arise within all intraembryonic mesoderm, with the exception of the notochord and prechordal plate (3), as loose aggregations of cells bearing early markers of the endothelial lineage and with the potential to coalesce into vascular cords.

The signals for angioblast induction are not entirely clear, but data support roles for members of the fibroblast growth factor (FGF) and bone morphogenetic protein (BMP) families in this inductive process. The initiation of vascular differentiation within the embryo occurs in opposition to endoderm, which suggests that endoderm-derived signals are required for angioblast commitment within mesoderm. Indian hedgehog is appropriately expressed in a spatial and temporal pattern within the endoderm to fulfill this role, and is required for normal vascular development (4). However, recent evidence suggests that angioblast commitment is not totally dependent on endoderm-derived signals, although later morphogenetic steps in vascular development may require endoderm-mesoderm interactions (5).

The pluripotency of vascular precursors also has been a vexing issue within the field. The close colocalization of endothelial and hematopoietic precursors (so-called “blood islands,” Figure 20.1) within the embryo has been recognized since early in the twentieth century (6). This raised the possibility that both lineages arise from a common precursor, the hemangioblast. Subsequent studies have indicated that both lineages bear certain common molecular markers, and cells with the potential to produce either lineage have been isolated from differentiating mouse embryoid bodies. The pluripotency of these putative hemangioblasts has not been completely characterized, although some data support the possibil-

ity that these multipotent cells also may assume characteristics of the smooth muscle lineage under appropriate inductive conditioning (7). It also does not seem likely that hemangioblast identity is a required step for all endothelial development and, in fact, the direct differentiation of angioblasts from mesoderm is also a well-supported phenomenon. The teleological rationale for direct endothelial differentiation from mesoderm under some circumstances, rather than passage through a hemangioblast intermediary stage, is not necessarily clear, but the direct differentiation of ECs appears to occur primarily within somites (8).

In spite of data supporting the existence of the hemangioblast, definitive isolation of these cells and localization within the developing embryo has been an extraordinary challenge. However, recent evidence indicates that cells with hemangioblast properties are present transiently in the posterior segment of the primitive streak during gastrulation and are defined by the coexpression of the vascular endothelial growth factor (VEGF) receptor FLK-1 and the mesodermal T-box gene brachyury (9). These data also suggest that the endothelial and hematopoietic fates of embryonic cells are established prior to the appearance of blood islands during development. In fact, some data suggest that the hemangioblast lineage may be committed prior to gastrulation within the epiblast (9).

## EXTRAEMBRYONIC VASCULOGENESIS

Blood vessel formation classically is divided into two categories. *Vasculogenesis* refers to the in situ differentiation of ECs to form blood vessels, with or without associated angioblast migration. In contrast, *angiogenesis* refers to the formation of new blood vessels via extension or remodeling of existing blood vessels. Angiogenesis occurs throughout development and in adulthood, whereas vasculogenesis generally is thought to occur during a limited period early in embryonic development. (The term *vasculogenesis* is occasionally used to refer to the development of blood vessels during adulthood, especially when associated with circulating vascular progenitor cells. This is an inappropriate use of this term based on its natural definition.) Vasculogenesis is further subdivided depending on whether it occurs within the extraembryonic or intraembryonic compartments. The best available evidence suggests that these two waves of vasculogenesis are temporally and spatially distinct, and molecular studies indicate that they are also partially distinct at the mechanistic level.

Extraembryonic vasculogenesis precedes intraembryonic vascular development, and, in most mammals, is first apparent as blood islands assembling within the mesodermal layer of the yolk sac. (It is important to note that not all species have yolk sac blood islands; for example, teleosts have similar structures that appear in the intermediate cell mass that arises during gastrulation. This suggests that extraembryonic vasculogenesis is an evolutionarily late adaptation in blood vessel development.) Blood islands are foci of hemangioblasts that

differentiate in situ, forming a loose inner mass of embryonic hematopoietic precursors and an outer luminal layer of angioblasts. Blood islands eventually coalesce into a functional vascular network that constitutes the vitelline circulation, which is adapted to transfer nutrients from the yolk sac to the embryo proper. Recent evidence indicates that extraembryonic blood vessels also may arise independently of blood islands via the direct differentiation of angioblasts from mesoderm (10). Vessels arising via yolk sac vasculogenesis communicate with the fetal circulation via the vitelline vein, but otherwise do not contribute to intraembryonic vasculature. Likewise, embryonic hematopoiesis arising within the yolk sac is eventually replaced by blood cell populations derived from definitive intraembryonic hematopoietic differentiation within the spleen, liver, and, ultimately, the bone marrow. Establishment of the extraembryonic circulation is particularly dependent on transforming growth factor (TGF)- $\beta$  signaling, which is required for matrix assembly, vascular remodeling, and coordinated hematopoietic differentiation within the yolk sac (11).

**INTRAEMBRYONIC VASCULOGENESIS**

Intraembryonic vasculogenesis initiates within the para-aortic mesoderm (the aorta-gonad-mesonephros or AGM region) (Figure 20.2) and the allantois, and gives rise to the dorsal aortae and the cardinal veins. (The para-aortic mesoderm is analogous to the lateral plate mesoderm in *Xenopus* and zebrafish systems.) The endocardium originates in mammals from clusters of migrating angioblasts derived from presomitic cranial mesoderm that enter the pericardial area to form a vascular plexus adjacent to the developing myocardium. This plexus undergoes remodeling to form the endocardial tube, which is the first intraembryonic vasculogenic event in the mammalian embryo (10). The development of the aorta follows the endocardium from a distinct subset of angioblasts derived from the AGM region that assemble into a primary vascular network. This network remodels in a bidirectional fashion to generate the bilateral embryonic aortae (10). The AGM also seems to be the major site for the initiation of intraembryonic hematopoiesis (12). Convincing evidence indicates that the allantois also contains dispersed precursors that differentiate and assemble in situ to form the allantoic vasculature shortly after the aortae are assembled (13).

Subsequent waves of intraembryonic vascular development occur primarily via angiogenesis. However, some endoderm-derived organs are capable of supporting vasculogenesis. This appears to be due in part to signals derived from undifferentiated endoderm that support angioblast differentiation from adjacent mesoderm. Remarkably, the developing vasculature in turn provides signals that are necessary for endodermal organogenesis (14) (see Chapter 22), which indicates that a rich interplay exists between endoderm-derived organs and their vasculature during the developmental process. As a corollary of this general mechanism, ectodermally

Figure 20.2. The AGM region. (A) Diagram of an E9.5 mouse embryo with a line indicating the location of subsequent sections. (B) A section at the indicated level with arrows indicating the AGM regions. (C) A high-magnification view showing the AGM (arrows) in relationship to the dorsal aorta (da) and neural tube (nt).

derived organs such as the brain are strictly dependent on angiogenesis for vascularization.

**DEVELOPMENTAL ANGIOGENESIS**

Beyond the vascular beds described above, the majority of vascular development occurs via the process of angiogenesis – the growth of new blood vessels from existing vessels. Anatomically, angiogenesis occurs via at least two mechanisms. *Sprouting*

*angiogenesis* is the classical mechanism, and involves the invasion of new capillaries into unvascularized tissue from an existing mature vasculature. Sprouting requires coordinated degradation of matrix proteins via the secretion and activation of matrix metalloproteinases, detachment and migration of ECs from the mature vessel into the avascular tissue, and proliferation of ECs at the leading edge of the extending vessel. Eventually, communications must be established between ECs in adjacent vessels for flow to be established, although the mechanisms by which this occurs are incompletely understood. Sprouting angiogenesis generally is activated in response to a gradient of growth factors. This method is the predominant mechanism for the vascularization of organs that lack the ability to develop vessels via vasculogenesis.

A second, less intuitive mechanism for vessel development is referred to as *intussusceptive* (or nonsprouting) *angiogenesis*. Intussusception involves the remodeling of existing vessels in such a way that a vessel enlarges, pinches inward, and eventually splits into two vessels that are invaded by pericytes and matrix to add stability. This awkward process is actually a complicated ritual of cellular rearrangement that requires flow-dependent signaling, alterations of cell–cell interactions, and rearrangements of blood flow. Intussusceptive angiogenesis is a versatile mechanism for new vessel development in organs that undergo extensive branching morphogenesis, presumably because rearrangements of vascular structure are obligatory. Intussusceptive angiogenesis plays a role in both early capillarization and in network remodeling and the formation of larger vessels in the embryo (15).

## MOLECULAR MECHANISMS

The anatomic basis for vascular development in the embryo has been clarified through studies that have been performed over the past century. In contrast, the molecular underpinnings for EC differentiation have become clear only in the last decade. In this section, we review briefly the interrelationships among some of the key steps in endothelial differentiation. Many of the signaling and transcriptional events that regulate endothelial differentiation are characterized in detail in other chapters of this anthology, and the reader will find more detail about individual pathways in these chapters.

Key to any inductive process in the embryo is the elaboration of signals that are integrated to mark the initiation of a developmental cascade. In the case of early events in endothelial differentiation, these cues must determine the spatial and temporal appearance of hemangioblasts from undifferentiated mesoderm, and also the further maturation and assembly of these precursors into nascent blood vessels. Of the well-defined signaling pathways, the best data indicate that crucial roles exist for members of the FGF and BMP families as proximal inductive cues for the hematovascular lineage. Remarkably, less is known about the roles for these families in the vascular development in zebrafish (Chapter 19), which raises the possibility that they play a greater role in mammalian vascu-

lar development than they do in teleosts, although no data are available to exclude a role for these proteins in zebrafish. FGFs appear to be key components required for hematovascular differentiation in differentiating embryonic stem cells (16). BMPs and their receptors within the BMP2/4 series have critical roles in early vascular development, as indicated by gene deletion experiments and by the potent effect of the endogenous endothelial BMP inhibitor BMPER in suppressing endothelial differentiation (17). In addition, Indian hedgehog is implicated as an endoderm-derived signal for vascular competence (4). However, remarkably little is known about how these upstream factors interact to specify vascular identity of precursors. In addition, none of these signals has specificity for the vascular lineage.

The first secreted molecule with specificity for the endothelium during the developmental cascade is VEGF, and the role of VEGF family members in developmental and adult angiogenesis is well-described. Cells that respond to VEGF must first express its receptors, FLK-1 and FLT-1 (VEGFR2 and VEGFR1), which are exquisitely restricted to the endothelial and early hematopoietic lineages. This indicates that VEGF cannot itself be the most proximal signal for endothelial differentiation, and it is still not clear precisely how early VEGF participates in vascular specification. Nevertheless, the impressive phenotype of mice lacking a single copy of the *VEGF* gene – which die in utero soon after vascular development initiates – indicates the critically necessary role of this signaling pathway (18).

The appearance of FLK-1 expression is presently recognized as the earliest marker available for the endothelial lineage during development; FLK-1 is expressed in earliest endothelial and hematopoietic cells and remains expressed in mature endothelium. It is, however, downregulated within the hematopoietic lineages as they mature. This pattern suggests that Flk1 may be a marker for hemangioblasts during early development, and this is borne out by studies that indicate that the coexpression of FLK-1 with mesoderm-derived transcription factors brachyury or *Scl/Tal1* denotes hemangioblasts (9,10). It is also important to note that, because FLK-1 marks angioblasts and mature ECs, it cannot be used solely to distinguish endothelial precursors or hemangioblasts at any stage of development. Nevertheless, upstream cues that initiate FLK-1 expression would be likely participants in early specification of the vascular lineage. Evidence supports BMP signaling as a proximal stimulus for FLK-1 expression and, at the transcriptional level, there appears to be necessary roles for GATA family proteins as well as the homeodomain protein HoxB5 in upregulation of FLK-1 during development (19,20). Nevertheless, an entire transcriptional program of the endothelial lineage has not been established, and this represents a major limitation in our understanding of how cell-autonomous mechanisms coordinate the development of vascular cell lineages.

Downstream of the early events, the cues required for blood vessels to form become better known, if also more complex. Among paracrine factors, the angiopoietin family members bind to receptors structurally similar to the VEGF

receptors and play crucial roles in EC survival and remodeling of capillary plexi, platelet-derived growth factors are required for the recruitment of pericytes and smooth muscle cells to invest developing arteries and establish vasomotor tone, and ephrins and their counter-receptors (Ephs) are required for arteriovenous communications. The specific molecular roles of each of these signaling pathways is discussed in detail in chapters devoted to these topics.

Likewise, much is known about downstream transcriptional events that participate in vascular assembly. These transcription factors include vascular endothelial zinc finger, GATA-2, several members of the Krüppel-like family of zinc finger proteins, and Ets proteins, all of which have all been linked to steps in angiogenesis by virtue of their cellular phenotypes of defined transcriptional targets. Homeodomain proteins such as HoxB3 and HoxD3 participate in morphogenetic events responsible for vascular tube formation. The transcription factor hypoxia-inducible factor 1 $\alpha$  and its family members play crucial roles in sensing changes in tissue oxygen (O<sub>2</sub>) tension and stimulating gene expression changes that enhance blood vessel growth into hypoxic tissues during postgastrulation development (when the passive diffusion of O<sub>2</sub> and nutrients becomes limiting due to the size of the embryo) as well as in pathological angiogenesis. The specific roles of each of these transcriptional events also are described in respective chapters. Remarkably, we have a much less well-informed understanding of the transcriptional cascades that determine the programs of development and plasticity of ECs and other vascular lineages than we do of, for example, cardiomyocytes or skeletal muscle cells. This may be due to the fact that greater heterogeneity and plasticity exists among vascular cells, making impractical the relatively simple mechanisms that are responsible for determining other lineages. Nevertheless, future effort will be needed to clarify those transcriptional hierarchies that culminate in blood vessel formation.

## CONCLUSION

The experimental database that we use to understand endothelial differentiation and vascular development is exceptionally rich and draws on approaches that range from the imaginatively observational to the rigorously inductive. A number of key controversies in developmental biology have concerned the origin of ECs and the means by which blood vessels are assembled. It has become obvious during the past decade that many of the principles of blood vessel development also apply to the assembly and disassembly of blood vessels in the adult, particularly in pathological circumstances. A notable example of this is the well-defined role for VEGF and its receptors in both developmental and pathological angiogenesis (21,22). Activators and inhibitors of developmental pathways have been tested for their ability to modulate angiogenesis in early-phase clinical trials and, in the case of anti-Flk1 antibodies, clinical utility has been demonstrated for antitumor strategies.

Likewise, the explosion of interest in stem cell biology and the potential for regenerative medicine have caused many to reconsider the utility of understanding vascular developmental events, with the notion that many of the pathways identified may be recapitulated in adult stem cells as they are coaxed toward the vascular lineage. Analyses of circulating endothelial progenitor cells, which have angiogenic potential, do indeed suggest that similarities exist in the biology of these cells compared with developmental endothelial precursors. Stem cell therapeutics therefore represents another potential arena for the translation of insights from vascular development to clinical practice.

Even though our understanding of endothelial development is much richer than it was even a few years ago, and despite the potential applications of this knowledge in clinical medicine, a number of key issues on this topic still remain to be resolved. Precisely how early are endothelial precursors specified during development, and what is the nature of this progenitor cell pool? What are the relationships among signaling pathways that specify endothelial fates in a coordinated fashion? Is there a transcriptional hierarchy that regulates vascular development? The answers to these and other questions about endothelial development are likely to be forthcoming in the near future as experimental methods continue to evolve.

## KEY POINTS

- Endothelial differentiation during embryonic development is tightly coordinated via spatial considerations, and is regulated through the interplay of diverse signaling and transcriptional cascades to effect the appropriate formation of the vasculature.
- The vascular endothelium arises from mesodermal precursors.
- Endothelial differentiation is tightly linked to the development of the hematopoietic system and to the differentiation of other vascular lineages.
- Developmental pathways are recapitulated in angiogenic processes in adulthood.

## Future Goals

- To elucidate a transcriptional hierarchy of endothelial differentiation
- To apply knowledge of vascular development to understand congenital disorders of the vasculature and to modulate angiogenic processes that recur during adulthood

## ACKNOWLEDGMENTS

## Fate Mapping

---

Takashi Mikawa

*Cornell University Medical College, New York, New York*

Endothelial cell (EC) precursors, termed *angioblasts*, form primitive vascular plexuses *de novo*, a process termed *vasculogenesis* (1–3). Cells of the primitive vascular plexus further differentiate into arterial, venous, endocardial, and lymphatic ECs. New vessels also sprout out from the existing vessels via *angiogenesis*. Angioblasts are highly migratory, often originating far from their destination (1,3). By tracking the migratory patterns and lineage specification of EC precursors, the mechanisms involved in EC commitment and diversity can be defined more precisely. The fate maps of groups of cells provide clues regarding the tissue–tissue interactions involved in EC differentiation and vessel development. Single-cell labeling and tracing can determine the specific timing and site of lineage segregation. This chapter describes the ontogeny of cardiac and noncardiac ECs as revealed by genetic and nongenetic fate mapping and lineage analysis.

### CELL TAGGING METHODS

Successful fate mapping or lineage analysis depends on a reliable cell tagging method that allows researchers to label a defined group of cells and to restrict the labeling to its progeny without dilution or horizontal spread. Several methods of genetic and nongenetic cell labeling have been developed.

#### Nongenetic Approaches

Labeling with a lipophilic fluorescent dye, such as DiI (1,1'-dioctadecyl-3,3,3',3'-tetramethyl-indocarbocyanine · perchlorate), is a widely used nongenetic cell labeling method for fate mapping studies (4,5). DiI stably integrates into cell membranes and generates a high fluorescent signal, but exhibits little diffusion to adjacent cells and insignificant cell toxicity. Because of their stable integration into the cell membrane, lipophilic dyes are passed mainly to the progeny of the labeled parental cells. The injection of fluoroprobe-conjugated dextran particles into a cell is another nongenetic cell tagging method best suited for tagging a large cell such as a frog blas-

tomere (6). Laser-assisted activation of a caged fluorescent dye in a single cell or a group of cells is another nongenetic option (7). This approach is suitable for fate mapping and cell lineage studies within a few cell layers of the embryonic surface, and is particularly powerful in zebrafish (*Danio rerio*) and *Caenorhabditis elegans* embryos. These methods allow us to trace migration patterns and/or morphogenetic movements of fluorescently labeled cells and to determine the cell types generated by the differentiation of a tagged cell population during a given developmental window. Obvious limitations of these approaches include: (a) physical accessibility of cells of interest; (b) the potential uptake of a dye by nonlabeled cells via cell fusion or phagocytosis; and (c) the exponential drop in the concentration of dye per cell as cells proliferate.

#### Genetic Cell Labeling Methods

The long-term tracing of cell fate requires a stable tag in all daughter cells of the originally labeled parental cell(s) without dilution by cell proliferation. Cell transplantation from a donor tissue carrying a recognizable trait to a host is often used in amphibian and avian embryos (8,9). Host cells are replaced with donor cells from an identical region of stage-matched embryos; the implanted donor cells are expected to follow the same developmental program in the host embryo. *Xenopus* chimeras are suitable for fate mapping of individual blastomeric cells (9). The chick–quail chimera approach often is used for fate mapping studies on a group of cells during and after gastrulation. Mouse chimeras also can be generated by mixing blastodermal cells from two strains carrying distinct traits (10). A broad range of mosaicism can be achieved simply by altering the ratio of cells from each strain. It is currently difficult, however, to control the position of transplanted cells either in the mouse blastocyst or inner cell mass, which is critical for fate-mapping studies. The use of chimeras requires skill in microsurgical techniques, and thus is not available to all researchers.

A number of methods also have been developed to introduce a genetic tag to a target cell population. These include the introduction of an exogenous tracer gene via microinjection,

electroporation, or viral-mediated gene transfer, and the activation of tracer gene expression via Cre-lox knockin or random mutation. The direct introduction of an expression vector plasmid DNA encoding a tracer such as bacterial  $\beta$ -galactosidase ( $\beta$ -gal) or green fluorescence protein (GFP) frequently is used in *Xenopus laevis*, in which individual cells are accessible and large in size (11). This method is suited for short-term cell-fate tracing, because most injected plasmid DNAs remain as an episome without integrating into the host genome. This results in an uneven distribution between daughter cells, and the tracer gene often is lost in some daughter cells as cells proliferate.

A Cre-lox approach is based on a recombination induced by Cre recombinase through which constitutive expression of a tracer gene, such as  $\beta$ -gal or GFP, is turned on and remains on in all daughter cells (12). The success of the Cre-lox strategies for fate mapping depends on the availability of a promoter that is active within a specific cell population only briefly and at a specific time during embryogenesis. Intragenic recombination is another approach developed for retrospective clonal analysis in the mouse embryo (13,14). This approach requires a mouse line that carries a tandem duplication of a reporter gene driven by a tissue-specific promoter. The reporter protein is produced only when an intragenic recombination takes place. Because intragenic recombination is a rare event, cells positive for reporter expression are likely to be clonally related. Because it relies on a tissue-specific promoter, this method is not suited for the study of cell lineage diversification. The growth rate of a clonal population cannot be precisely studied by this method, because an intragenic recombination can occur long before cells become permissive for the promoter function.

Replication-defective retroviruses and adenoviruses have been developed to trace cell fate and lineage (15–18). In both cases, the virus is engineered to encode a reporter gene that replaces the genes necessary for viral replication; as a result, the reporter gene is inherited only by progeny of the originally infected cells without horizontal spread. Adenoviral vectors can infect cells regardless of their proliferative state, but the

copy number of the introduced gene cannot be controlled and may provide drastically different levels of marker expression. Because the adenoviral DNA remains as a linear episome in a host cell, the gene often is not stable and is exponentially diluted over time by subsequent cell divisions. Thus, the adenoviral approach is suited for a short-term cell tracing but not for long-term lineage studies. In contrast, a retrovirus-mediated gene transfer assures the stable integration of a single copy of the reporter gene into the host DNA. However, because the integration process requires a host-cell division, the retroviral approach is applicable to dividing cells, but not postmitotic cells. The stable integration of retrovirally introduced genes makes retroviral gene delivery ideal for long-term lineage studies, because marker expression does not decline over time. Retroviruses have been the major tool used in the study of EC lineage in birds and mammals.

## ORIGIN OF CARDIAC ENDOTHELIAL CELLS

Four EC types are present in the heart: endocardial, coronary arterial, venous, and capillary. Endocardial ECs exhibit phenotypes distinct from coronary ECs. They form an epithelial tube with a large diameter but never undergo angiogenic sprouting into the myocardium, whereas coronary ECs establish a complex but typical vessel network throughout the myocardium. Despite close proximity, subendocardial coronary vessels do not fuse with the endocardium or open to the heart chamber. Although the exact mechanism that confers these distinct phenotypes to endocardial and coronary ECs is not known, a series of retroviral cell lineage studies in the chick embryos have identified distinct ontogenies for these two cardiac EC populations.

### Origin of Endocardial Endothelial Cells

The heart begins to function before any other organ system is established during embryogenesis (Figure 21.1). Fate

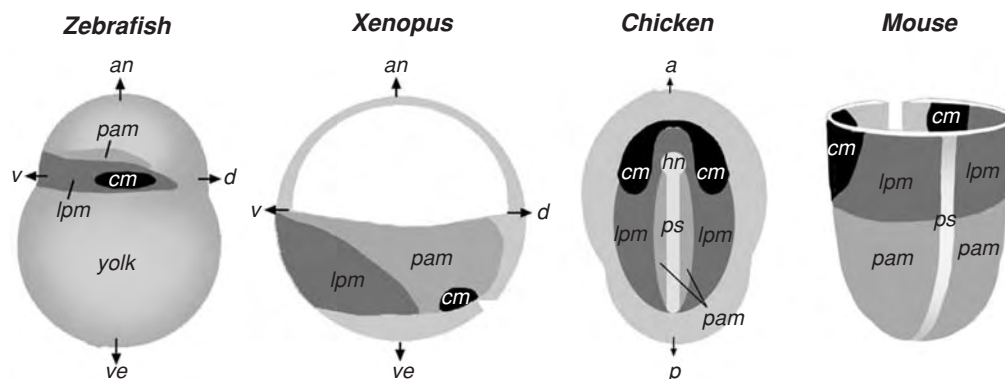

Figure 21.1. Schematic illustration of fate maps of progenitor cells for cardiogenic mesoderm (cm, black) in various vertebrate species. The relative position of the cardiogenic mesoderm progenitor to paraxial mesoderm (pam, light gray) and lateral plate mesoderm (lpm, dark gray) is illustrated. an-ve, the animal-vegetal axis; v-d, the ventral-dorsal axis; a-p, the anterior-posterior axis; ps, the primitive streak.

map studies in chick embryos during early gastrulation have revealed that endocardial and cardiomyocyte precursors both arise from a rostral portion of the primitive streak (19). As gastrulation begins, they migrate rostrolaterally, forming bilateral heart fields called cardiogenic mesoderm (20–21). During the lateral body fold, the bilateral cardiac fields fuse at the ventral midline of neurula-stage embryos and form a single tubular heart that soon begins to beat (22). During this fusion process, the majority of cardiogenic cells differentiate into the presumptive myocardium, while a minor population segregates from the original epithelioid myocardium and forms the presumptive endocardium via a vasculogenic mechanism (22, 23). Thus, both cardiomyocyte and endocardial EC lineages arise from the cardiogenic mesoderm.

The induction of these two cardiac cell types in the heart field mesoderm requires paracrine factors secreted by the underlying endoderm (24). Cardiomyocyte-specific gene expression can be induced by endoderm-derived paracrine factors such as fibroblast growth factors (FGFs), bone morphogenic proteins, insulin-like growth factor, and activin (25–28), whereas EC differentiation is promoted by angiogenic peptides, such as vascular endothelial growth factor (VEGF) and FGFs (29,30). It was once postulated that cells of the cardiogenic field are bipotent progenitor cells that differentiate into both cardiomyocytes and endocardial cells, based on expression patterns of myocardial and endocardial cell markers in cardiogenic mesoderm (23) and an immortalized myogenic cell line (31). However, because these signaling molecules are expressed broadly in the underlying endoderm, the bipotent progenitor model does not explain how they instruct individual cells of the heart-field mesoderm to enter either the cardiomyocyte lineage or the endocardial cell lineage. It is also unclear how more myocardial cells than endocardial cells are generated from the cardiogenic mesoderm.

To clarify these issues, the fate of individual cells within the primitive streak and the heart-field mesoderm has been studied in the chicken embryo using the retroviral single-cell tagging and tracing method. The retroviral cell lineage studies have demonstrated that individual cells in the rostral half of the primitive streak and those in the heart field give rise to a clone consisting only of one cell type, either endocardial or myocardial (32–34). These data support a model in which these two cell lineages of the heart are segregated already within the primitive streak, significantly prior to their migration to the heart field. It is likely that the precardiomyocytes and pre-endocardial cells already may be receptive to inductive signal(s) from underlying endoderm. Consistent with this model, it has been suggested that EC commitment may occur before and independent of gastrulation, whereas myocyte commitment has not yet occurred at the prestreak stage (35). Cell fate studies in zebrafish also have identified a blastomere population that produces only endocardial or myocardial cells (36). These studies in both fish and avian embryos indicate that the separation of these two lineages can occur at the blastula stage, prior to formation of mesoderm. In the mouse embryo, it is known that endocardial and myocardial cells also arise

from bilateral clusters of distal epiblast cells (37), but it remains unknown when these two cardiac cell lineages are established.

### Origin of Coronary Vascular Endothelial Cells

Coronary vessels are originally absent from the presumptive heart tube but develop as the myocardium becomes thickened (38). Although the coronary vessel network was once thought to be established by angiogenic sprouting from the aorta (39–42), this model did not explain the presence of discontinuous EC channels in the myocardium prior to the establishment of a closed coronary vessel network (43,44). A clear understanding of the embryonic origin of coronary vasculature is critical to address the mechanism of coronary vessel formation. Chick–quail chimera studies have shown that smooth muscle cells of the great vessel arise from a subset of ectoderm-derived neural crest cells termed *cardiac neural crest*. This finding raised the possibility that the coronary arteries originated from neural crest derivatives. Another possibility was that they arose from the heart-field mesoderm, as do the myocardium and endocardium. However, retroviral labeling of cardiac neural crest or the heart tube never gave rise to tagged cells within the coronary system (32,45,46).

In addition to cardiac neural crest, another cell population migrates to the heart. The mesoderm-derived proepicardium (47,48) is a transient embryonic tissue located at the septum transversum. Proepicardial cells form multiple epithelial cell villi that protrude toward the myocardium of the looping-stage heart and that, once attached to the heart, begin to envelop the myocardium, forming the epicardium. The retroviral tagging of proepicardial cells produces either virally tagged cardiac fibroblasts or coronary vessels containing tagged endothelial and smooth muscle cells (45,46). These studies have provided direct proof for the proepicardial origin of coronary vasculature, including its ECs. This conclusion has been further confirmed using both adenoviral tagging (18) and chick–quail chimera analysis of the proepicardium (49,50). Importantly, individual virally labeled clones contain only one cell type, either ECs, smooth muscle, or fibroblasts, suggesting these lineages are already determined within the proepicardium. Regardless of the cell type of the clone, each clone occupies only a segment of a coronary vessel, and in no case does it populate the entire length of a vessel (45,46). The data have provided the experimental proof that the coronary vasculature arises from the proepicardium and forms via a vasculogenic mechanism (51).

### ORIGIN OF NONCARDIAC ENDOTHELIAL CELLS

The embryonic vasculature was originally thought to form by the invasion of the embryo by extraembryonic blood vessels (52,53). This model was challenged by the finding that vascular development occurs in embryos from which the extraembryonic tissue has been ablated prior to blood vessel

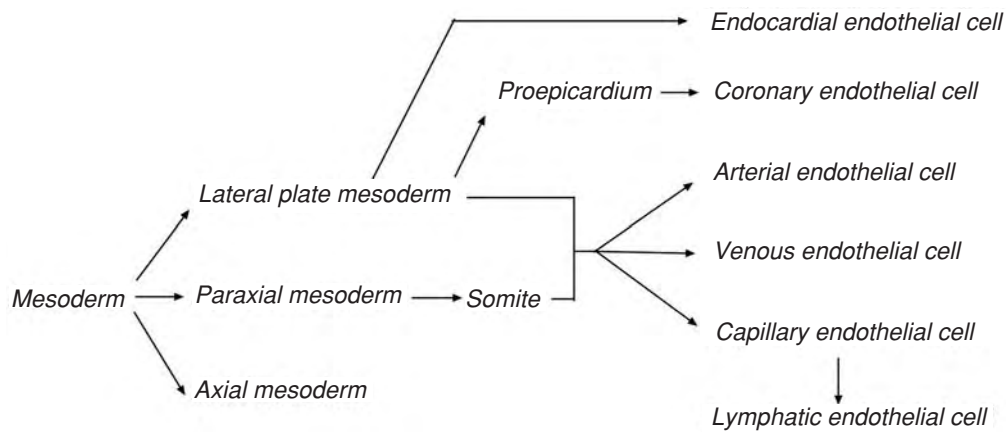

Figure 21.2. Lineage relationships between multiple EC types generated from mesoderm. As three germ layers form via gastrulation, endocardial ECs differentiate from the cardiogenic mesoderm, while noncardiac arterial, venous, and capillary ECs are generated from the lateral plate and somatic mesoderm. Coronary vasculature, including ECs, differentiates from a distinct mesodermal tissue, the proepicardium. Lymphatic ECs appear to differentiate from capillary or venous ECs during budding off.

formation (54). Thus, the embryonic germ layers are sufficient for producing embryonic vasculature (Figure 21.2). Further studies have established that, of three germ layers, only the mesoderm gives rise to ECs (1). In the avian embryo, it has been demonstrated that all mesoderm, with the exception of prechordal mesoderm, has the potential to produce angioblasts (55,56).

Fate mapping studies in zebrafish suggest that EC populations may be committed to a vessel-type fate within the lateral plate mesoderm before vascular assembly (57): Laser-assisted labeling of single angioblasts with a caged dye in zebrafish embryos has shown that individually labeled ECs were found in either arterial or venous vascular beds. On the contrary, data from the avian embryo suggest that the arterial or venous identity is determined only on recruitment into the vascular network by local environmental cue(s). For example, donor quail venous ECs can incorporate into the arteries of the host chick embryo and express an arterial marker, ephrinB2 (58,59). Conversely, donor arterial ECs can incorporate into the veins of host embryos and downregulate ephrinB2.

In contrast to extensive studies of vascular EC origins, the ontogeny of the lymphatic EC has been examined only recently. It was once thought that the lymphatic system of the forelimbs develops through the sprouting of the jugulo-axillary lymph sacs into the limb buds (60). However, recent studies using markers for the lymphatic endothelia have detected lymphangioblasts in the wing buds 1 day prior to the formation of the jugulo-axillary lymph sacs (61). Currently, it is thought that a local budding from existing capillary or venous network is the key event in initiating lymphatic vessel formation. It has further been shown that dorsal somatic cells at the wing bud level migrate into the limb and differentiate into lymphatic endothelia (62) in a process similar to how the vascular ECs of wing blood vessels arise from somatic mesoderm (63).

#### KEY POINTS

- Fate mapping and single cell lineage studies have identified both the timing and location of vascular cell commitment and differentiation.
- The cell fate mapping and lineage data have provided clues for defining cell–cell and molecular interactions that regulate EC differentiation and diversity.
- Cell lineage studies of cardiac ECs have led to new questions regarding the induction and patterning of endocardial and coronary EC populations
- Understanding the mechanisms that govern these processes will substantially further our understanding of vascular system development and patterning during embryogenesis.

#### Future Goals

- To understand how are endocardial precursors specified within the cardiogenic mesoderm, while exposed to the same signals as cardiomyocyte precursors
- To understand how is the proepicardium, the source of coronary vasculature, induced at a specific embryonic site
- To understand what mechanisms govern the oriented migration of coronary progenitors from the proepicardium to the looping-stage heart
- To understand what cell–cell and molecular interactions are responsible for patterning of the coronary endothelia and the establishment of a connection with the proximal aorta

- To understand the degree of EC plasticity to their arterial, venous, capillary, or lymphatic identities in the embryonic heart

## Pancreas and Liver

### Mutual Signaling during Vascularized Tissue Formation

---

Eckhard Lammert

*Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany*

The cardiovascular system is the first functional organ system to develop in the mammalian embryo. Early during development, it consists mainly of vascular endothelial cells (ECs), which form tubes connected with the heart. Later in development, these vascular tubes develop and branch into a more complex tubular system with a variety of tissue-specific properties. Some of these vascular properties develop when ECs receive signals such as growth factors from surrounding non-vascular tissue cells.

Because blood vessels are present in the embryo at the onset of organogenesis, it is reasonable to expect that they shape the development of organ tissues. Indeed, the pancreas and liver consist of tissues whose features are shaped by signals derived from vascular ECs.

The fact that tissue cells are modulated by signals from ECs and that, in turn, EC phenotypes are influenced by tissue-derived signals, suggests that the development of vascularized tissues is critically dependent on mutual signaling. This mutual signaling results in structural and functional coupling between tissues and their respective vascular beds.

#### THE PRINCIPLE OF MUTUAL SIGNALING

The dorsal aorta is the first intraembryonic artery to form in vertebrates. Despite some differences between vertebrate species, the aorta normally develops through migration of angioblasts from the lateral plate mesoderm towards the midline of the embryo and subsequent formation of a vascular tube connected with the heart. The venous blood vessels, such as the cardinal veins, develop at around the same time and, together with heart and aorta, form the first circulatory system within the embryo. In mammals, additional blood vessels are present, such as those needed to connect embryonic and maternal circulations.

After formation of the primitive circulatory system, blood vessels begin to sprout, thus increasing the complexity of the vasculature. During this time, inner organs start to develop

(1). The liver bud forms at the onset of blood circulation, and the pancreas starts to develop shortly thereafter. Other inner organs such as the lung and kidney similarly form during the formation of the primitive vascular plexus.

In mammalian models, a developmental blockade of the circulatory system leads to embryonic lethality (2,3). In general, the stronger the defect in the circulatory system, the earlier the embryo is aborted. In contrast to mammals, fish embryos may meet their oxygen ( $O_2$ ) needs through simple diffusion and can develop much further in the absence of a circulatory system (4). Thus, the prevailing view is that blood circulation is important during development insofar as it is required to supply the bulk flow delivery of  $O_2$  and nutrients. However, in mouse and frog, defective tissue development can be observed, when ECs are absent, even before blood flow takes place (5,6). These observations suggest that the vascular system is critical not only for delivering  $O_2$  and nutrients to tissues, but also for providing EC-derived cues necessary for tissue development (Table 22-1). It is noteworthy that this EC requirement for early tissue development might not exist in fish (7).

It has long been recognized that mutual signaling between blood vessels and tissues plays a critical role in optimizing  $O_2$  supply and demand. In brief, a reduction in tissue oxygenation induces the production of hypoxia-responsive angiogenic signals, such as the vascular endothelial growth factor (VEGF)-A, in tissues. VEGF-A binds to its signaling receptor VEGF receptor 2 (VEGFR2) on vascular ECs and thereby initiates a variety of different responses, the outcome of which is the growth of blood vessels (hence,  $O_2$  delivery) into the hypoxic tissue. Once the tissue is adequately oxygenated, VEGF-A levels return to baseline, and new blood vessel formation ceases (8).

This model of mutual signaling is oversimplified, because some tissues express high basal levels of VEGF-A despite adequate oxygenation and in the absence of neoangiogenesis (9,10). These limitations notwithstanding, the above example demonstrates the importance of bidirectional crosstalk and provides a rationale for therapeutic intervention. For example, the finding that tumor growth depends on a vascular supply

**Table 22-1: Endothelial Signals and Responding Tissue Cells**

<i>Endothelial Signals</i>	<i>Responding Tissue Cells</i>	<i>Developmental Change in the Tissue Cells</i>
BMPs	Neural crest cells	Autonomic neuronal differentiation
BDNF	Neurons	Neuronal cell survival
TGF- $\beta$	Mesenchymal cells	Mural cell specification
PDGF- $\beta$	Mural cells	Chemoattraction
FGFs	Pericytes	Cell proliferation
HGF	Hepatocytes	Hepatocyte proliferation
MMPs	Podocytes	Glomerular assembly
Jagged-1	Podocytes	Glomerular epithelium formation

represents the foundation for antiangiogenic therapy in cancer (11). An important obstacle in the field of tissue engineering is the limited growth potential of grafts that lack a vascular supply. Indeed, an urgent goal is to develop strategies that promote the vascularization of tissue implants.

In addition to matching O<sub>2</sub> supply and demand, it is clear that mutual signaling is involved in many other aspects of tissue development (Figure 22.1). In one direction, vascular ECs provide the developmental signals required for morphogenesis, differentiation, and growth of embryonic tissues (Figure 22.2). In the other direction, cues from the microenvironment play a critical role in mediating EC phenotypes. This bidirectional exchange of signals results in a match between the needs of tissue cells and vascular bed-specific ECs, allowing organs to fulfill their physiologic function in the context of the entire organism (Tables 22-1 and 22-2) (1).

### TISSUE CELL-DERIVED SIGNALS

A variety of tissue-derived paracrine signals promote vascular development (Table 22-2), in part by altering EC gene expression (see Figure 22.1). When gene expression patterns are compared between cultured ECs derived from different tissues, tissue-specific differences in gene expression become apparent (12). In addition to these mitotically heritable differences, many other environmentally dependent vascular bed-specific

Figure 22.1. Development of a vascularized tissue. The suggested principle behind the development of a vascularized tissue is the mutual signaling between vascular ECs and nonvascular tissue cells. The result of these signaling events is a tissue with specific cell types (e.g., pancreatic  $\beta$ -cells) and ECs optimized for the function of these cell types (e.g., secretion of insulin). Tissue cells secrete signals or harbor signals on their cell surface that permit and change the development of adjacent ECs, for example, by turning on the transcription of Gene A. In turn, ECs secrete signals or harbor signals on their cell surface that permit and change the development of adjacent tissue cells, for example by turning on the transcription of Gene B. The tissue signals and endothelial signals exchanged during development assist the formation of a functional vascularized tissue.

transcriptional profiles are likely to exist in vivo, which are otherwise lost upon in vitro culture. In disease states, alterations in tissue-derived signals may cause ECs to undergo changes in gene expression (13).

ECs are capable of sensing and responding to a multitude of extracellular signals, including growth factors, cytokines, chemokines, and serine proteases. At any given site in the body, ECs are exposed to a unique mix of tissue-derived signals. For example, endocrine cells express a number of different VEGF molecules (9), including the tissue-specific angiogenic factor, endocrine gland-VEGF (EG-VEGF) (14). These growth factors are likely to play a role in regulating endothelial permeability and hence secretion of hormones. In contrast to endocrine glands, paracrine factors derived from astroglial cells in the brain are important in mediating the tight junctions of the blood-brain barrier.

The site-specific properties of ECs render the vasculature vulnerable to focal pathophysiology (15). For example, in diabetes mellitus, systemic hyperglycemia is associated with early

Figure 22.2. Endothelial signals in pancreas and liver development. ECs provide developing tissues with signals that promote developmental processes as diverse as cell proliferation, cell differentiation, and delamination of cells from an epithelium. (A) During pancreatic development, ECs induce the outgrowth of the dorsal pancreatic epithelium. Moreover, ECs are capable of inducing endocrine pancreatic differentiation. In particular, the expression of the transcription factor *Pancreas-duodenum homeobox (Pdx)-1* and the p48 subunit of the *Pancreas transcription factor 1 (Ptf1)* as well as the  $\beta$ -cell hormone insulin are turned on when pancreatic epithelial cells interact with ECs. The inductive signals for endocrine cell differentiation are not yet known. (B) During liver development, ECs are required for the delamination of liver cells, which is an essential part of liver morphogenesis. In addition, ECs stimulate the proliferation of hepatocytes by secreting growth factors such as hepatocyte growth factor (HGF), heparin-binding epidermal growth factor (HB-EGF), interleukin (IL)-6, and connective tissue growth factor (CTGF). The genes turned on in developing hepatocytes in response to endothelial signals are not yet known. The comparison of the EC-induced processes during pancreas and liver development reveals both similar and diverse outcomes of endothelial signals during tissue formation.

Table 22-2: Tissue Signals and Developmental Changes in ECs

<i>Tissue Signals</i>	<i>Developmental Change in ECs</i>
VEGFs	Angiogenesis, cell proliferation, cell survival, migration, fenestration
EG-VEGF	Steroidogenic gland angiogenesis, cell proliferation, cell survival, migration, fenestration
FGFs	Angiogenesis, cell proliferation, migration
Angiopoietin 1	Blood vessel stabilization, migration, sprouting
Angiopoietin 2	Cell proliferation, migration, sprouting
EGF, TGF- $\alpha$	Angiogenesis, cell proliferation
Colony stimulating factors (CSFs)	Cell proliferation, migration
Insulin-like growth factor (IGF)-1	Cell proliferation
TGF- $\beta$	Angiogenesis, tube morphogenesis, blood vessel stabilization
Tumor necrosis factor (TNF)- $\alpha$	Angiogenesis, migration, tube morphogenesis
IL-8	Angiogenesis

vascular complications in the arterioles of the retina and kidney, suggesting that these vascular beds are preferentially susceptible to the elevated blood glucose levels. An understanding of the unique EC–tissue-cell interactions underlying focal vasculopathy might provide important new insights into therapy.

The remarkable heterogeneity of the endothelium has been exploited for purposes of drug targeting (16). Based on studies of *in vivo* phage display, Pasqualini and her colleagues have advanced the concept of “vascular zip codes,” in which each vascular bed harbors specific molecules to which peptides or chemical compounds can bind specifically (17) (see Chapter 100). Linking drugs to such peptides or chemical compounds would help to more specifically deliver drugs to the tissue of interest. For example, linking cytotoxic compounds to peptides, which specifically home to a tumor tissue, has been shown to enable a more specific elimination of the tumor (18). Discovering compounds specific for vascular beds would enable a much better treatment of diseases in which a specific tissue is affected. Rather than affecting all tissues, homing drugs to the diseased tissue would prevent side effects in nontarget tissues and allow lower doses of drugs to be used.

## ENDOTHELIAL CELL-DERIVED SIGNALS

As shown in Table 22-1, a number of EC-derived molecules that signal to tissues both during development and in the adult have been identified. In general, these molecules are expressed by some, but not all ECs and include members of the fibroblast growth factor (FGF), transforming growth factor (TGF), Wingless (Wnt), and platelet-derived growth factor (PDGF) families; Notch ligands; neurotrophins; cytokines; and matrix metalloproteinases (MMPs).

EC-derived signals act in a paracrine manner to influence the phenotype of nonvascular tissue cells, including changes in gene expression (Figure 22.1). Studies on embryonic neuronal development have provided examples of such signals. For example, the development of sympathetic neurons from neural crest cells was observed to occur adjacent to the dorsal aorta. Bone morphogenetic proteins (BMPs) expressed by aortic endothelial and mesenchymal cells were found to be responsible for inducing sympathetic neuronal differentiation (19,20).

Because endothelial signals induce neuronal differentiation in the embryo, the question was raised as to whether such signals could be used to regenerate neurons in humans (e.g., in spinal cord injuries). For a long while, it was believed that neurons residing in the central nervous system could not be renewed. However, in mammals, adult neuronal proliferation and differentiation was found to take place in the hippocampus, a brain region responsible for learning and memory, among few other brain regions. Proliferating precursor cells reside in a region of the adult hippocampus particularly rich in capillaries, suggesting that capillaries could promote the proliferation of neurons (21). Direct evidence for endothelial signals in adult neuronal development was provided by studies on male songbirds, which sing at high rates when testosterone levels are high (22). It was shown that testosterone induces VEGF-A in the high vocal center of the songbird brain, where it leads to local EC proliferation. The proliferating ECs secrete the brain-derived neurotrophic factor (BDNF), which stimulates precursor cell migration as well as neuronal maturation and survival. This results in an expansion of the entire high vocal center, including the neurons of the songbird brain. Moreover, ECs stimulate self-renewal and expand neurogenesis of neural stem cells *in vitro* (23). These observations point to the possibility of treating neuronal injuries, such as spine injuries, with ECs or endothelial signals. In addition, VEGF-A directly promotes the proliferation, survival, and differentiation of VEGFR2-expressing neurons and neuronal stem cells (24). Thus, VEGF-A might have both direct and EC-mediated positive effects on neuronal development.

## ENDOTHELIAL CELLS IN PANCREATIC DEVELOPMENT

The inner organs, including the liver, lung, stomach, and pancreas, develop by budding from the embryonic gut epithelium

(the endoderm). The buds then start to grow into morphologically distinct organs with organ-specific cell types. Several lines of evidence support the notion that vascular ECs induce pancreatic budding as well as the development of endocrine pancreatic cells in the dorsal gut epithelium (summarized in Figure 22.2A) (6).

First, when the precursor cells of the aortic ECs are removed in frog embryos, the aorta does not form, and endocrine pancreatic genes (NeuroD/BETA2, Pax6, and insulin) are not expressed in the gut epithelium of these embryos (6). This experiment showed that the aorta is required for endocrine pancreatic development, but it did not discriminate between the effect of the blood circulation and the vascular endothelium. To determine whether the aorta ECs are responsible for inducing endocrine gene expression in the embryonic gut epithelium, mouse embryonic tissue co-cultures were performed using isolated gut epithelial cells and aortic ECs (6). In these co-culture studies, embryonic gut epithelial cells were shown to express endocrine hormones in the presence, but not absence, of aortic ECs. Moreover, the epithelium grows and forms buds. These experiments provided evidence for aortic ECs as a source of signals inducing endocrine pancreatic development.

A second line of evidence derives from studies of transgenic mouse embryos, in which VEGF-A was ectopically expressed in the embryonic gut epithelium fated to become duodenum and stomach (6). As a result of VEGF-A expression, ECs were attracted to this nonpancreatic gut epithelium. It was shown that these ECs were able to induce the ectopic development of insulin-producing  $\beta$ -cells in the epithelium of the posterior part of the stomach and anterior part of the duodenum, thus showing that ECs can instruct some nonpancreatic epithelial cells to adopt a pancreatic  $\beta$ -cell fate.

Finally, in a converse experiment, endocrine pancreatic development and dorsal pancreatic budding did not take place in VEGFR2-deficient mouse embryos (25) that lacked ECs (26). In these mice, the pancreatic transcription factor Ptf1a was not turned on, and the expression of the pancreas-duodenum homeobox transcription factor Pdx1 was not maintained in the dorsal pancreatic epithelium. These data provided further evidence that ECs induce endocrine cell differentiation and dorsal pancreatic budding in the embryonic gut epithelium (see Figure 22.2A). Because the pancreas develops from ventral and dorsal buds, it is noteworthy that the ventral buds do develop in the VEGFR2-deficient mouse embryos. This suggests that ECs are not the only source for signals capable of inducing organ buds.

Endothelial signals act on a so-called prepatterned embryonic gut epithelium. The term prepatterned implies that the distinct regions of the gut epithelium can only develop into a limited number of cell types (27). It was observed that only cells within the stomach and duodenum can be induced to become pancreatic  $\beta$ -cells if they express the pancreas-duodenum-homeobox gene Pdx1 (E. Lammert, unpublished observation). In contrast, Pdx1-negative gut epithelium, such as the anterior part of the stomach, would not start to express

insulin in response to endothelial signals. It is possible that these gut regions have a different *pre-pattern* and might respond to endothelial signals by turning on their own tissue-specific genes. Common responses to endothelial signals also exist, because inner organs have some morphogenetic events in common. For example, budding morphogenesis is impaired in both the developing pancreas and liver when ECs are missing (5,6,25).

Many research laboratories are currently aiming toward producing pancreatic  $\beta$ -cells for the treatment of diabetes mellitus, for example, by using human embryonic stem cells (28). Thus, it is useful to identify the endothelial signals involved in pancreatic  $\beta$ -cell development. In the juvenile,  $\beta$ -cells seem to proliferate to a certain extent (29), and the discovery of signals (possibly derived from ECs) that support  $\beta$ -cell proliferation would help to expand the  $\beta$ -cell mass in diabetic patients. A detailed molecular analyses of factors secreted by ECs would help to make progress in generating more  $\beta$ -cells for the treatment of insulin-dependent diabetes mellitus.

#### ENDOTHELIAL CELLS IN HEPATIC DEVELOPMENT

During liver development, hepatocytes undergo an epithelial-mesenchymal transition and grow into the surrounding mesoderm. This happens at a time when ECs surround the liver bud. In VEGFR2-deficient mouse embryos, which lack ECs (26), hepatocytes fail to detach from the epithelium, suggesting that ECs are required for liver morphogenesis (5). Tissue culture experiments showed that liver buds did not grow when an angiogenesis inhibitor prevented EC proliferation, thus showing that liver morphogenesis depends on EC-derived signals (see Figure 22.2B).

In the adult liver, endothelial signals play an important role in liver cell growth and survival (30). It was shown that the systemic administration of VEGF-A in mice increased liver size and induced cell division in both liver sinusoidal ECs and hepatocytes. In vitro, VEGF-A did not stimulate the growth of hepatocytes unless liver sinusoidal ECs were present, suggesting that EC-derived signals are necessary for hepatocyte mitogenesis.

Interestingly, depending on which VEGF-A receptors were activated, different sets of endothelial signals were produced. Activation of VEGFR1, but not VEGFR2, led to secretion of hepatocyte growth factor (HGF) by ECs, which promotes liver cell division. In contrast, activation of both VEGFR1 and VEGFR2 receptors led to responses in the gene expression of other endothelial signaling molecules including interleukin (IL)-6, heparin-binding epidermal growth factor (HB-EGF), and connective tissue growth factor (CTGF). During toxic injury, activation of both VEGF receptors led to improved liver-cell survival. From a medical point of view, it is interesting that selective activation of VEGFR1 stimulated hepatocyte, but not EC growth. Moreover, VEGFR1 agonists reduced liver damage in mice exposed to a hepatotoxin. These experiments

point to the possibility that VEGFR1 agonists may have therapeutic potential in certain liver disorders (30).

The exchange of signals between hepatocytes and ECs illustrates once again the principle of mutual signaling between tissue cells and ECs. Because angiogenic factors activate distinct receptors, the composition of such factors might help to determine the distinct properties of the adjacent vascular beds. The finding of tissue-restricted angiogenic factors (such as EG-VEGF or Bv8) supports this idea (31).

#### SPECIAL FEATURES OF ENDOTHELIAL CELLS IN PANCREATIC ISLETS

Adult pancreatic islets are oval-shaped cell aggregates (Figure 22.3A; for color reproduction, see Color Plate 22.3A) that consist of five endocrine cell types: the insulin-secreting  $\beta$ -cells that form the islet core, and the non- $\beta$ -cells ( $\alpha$ -,  $\gamma$ -, PP-, and  $\epsilon$ -cells) that form the islet mantle. Pancreatic islets usually are between 50 and 500  $\mu\text{m}$  in diameter and express high VEGF-A mRNA and protein levels. The mRNAs of the other members of the VEGF family (VEGF-B, -C, -D, and placenta growth factor PlGF) also are expressed, in contrast to EG-VEGF, which is not present in islets (9). The islet vasculature is characterized by one to three arterioles that enter the islet core and branch into a dense network of capillaries (see Figure 22.3) (32). These capillaries drain into venules at the periphery of the islet. About 12% of the islet mass is made up by EC bodies, and every  $\beta$ -cell is in contact with at least one vascular EC.

Islet capillaries are characterized by thin, perforated or fenestrated EC bodies separated from the islet cells by a basement membrane (see Figure 22.3B and Table 22-3). The fenestrae of islet capillaries have a diaphragm, which is a mesh composed of fibrils. The function of the diaphragm is unknown. Because of its structure, it might prevent certain macromolecules or particles from passing through the EC. The observation that horseradish peroxidase quickly passes through these fenestrae, when injected into the pancreatic bloodstream, shows that these fenestrae are permeable to at least some proteins (33).

In contrast to the pancreatic islets, the exocrine pancreas does not express high levels of VEGF-A, and the capillary network is about five times less dense than is the capillary network of islets. Moreover, ten times less fenestrae are present in the capillaries of the exocrine tissue, when compared with islet capillaries.

To understand the function of VEGF-A expression in pancreatic islets, VEGF-A was specifically deleted in the pancreatic epithelium of mice (9,10). It was shown that without VEGF-A, fewer capillaries form in islets, and the few remaining capillaries have fewer fenestrae. These results show that the VEGF-A expressed by endocrine islet cells is required for the density and morphology of the islet capillary network. In addition, mice with VEGF-A deficient pancreatic islets reveal defects in steady-state blood glucose levels and glucose tolerance, demonstrating that VEGF-A is required for islets to

**Table 22-3: Pancreatic Islet and Liver Sinusoidal ECs**

Property	Pancreatic Islet ECs	Liver Sinusoidal ECs
EC cell body	100-nm thick at many locations	100–300 nm thick at many locations
Fenestrae	Abundant, ~100 nm in diameter (mouse), contains a diaphragm	Abundant, ~100 nm in diameter (mouse), contains no diaphragm
Extracellular space	Continuous basement membrane	No continuous basement membrane
Microvilli	No microvilli from pancreatic $\beta$ -cell	Microvilli from hepatocyte

optimally fulfill their physiologic function: insulin secretion in response to blood glucose (10).

It is noteworthy that VEGFR2 is not expressed on pancreatic  $\beta$ -cells, but only on the ECs within islets. Similarly, VEGFR1 is not expressed by  $\beta$ -cells. Thus, the diabetic phenotype of mice with VEGF-A-deficient islets is not due to the missing autocrine VEGF-A signaling of  $\beta$ -cells, but results from the missing paracrine VEGF-A signaling from  $\beta$ -cells to ECs. How ECs are involved in the ability of  $\beta$ -cells to better secrete insulin is currently under investigation. The working

hypothesis is that: (a)  $\beta$ -cells require endothelial signals to improve their insulin secretory function (mutual signaling) and, (b)  $\beta$ -cells require ECs to pass insulin into the blood stream (transendothelial permeability) (32).

### SPECIAL FEATURES OF LIVER SINUSOIDAL ENDOTHELIAL CELLS

Liver sinusoidal ECs (LSECs) account for up to one-fifth of the total number of liver cells (34). These ECs are fenestrated, and the fenestrae lack a diaphragm. During liver development, ECs produce a continuous basement membrane between LSECs and hepatocytes, which disappears once the liver tissue is fully developed (35). Although the adult liver lacks an organized basement membrane, liver injury may lead to the abnormal formation of a continuous basement membrane.

The space between hepatocytes and LSECs is called the space of Disse (SD). Lipid particles occasionally are found in this space, suggesting a role for this site in lipid exchange. The morphology of LSECs might be suited to facilitate the bidirectional exchange of macromolecules and particles between blood plasma and hepatocytes. In the case of the endocrine pancreas, ECs are next to a continuous basement membrane, and they have fenestrae with a diaphragm (see Figure 22.3B), whereas, in the case of the liver, ECs do not have any continuous basement membrane, and their fenestrae are without any diaphragm. The endocrine pancreas primarily

Figure 22.3. The vascular system of pancreatic islets. Islets are vascularized by a dense network of fenestrated capillaries. (A) A confocal image of a section through a mouse pancreas is shown. The  $\beta$ -cells are shown in gray (insulin), the ECs in white (PECAM-1), and the cell nuclei in dark gray (DAPI). Scale bar: 50  $\mu$ m. (B) An electron microscopic image of a mouse pancreatic islet is shown. A  $\beta$ -cell is adjacent to a thin and fenestrated capillary EC, which surrounds a capillary lumen. Scale bar: 500 nm. For color reproduction, see Color Plate 22.3A.

secretes polypeptide hormones such as insulin, whereas the liver must be capable of exchanging a large variety of heterogeneous substances with the blood, including lipid particles, serum proteins, blood toxins, and bilirubin. Thus, it is possible that the fenestrated liver sinusoidal capillary endothelium with no basement membrane and no diaphragm is optimally suited to the exchange of these diverse substances and particles.

## CONCLUSION

As illustrated for pancreas and liver, tissue development is accompanied by mutual signaling events taking place between nonvascular tissue cells and vascular cells, in particular ECs. Endothelial signals have been shown for other cellular processes, including kidney morphogenesis (36), neural stem cell proliferation and differentiation (23), as well as for neural stem cell transdifferentiation (37). The result of mutual signals is a tissue in which the nonvascular tissue cells and their vascular beds are matched to enable the physiologic function of the tissue. Liver and pancreas are organs that develop from the embryonic gut epithelium. Vascular ECs are required for the early morphological development of these organs. Later during development, ECs obtain tissue-specific properties to enable the specific physiologic function of the tissue.

### KEY POINTS

- ECs provide tissues with developmental signals and, in turn, receive diverse angiogenic signals from the tissues.
- ECs are required for hepatic and pancreatic development; pancreatic islet ECs and LSECs differ in their morphology.

### Future Goals

- To identify endothelial signals and their application

## Pulmonary Vascular Development

---

Peter Lloyd Jones

*Institute for Medicine & Engineering, University of Pennsylvania, Philadelphia*

“The subtle blood is urged forward by a long course through the lungs . . . and is poured from the pulmonary artery into the pulmonary vein, where the blood is mixed with inspired air.” So wrote Michael Servetus (1511–1553), a Spanish physician and theologian who was burnt at the stake for his beliefs. Although the contemporary pulmonary vascular biologist is unlikely to face such a fate, the field of lung vascular developmental biology is nevertheless fraught with historic and technical obstacles that have impaired evolution of a unified theory of lung vascular development. On the other hand, tremendous advances have been made in comprehending morphogenesis of the lung at the level of the epithelium. When coupled with the knowledge that a dynamic and reciprocal relationship exists between the developing lung epithelium and their endothelial cell (EC) neighbors, the time appears ripe to re-evaluate the mechanisms controlling genesis of the pulmonary circulation. What is more, the recognition that a cache of postnatal lung diseases that perturb or destroy respiratory function may arise, in part, as a result of pulmonary vascular defects underscores the need to re-examine the “lesser circulation” (known as such because the flow path is short and lower pressure is required for it to operate efficiently), not only within its unique historical context, but also in the setting of modern biology. In fact, recent discoveries in fields as diverse as developmental biology, in silico modeling, and stem cell and gene therapy suggest that this time already has arrived. In this chapter, I begin by outlining the existing state and outstanding questions in the pulmonary vascular field and then detail the molecular mediators believed to be critical to pulmonary vascular development, with particular emphasis on homeobox gene transcription factors. Finally, I argue for the need to re-evaluate and potentially treat certain chronic lung disease from an endothelial perspective, using information derived from an understanding of development.

### LEARNING MORE ABOUT THE LESSER CIRCULATION: UNIQUE FEATURES AND CHALLENGES

The primary role of the postnatal pulmonary endothelium – the largest vascular bed in the human body, which eventually reaches the size of a tennis court in surface area – is to maintain an efficient and functional interface with the alveolar epithelium in which ventilation and perfusion are precisely matched. To achieve this, lung capillaries that bridge the pulmonary arterial and venous beds must develop and remain in close apposition with the terminal gas-exchanging units of the lung, the alveoli. Pulmonary arteries deliver deoxygenated blood to the alveoli, where gas exchange occurs. Pulmonary veins collect the oxygenated blood, delivering it to the left atrium of the heart (Figure 23.1). Extrapulmonary bronchial arteries branch off to the esophagus and perihilar region, whereas intrapulmonary bronchial arteries feed the airways, visceral pleura, and walls of the pulmonary artery (vasa vasorum). At these sites, bronchial arteries function to supply oxygen (O<sub>2</sub>) and nutrients before draining into the venous network (see Chapter 127). Thus, a minimum of six distinct lung EC subtypes (i.e., those from pulmonary arteries, alveolar-associated capillaries, pulmonary veins, bronchial arteries, bronchial veins, and bronchial capillaries) coexist within the lung (still other EC subtypes exist within arterioles, venules, and lymphatics). Moreover, even neighboring ECs within a given segment of the vasculature may display phenotypic heterogeneity (see Chapter 126). Thus, the pulmonary endothelium cannot and should not be viewed as a single entity.

Another distinctive feature of lung ECs is that their biophysical and biochemical niche in utero is radically different from their postnatal microenvironment: Although the pulmonary vascular bed receives approximately 8% to 10% of the cardiac output volume prior to birth, this hemodynamic

Figure 23.1. Development of the pulmonary arterial tree. Mercox casts of the pulmonary circulation show development of peripheral vessels over time in a (A) 12-day, (B) 14-day, and (C) 15-day mouse fetus. S, systemic; R, right; L, left; PA, pulmonary artery; PV, pulmonary vein; CL, cardiac lobe. (Reproduced with permission from deMello DE, Sawyer D, Galvin N, Reid LM. Early fetal development of lung vasculature. *Am J Respir Cell Mol Biol.* 1997;16(5):568–581.)

state changes at birth, when pulmonary blood flow that was previously diverted away from the lungs via the ductus arteriosus (prior to its programmed closure at birth) increases eight- to tenfold at birth. Accordingly, the pulmonary endothelium must develop in a manner that fully prepares it for the switch at birth from a low-flow, high-pressure, high-resistance setting, to a high-flow, low-pressure, low-resistance environment that is suddenly in contact with oxygenated blood at the levels of the alveolar capillaries and veins. Altered hemodynamics and  $O_2$  tension, together with other environmental factors (including changes in the underlying extracellular matrix [ECM]), contribute to structural and functional alterations in the vessel wall, such as flattening of the endothelium, alterations in vessel lumen diameter, and a concomitant fall in pulmonary artery pressure.

Like other cell types, ECs from the lung are studied most often as monolayers in a noncompliant, biomechanically inert microenvironment under conditions of normoxia (i.e., 21%  $O_2$ ). Note, however, that depending upon their location, cells within tissues most probably experience only between 6% to 16%  $O_2$ , with  $O_2$  tension in the thymus being registered as low as approximately 1% (1). Although these conventional systems provide a valuable first approximation, standard tissue culture conditions fail to fully recapitulate many of the important features that define normal pulmonary EC architecture and behavior *in vivo*. Similar limitations apply to studies of lung epithelium. Indeed, modern-day assays for epithelial branching morphogenesis frequently incorporate relevant variables, including tissue biomechanics, fetal  $O_2$  tension, and the composition and compliance of the ECM (2,3). Similarly, researchers studying lung vascular development are beginning to pay heed to the notion of organ recapitulation (4). For example, several groups have employed static organ cultures to assay for vascular development, in which whole fetal lung explants are isolated and used. Even in the absence of blood

flow, these explants develop a discernible vasculature. These studies have shown that fetal  $O_2$  tension, which is designated as 1% to 3%  $O_2$  in culture studies, is essential for fetal lung vascular development, whereas increasing  $O_2$  to 21% limits epithelial branching morphogenesis (4). Furthermore, it already has been established in multiple tissue systems that shear stress- and adhesion-dependent alterations in cell shape control cell behavior, including EC growth, differentiation, tubulogenesis, and survival (5–8). These types of considerations lead to additional outstanding questions, such as: How do pulmonary ECs sense and interpret physical forces,  $O_2$  tension differentials, and changes in cell adhesion and shape? How are these factors interrelated? And, do all ECs within the lung respond to these and other stimuli in the same manner as ECs at other sites?

The complex interactions and functional codependence that exist between pulmonary arterial and capillary ECs and adjacent airway epithelium represents another unique feature of lung vascular development, and a breakdown in communication between these distinct compartments can result in loss of normal respiratory structure and function. However, the intimate juxtaposition and functional interrelationship between the epithelium and pulmonary vessels does not exist for all vessels within the entire lung. For example, apart from sites of coalescence with the capillary bed at the alveolar level, pulmonary veins are distributed in a more peripheral pattern within the lung. Although pulmonary veins and arteries branch to the same extent, pulmonary veins differ in that they do not follow the airway architecture (9). Understanding the origins, intrinsic behavior, and external cues that combine to generate these distinct lung vascular networks may help to explain their unique spatial relationships to the epithelium, as well as to one another. It is likely that the spacing patterns between different pulmonary vascular networks also rely on intricate and overlapping gradients of specific

microenvironmental cues emanating from the adjacent epithelium, the vessels themselves, or from other tissue elements within the lung that have been largely ignored, such as fibroblasts, pericytes, and nerve cells.

Once all the principal players that dictate lung vascular patterns have been identified, it should be possible to model in silico spatially distributed properties that exist for multiple cell types within the lung, including epithelial cells and ECs. Toward this end, Tawhai and colleagues have developed a combined morphometric and computational space-filling three-dimensional Voronoi diagram,<sup>1</sup> to generate the alveolar honeycomb-like geometric mesh, which is then superimposed and covered with a two-dimensional pulmonary capillary network in silico (10,11). Furthermore, blood flow through the capillary network from arteriole to venule has been modeled implementing a solution procedure, which takes into account the hematocrit and capillary dimensional changes in each segment (12). This solution procedure determines the pressure at each junction and flow and red blood cell concentration in each segment, and red blood cell and neutrophil transit times across the network. Such mathematical tools, based on the integration of anatomical, biophysical, cellular, and molecular information, also have been implemented to generally model capillary morphogenesis (13,14). For example, Merks and colleagues have developed a cell-based model that assumes that ECs chemotactically attract one another. This cell model allows the user to assign different properties (i.e., intercellular adhesion, cell shape, and chemoattractant saturation) to each cell and its surroundings, and allows the user to study how these properties affect vascular patterning, based on in vitro capillary formation on Matrigel (Figure 23.2). Ultimately, it is hoped that these types of systems also will be adopted by pulmonary vascular biologists as standard tools in order to pretest hypotheses and to suggest new experiments. Of course, continued progress in this area will rely on collaborations between investigators in diverse fields, as well as retraining of lung EC biologists to embrace and unleash the power of information technology, engineering, and mathematics.

In the meantime, cellular and molecular biologists alike have continued to generate important information that has provided new details regarding EC differentiation and patterning in the developing lung. For example, systematic transcript profiling of genes expressed within the whole lung has been potentially useful in identifying new molecules involved in specification, patterning, and homeostatic control of the pulmonary endothelium. This technology not only has confirmed the expression of markers already known to be expressed in pulmonary ECs in vivo, such as vascular endothelial (VE)-cadherin, CD31, vascular endothelial growth factor receptor 1 (VEGFR1), VEGFR2, Tie1, Tie2, and angiopoietin 2 (Ang2), but also has led to the identification of other mediators that were not previously known to be expressed by lung

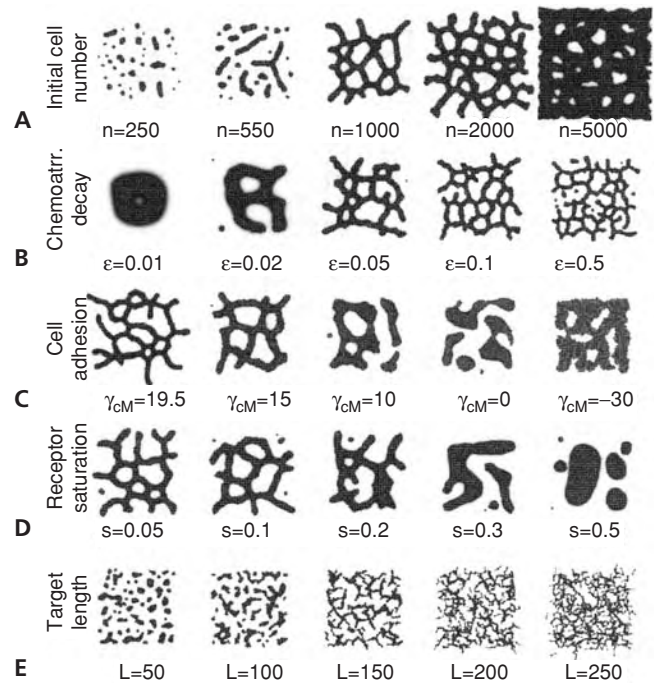

Figure 23.2. *In silico* modeling of vascular development. Overview of computational parameter sweeps showing development of a cell-oriented approach to model in vitro vascular network formation, based on the Gambini-Serini chemotaxis model. Computational models of individual human microvascular ECs were constructed that mimic experimentally observed phenomenology, including response to external chemical signals, cell elongation, cell adhesion, chemotaxis, and haptotaxis. These simulated cells are then released into a virtual tissue culture dish and their macroscopic, collective behavior is quantitatively compared. In conducting these studies, the researchers attempt to recover minimal sets of physiochemical properties and behavioral rules for the cells that reproduce the experimentally observed tissue-level pattern. (A) When cell density is high,  $n > 1,000$ , all cells interconnect. (B) Size of lacunae depends on the rate of chemoattractant decay. In C–E, the Gambini-Serini model is systematically modified by changing the biophysical properties of the individual cells. In this model, cell adhesion is essential (C). If adhesivity is reduced, a network no longer forms, and the cells aggregate as islands. Figure D shows the effects of changes in  $s$ , the threshold for chemotaxis saturation (sensitivity). Up to about  $s = 0.01$ , vessel-like patterns emerge, whereas for larger values more amorphous patterns with larger clusters form. The effect of cell elongation at low cell densities was also tested (E), and this indicates that cell elongation facilitates the interconnection of isolated parts of the vascular network pattern. (Reproduced with permission from Merks RM, Brodsky SV, Goligorsky MS, et al. Cell elongation is key to in silico replication of in vitro vasculogenesis and subsequent remodeling. *Dev Biol*. 2006;289(1):44–54.)

ECs, such as semaphorin 3C and its receptor neuropilin 1 (NRP1) (15). Yet major intrinsic problems also are associated with this type of approach. For example, one recent microarray study using isolated tissue showed that mRNA transcripts encoding the ECM protein tenascin (TN)-C are enriched in nonbranching regions of the developing lung epithelium when compared with distal branching regions, which harbors the

1 Also known as a Voronoi tessellation or decomposition; named after Georgy Voronoi, this type of modeling is a representation of metric space determined by distances to a specified discrete set of objects in the space.

capillary bed (16). At face value, these data suggest that TN-C may serve as a negative regulator of lung branching and capillary morphogenesis, yet TN-C is known to be a potent inducer of both developmental and tumor angiogenesis (3,17,18). In fact, TN-C is subject to posttranscriptional control in the fetal lung, and protein levels are enriched around the distal branching airways and capillaries (3,19). Thus, the powerful method of gene profiling, when applied to the lung (or any other tissue for that matter), must be utilized with a full understanding that newly identified genes exist within a highly dynamic environment, and that such genes are controlled at multiple levels that can modify their expression and function. In this regard, ongoing proteomics studies represent a necessary and complementary approach.

Although numerous molecular features are shared between the pulmonary and systemic circulations, a misconception is that all information gleaned from the systemic circulation can be automatically extrapolated to the pulmonary circulation and vice versa. For example, in developing systemic vessels, ephrinB2 (a transmembrane ligand) and EphB4 (a receptor for ephrinB2) are expressed on embryonic arterial and venous cells respectively, where they are believed to specify boundaries between developing arteries and veins (20). In human fetal lungs, however, EphB4 is expressed on both arteries and veins (9), indicating that the specification of arterial and venous identity in the developing pulmonary circulation relies on other factors. Answers to these and other intriguing lines of inquiry will be revealed over time, but they are eclipsed by a major unresolved question: How do pulmonary ECs arise within the lung?

## TOWARD A UNIFIED THEORY OF PULMONARY VASCULATURE DEVELOPMENT

### Formation of the Primary Lung Vascular Plexus

Pulmonary vessels originate both outside and within the lung in utero, and they continue to develop at all stages of lung development through early adulthood (i.e., 16 to 18 years in humans) via repeated rounds of growth and regression until the final template is established (Table 23-1), in which each generation of airway is accompanied by a pulmonary artery, as well as numerous supernumerary arteries, defined as vessels that branch off from pulmonary arteries, away from the primary vascular tree (21). During fetal life, the pulmonary trunk, which is derived from the truncus arteriosus, represents the most proximal part of the developing pulmonary circulation, and it connects to the pulmonary arch arteries, which are derived from the sixth branchial arch arteries by 7 weeks of gestation in humans, or approximately 9 to 9.5 days of gestation in mice. These proximal vessels supply the upper poles of the right and left lung and infiltrate these tissue elements through one or more mechanisms, including sprouting and intussusceptive and expansive angiogenesis, the latter being defined as a slow expansion of vascular networks via an increase in volume. Similarly, angiogenesis from a pair of

**Table 23-1: Lung Development by Vascular Phenotype**

<i>Stage of Lung Development</i>	<i>Vascular Phenotype</i>
Embryonic	Vasculogenesis within immature mesenchyme, pulmonary arteries branch from 6th aortic arch, veins as outgrowths from left atrium
Pseudoglandular	Parallel branching of large pulmonary arteries with central airways, lymphatics appear
Canalicular	Increased vessel proliferation and organization into capillary network around airspaces
Saccular	Marked vascular expansion with thinning and condensation of mesenchyme, thin air-blood barrier, double capillary network in septae
Alveolar	Accelerated vascular growth, fusion of the double capillary network with thinning of septae
Postnatal	Marked vessel growth + remodeling, as surface area increases >20-fold

intersegmental arteries, which arise from the dorsal aorta, supplies the lower poles of the lung via penetration up through the diaphragm.

Sprouting angiogenesis is initiated by the loss of cell-cell adhesion and proteolytic degradation of the underlying ECM, which is composed predominantly of basement membrane proteins. The extension of EC microspikes into the resulting gaps signals the onset of migration of sheets of cells into the surrounding space. A proliferation of cells then ensues in the lagging cells, resulting in an increase in sprout length. Sprouts continue to branch and fuse, and eventually they form a slit-like lumen, before reassembling a basement membrane and recruiting surrounding mural cells. Intussusceptive angiogenesis occurs when opposing ECs form a capillary interendothelial bridge, which is then sealed and organized into an interendothelial junction. The endothelium then thins centrally and gives way to invading components of the interstitium that divide the capillary channel (22).

As for the distal intrapulmonary vessels, it was originally proposed that these vessels form exclusively through vasculogenesis (23), defined in this instance as a differentiation of lung mesodermal cells in situ into hemangioblasts, angioblasts, and ultimately ECs. These mesodermal cells develop into isolated and discrete nests within the distal lung mesenchyme and ultimately form primitive networks of angioblasts that envelope pools of blood cells.

Based on morphological and vascular casting methods using polymers injected into the pulmonary circulation, it was thought that the onset of pulmonary vascular development

was initiated at embryonic day (E)13 to E14 in the mouse (23), that angiogenesis was restricted to proximal areas of the lung, and that vasculogenesis occurred only in distal regions. Recent studies using developmental biology approaches, however, have radically changed this overall picture. For example, by using a  $\beta$ -galactosidase tagged *Flk-1* locus, Schachtner and colleagues demonstrated that connections already exist between the lung mesenchymal vascular network and the aortic sac by as early as E10.5 (24). This study not only supports the idea that central vessels may arise via vasculogenesis, rather than exclusively by angiogenesis, but it also supports the idea that blood vessel formation occurs concurrently with development of the lung epithelium, which starts to bud from the ventral foregut into the neighboring mesenchyme by E9.5 in the mouse. Furthermore, a recent study suggests that distal vessels may arise via angiogenesis (25). In this instance, lungs of *Tie2-LacZ* transgenic mice were examined from the onset of lung development (E9.5) until the pseudoglandular stage (E13.5). Using this approach, these investigators reported that from the first morphological sign of lung development, a clear vascular network was evident that was in contact with the proximal vasculature arising from the great vessels of the heart. Overall, these models indicate that capillary networks surround the terminal buds and expand by formation of new capillaries from pre-existing vessels as the lung bud grows. Figure 23.3 summarizes these findings, as well as other previous models of pulmonary vascular development. Clearly, alternative approaches still are needed, such as live tracking of the developing lung vasculature in utero, or in the very least, organ culture or animal models that will allow testing of these models *ex vivo* or *ex utero*. In this regard, murine lung allograft models still represent the most sophisticated means for recapitulating and controlling lung epithelial and vascular development (26,27), whereas isolated fetal lung mesodermal cell cultures have proven to be useful in identifying factors involved in both vasculogenesis and angiogenesis (19,28).

#### ASSEMBLING THE PULMONARY VASCULAR WALL

Once the primary lung vascular plexus has formed, prior to birth, the pulmonary vascular wall begins to assemble and mature. Different cell layers become apparent, and this is accompanied by the deposition of specialized extracellular matrices between distinct cell layers, as well as the recruitment, proliferation, and differentiation of surrounding mural cells (i.e., pericytes, fibroblasts, and vascular smooth muscle cells [VSMCs]) that are recruited from the surrounding mesenchyme, depending on their position within the pulmonary vascular tree. For example, in the fetus, preacinar arteries and arteries at the level of the terminal bronchiolus (i.e., vessels that are not in proximity to the alveolar duct) are muscular, whereas the intra-acinar arteries (which accompany the respiratory bronchioli) are partially muscular (i.e.,  $\alpha$ -smooth muscle actin positive) or nonmuscular. Arteries at

the level of the alveolar duct and alveolar wall are not invested with smooth muscle, although they are surrounded by pericytes, and this state remains throughout infancy. In childhood, however, the preacinar arteries become partially muscularized, whereas those in the alveolar wall remain largely nonmuscular, even in the adult. How ECs recruit or repel these different mural cells to the developing pulmonary vascular wall is not known, yet studies in pulmonary hypertensive vessels, where this process is recapitulated (albeit at exaggerated levels) may provide some clues (see the section Molecular Control of Pulmonary Vascular Development).

It is important to note that most of the aforementioned studies refer to the interconnected and contiguous pulmonary arterial, capillary, and venous beds, and not to the lymphatic or bronchial circulations. Until such time as lung lymphatic and bronchial ECs can be accurately distinguished at the cellular and molecular levels it will not be possible to state with certainty how ECs arise within these other vascular beds. For example, the hyaluronan receptor lymphatic endothelium-specific hyaluronan receptor (LYVE)-1 is widely accepted as a lymphatic endothelial marker, but this receptor also is expressed by pulmonary capillary ECs (15). To further complicate matters, lung vasculogenesis and angiogenesis most often are described as separate processes, yet they likely share overlapping cell differentiation and maturation makers, and both networks rely on common cellular processes, including cell proliferation, migration, and the ability to recruit surrounding mural cells. Further, the fact remains that the currently available methods used to assess the connectivity and spatial positioning of emerging lung ECs and networks derived thereof (e.g., casting of vascular channels using high-viscosity polymers, immunohistochemistry on serial sections, and electron microscopy) are unable to provide a complete and accurate temporal-spatial map of lung vascularization by pulmonary, bronchial, and lymphatic networks. This process will rely ultimately on the use of new technologies, such as real-time imaging of lung EC network formation using fluorescently labeled early EC precursor markers and the identification of lung EC-specific markers that can be used to generate conditional transgenic animals. In the meantime, headway has been made in identifying some of the molecular factors involved in generating and maintaining the pulmonary vasculature.

#### MOLECULAR CONTROL OF PULMONARY VASCULAR DEVELOPMENT

Numerous genetic and epigenetic factors collaborate (in both positive and negative ways) to generate, remodel, restrict, and maintain the pulmonary vasculature, including  $O_2$  tension, hemodynamics, peptide growth and antigrowth factors, transcription factors, and components of the ECM. It should be stated, however, that despite the demonstration of the importance of many of these factors in cardiovascular development, the systematic functional evaluation of the majority of

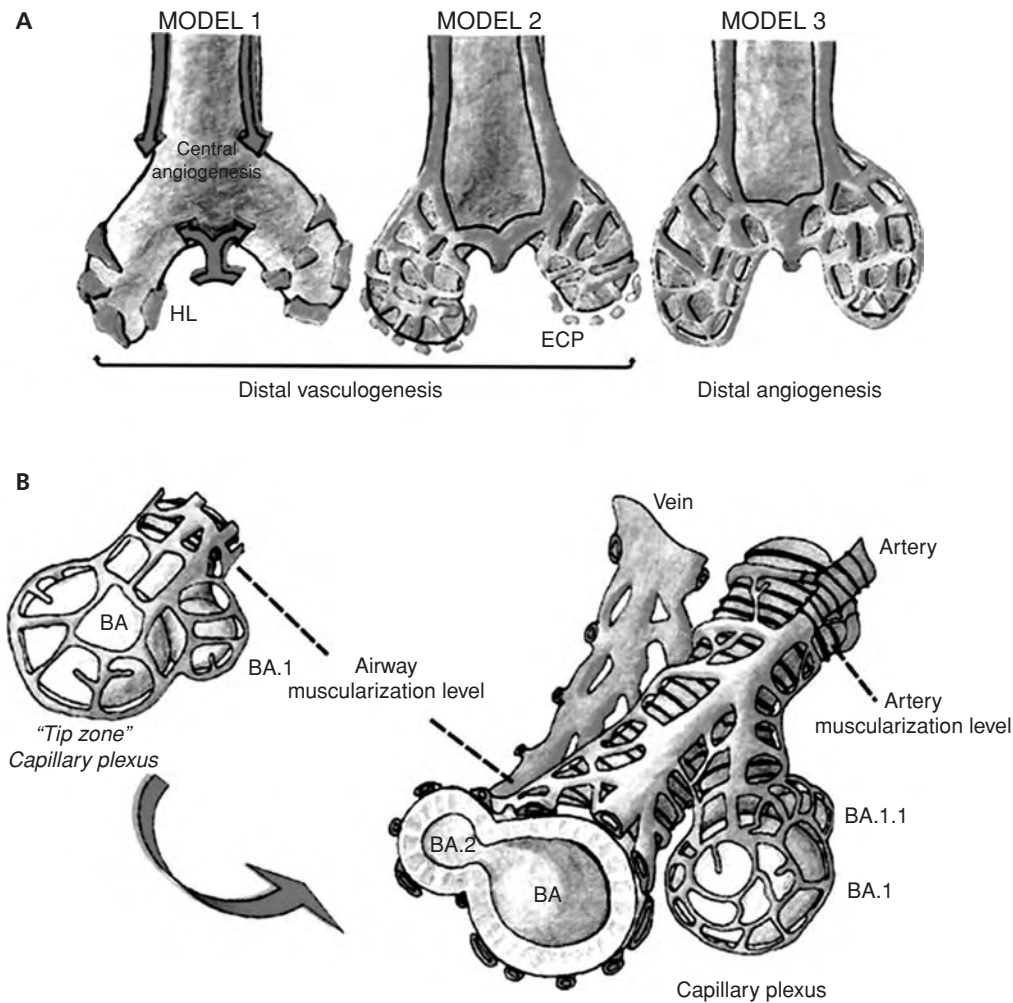

Figure 23.3. Models of lung vascular morphogenesis. (A) Model 1, proposed by deMello describes two mechanisms of lung vascular morphogenesis, central angiogenesis (sprouting of arteries and veins from central vascular trunks), and distal vasculogenesis (development of hematopoietic lakes in the mesenchyme). Connection between the two vascular beds would occur at E13–14. Model 2, proposed by Hall, shows distal vasculogenesis (development of new vessels from EC precursors) as the mechanism of the lung vascularization. Model 3, proposed by Parera, shows that distal angiogenesis also occurs. HL, hematopoietic lakes; ECP, EC precursor. (B) Detail of the distal angiogenesis model proposed by Parera. Formation of new capillaries from pre-existing vessels takes place in the “tip zone,” where airway and capillary networks expand in a coordinated way through epithelial–endothelial interactions. Newly formed vessels remodel dynamically as they form part of the afferent or efferent component. BA, airway branch A; BA.1, and BA.2, daughter branches from branch A. (Reproduced with permission Parera MC, van Dooren M, van Kempen M, et al. Distal angiogenesis: a new concept for lung vascular morphogenesis. *Am J Physiol Lung Cell Mol Physiol.* 2005;288(1):L141–L149.)

these factors in the lung has mostly been restricted to descriptive studies that do not prove directly their role in lung vascular development. Such conclusions will rely on the introduction of inducible systems to control gene expression specifically in the pulmonary vasculature; currently, no such markers exist. Nevertheless, Table 23-2 summarizes the nature of a number of molecules that have been examined and described in detail in the lung and/or systemic circulation, and that are known or believed to contribute to vascular development. As can be seen from the table, the initial template and final fractal patterns

that define the developing pulmonary vasculature are likely to be controlled by numerous sets of genes and signal transduction networks that collectively dictate positional identity and morphogenesis. The question remains, however, as to which genes exert ultimate control over these multiple factors. In this regard, homeobox (Hox) gene transcription factors represent ideal candidates, because these evolutionarily conserved transcription factors are able to simultaneously regulate and coordinate the expression of collections of genes already implicated in vasculogenesis and angiogenesis, and they represent

**Table 23-2: Examples of Homeobox Genes Expressed in the Lung Vasculature and Cells Controlled by the Lung Vasculature and Vice Versa**

<i>Gene</i>	<i>Expression Pattern, Regulation, and Function</i>	<i>References</i>
<i>Hoxa-1</i>	Null mice are anoxic and die at birth	32
	Co-expressed with <i>Hoxa-3</i> , <i>Hoxa-5</i> , <i>Hoxb-3</i> , <i>Hoxb-4</i> , <i>Hoxb-6</i> , <i>Hoxb-7</i> , and <i>Hoxb-8</i> in branching region of E11.5 mouse lung	42
	<i>Hoxa-1/b-1</i> double knockouts possess smaller lungs	78
	<i>Hoxa-1</i> -regulated-62 (HA1R-62) gene represents putative target in adult lung	79
	Transcripts are expressed in normal adult lung	48
<i>Hoxa-2</i>	Expression pattern suggests role in differentiation of proximal mesenchyme derivatives and in vasculogenesis	39
<i>Hoxa-3</i>	Null mice die shortly after birth, conceivably of pulmonary failure	33
<i>Hoxa-4</i>	Expressed between E8.5–12.5 in lung mesenchyme	80
	Expression in lung relies on a conserved retinoic acid response element (RARE) in the 5' flanking region	81
	By E14.5, <i>Hoxa-4</i> restricted to proximal mesenchyme, smooth muscle cells, subepithelial fibroblasts, and alveolar cells; expression may be determined by opposing effects of RA and TGF- $\beta_1$	82
<i>Hoxa-5</i>	Expressed in E8–E13 lung, but not by E18	83
	Null mice display improper lung morphogenesis, respiratory distress, and perinatal lethality; controls tissue interactions, because loss of mesenchymal <i>Hoxa-5</i> leads to surfactant deficiency and altered expression of <i>Nkx2.1</i> , <i>HNF-3</i> , and <i>N-myc</i> in pulmonary epithelium	34
	Induced by RA in human bronchial fibroblasts	84
	Induction by RA relies on <i>Hoxa-4</i>	82
<i>Hoxa-10</i>	Expressed in normal human lung and primary pulmonary hypertension	48
<i>Hoxb-1</i>	Expression in foregut endoderm, which gives rise to lungs, depends on a 3' RARE	85
<i>Hoxb-2</i>	Coexpressed with <i>Hoxb-5</i> in distal lung mesenchyme at E10.5–E14.5; <i>Hoxb-3</i> and <i>b-4</i> detected in mesenchyme of trachea, mainstem bronchi, and distal lung; indicates that specific combinations of <i>Hoxb</i> genes specify differences between proximal and distal mesenchyme	86
	Present in human fetal and adult lung, as well as in emphysema and primary pulmonary hypertension	48
<i>Hoxb-3</i>	Co-expressed with <i>Hoxb-4</i> and <i>b-5</i> in E9.5 foregut	86
	Expressed in prenatal lung, involved in retinol-induced gene expression of Clara-specific secretory protein Reduces expression of surfactant protein C	45
<i>Hoxb-4</i>	Expressed in embryonic lung mesenchyme	87
<i>Hoxb-5</i>	In fetal mouse lung, mesodermal cells surrounding branching epithelial cell layer accumulate high levels of <i>Hoxb-5</i>	88
	In E13.5 mouse to postnatal day 2, expressed in conducting airways and surrounding mesenchyme; at E14.5, levels decrease in mesenchyme distal from airways, but persists in fibroblasts underlying conducting airways	89
	Expressed with <i>Hoxb-6</i> in developing chick respiratory tract; prior to branching, expressed around ventral–distal tip of lung bud, eventually demarcating trachea, bronchial tree, and air sacs; may specify positional identity, because <i>Hoxb-6</i> through <i>Hoxb-9</i> expression corresponds to morphologic subdivisions of air sacs along proximo distal axis	90
	Required for branching morphogenesis in cultured fetal lungs; controls morphogenesis of the first airway divisions from the mainstem bronchi; RA-induced alterations in branching are mediated in part by <i>Hoxb-5</i>	91
	At E14, primarily in mesenchymal cells; by E19, appears mainly in epithelial cells of prealveolar structures and adjacent subepithelium; potential role in lung maturation, because expression persists in hypoplastic lung mesenchyme throughout development and in postnatal lung	92
<i>Hoxb-6</i>	<i>Hoxb-6</i> expression reduced during lung development; potential role in distal airway branching	39
<b>Divergent homeobox genes</b>		
<i>Barx2</i>	Expressed in developing mouse lung buds	93
<i>Gax</i>	Expressed in adult rat cardiovascular tissues, including lung	94
	Inhibits vascular SMC proliferation and migration	56

Gene	Expression Pattern, Regulation, and Function	References
<i>Hex</i>	Expressed in newborn mouse lung	35
	Detected in E12.5 and E15.5 lung	95
	Expressed at E11.5, especially in distal lung mesenchyme; suppressed by E16.5, and upregulated in adult lung; indicates role in later stages of development and in control of gene expression in adult lung	96
<i>Hlx</i>	Expressed in E10.5 mouse foregut lung mesenchyme; suggested role in controlling tissue interactions	97
<i>Irx1</i> and <i>Irx2</i>	Expressed in E8.5 foregut region; during glandular development, present in lung epithelium; expression declines at end of cannicular stage; suggested control epithelial–mesenchymal tissue interactions in concert with <i>Gli1</i> , -2, and -3	98
<i>Nkx2.1</i>	Controls surfactant protein A and B gene promoters	99
		100
	Antisense oligonucleotides inhibit epithelial branching morphogenesis in embryonic mouse lungs explants	101
	Activates transcription of Clara cell-specific protein	102
	Null mouse lungs consist of dilated sacs arrested at E11–E15	103
	Reduction in <i>Bmp-4</i> expression may account for this branching defect; controls VEGF and pulmonary epithelial surfactant expression	
	Transactivation of <i>Nkx2.1</i> gene promoter in pulmonary epithelial cells relies on interactions with Sp1 and Sp3 transcription factors	104
	Detailed examination of null mice indicates that distal lung morphogenesis is <i>Nkx2.1</i> -dependent	105
	Siblings with heterozygous deletion of <i>Nkx2.1</i> display congenital thyroid dysfunction and recurrent acute respiratory distress	106
	Controls RA stimulation of surfactant protein B promoter activity	107
	Appears to cooperate with <i>C/EBP<math>\alpha</math></i> in determining high level, lung epithelial-specific expression of Clara cell secretory protein during later stages of lung development and in adult lung	108
SMAD3 interactions with <i>Nkx2.1</i> and HNF-1 underlie basis for TGF- $\beta$ -dependent repression of surfactant protein B	109	
<i>Pitx2</i>	Null mice develop right pulmonary isomerism	110
<i>Prx1</i> and <i>Prx2</i>	Expressed in walls of developing muscularized chick pulmonary arteries; <i>Prx1</i> especially is prominent at adventitial–medial boundary; <i>Prx2</i> also expressed in media; indicates roles in assembly of the vascular wall by promoting recruitment and segregation of smooth muscle and fibroblasts, as well as matrix synthesis and deposition	50
	<i>Prx1</i> -null mouse exhibits cardiovascular defects and die of respiratory distress soon after birth	111
	Activate transcription of TN-C, an ECM protein that promotes pulmonary artery SMC proliferation and survival	62
	Required for in vitro and in vivo lung vasculogenesis	19
<i>Six4</i> and <i>Six5</i>	<i>Six4</i> is present in embryonic lung, whereas <i>Six5</i> is expressed in adult lung	112

major determinants of pattern formation and morphogenesis throughout development.

### Homeobox Genes as Tools to Comprehend Lung Vasculogenesis and Angiogenesis

All proteins encoded by Hox genes contain a 60-amino acid DNA-binding motif – designated the homeodomain – which folds into three  $\alpha$  helices. The base sequence for the homeodomain is virtually identical in all the genes that contain it, and it has been found in many organisms, from fruit flies to man. This motif arises from an 180-nucleotide sequence designated the homeobox, so called because mutations in some of these genes result in homeotic transformations in *Drosophila*,

in which one body structure replaces another (29). Since the discovery of Hox genes in *Drosophila*, homologous genes have been identified in vertebrates. In mice and humans, these Hox genes are arranged as four unlinked complexes, designated *Hoxa*, *Hoxb*, *Hoxc*, and *Hoxd*, which contain a total of 39 genes that are believed to have arisen through the gross duplication of an ancestral cluster. Thus, corresponding genes (or paralogues) located in different clusters on separate chromosomes resemble one another closely, and members of the same paralogous group often collaborate with one another during development (30). Another feature of Hox genes is that those located at the 3' end of each cluster are expressed prior to those at the more 5' end, and this is also reflected in their spatial pattern of expression – that is, 3' genes are expressed in the

anterior to thoracic positions, whereas 5' genes are more posterior (31). This colinearity likely explains why the majority of Hox proteins found in the developing lung are encoded by genes located at the more 3' end. In addition to Hox genes, at least 160 other divergent homeobox genes have been identified that lie outside Hox clusters, all of which possess a homeodomain.

A review of the prevailing literature indicates that at least 30 homeobox genes are expressed in the developing lung. Although the precise functions of many of these genes remain to be defined, knockout experiments in mice reveal that a number of them may control airway and vascular development, or both. For example, *Hoxa-1*-knockout mice fail to initiate breathing (32), and *Hoxa-3*-null mice die shortly after birth, possibly as a result of pulmonary failure (33). *Hoxa-5*-deficient mice display respiratory distress at birth due to profound dysmorphogenesis of the developing lung and decreased expression of surfactant proteins (34). Furthermore, expression of Nkx2.1 and hepatic nuclear factor (HNF)-2 $\alpha$  (genes that regulate the production of surfactant-associated proteins in the endoderm) is altered in *Hoxa-5*-null mice (34). Because *Hoxa-5* expression is confined to the respiratory tract mesenchyme (i.e., embryonic connective tissue developing mainly from the embryonic mesoderm), which interacts with the overlying endoderm during lung morphogenesis, this study exemplifies how homeobox genes may regulate lung tissue interactions between the epithelium and mesenchyme during development.

Although it is still not clear how cells within the lung mesenchyme are selected to undergo vasculogenesis, early evidence indicates that the divergent homeobox gene, *Hex*, may be involved (35,36). This gene is expressed in a range of multipotent progenitor lines and is generally downregulated during terminal differentiation (37). In the mouse embryo, *Hex* first materializes in the primitive endoderm of the implanting blastocyst. Subsequently, it appears in the foregut endoderm and within the mesoderm, where it is transiently expressed in the nascent blood islands of the yolk sac and later in the embryonic angioblasts and endocardium (36). In the embryonic mouse lung, the highest levels of *Hex* are observed in the distal lung mesenchyme (35). Taken together with the aforementioned studies, *Hex* appears to be well poised, both temporally and spatially, to drive vasculogenesis. In fact, a comparison with FLK-1 expression indicates that *Hex* is an earlier marker of endothelial precursors (36) that is required for the initial stages of EC selection within the mesoderm, rather than differentiation, an idea substantiated by the finding that expression of the *Hex* homologue *hHex* in zebrafish leads to early and ectopic expression of FLK-1 (38). In addition to *Hex*, *in situ* hybridization studies suggest that *Hoxa-2* may play a role in lung vasculogenesis (39), yet ablation of this gene has no effect on the normal lung phenotype (40). Other approaches, including analysis of compound knockouts involving one or more *Hoxa-2* paralogues will no doubt reveal whether this or other Hox genes truly contribute to pulmonary vascular development.

As well as regulating vasculogenesis, Hox genes also have been implicated in angiogenesis. Once again, little is known about how these genes control this process in the lung, but studies in other tissues indicate that they are likely to be involved because a number of their targets have been shown to be important for lung development and homeostasis (41). For example, *Hoxb-7*, which is expressed in the fetal lung (42), upregulates a variety of angiogenic stimuli, including fibroblast growth factor 2 (FGF2), vascular endothelial growth factor (VEGF), and matrix metalloproteinase (MMP)-9 (43). Similarly, HOXD3 (i.e., the human homologue of mouse *Hoxd-3*) colocalizes with integrin  $\alpha v \beta 3$  in angiogenic vessels formed in response to FGF2 on a chick chorioallantoic membrane assay, and it also promotes the invasive phenotype of human umbilical vein and dermal microvascular ECs by stimulating the expression of urokinase-type plasminogen activator (u-PA) and  $\alpha v \beta 3$  (44), recognized components of the angiogenic cascade. Although HOXD3 and HOXB7 participate in the invasive phase of angiogenesis, HOXB3 (a HOXD3 paralogue expressed in prenatal lung tissue [45]) promotes capillary morphogenesis on basement membrane ECM by controlling the expression of ephrinA1 and subsequent activation of the EphA2 receptor (46).

Following capillary morphogenesis, angiogenic ECs become quiescent. Appreciating that, during development, Hox genes at the 3' end of each Hox cluster are expressed prior to those at the more 5' end, Myers and colleagues hypothesized that subsequent to the initial stages of angiogenesis, maturing capillaries would begin to express more 5' Hox genes (47). Indeed, HOXD10 expression is greater in quiescent ECs when compared with their angiogenic counterparts. Consistent with this, the expression of HOXD10 *in vivo* reduces the angiogenic response of ECs to FGF2 (47). Mechanistically, HOXD10 suppresses the expression of u-PA receptors and blocks FGF2-dependent migration of ECs into fibrin gels, a process that relies on u-PA receptors. Because HOXD10 appears to be expressed in adult but not fetal lung tissue (48), it is conceivable that this gene actively maintains the fully differentiated state of ECs within the mature lung.

*Prx1* represents another homeobox gene that may support both vasculogenesis and angiogenesis within the lung (19). This Hox gene (which is also known as *Mhox*) encodes a divergent, paired-related homeobox gene. In the developing chick cardiovascular system, *Prx1* is first evident in the endocardial cushions and valves, the epicardium, and in the walls of the great arteries and veins (49). In the embryonic chick and mouse pulmonary vasculature, *Prx1* appears in the endothelium from early stages onward, and later in the adventitial and medial cell layers (19,50), indicating that this homeobox gene may promote differentiation and patterning of pulmonary vessels. In support of this, *Prx1*-null mice exhibit a variety of pulmonary and systemic vascular anomalies, including abnormal positioning and awkward curvature of the aortic arch and an elongated ductus arteriosus (51). As well, *Prx1*<sup>-/-</sup> mice are cyanotic and die soon after birth from respiratory distress, which had been suggested to arise from

palatal defects. Alternatively, it is possible that Prx1 affects respiratory function, because it is required for one or more stages of lung vascular development. Indeed, our group has shown that Prx1 can not only promote differentiation of fetal lung mesodermal precursors to an EC phenotype, but that this gene product also promotes capillary morphogenesis in vitro by inducing transcription of the *TN-C* gene, a proangiogenic ECM protein (19). In keeping with these data, lungs from *Prx1*<sup>-/-</sup> mice express reduced levels of TN-C, they fail to form capillary networks, and their epithelium is hypoplastic (19). Thus, ablation of lung mesenchymal Prx1 not only affects vascular cell behavior, but also results in epithelial defects and early demise following birth due to respiratory distress.

The lymphatic vasculature in the lung collects extravasated immune cells and keeps the airways dry by collecting fluid leaked from blood vessels. Identifying factors that regulate lymphangiogenesis is a crucial, yet understudied, aspect of lung vascular developmental biology. However, a relatively recent study reveals that the *Prox1* homeobox gene is essential for this process (52). *Prox1* is expressed in a subpopulation of ECs that, after budding from veins, give rise to the mammalian lymphatic system. In *Prox1*-null embryos, budding is arrested at E11.5, resulting in embryos that are capable of undergoing vasculogenesis and angiogenesis, but not lymphangiogenesis. Furthermore, ECs that ordinarily express lymphatic markers – including VEGFR3 and LYVE-1 – are absent in these mice, being replaced by markers that characterize the blood vascular phenotype. Thus, *Prox1* appears to be required for the maintenance of budding of venous ECs and differentiation toward the lymphatic phenotype. In light of this work, it will be important to determine when and where *Prox1* is expressed in the developing lung lymphatics, and whether this gene is dysregulated in lung lymphatic diseases, such as familial pulmonary lymphangiectasia.

### Homeobox Genes and Assembly of the Pulmonary Vascular Wall

Homeobox genes also have been implicated in a variety of processes required for assembly and elaboration of the vascular wall, including the promotion and inhibition of VSMC proliferation, differentiation, and changes in cell adhesion to the ECM. For example, *Hoxb-7* – which appears in the developing lung (42) – is expressed more highly in fetal than in adult VSMCs (53), indicating that this gene may play a role in the early expansion and differentiation of VSMCs. Consistent with this, *Hoxb-7* promotes proliferation, as well as inducing the expression of early VSMC markers, such as SM22- $\alpha$  (54). In contrast to *Hoxb-7*, the divergent homeobox gene product *Gax* (which is expressed in adult cardiovascular tissues including heart, lung, and blood vessels) inhibits VSMC proliferation (55). Within the vasculature, *Gax* is expressed in quiescent VSMCs and is downregulated when these cells are stimulated to proliferate (56,57). In keeping with this growth-suppressive role, overexpression of *Gax* inhibits VSMC prolif-

eration by activating the cell cycle inhibitor protein p21 (57). *Gax* also attenuates VSMC motility by downregulating integrins  $\alpha v \beta 3$  and  $\alpha v \beta 5$  in a manner that is dependent on the cell cycle (58).

*Prx1* and another homeobox gene product designated *Barx2* are believed to regulate VSMC differentiation (59,60), and both of these genes are expressed in the developing lung. Functionally, *Prx1* and *Barx2* have been shown to control smooth muscle-specific gene expression in vitro by enhancing the binding of serum response factor (SRF) to CarG elements, a DNA motif present in many smooth muscle-specific gene promoters (60). Furthermore, the *Barx2* gene promoter contains an SRF-binding serum response element, which is essential for its activity (61), indicating that this gene may be autoregulated. However, whereas *Barx2* is expressed in the differentiated adult aorta, *Prx1* only appears in the walls of developing and injured blood vessels, when VSMC differentiation is being actively suppressed in favor of proliferation (50,62). It is possible, nonetheless, that *Prx1* and SRF cofunction in other cell types within the blood vessel wall (i.e., activated adventitial fibroblasts) that express VSMC markers during development and in pathologic remodeling.

In addition to arteries, homeobox genes appear to play a role in the assembly of pulmonary veins. *Hoxa-3*-null mice die shortly after birth and frequently have heart and blood vessel defects, including hypertrophy of the atria and enlargement of the pulmonary veins (33). This finding is intriguing, given that the wall of pulmonary veins not only possesses EC lining and smooth muscle tunica media, but also an outer layer of cardiac troponin I-positive cells, indicating that these may arise from the developing heart (63). Considering the phenotype of *Hoxa-3*-null mice, it is plausible that this gene functions to limit cardiac cell migration during pulmonary venous development.

Studies with homeobox genes in the setting of occlusive pulmonary vascular disease associated with pulmonary arterial hypertension also have provided potentially important clues regarding the role of these transcription factors in the assembly and disassembly of the pulmonary vascular wall. As in development, the formation of occlusive vascular lesions in the lung also depends on the migration and proliferation of ECs, VSMCs, and fibroblasts, as well as inappropriate expression of VSMC markers and excessive catabolism and synthesis of specific ECM proteins. It is therefore not surprising that many of the homeobox genes involved in pulmonary vascular development are re-expressed in pulmonary vascular disease. In keeping with this, a comparison of Hox gene expression in human fetal lungs versus tissue derived from patients with primary pulmonary hypertension and emphysema indicates that this is the case for certain Hox genes, including HOXA5 and HOXB2 (48). On the other hand, the tissue distribution of some of these Hox genes appears to differ between fetal and remodeled adult lung. For example, whereas HOXA5 expression is confined to the mesenchyme of the respiratory tract in the developing lung (34), this gene has been reported to be expressed by ECs in hyperproliferative, occlusive plexiform

lesions in adult patients with primary pulmonary hypertension (48). It is possible, however, that HOXA5 also is expressed in those muscle cells that are known to contribute to these lesions.

Recent work in our laboratory indicates that both Prx1 and Prx2 (a gene arising from duplication of *Prx1*), contribute to pulmonary vascular disease by promoting the expression of TN-C, an ECM glycoprotein that supports VSMC proliferation and fibroblast migration (62,64). TN-C is expressed in the developing vasculature, but it is suppressed in normal, quiescent pulmonary vessels. In hypertensive vessels, however, TN-C reappears at the adventitial–medial boundary, and later throughout the vascular wall, where it surrounds proliferating and migrating VSMCs and fibroblasts (65–67). At a functional level, TN-C promotes the proliferation and survival of pulmonary artery VSMCs via its ability to cross-modulate the activity of receptor tyrosine kinases. In terms of its effects on migration, TN-C destabilizes focal adhesions, thereby facilitating cell detachment from the underlying ECM (64). Given the importance of these functions in pulmonary vascular development and disease, it is of interest to determine how this ECM protein is regulated.

Multiple factors induce TN-C, including ECM-degrading MMPs. For example, inhibition of MMP activity suppresses TN-C expression and pulmonary artery VSMC proliferation, and reduces the severity of vascular lesions (68). These studies indicate that MMPs lie upstream in an adhesion-dependent signaling pathway that controls TN-C. Consistent with this, the *TN-C* gene promoter contains an ECM-responsive element that is silenced on native type I collagen, an  $\alpha 2\beta 1$  integrin ligand, but is activated on the MMP-proteolyzed or denatured type I collagen, which represents an  $\alpha v\beta 3$  integrin ligand (69). This ECM/ $\beta 3$  integrin-responsive element in the *TN-C* gene promoter was subsequently shown to harbor a homeobox binding site, suggesting that the induction of TN-C in response to changes in VSMC adhesion might depend on homeobox proteins and, in this regard, Prx transcription factors represent ideal candidates. For example, like TN-C, Prx1 and Prx2 are expressed during embryogenesis, predominantly in mesenchyme-specific patterns. In the developing cardiovascular system, Prx1 and Prx2 expression overlaps with TN-C in the endocardial cushions and valves, the epicardium, and the wall of the great arteries and veins. Further, *Prx1* and *Prx2* gene knockouts exhibit skeletal defects and vascular anomalies, including a twisted aorta and elongated ductus arteriosus (50), defects that conceivably arise due to dysregulated TN-C synthesis. In further support of a link between Prx proteins and TN-C expression, examination of hypertensive adult rats lungs showed that Prx1 and Prx2 are re-expressed at the adventitial–medial boundary of remodeling pulmonary arteries, and later within the arterial wall, colocalizing with TN-C protein and proliferating VSMCs (62). Moreover, identical to TN-C, Prx1 and Prx2 expression also is suppressed and induced by native and denatured type I collagen respectively, and overexpression of Prx1 promotes *TN-C* gene transcription and VSMC proliferation. Whether Prx1 promotes VSMC proliferation by

inducing TN-C remains to be determined. Because expression of Prx1 and TN-C both depend on changes in cell adhesion to the ECM via integrins, we hypothesized that the activation of focal adhesion kinase (FAK), an integrin-activated nonreceptor tyrosine kinase that is required for VSMC and fibroblast migration as well as EC differentiation and capillary assembly (70), supports the Prx1-dependent induction of TN-C. In keeping with this, migration-defective fibroblasts and E8.5 embryos devoid of FAK express reduced levels of Prx1 and TN-C when compared to their wild-type counterparts, whereas overexpression of Prx1 in FAK-null cells restored TN-C expression and cell migration (64). Taken together with previous studies, a tenable working hypothesis is that, during vascular development and following injury, MMP-dependent activation of FAK stimulates Prx1-dependent induction of TN-C, which subsequently contributes to the formation of an ECM that supports VSMC and fibroblast proliferation and migration, as well as EC differentiation and network formation. The consequences of perturbing one or more of these processes during lung development are discussed in the next section.

#### SOCIETAL COLLAPSE: VASCULAR DEVELOPMENTAL DEFECTS ASSOCIATED WITH LUNG DISEASE

Numerous experimental and clinical data indicate that reciprocal tissue interactions between the developing pulmonary vasculature and the adjacent epithelium are critical for normal lung development and postnatal function. For example, when fetal rat lung mesenchyme is cultured alone with fetal lung epithelium, differentiated ECs emerge from within the distal mesenchyme. However, when fetal lung mesenchyme is cultured alone, EC differentiation is suppressed (71). A major factor that appears to be critical for lung-tissue interactions is VEGF, which is expressed at high levels by the epithelium. For example, mice that do not express the VEGF-A<sub>120</sub> isoform fail to develop a normal peripheral lung vasculature (72). Similarly, the genetic ablation of hypoxia-inducible transcription factor (HIF)-2 $\alpha$  results in diminished VEGF levels in alveolar cells and a defect in vascularization of alveolar septa (73). These studies indicate that compromising the pulmonary vasculature might have major effects on respiratory function. Indeed, numerous lung diseases are defined by vascular developmental defects, including persistent pulmonary hypertension of the newborn, bronchopulmonary dysplasia, congenital diaphragmatic hernia, lung hypoplasia, alveolar capillary dysplasia, arteriovenous malformations, pulmonary hemangiomatosis, pulmonary lymphangiectasis, pulmonary venoocclusive disease, pulmonary vein stenosis, and many forms of congenital heart disease.

Bronchopulmonary dysplasia (BPD) represents a good example of how knowledge of pulmonary EC developmental biology eventually may be applied to the clinical treatment of a human disease. Historically, pulmonary hypertension was

regarded as a major determinant in the pathophysiology of BPD, with the assumption that pulmonary vascular abnormalities were a secondary consequence of primary injury to the airspace. Recent studies, however, indicate that alterations in the growth and structure of the pulmonary vasculature may contribute directly to the abnormal and hypoplastic alveolarization that characterizes this disease. Although treating many premature infants via assisted ventilation and O<sub>2</sub> therapy is a necessary step for their survival, this standard therapy is believed to contribute to the lung vascular injury associated with BPD. Most research into this disease has been focused on alterations in vascular tone and reactivity in infants and children with BPD, with less emphasis being placed on disordered vascular growth as an underlying feature of this disease. However, studies with neonatal rats demonstrate that pharmacologic inhibition of VEGF receptor activity and angiogenesis attenuates pulmonary vascular growth, leading to a BPD-like phenotype characterized by reduced alveolarization (74). Work in our laboratory has shown that ablation of pulmonary vessels via inactivation of the *Prx1* homeobox gene also results in a BPD-like hypoplastic epithelial phenotype (19). Also, premature baboons placed on mechanical ventilation exhibit decreased lung capillary density, and this is associated with a significant reduction in VEGF levels in the lung (75). This finding is interesting, because VEGF expression levels are decreased in human infants with BPD who die from this disease (76). Although more basic studies are required to understand the relationship between the developing lung vasculature and the airspace, it is hoped that implementation of therapies that will result in the restoration of the pulmonary endothelium will eventually become standard practice for the treatment of BPD and other chronic or fatal lung diseases, including asthma and pulmonary hypertension. Along these lines, Stewart and colleagues have demonstrated that bone marrow–derived endothelial-like progenitor cells, re-engineered to express human endothelial nitric oxide synthase, can restore microvascular structure and function in a rodent model of pulmonary arterial hypertension (77). This compelling experimental study argues strongly that stem cell–based therapies represent a viable option for the treatment of lung diseases underscored by vascular changes, and that restoring the pulmonary endothelium may represent a novel therapeutic option whose time has come.

#### KEY POINTS

- Recent studies have led to major insights into the mechanisms underlying the development of the normal pulmonary circulation and the critical relationship between the vasculature and its surrounding tissue elements, including the epithelium.

- Nevertheless, much still is to be learned and many scientific and political challenges lie ahead. However, it is hoped that continued study of the lesser circulation will ultimately herald a new era in respiratory medicine, especially one that reconsiders the importance of the pulmonary endothelium as a central regulator of normal lung structure and function.

#### Future Goals

- To resolve the origin of the pulmonary vasculature
- To develop computational modeling to predict pulmonary vascular cell behavior in development and disease
- To integrate biology, medicine, physical, and mathematical sciences to generate new hypotheses in pulmonary vascular development and disease
- To restore the pulmonary vasculature and respiratory function via gene- and stem cell–based therapies

# Metaphors

# Shall I Compare the Endothelium to a Summer's Day?

## The Role of Metaphor in Communicating Science

Steven Moskowitz\* and William C. Aird†

\*Advanced Medical Graphics, Boston, Massachusetts; †Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

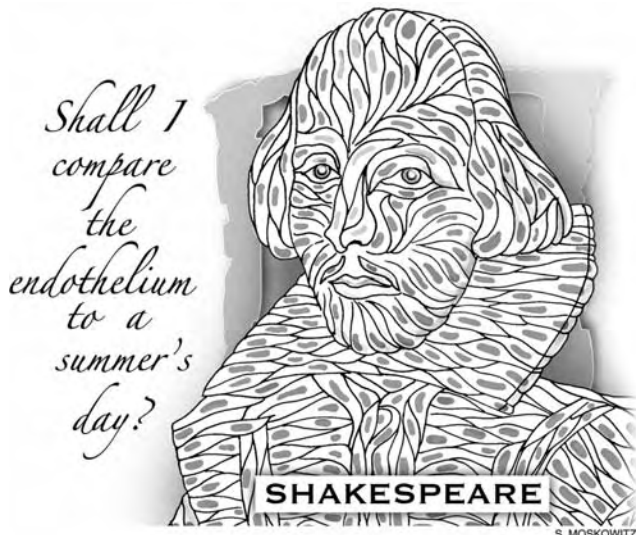

Figure 24.1. The metaphorical twist. Our Shakespeare attempts to portray endothelium with an elegant phrase, as the endothelium attempts to portray Shakespeare with individual cells.

When a complex biological system such as the endothelium is under scientific scrutiny, rigorously objective tools and techniques are used to make measurements, collect data, and analyze results. While adhering to the hallmark objectivity of science, a scientist may find it difficult to imagine a welcome role for something so fraught with subjectivity and prone to misinterpretation as metaphor. To refer to an arterial “wall” in the context of vascular medicine seems straightforward enough, because the term refers to a barrier or demarcation of the vascular structure. But we might ask: Does it hinder or further our understanding of blood vessels by likening endothelial and perivascular cells to the bricks and extracellular matrix to the mortar that make up an actual wall? At best, the term incompletely conveys the endothelial cell’s functions. Might it be

better to use the metaphor of a “gate” or “gatekeeper” instead of “wall” to capture the role of the endothelial cell (EC) in mediating permeability? The distinction between these two metaphorical descriptions is of paramount importance to our understanding: A permeable “wall” might be considered breached; whereas a permeable “gate” is functioning properly.

The purpose of this chapter is to recognize the role of metaphor, both past and present, in the field of endothelial biomedicine. We discuss how metaphors serve scientists on a regular basis; we consider some reasons why seemingly subjective descriptions can be a basis for scientific understanding; and we analyze the merits of both linguistic and visual expression in communicating science.

### WHAT IS METAPHOR?

A metaphor is a figure of speech – typically a few words (although sometimes conveyed as a single word or as many hundreds of words) – that compares two different things (abstract or concrete) for the purpose of indicating a resemblance between them.<sup>1</sup> Metaphors also can be communicated through other modes of expression, such as illustration or photography. Key to the definition is that its literal meaning is bypassed as it takes on a new figurative meaning. For example, if we think of blood vessel ECs, perivascular cells, and

1 For the purposes of this chapter, we use *metaphor* as an umbrella term, even though metaphor is one of many types of expression (including simile and analogy) that draws comparisons by using words (or pictures) other than in their literal sense. Simile is generally considered a subcategory of metaphor, and metaphor itself is considered by some a subcategory of analogy. A simile overtly indicates its figurative sense to a reader by using the words *like* or *as* to compare two things. The sentence “Endothelial cells stack up *like* bricks in a wall” is a simile, although its underlying concept is metaphorical. An analogy often compares things known to be similar and builds on these known similarities as a form of reasoning.

extracellular matrix as forming a wall, the word *wall* loses its common literal meaning (i.e., a solid, upright structure) and takes on a figurative meaning derived from our common experience with walls. So, in this instance, we draw less from our understanding of the physical qualities of a wall than from the conceptual qualities; bricks and mortar become irrelevant, while the notion of separation (“barrier”) or confinement (“container”) is ultimately conveyed.

Such fundamental conceptual qualities commonly are conveyed in metaphors and, as Theodore Brown points out, they “arise from our most ubiquitous physical experiences,

such as verticality, space, and vision” (1). Metaphors based on human sensory experience may be conveyed by language, but they are not merely a by-product of language or word play. Rather, they are tied deeply to the conceptualization of “one mental domain in terms of another” (2).

In seeking answers to how we compare and utilize concepts in a metaphor, ongoing studies in the fields of psychology, philosophy, anthropology, and linguistics have recognized some of its key features. Each metaphor consists of two domains: a source domain, and a target domain (Figure 24.2A). The *source* refers to the concept (or thing) *from* which we derive a

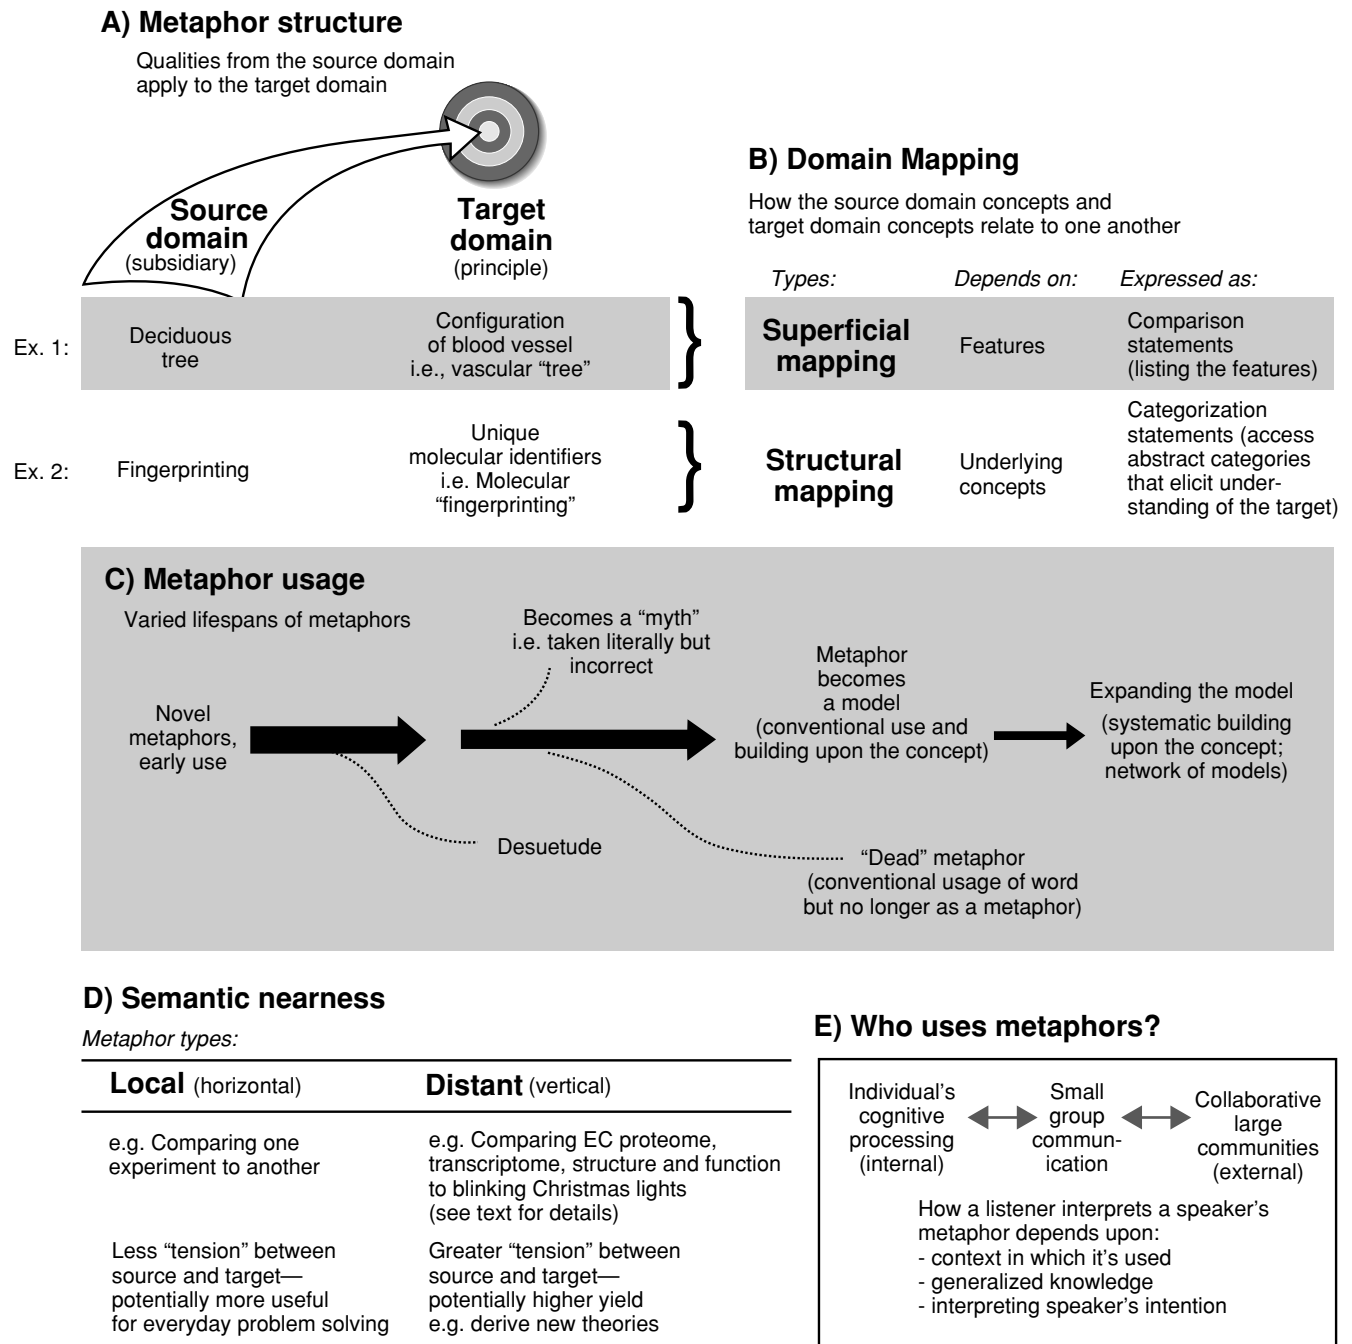

Figure 24.2. A summary of key concepts and terms to describe and analyze metaphors.

known quality; the *target* is the concept (or thing) to which the quality applies. For example, in the phrase “The endothelium is a gatekeeper,” *endothelium* is the target domain; *gatekeeper* is the source domain. The source domain and target domain each embody properties that are being compared, some of which are emphasized by this comparison, and others that are suppressed.

Comparing properties of a given source domain and its target domain is called *mapping*. The source and target may correspond in a predictable way, whereby their superficial features are compared and matched (Figure 24.2B). As an example of superficial mapping, when vasculature is called a “tree,” the salient features being compared are branching and tapering. Alternatively, an understanding may be more appropriately based on deeper, underlying concepts (termed *structural mapping*). An example is the use of the term blood vessel “wall,” to describe a barrier or container. A more extreme example of a metaphor that invites structural mapping would be to describe the endothelium as an ant colony – the underlying concept being that the component parts – ECs (ants) – go about their business oblivious to the needs of the organ or system at large (colony), following local rules that generate an apparently complex global behavior.

Source and target can be further analyzed in terms of their semantic nearness (Figures 24.2D and 24.3). If the source and target are from similar fields, the metaphor is termed *local*, and the comparison deemed *horizontal*. For example, “ultramicroscopic circulation” is used as a metaphor borrowed from within its own field. Originally the term *circulation* was used to describe forward, circular flow of blood through the vasculature. In the case of ultramicroscopic circulation, the word *circulation* also is being used to convey movement of blood substances, but only in the metaphorical sense because transendothelial transport is neither forward nor circular. Here it appears in its original context:

... visible flow of blood through the capillaries is, in fact, very small in comparison with the *invisible* flow of water and dissolved materials back and forth through the capillary walls. . . . this *invisible* component of the circulation takes place at a rate which is many times greater than that of the entire cardiac output. Indeed, it is by means of this “**ultramicroscopic circulation**” through the capillary wall that the circulatory system as a whole fulfills its ultimate function in the transport of materials to and from the cells of the body. (3, Emphasis added.)

When metaphors consist of a source domain *distant* to the target domain, they are said to have a greater *tension* between them.<sup>2</sup> The underlying concept may require explanation in

2 Tension should not be confused with the emotional response elicited by a metaphor. For example, although the metaphors of endothelium as a gatekeeper and as an ant colony are both distant in the strict sense of the word (i.e., they draw on sources outside the field of biology), they are certain to provoke different emotional responses.

Figure 24.3. Semantic nearness. A unicyclist is used to represent the modulating effect of endothelium based on the heterogeneity of individual cells and their orchestrated effects at a systemic level. The figure conveys a reductionist–holist spectrum from single cells (in cell culture) to blood vessels to whole organism. Moreover, the endothelium, like the unicyclist, appears from a distance to be inactive or quiescent, but on closer inspection is constantly acting and reacting, making fine adjustments to its environment. Because the metaphor is presented visually, the context of the metaphor—its laboratory setting—is made apparent in an attempt to add “local” attributes to a more “distant” metaphor. As reported by Dunbar and Blanchette, scientists use those analogies more frequently that are derived from their own or similar fields.

order to be understood by the reader, but the payoff can be great. The use of the distant metaphors “fingerprint” and “zip code” are shown here in context:

The importance of specific morphological changes elicited by FGF-2 [fibroblast growth factor -2] is underscored by our recent observation that major stimulators and inhibitors of angiogenesis induce distinct “**fingerprint**” patterns of vascular morphology when applied to the quail CAM [chorioallantoic membrane]. (4, Emphasis added.)

And,

Vascular targeting exploits molecular differences that exist in blood vessels of different organs and tissues, as well as differences between normal blood vessels and angiogenic or remodeled blood vessels. Differences in

plasma-membrane proteins (“vascular zip codes”) can be used to target therapeutic or imaging agents directly to a particular organ or tumor. (5, Emphasis added.)

Additional examples from published papers that utilize terms distant from the field of biomedicine abound. Because the endothelium is invisible to the human eye, it is common to apply meanings derived from the macroscopic world to the microscopic one. For example, in 1983, Thorgeirsson (6) referred to a series of metaphors (most of which had been previously introduced by other investigators):

**Architecture:** “The general architecture of the endothelial lining . . . .”

**Constellation:** “. . . in addition to the usual constellation of intracellular organelles, most endothelial cells contain a unique structure, the Weibel-Palade body . . . .”

**Flask, teardrop, mouth:** “The flask or teardrop shaped caveola connecting to the cell surface through a mouth or soma . . . .”

**Hairy:** “The so-called ‘coated’ or ‘hairy vesicles’ . . . .”

**Channels, thoroughfare:** “. . . such chains might form channels through the cytoplasm of the endothelial cells and thus provide for a continuous, water-filled thoroughfare for molecular transport.”

**Foot:** “. . . the astrocytic foot processes . . . .”

**Sieve, plate:** “. . . were arranged in characteristic patches, termed sieve plates.”

And Thorgeirsson’s following passage even has a hint of a merchant marine report:

. . . molecular **transport routes** (pores) in both large and **small vessels, migration routes** for blood cells . . . (6, Emphasis added.)

Other notable examples in the literature include:

**Taps, sink, carrier:** “Does this water merely follow protein as it leaks from open ‘taps’ in the cortex, with both protein and water flowing from the taps into the white matter ‘sink’ below . . . substances transported by facilitated diffusion are thought to be moved by some ‘carrier’” (7).

**Cobblestone:** “However, tumors followed for 16, 21, 34, and 44 days retained their ovoid shape and gray cobblestoned surface . . . .” (8).

**Starve:** “‘Tumors unable to induce angiogenesis remain dormant at a microscopic size: 1–2 mm<sup>3</sup> in situ,’ he wrote in 1971 in the *New England Journal of Medicine* (Folkman, 1971), so by attacking cancer’s lifeline, it might be possible to starve tumors into regression” (9).

Previous studies have provided insight into the use of metaphor by scientists. Dunbar (10,11) reported a total of 99 analogies used by four groups of scientists during their weekly lab meetings (four meetings per group). They classified analogies into four groups, depending on how scientists used them to achieve their goals. Three of the uses (formulating a hypothesis, designing an experiment, and working out problems in an existing experiment) used analogies that were *local/horizontal* (i.e., comparing work to similar experiments or similar organisms). They write: “Rather than new theories and hypotheses being generated by making analogies to very different domains, new theories are generated by making analogies to related domains” (11). Scientists frequently used science as sources for their analogies.

The fourth use by scientists was “to explain a result.” For that, the scientists sometimes used more *distant/vertical* analogies, derived from sources outside their field. If the scientists obtained a series of unexpected findings in a given organism, they would draw on other organisms for the source of their analogies. The analogies became more *distant/vertical*, and the scientists tended to make broader generalizations, linking their results to similar results obtained by others’ experiments. They used *distributed reasoning*, which is noted to work better if the scientists in the group have varied backgrounds (to provide varied perspectives) (Figure 24.2E).

The lifespan of metaphors varies considerably: Some metaphors are used in an ad hoc fashion, never to be used again, whereas others provide such elucidation that they are adopted and become widely used (Figure 24.2C). The word *wall* has been used in the sense of separation (or confinement) for so long that, for most people, it is no longer considered a metaphor, but a *dead metaphor* (also called *conventional metaphor*) – one that has allowed the literal interpretation of the word to expand to include the former metaphorical meaning. This is the case for innumerable words and expressions in language. In her book, Mary B. Hesse (12) offers this thought: “Rationality consists [of] the continuous adaptation of our language to our continually expanding world, and metaphor is one of the chief means by which this is accomplished.”

Bowdle and Gentner (13) describe this evolution of meaning as the *career of a metaphor*, highlighting the fact that originally a metaphor may introduce a novel concept, but as it is adopted by a culture, it becomes a conventional part of the language with a formal definition less likely to be misinterpreted. An example of this is seen with the word *virus*, which has a literal interpretation expanded from its former metaphorical meaning. The biological term *virus* was introduced in the 1700s. In the 1970s, it was first used by fiction writers in conjunction with computers and, by the early 1980s, “computer virus” was academically recognized and defined as a program that modifies (“infects”) other programs “to include a possibly evolved version of itself” (14).

In endothelial biomedicine, the term *vascular labeling* was introduced, defined, and quickly adopted from its metaphorical usage. The properties of vascular labeling related to, and expanded on, existing meanings of the word *labeling*.

Our experiments were based on a method to which we refer as “**vascular labeling**,” and which permits one to identify leading vessels by means of visible accumulation of foreign particles within their walls. (15, Emphasis added.)

In some cases, the metaphor is ultimately judged to be a myth (e.g., the endothelium as an inert layer of nucleated cellophane). Other metaphors may stand the test of time by providing a completely different perspective on their targets of interest and subsequently evolve into accepted scientific models (e.g., William Harvey’s metaphorical use of the word *circle* to describe the vascular system).

According to Lakoff and Johnson, our understanding of the world is derived from metaphors. They assert a pervasiveness of metaphor in our lives and refer to *conceptual metaphors*, which structure the way we think, speak, and act (16). *Container metaphors*, for example, are the underlying concept for all things that have an inside and an outside. Some containers, such as jars and boxes, literally are containers; other things have insides and outsides that have emerged metaphorically, such as blood vessels and their walls. *Oriental metaphors* are based on the way we experience the physical world. If I were to say, “I’m feeling ‘up’ now that I’ve received the NIH grant,” I have expressed an abstract emotion based on concepts derived ultimately from the physical environment.

Linguistic and philosophical considerations of how words have meaning, and how meaning relates to the world, impact any discussion of metaphor. The issues surrounding our natural ability to learn and use language are intertwined with the methods used for analyzing the issues. Is it the nature of the world that structures our language, or do we apply language (concepts and words) to structure it? How is it that we can derive meaning from language? How are our thoughts related to the words we use? The work of a number of philosophers exemplifies these issues: Gottlob Frege (1848–1925) put forth the *context principle*, which states that the meaning of words can be derived only within the context of an entire expression. Ferdinand de Saussure (1857–1913) stated that language depends on an entire community – not on individuals. Lev Vygotsky (1896–1934) asserted that thought and language are a “unity” and therefore dependent on one another; in his view, speech is not a secondary result of thought. Alfred Tarski (1902–1983) believed that “truth” is something that can be said of sentences because of properties of language, and that it can indeed correspond to the things in the world. Noam Chomsky (1928–) professed that people are born with an innate ability to understand the *universal grammar* of language, which itself possesses a “universal structure” to be understood. Ludwig Wittgenstein (1889–1951) argued that meaning is not simply derived from words in the context of a sentence but also depends on what the expressions are being used. Meaning, therefore, includes the activities of people and the circumstances in which language is being used.

Wittgenstein also proposed that different uses of one word share a *family resemblance*, similar to the way siblings and

parents share a resemblance, or how baseball and checkers can both be considered games without any well-delineated similarity. He asserted that no boundaries exist for words, so a radish can be bitter, just as a memory can. A lemon can be sour; my car can be a lemon, and my experience can be sour due to my lemon of a car. Identical words can be used to convey different meanings depending on context, a feature of language that denies meaning is tied to the world in a set way.

We create analogy and metaphor with ease, but their *affordances* – what their features provide for us – also vary depending on use. Dawkins wrote: “The trick is to strike a balance between too much indiscriminate analogizing on the one hand, and a sterile blindness to fruitful analogies on the other” (17). Ancient Greeks used analogical descriptions in a quest to define all that couldn’t be seen – gods, soul, elemental workings – and in describing nature and human behavior. Likewise, according to Gombrich, the visual arts developed as a means to produce “plausible narration of sacred events” (18). Anaximenes’ and Heraclitus’ early use of analogy to describe cause-and-effect changes opened the way for scientific explanation. In an effort to distinguish knowledge from opinion, Plato warned that the wrong message could be derived from the use of analogy if its use was not a part of carefully constructed discourse. Although the use of unbiased reason is necessary to gain knowledge of the world, Plato’s dialogues demonstrate that analogy and metaphor are part of the art of discovery.

## METAPHOR IN ENDOTHELIAL BIOMEDICINE

Modern vascular science began with a splash of metaphor by William Harvey. Harvey’s scientific revolution hinged upon a single word: *circle*. This pivotal word is part of a metaphor in his passage describing the course of blood flow:

... the blood should somehow find its way from the arteries into the veins, and so return to the right side of the heart, I began to think whether there might not be a Motion, As It Were, In A **Circle** (19). (Emphasis added.)

Harvey used analogy to compare blood circulation with the hydrological cycle recognized by Aristotle:

Now, this I afterwards found to be true; and I finally saw that the blood, forced by the action of the left ventricle into the arteries, was distributed . . . This motion we may be allowed to call circular, in the same way as Aristotle says that the air and the rain emulate the circular motion of the superior bodies; for the moist earth, warmed by the sun, evaporates; the vapours drawn upwards are condensed, and descending in the form of rain, moisten the earth again (19).

And here, multiple use of metaphor and analogy in an effusive letter from Harvey to Charles I, King of Great Britain at the time (1628):

The heart of animals is the foundation of their life, the sovereign of everything within them, the sun of their microcosm, that upon which all growth depends, from which all power proceeds. The King, in like manner, is the foundation of his kingdom, the sun of the world around him, the heart of the republic, the fountain whence all power, all grace doth flow. What I have here written of the motions of the heart I am the more emboldened to present to your Majesty, according to the custom of the present age, because almost all things human are done after human examples, and many things in a King are after the pattern of the heart (19).

Here “heart” metaphorically is sovereign (like the King) and the sun. Likewise, the “King” metaphorically is sun, heart, and fountain. Harvey’s lavish use of metaphor demonstrates several of its key functions: (a) to interpret observations, (b) to produce knowledge and further understanding, and (c) to convey this understanding to others.

Drawing on the brain’s natural associative tendencies, we use metaphor to describe something novel in terms of something familiar, and for that reason their use is common among those at the leading edge of a scientific field. Arthur I. Miller writes: “Metaphors are an essential part of scientific creativity because they provide a means for seeking literal descriptions of the world . . . metaphors underscore the continuity of theory change . . .” (20). Some of the most common terms for vascular structures were derived from superficial similarities to the easily visible natural world. Robert Hooke first used the word “cell” (1665), because the structures of cork slices he saw resembled the familiar cells in which monks lived. Arteries were named for their capacity to carry air ([Gr.] *aer*) and spirits, not blood. The term *capillary* is derived from the word *hair* (capillary: 1656, from L. *capillaris* “of hair,” from *capillus* “hair” [of the head]).

According to Thorgeirsson and Roberston, the word *endothelium* was:

. . . introduced in 1865 by the German anatomist His, combining the Greek words “end,” meaning within, and “thele,” meaning nipple. Its literal meaning is thus: “within the nipple.” It was proposed as a complementary anatomic term to “epithelium” (“over the nipple”) first used by Ruysch around 1700 to describe the cell layer covering the tongue and other areas with nipple-like papillae. Henle expanded the domain of the latter term to include all specialized cell surface layers, including those linking the respiratory, gastrointestinal, and urinary tracts (21).

In addition to the plethora of metaphors already cited (architecture, constellation, flask, teardrop, mouth, hairy, channels,

thoroughfare, foot, sieve, plate, taps, sink, carrier, cobblestone, fingerprint, zip code, and so on), a review of early papers reveals common uses of analogical comparison, which are easy to spot due to the direct reference to it:

**Similar, striking parallel:** “Some of our data is strikingly similar to that of Kontos who employs acute hypertension to injure the endothelium. The hypertension is either initiated indirectly by . . . We see a striking parallel between these data and those of our light/dye model of injury” (7).

In the first few paragraphs of an abstract by Simionescu and colleagues, the authors employed no less than five analogical comparisons, using the following phrases:

“ . . . **comparable to**, though less elaborate than”  
 “. . . behave **like** ‘single unit’ particles”  
 “. . . junctional elements are **similar to**”  
 “. . . appears to be a stretched-out **version of**”  
 “The other type is **reminiscent of** . . .” (22).

In a classic paper by Folkman and colleagues:

New capillaries are elicited and the tumor then enters a phase in which nutrients arrive by perfusion. It is possible that TAF is responsible for this final stage. It is tempting to suggest that tumor growth might be arrested at a very small size if the angiogenesis activity of this factor could be blocked. **This would be analogous** to the cessation of growth of bacterial colonies when their size exceeds the diffusion of nutrients. (23, Emphasis added.)

## ORGANIZING INFORMATION

The concept of analogy may be predicated on the philosophical problem of unity and multiplicity in the world. “Are things so different that they can never be classified? Or so unified that they can never be distinguished?” (24). Between these extreme notions exists the similarity and dissimilarity from which we make comparisons. Attempts to relate large, universal concepts in the “big picture” to the particulars all around us can be a lifelong philosophical quest. Although we may be short-sighted in trying to get the big picture, we have a natural ability to see relationships in the physical world. The Gestalt psychologists point out our propensity toward perceiving groupings of shapes and things (rather than isolated things – at least in certain circumstances); they note a predilection for wholeness (rather than parts) and continuity (rather than interrupted shapes). When looking at a dashed line, for example, we first perceive the cohesive line, rather than the isolated line segments and intervening spaces. Only by scrutinizing it do we note its component parts. Grasping wholes aids pattern recognition, which is an important skill in biomedicine;

as best demonstrated by the ability of an experienced cardiologist to diagnose acute myocardial infarction based on a patient's electrocardiogram, without having to attend to the minute details of the tracing.

The fact that we recognize parts within a whole, or multiplicity of wholes, relates to an ability to understand the concept of quantity. Research on preverbal infants and on people in primitive societies without arithmetic systems demonstrates that such mathematical abilities are innate or occur at a very early age.

Graphs, which are commonly used to visually convey quantitative information, rely on this innate concept of quantity. A rectangular bar (on a graph) that appears tall means "greater" compared to the shorter bar, which means "less." The analogical component – the correlation of bar height to the data it represents – takes advantage of our effortless understanding of quantity. Cortical mapping of the shapes in our visual field may provide some explanation for our ability to correlate size, but even without images, comparative forms of words also reveal our understanding of quantity. "Big, bigger, biggest" describes the relative degree of bigness. The series can be extended to include new words (e.g., slightly bigger, somewhat smaller).

If one were to use the subjective words *happy*, *happier*, or *happiest* – their qualities can be compared and ordered in the same way. Although no standard units for happiness exist, we can still make a qualitative distinction between degrees of the emotion. Qualitative distinctions – the ability to tell things apart and describe them without measurement – are nonetheless assessed in terms of the *degree*. The degree of a quality is tantamount to an amount of it so, in a sense, we're still measuring it in terms of similarity and dissimilarity to something else. For example, when we take a medical history, we might ask the patient: "On a scale of one to ten, how would you rate the pain you are experiencing?"

In science, and in other endeavors, technical language is useful only to the extent that it is familiar to us. For example, precise geographical coordinates of latitude and longitude are irrelevant in our daily routine. The complexity of technically accurate descriptions can conceal the obvious: "I observe one vertical member, and one horizontal, fastened perpendicularly to it at the base. Above it are two cantilevered members of the same length fastened perpendicularly. One is fastened at the top of the vertical member, and the other is halfway between the upper and lower ones."

Or I could simply say: "It looks like a capital E."

In fact, a similar description was used by Gudmundur Thorgeirsson:

In the early stages of realignment C and L shaped nuclear forms were seen giving the impression of nuclei being caught in the act of reorienting themselves under the new conditions of flow (6).

How do analogy and metaphor fare against more conventionally objective descriptions? In lieu of epistemological formal-

ity, we turn to another metaphor to consider the informational content of a description. Paul Laffoley's "epistemic ladder" considers gradations of information arranged by degree (25). Rather than delineate between "that which we know to be true" (fact) from "that which we know to be false" (fiction), the epistemic ladder describes successive steps in a progression from partial to complete knowledge. The metaphor of a ladder imparts a sense of order without putting limits on the content. In Laffoley's model, near the base is knowledge that is mostly incomplete, such as that conveyed by arbitrary representation. As an example, we might use a highly simplified (cartoon) silhouette, such as one found on a deer-crossing sign to represent a deer. The next step advances to a closer representation: A deer's track in the snow, for example, would indicate the presence of a deer at that place and time. "Contact" has been made between knower and known in this step. Extension proceeds from contact, in the form of an *icon*, such as a photograph of the animal or a specimen preserved by taxidermy. Evidence gleaned from indirect observation, common in modern science, would be tantamount to the found deer tracks, whereas analogy and metaphor are lower on the epistemic ladder, akin to the image on a sign.

In endothelial biomedicine, the ladder is "bottom heavy." That is, we rely on metaphor and analogy (and to some extent, on indirect measures of structure and function) to represent the endothelium *in vivo*. Although tens of thousands of studies exist in the literature pertaining to cultured ECs, many of the data obtained from these investigations can be assigned to the lowest rungs of Laffoley's ladder, owing to their poor correlation with *in vivo* biology.

Wurman has listed additional ways in which to organize information logically (26). The most obvious ones appeal fundamentally to our innate sense of time and space, and to our innate abilities with quantity and language. Depending on what information needs to be conveyed, we may choose to present it chronologically, alphabetically, in numerical sequence, as a hierarchy (or continuum), by category, or by location (spatially), among others. Organizing information spatially utilizes our visual system, which encompasses innate perceptual and cognitive abilities. The visual system is able to identify objects and their positions in space and, despite myriad viewing conditions, objects can be identified in a fraction of a second, from different viewing angles, and even if partially occluded or attached in an unfamiliar way to another object.

Alternative ways to organize content can reveal or highlight relations between particular information. Some anatomy texts are organized by region of the body, whereas others are organized by system or by tissue similarity. In the case of this book, sections are divided according to time; the first section deals with the past (history of medicine and evolution), the middle section with the present, and the last section with the future. Chapters also are organized around the metaphor of the EC as an input–output device; some chapters refer to input, others to coupling (i.e., intracellular signaling), and yet others to output (i.e., cell phenotype).

## VISUAL METAPHOR

The visual system is at our disposal for tasks other than direct perception. Visual mental imagery has much in common with visual perception – that is, what we picture in our minds “without looking” shares neural framework and processes with what we see with our eyes. Kosslyn found that information from mental images corresponds to the information perceived in similar real-world scenes: We can “inspect” mental images in a way similar to that in which we inspect real-world scenes, an ability that can aid in interpreting metaphors (27). For example, the endothelium-as-nucleated-cellophane metaphor conjures up a mental image of extraordinary thinness and robustness (but the metaphor is misleading when inferred to represent a nonpermeable barrier and may even distract as we actually visualize a shiny, cellophane surface). Compared with schematic representations, mental images can be far more powerful and instructive (just as reading a book often is considered to be more fulfilling than watching a movie based on that book); however, there is still debate on how many new properties can be discovered simply from the mental manipulation of imagery.

Analogy and metaphor serve to intensify and personalize the empirical and make good use of our capacity to visualize and conceptualize. Scientists, in turn, occasionally devise thought experiments that rely on such ability. With relative ease, we picture a scene, perhaps calling on exemplars or archetypes, and, with basic language skills, come to an understanding of the problem at hand. Both logical and analogical components are part of the thought experiments, which indirectly enlightens the reader to science, as art, literature, and philosophy do, without relying on data or experience. Theodore L. Brown (1) relates metaphor to “implicit learning,” which can occur outside awareness and in contrast to explicit, overt learning. We make decisions and act based on unconscious mental processes. Brown quotes David Gooding: “Thought experiments work because they are distillations of practice, including material world experience” (1).

Consider the following to describe EC heterogeneity in its vast array of (about 60 trillion) cells. It has a touch of metaphor, thought experiment, and mental imagery:

For purposes of discussion, let’s formulate a hypothesis that endothelial cells are heterogeneous, and that phenotypic differences between endothelial cells are governed by spatial and temporal differences in the local microenvironment – just as individual differences in human physical and behavioral traits are shaped by different personal experiences. We could design an experiment in which we map the phenotypes of endothelial cells from different sites of mouse vasculature by using immunohistochemistry to monitor different proteins – just as we might determine protein expression in two different cell types in culture – and then determine whether these patterns change when the mice are administered endotoxin. The study would

show that at any given moment, different vascular beds express different proteins. Moreover, at any one site, endotoxemia would result in a change in the expression pattern. We would conclude that indeed the endothelium displays marked heterogeneity and that endotoxin results in phenotypic alteration. In explaining the results, we would argue that endothelial cells are highly sensitive and responsive to extracellular signals. Like a barcode reader, the endothelium is constantly taking inventory of its surrounding environment. Similar to a chameleon, the endothelium is molding itself to the requirements of the underlying tissue. If we could somehow color-code the phenotype of the endothelium – for example, by assigning a shade of color based on that cell’s proteome, transcriptome and function – then at any given moment, the endothelium would display a remarkably rich color palette. If we were then to “roll the film” and observe the color palette in real time the colors would fade in and out or even blink on and off like lights on a Christmas tree (insofar as the microenvironment changes from one moment to the next).

As the above example illustrates, we have transitioned from local to distant analogies and metaphors to explain endothelial cell heterogeneity in terms that most biomedical practitioners will understand.

The ubiquity of images and graphical representations reveals the confidence we have in constructing and interpreting them. Organizing information by location, referred to as mapping, is the correlation of size or position of something to its representation. We not only analogize three-dimensional (3D) space into two-dimensional (2D) representations, but the representation can be a metaphor for something else, if need be. Willats distinguishes between “drawing” and “denoting”; denoting assigns meaning to the points, lines, and shapes that comprise a picture, whereas drawing refers to the position (and size) of elements. Our understanding of the schematic diagrams used to represent biochemical pathways depends on such denotation. Arbitrary shapes, connected by arrows, analogize the chain of cause and effect in a cascade of biochemical events, as exemplified by many of the figures in this volume. The words, shapes, and color in diagrams provide us with a conceptual understanding of cellular processes not directly observable. We infer an objective resemblance between process and representation but, in fact, the assigned elements and their spatial relation are analogical at best and therefore somewhat subjective. Ephemeral processes can be slowed down and stabilized in diagrams, just as lengthy processes can be sped up and summarized. A potentially wide range of interpretations for a diagram is narrowed by the viewer’s ability to discern, the author’s ability to explain, and the designer’s ability to utilize principles of design.

On the printed page, the spatial arrangement of information must be utilized to convey time. One of the most prevalent metaphors in this regard is seen in the face of a clock, which

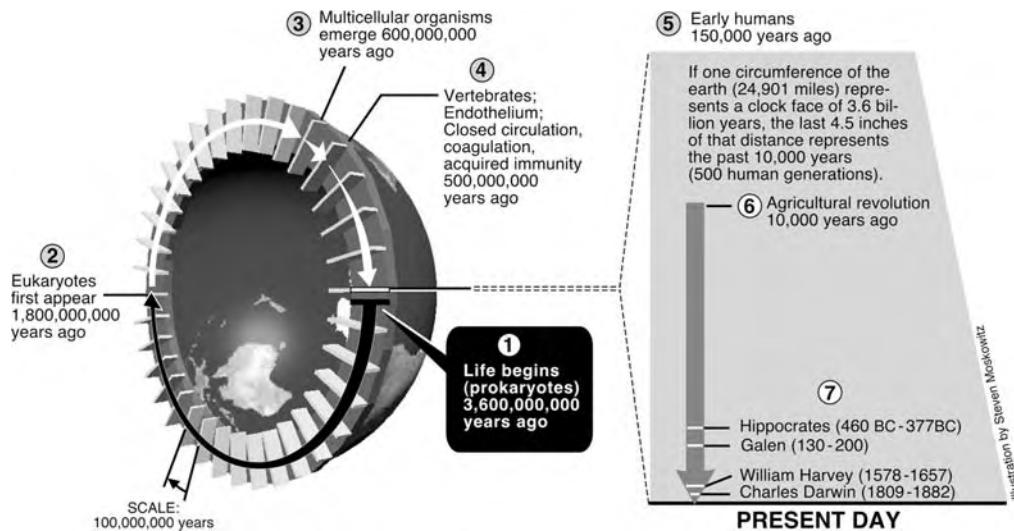

Figure 24.4. Earth as a timeline. The metaphor of the clock is changed in scale to dramatize the relative incipience of the human species. The human species is 150,000 years old, whereas the transition from the Stone Age (Paleolithic) to the agricultural revolution (Neolithic) occurred a mere 10,000 years ago. If one circumference of Earth (24,901 miles) represents a clock face of 3.6 billion years, the last 4.5 inches of that distance represents the past 10,000 years. The history of medicine (particularly as it relates to the cardiovascular system) is a mere blink of the eye in evolutionary terms.

has a unit of time (an hour) measured by a unit of space (the distance around the clock) (Figure 24.4).

We are just as easily able to apply relative quantities to time as we are to space, and we readily understand graphical representation of temporal events such as time lines, sequences of individual movie frames, and other graphical cues for time, such as directionally blurred edges to indicate motion. Indeed, an important goal in endothelial biomedicine is to develop improved tools for representing the complex temporal dynamics of this cell layer.

An artist's rendering attempts to analogize percepts and concepts to visually express them to an observer. Linear perspective, overlap, shadow and light, and tints of color are among the artistic devices used to provide visual cues to an observer when seeing spatial relationships on a flat page. Radiographs, radio-labeling, and innumerable techniques used to formulate scientific understanding all depend on the ultimate placement of abstracted data into the human realm for observation. The invisible must be made visible through photographic or illustrative means.

An understated and unadorned artistic style is concordant with the objectivity sought by science. If a color can edify, or an outline correctly delineate, or a pattern distinguish one thing from another without being superfluous – then it's deemed acceptable. But, given the numerous options for representation, an analogical approach may be most logical. For example, consider the rendering of blood vessels. The arterial wall is not red, nor is the venous wall blue. But they are often illustrated that way for a resemblance to the oxygenated or deoxygenated blood they carry, respectively. In other words, the color metaphor is relevant for the state of oxygenation of the blood, not the physical appearance of arterial or venous

tissue. To be useful to an observer, a salient graphic distinction between arteries and veins has been made based on analogy.

The precise color, texture, or line thickness used in a diagram can be selected by any number of practical or aesthetic criteria. When Copernicus postulated an orbiting earth, a concept that refuted Ptolemaic geometry, religious doctrine, and common sense, any model that placed the sun (instead of the Earth) at the center of the solar system would have sufficed. Galileo preferred circular orbits for aesthetic reasons, but Kepler, more accurately, used ellipses. At the time, one's own eyes could not be trusted – empirical accounts of the sun moving across the sky were deemed illusory – but the analogical motions of little mechanical orreries (i.e., mechanical models of the solar system) were deemed truth.

By way of technology our vision is extended through the use of microscopes and telescopes, and our computational ability is augmented with computers. Instrumentation allows for degrees of precision beyond the normal threshold of experience. Innate abilities are built on in a structured way to gain understanding of the world. To this extent, scientists become pilots of a windowless aircraft, only able to directly observe the instrument panel. With *in silico* research, biologists delve further into analogical and metaphorical means of observation, another step removed from living tissue.

After completing all the machine processing, we are allowed periodic glimpses at the resulting visual forms translated from the data. Our innate mathematical abilities have limited prowess in statistical computation, but when the results are graphically displayed, we can more easily digest or “explore” the data – using the same visual and cognitive skills that have evolved in response to stimuli posed by our environment,

which allowed us to avoid predators, hunt for food, and find mates. We compare and contrast the appearance of points and lines on a line graph, for example, and easily find trends and patterns among the shapes that may reveal trends and patterns in data. We find coherence between the big picture and the minutiae, and distinguish similarities and differences among these analogical forms.

As scientific descriptions lengthen, and the relationships become more complex, it becomes advantageous for a reader to view a diagram, table, or other graphic to address the ambiguity inherent in linguistic description. Spatial arrangement of the type found in tables and other graphic elements found in diagrams might present additional forms of ambiguity that must be avoided as well. By taking into consideration the noted principles of Gestalt psychology on human visual perception, graphic representation can communicate information more reliably. These principles include: *Proximity*, which refers to the fact that we perceive a relation between elements that are close to one another. If two curves occur on a graph, we'd expect the descriptive labels to be in proximity to their corresponding curves. If that isn't possible, (e.g., due to space constraints) we may utilize the principle of *Connectedness* and draw a line between the curve and its corresponding label, to visually connect them. If that doesn't work, we might employ the principle of *Similarity*, which finds greater relatedness between similar elements, and make the curve and its corresponding label the same color. *Closure*, *Continuity*, and *Common Fate* are described in Figure 24.5.

Once it's understood how we see shapes on a page, an optimized presentation, which might incorporate a mixture of words and pictures, can be arranged in such a way that an observer's perception of the forms can be anticipated. The resulting composition can maximize the conveyance of information by removing ambiguity and overall reinforcing the intended message. The Gestalt principles expose how designers use fonts, sizes, alignments, color, contrast, and graphic elements in concert to better present information.

Whether by looking at a table, diagram, or visualization of data generated by computer, the observer's own analysis proceeds from a natural ability to see in ways described by Gestalt psychology.

An undisputed role exists for visualization in communication, but a varying degree of usefulness is found in its use for advancing science. A 3D protein structure exquisitely rendered by a computer brings the unseen realm into view. We acquire instant familiarity as we observe the protein structure as readily as we would if it were right here sitting on our desk – but press a button and the balls and stick model changes to a ribbon diagram, then a smooth-surfaced structure with planetary-like topography – then from blue to red, large to small, rotating, or in cross-section. We get a glimpse of the data, and the accumulation of these glimpses forms our understanding. The representations are not molecules, not even pictures of molecules, but pictures of icons that we believe represent some aspects of the molecule's properties. We don't immediately grasp the scale or other important characteristics, but never-

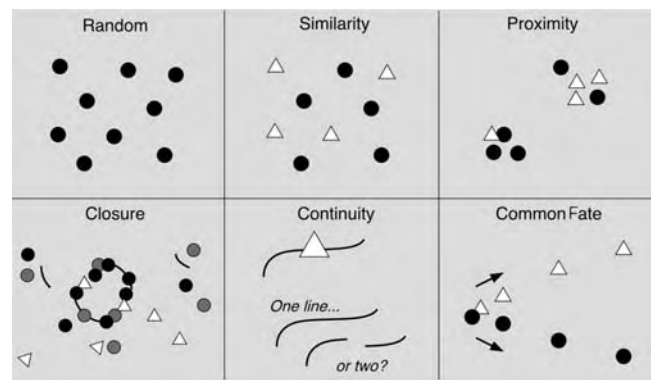

Figure 24.5. Gestalt principles of perceptual organization. Visual perception allows us to interpret the shapes on a page in a fashion similar to how we interpret our physical environment. We group objects according to some of the “rules” that Gestalt psychologists have identified, which have evolved to allow us to make sense of visual stimuli. This figure appears in a gray box, which identifies it as separate from the background of the white page, thus demonstrating figure–ground relationship. We are able to distinguish figures from backgrounds in usual circumstances, although camouflage, for example, may be deliberately designed to undermine this ability. *In the top row*, random dots appear in the first panel; they become visually separated into two, easily recognizable groups in the second panel by using two distinct shapes (Similarity). The principle of grouping by proximity is demonstrated in the third panel (as well as in the overall layout): Labels are deliberately placed closest to the designated part of the diagram. (The proximity of individual letters within a printed word allows us to consider it to be a word). *In the bottom row*, the principle of Closure readily demonstrates that the elements linked together are interpreted as one group, despite the proximity or similarity to other nearby elements. Continuity allows us to interpret a partially occluded line as a single line rather than two segments. The last panel, Common Fate, refers to the fact that objects moving in the same direction are interpreted as being grouped together. This static view is reminiscent of line graphs in which the trends are made obvious by their “trajectory.” It's this trajectory that allows the data points to be easily identified as part of the group, and not just the fact they may be similar symbols.

theless the model satisfies us by its naturalistic appearance. Our machines make the analogical representations, utilizing the same aforementioned artistic devices – linear perspective, overlap, shadows and light, tints of color – to provide visual cues to an observer in the same way they have done throughout the history of science. Our interest is piqued by imagery and, as Martin Kemp wrote: “how something works acquires a different status when it can be visualized as a working model – regardless of however schematic the representation may be with respect to reality of the phenomenon” (28). Key concepts in biology, such as Darwinian evolution, can be understood with words alone (although as Figure 24.6 shows, they may be embellished by schematic representation), but the complex processes of biology that support the theory, at any level – the cell, tissue, organ, individual, population, species – often require visualization from all but the most reductionist point of view. The role of imagery is as integral to the modern scientific process as it has been for any role in the past.

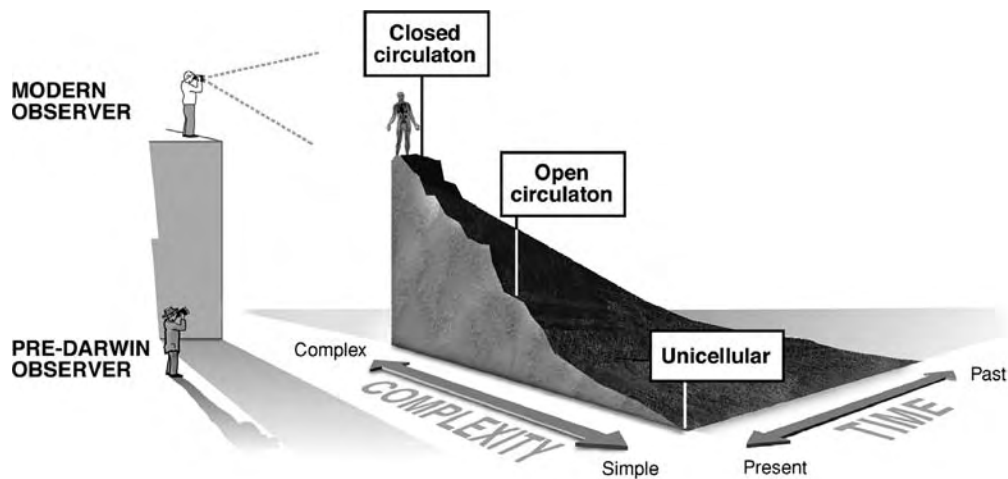

Figure 24.6. Multiple uses of metaphor. The modern observer, looking on an evolutionary “landscape” has a vantage point high above a pre-Darwin observer. Conceptually the modern observer has a better “perspective,” which is represented as elevation above the ground where the pre-Darwin observer stands. The pre-Darwin observer can see only the present façade of the landscape, whereas the modern observer is informed by a view of the past. The evolutionary landscape (itself a metaphor) has a spatial axis that serves as a metaphor for “time.” The summit of the landscape marked by “Closed circulator” represents a greater evolutionary complexity. Finally, the angular presentation of the arrows, along with the tapering of the labels “Complexity” and “Time” are among the graphical cues that serve as a metaphor for receding space. The modern observer might utilize Darwin’s “tree of descent” metaphor, which contrasted with the “ladder of life” metaphor held by the pre-Darwin observer which held that a linear, unbroken relationship existed between organisms culminating in humans rather than a diversification from common ancestry.

The use of image, and the artistic devices to create them, may have originated historically in the same way that linguistic analogy and metaphor have – to satisfy “demand for the plausible narration of sacred events” (18). Through trial and error, and an interaction with science and technology, artistic devices have “evolved” toward better means of representation, culminating in various modes of film and digital photography.

But even the photographic image has its problems in terms of verisimilitude. First, each photographic image is mediated by lens, camera setting, film or digital capture resolution, and light intensity. It is subsequently modulated by digital or chemical means. Recording the scene from a different angle, with a longer exposure, a different lens, a brighter light, alters the result. The photographic end product may be considered an unbiased representation at a particular place and time but, due to a host of intervening factors, it is only objective to the point that the parameters of the recording process are known. In addition, when looking at the image, “truth” becomes what the viewer infers, based on a host of psychological factors. To understand photographic images, the viewer must make assumptions about what is being seen, such as the size of the subject, its 3D form, or the brightness of the scene, all of which can be misinterpreted without sufficient visual cues or explanations.

We rightfully place heavy reliance on visual representations and common-sense (innate) ability to interpret them. It’s nevertheless notoriously difficult for people, including sci-

entists, to abandon erroneous viewpoints. Eric Mazur, who teaches physics at Harvard University, was queried by one student as to how questions on a physics survey should be answered: “According to what you taught us, or by the way I think about these things?” (29). This student, who had seen firsthand demonstrations of physics principles, may well have asked: “Shall I believe my own eyes, or shall I believe yours?” When visual representation fails to convey, linguistic metaphor may be just what is needed to bridge the communication gap.

#### KEY POINTS

- Analogy and metaphor have played a pivotal role in not only building scientific terminology, but also in making sense of data and creating models for understanding.
- Metaphors utilize a type of reasoning that allows scientists to view novel phenomena in terms of that which has already been encountered, and to build on that knowledge. Barbara Stafford writes: “Analogizing has the virtue of making distant people, other periods, and even diverse contemporary contexts part of our world” (30).

- The benefits to an objective science are no different from the benefits to culture in general. “The very nature of science,” notes Earl R. MacCormac, “is such that scientists need the metaphor as a bridge between old and new theories” (31).
- Metaphors utilize the similarities between their target and source. The meaning that emerges from the relationship doesn’t rely simply on the meaning of words, but on our thoughts, perceptions, and underlying core concepts, which are understood in terms of one another.
- In the final analysis, metaphors structure our thinking, reasoning, and understanding of science in very fundamental ways.

## The Membrane Metaphor

### Urban Design and the Endothelium

Kenneth L. Kaplan\* and Daniel L. Schodek†

*\*Patient Stroke Treatment Module Project; †Harvard Design School,  
Cambridge, Massachusetts*

Scholars, from scientists to artists, have been drawing analogies between the human body and the built environment for centuries.<sup>1</sup> The functioning of major transportation networks within a city has frequently been explained in terms of how the circulatory system in a body works, and vice-versa, with major roadways compared with arteries and veins. The comparisons are surprisingly interesting. In both systems, major and minor pathways exist, with varying capacities and roles that connect and/or service different functional components of the overall city or of the body. In both systems, clogging, with its unfortunate consequences is caused by either temporary blockage or longer-term capacity reduction due to narrowing of pathways. A blockage at one point can affect far-removed locations. Mathematical models that bear some similarities have been developed to describe each of these systems. In the urban context, for example, the effects of closing a major pathway on traffic redistribution throughout the whole system of roadways can be predicted. These models find everyday use in our cities.

Although analogies between urban functions and human bodily functions are common, we should carefully think about their appropriate use. The two systems are obviously radically different for innumerable reasons, and this in turn undermines the usefulness of the analogy. It is axiomatic that nothing can ever be proven by use of analogies or metaphors to begin with. Analogies or metaphors, however, do often prompt the scholars or researchers in each field to view their own problems in a different light. New approaches to thorny issues are occasionally suggested (4). It is in this spirit that we push forward with the risky business of speculating how some aspects of a city's functioning might be relevant to studies of the endothelium (and perhaps vice versa).

We begin by noting that the models described in the opening paragraph are intrinsically limited. In the urban context, these transportation network models deal only with the ebb and flow of primary traffic on major roadways (analogous to the conduit vessels of the human body). They deal with surrounding areas of the built environment in only the most rudimentary ways, if at all. An urban area, however, consists of a highly complex environment made up of an intense fabric of streets (analogous to the tens of thousands of miles of invisible capillaries in the human body) and other primary transportation networks, utility and service networks (including wired and wireless communications), pedestrian pathways, open spaces, a variety of building forms and types serving many different functions, and many other features. Some elements in a city provide control or regulatory functions, some are service- or transactionally oriented (including common retail areas), others are essentially productive in nature (industrial zones, power plants) or deal with pragmatic issues of waste disposal, and yet others deal with habitation or with the mind and even the human spirit. The list goes on. These many functions are housed in physical constructions that assume an astonishing array of specific forms. Although the forms individually assumed may vary widely, distinct patterns of land use can be perceived in most cities (e.g., residential, retail, industrial). The character of the supporting networks (including transportation) is both influenced by these patterns and, in turn, helps shape them.

At a far more specific level, we see that marvelous interaction zones occur in an urban area at the interface zones between streets, pedestrian walkways, and adjacent buildings.<sup>2</sup> It is here that writers such as Jane Jacobs have noted that the

1 From the architects Vitruvius and Alberti, to Michelangelo (1), to William Harvey, to contemporary author Peter Ackroyd (2) (to name but a few) many have anthropomorphized buildings and cities; researchers in the emerging area of urban metabolism view cities as biological systems (3).

2 In the circulation, blood is delivered by arteries to the tiny capillaries. The arteries are large and have a really thick wall – much like a superhighway with guard rails. These arteries serve only as conduits. It is at the level of the capillary where (as in the case of the inner city streets) all the exchange of nutrients, wastes, and gases takes place between blood and underlying tissue.

truly dynamic “life of the city” actually takes place. Pedestrians move back and forth on their own pathways, entering and leaving shops and housing, but also interacting with and affecting traffic flows in adjoining streets. Specific city nodes act as large-scale attractors or sources (e.g., cultural centers, major retail or office centers, train stations) that in turn influence pedestrian and vehicular flows between them in a way that is dependent on their spatial relationships. The accompanying pedestrian flows between major nodes also infiltrate through an interface zone comprised of entry portals and other ancillary path entries directly into a multitude of small shops and other elements that line city streets. The complex set of human actions that occur at these interface zones between buildings and networks contributes much to the life of a city.

If we step back a moment, we can conceptualize the interface zone just described as a kind of porous membrane that surrounds a major flow network component and separates it from functional volumes. The membrane provides access, as well as control, along its length to passage from the major flow networks (e.g., streets and major sidewalks) into adjacent spatial zones (e.g., building interiors) having different functions and utilities. It is a zone of intense and highly complex activity, and it is here where an analogy with the endothelium – admittedly slightly strained – is suggested.

Curious parallels do indeed exist. In the urban example, the varying interior functions of adjacent buildings have both needs for goods and demands for services that are at least partly provided for via passages through the portals that comprise the putative membrane from the adjacent network elements. Different functions provide different kinds of draws. The very acts of passage, as well as activities inside, in turn influence the behavior of not only the adjacent network, but of the whole system itself.

Thinking in these terms brings up a number of questions. What are the factors that control the level of porosity of the membrane, and hence movement rates and volumes of passage? In the urban example, a whole host of complex factors enter into the discussion. Many relatively steady-state influences stem from the need for a normal level of services. Unusually high levels of porosity also can be externally generated and stem from many broad cognitively, culturally, or psychologically based rationales (e.g., holiday shopping days cause more stores to be open longer hours). On the other hand, high porosity levels can be generated internally (e.g., a store might deliberately have a sale and extended hours to make itself more attractive to individuals on adjacent flow networks, and nearby competing stores quickly follow suit). In view of the present attempt to draw broad parallels with the endothelium, the latter observation raises the curious question of whether any human body element adjacent to an endothelium layer ever attempts to make itself “more attractive” in a comparable way. Although this proposition may be completely absurd, it does suggest the power of analogy – truly odd questions can be raised.

As we look closer at the buildings within an urban area, we see that the outside envelope of a building (often referred to

as its “skin”) serves many functions that are surprisingly analogous to its counterparts in living organisms. Building skins traditionally have served to provide a protective covering (in this case from the elements), but also have served as a mediating system between the inside building functions and the outside environment, for example, operable windows that control air flows or selectively admit light. Exciting new research into “smart skins” has pushed the roles that building skins can play even further. One new role is that of a wall serving to gather, send, receive, and display information via various embedded sensor-based technologies. Here, large-area light, thermal, and sound sensors can be used to gather information about surrounding environmental conditions, and tactile sensors can be used to gather information about forces acting on the wall. When coupled with other communication technologies, this information can be used for a wide variety of monitoring and control functions. These same walls also can be used to display a wide variety of information, typically visual but also audio. Many are interactive. Individuals simply either passing by or directly interacting with the wall can cause different responses. Intriguingly, the potential for a kind of information-based system intelligence becomes possible. Smart skins can go beyond the role of dealing with sensor-based information alone, and can be used to mediate surrounding environments via intrinsic smart material characteristics related to properties such as porosity (so-called “breathable” walls) and to absorbing, storing, distributing, and releasing heat. Here, properties intrinsically provide variable responses to external stimuli via material properties alone. All these different approaches make the “smart skin” a truly active and interactive responsive boundary surface.<sup>3</sup>

We now return from the realm of largely idle speculation to harder questions. We began by noting that there do indeed exist mathematical modeling techniques for simulating the behaviors of major transportation networks. Are there any such modeling techniques developed in relation to urban design and planning that even begin to reflect the complexity of actions within the interface zones (at the “membrane”) described above? At this point, the answer is largely negative. Current network transportation models only deal with surrounding environments in only instrumental ways and are structured in largely deterministic forms that are only doubtfully conceptually valid for the kinds of interactions described. Various cellular automata approaches that remain largely undeveloped might ultimately prove to be of some value here (5). Some hope exists in this modeling approach, in that it appears that the behavior of any specific member on our streetscape is indeed affected by the immediate actions of surrounding members, and that the behavior of the whole is in turn markedly influenced by the nuances of the actions of individual members. It is not impossible to imagine influences associated with the idea of attractors, sources, and sinks that also affect the behavior of the whole. Could corresponding

3 Perhaps the endothelial lining of tubular blood vessels may be viewed as a smart skin that senses and responds to the extracellular environment.

computational rule structures be established that have any validity? Perhaps, but we have a long way to go. Does the medical and biology community have valid computational models for their systems that might help us in understanding urban activities? Understandings can flow in both directions.

If computational models are not yet mature enough for our purposes, let's look at conceptual models. Of particular interest to architects and urban designers is the definition of the endothelium as a "distributed spatial system" that interfaces with adjoining biological systems. Although the definitional parameters of "system" as applied to the endothelium and to other complex biological systems is a topic of great debate among the life-science disciplines, its relevance to architectural design thinking is the notion that the endothelium is a spatial continuum within the context of the interior spatial volume of the human body. Space is a key concept for architects and urban designers, along with proportion, symmetry, harmony, ornament, color, and, of course, function. As well, they must incorporate culture, history, and the interaction of the built and natural environments. Designers are taught to calibrate the relationship of the detail to the whole. They study spatial phenomena and have the conceptual tools to understand formal principles of system growth or demise.

With regard to cities, architects – or more specifically urban and landscape designers – must be able to collect data and then analyze the data at various spatial scales. For example, the recent re-evaluation of lower Manhattan after 9/11 required a precise understanding of the specific site of the Twin Towers in relationship to the surrounding city blocks at one scale, and then a larger spatial measure of the neighborhoods of Manhattan and the other boroughs of the city, to an even larger scale of the regional impact to the surrounding states, because the site also served as a critical transportation hub for commuters from the tri-state area of New Jersey, Connecticut, and metropolitan New York. Designers have the ability to manipulate and calibrate spatial perspective, both conceptually and then with an assortment of tools ranging from clay urban-site models to data-rich GIS mapping software at multiple scales. Although these tools give the designer some flexibility in understanding the dynamic interplay of human and urban space, which in real terms is a constantly shifting landscape that embodies a vast assortment of levels of data from the economic to the sociopolitical, they do not provide the level of detail to robustly address the "membrane" issue. Complex human interaction, communication, and movement patterns in the city are not well understood by designers or their counterparts in the various specialized disciplines that comprise the larger field of urbanism.

It appears that, traditionally, biologists and clinicians have not approached the biological systems from a spatial perspective. Most biologists don't seem to use spatial concepts, and math used in biology doesn't measure "geometric" space. Most models of biological systems illustrate their two-dimensional (2-D) aspects or physical and chemical properties. An exception is the interest in spatial and temporal concepts relative to cell differentiation (6).

Yet medicine and science have been advanced recently by an assortment of imaging and digital technologies that now translate the body into a rich three-dimensional (3-D) spatial geography that is stimulating these disciplines to think more broadly about the body from a perspective that is in fact suitable to the insights of architects, who are much more comfortable with the notion of space as an observable and measurable phenomenon. This suggests an opportunity that harkens back to the Renaissance, when artists and architects were viewed as valuable contributors to scientific and medical knowledge.

Underpinning and sometimes confusing the issue is the struggle to comprehend the vast amounts of data made available by recent discoveries related to the molecular structure and functioning of discrete aspects of biological systems. This drive for data collection is defined by a necessary obsession for "microscopic" detail that is both the strength and weakness of the current biomedical community *modus operandi*. What seems to have been lost in the process of specialization is how to think about the relationship of the parts to the larger conceptual bedding of the whole. The design fields have long been occupied with what constitutes a system – including complex anatomy, typology, and functionality – for the primary reason that the designer's principal task is to conceive of and build new systems (7). Accomplishing this task requires a specialized knowledge and toolkit, but more importantly, a uniquely holistic perspective of systems at multiple scales. This conceptual perspective could be of value as life scientists puzzle the relationship of the part to the whole.

Let's further complicate this exercise and again summon the power of analogy, even stretch the notion of metaphor and look at a city as an actual function, or expression, of human biological systems. Cities are built by people, often without much apparent planning. Perhaps we humans do pattern our built environment, consciously or unconsciously, on the systems from which we are built. Human behavior creates the city: Just as DNA evolves as a result of external environment and internal chemistry, so does the city evolve.

Although the city as organism is not a new idea, as noted earlier, the relationships of humans (and the biological systems that comprise them) to their built environments is still largely misunderstood. Could designers better understand the city by integrating some reductionist thinking into the holistic, urbanist approach? Biologists seem to be further along in understanding the parts. As life scientists learn more about the systems behavior of cells at the micro-environmental level, they discover striking parallels between human social behavior and cell social behavior. If designers were to perceive the city as the ultimate expression of these two populations – populations that are intertwined, yet operating blindly of each other – might that transform how they respond to the pressing problems of our urban centers?

Recent research programs (e.g., funded by NSF, NIH, CDC) demonstrate a growing (albeit slowly) recognition that we need truly multidisciplinary teams to study cities and their impacts on humans and the environment – teams that integrate urban designers and planners, public health experts,

and social scientists with scientists such as ecologists and biologists. But the future of our cities may depend on our understanding of the biological mechanisms underpinning the self-organizing tendencies of cells and cities. Will the designers of the future be trained in cell biology, as well as social sciences, or will the nature of their work be profoundly impacted by collaborations with life scientists? Could we work together to better understand the “life of the city” as well as the workings of the human body?

#### KEY POINTS

- Endothelial biologists and urban designers and architects are all interested in distributed spatial systems. Sharing concepts, perspectives, and tools may help us learn how some aspects of a city’s functioning might be relevant to studies of the endothelium (and vice versa).
- Although we should carefully think about their appropriate use, metaphors allow the freedom to raise speculative questions. Researchers in each field may view their own problems in a different light, and new approaches to thorny issues are occasionally suggested.
- In an urban area, the interface zones between streets, pedestrian walkways, and adjacent buildings serve as a type of porous membrane that surrounds a major flow network component and separates it from functional volumes. It is a zone of intense and highly complex activity, with curious parallels to the endothelium.
- Although design tools provide some flexibility in understanding the dynamic interplay of human and

urban space, they do not provide the level of detail to robustly address the “membrane” issue.

- Discoveries regarding the discrete aspects of biological systems could help designers solve complex problems of urban life.
- The designer’s holistic perspective of systems at multiple scales could be of value as life scientists puzzle the relationship of the part to the whole.

#### *Future Goals*

- To undertake collaborations that enable micro- and macro-scale researchers to exploit converse perspectives and to develop and share new approaches and tools

## Computer Metaphors for the Endothelium

---

Dexter Pratt

*Genstruct, Cambridge, Massachusetts*

*“It was a dark and stormy night. The Weibel-Palade bodies surged to the surface, releasing their witch’s brew into the turbulent surf downstream of the rupture. Neutrophils shuddered to a stop as selectins grappled, tore away, and then finally caught.”*

### INTRODUCTION

“Endothelial biology is weather.” That is a metaphor, and a bold one, because it compares two systems of enormous complexity and implies that they share fundamental features despite an utterly different scale and mechanism. But is that a “computer” metaphor? Shouldn’t this chapter find its metaphors in circuits, signal processing, and the Internet? My answer is “No,” because in the mechanics of computation, the details of technology, we see an entirely artificial landscape, a world dominated by well-defined protocols, regimented structures, and perfect repeatability. It is a world in which “crosstalk,” the secondary interaction between components or processes, is scrupulously avoided.<sup>1</sup> By contrast, crosstalk is the norm in biological systems. Signaling “protocols” exist in biology, but their effect is nuanced and context-dependent, shifting the behavior of systems that are the dynamically balanced product of many competing and overlapping processes.

To find meaningful computer metaphors, we need to look at computer applications that attempt to deal with natural, emergent complexity. The metaphors derived from these applications are not just “computer” metaphors, but are “computable” – they provide insight into the pragmatic construction of systems that can encode biological theories and

hypotheses. The scientific process is essentially the discovery and articulation of rules that describe and predict the events we can observe in the world around us. When those rules are expressed in a computable form, algorithms can perform useful inferences about systems and datasets too large for a scientist to reason about. In that spirit, the current chapter explores the following three metaphors for the endothelium:

- Endothelial biology is weather.
- The endothelium is the vegetation covering a vast terrain.
- Endothelial biology is a rule-based system.

The comparison of endothelial biology to weather is an important computer metaphor because a rich field exists in which computational models of weather and climate have been employed in short-term forecasting, long-term climate prediction, and paleo-climatology. The limitations of weather modeling highlight how difficult it is to make specific predictions about the behavior of a complex system and the need for copious and detailed measurements to initialize and test the model. But the successes of weather forecasting show that a partial solution to an important problem can still have great value.

The computer models of vegetation patterns considered in the second section are interesting because they demonstrate techniques in which complicated behavior emerges from relatively small and simple sets of rules. But the hope that these techniques can help us find and articulate simple rules for complicated endothelial behavior is tempered by the need for detailed measurement and testing. Many rule sets – *hypotheses* by another name – may generate patterns of simulated behavior that resemble the behavior of the natural system, but the proof of any hypothesis still relies on specific measurement and experiment. Complex predictions by a hypothesis can be evaluated only when enough observations are made to distinguish them from the results of competing hypotheses.

In the third section, the comparison of endothelial biology to a rule-based system seems more like a computer metaphor, drawing on the jargon of artificial intelligence. In each of the three metaphors, biology is made computable by reduction

<sup>1</sup> The basic kind of crosstalk – in which signals in adjacent wires interfere with each other – is avoided in any sort of computer. In principle, one *could* make a parallel system that had fuzzy secondary interactions between processors in order to run some sort of probabilistic agent interaction faster, but you would be far better off doing that in a software simulation. Basically, computer hardware is made to perfectly execute exact instructions trillions and trillions of times without error, *and* to be debuggable: to be cleanly broken down into well-articulated separate pieces so that it’s possible for humans to design, program, and repair.

to rules, but the term “rule-based system” will be used in the sense of systems characterized by large databases of IF-THEN rules, compared to the small rule sets in the previous section. Viewed in a broad sense, rule-based systems provide a way to define hypothesis and deduction in the face of systems too large to be encompassed by the mind of any single scientist. Although the behavior of the endothelium emerges from the interactions of trillions of independent cells, it is nevertheless the case that important aspects of our knowledge can be described by simple, qualitative rules: Rules that can be manipulated mechanically, rules that can be processed by algorithms to derive conclusions. Any given deduction processed by such a biological rule-based system may seem trivial, but great value exists in the straightforward consideration of tens of thousands of deductions at once.

The theme that emerges from these three metaphors is that systems biology, and specifically endothelial systems biology, can attempt to deal with the enormous complexity of the living systems by using diverse computational techniques. No technique will be a free lunch: Very large models are hard to build, require the input of many high-quality observations, and face fundamental limitations in their ability to predict the specific behavior of complex systems. But practical value can be realized from partial solutions.

## ENDOTHELIAL BIOLOGY IS WEATHER

In weather forecasting, computational models must grapple with an enormous system exactly as it occurs in nature. They must make specific, local predictions in a timely manner. Research in this field is highly rewarded for successful “snow in Chicago starting 6 PM Tuesday” predictions. In endothelial biology, we too, must contend with a naturally occurring system of great – probably much greater – complexity. We desire to make specific predictions for individual humans, such as “Lydia Jones will suffer a rupture of one or more large plaques in her coronary arteries within the next 60 days, whereas Janet Wu, despite greater stenosis and higher levels of low-density lipoprotein (LDL), will have stable arterial plaques for at least the next decade.” Unlike weather forecasting, we also want to make predictions about possible interventions: “Statin therapy will prevent a predicted stroke for Peter Simpson, but will be of no value for Robert Stein.”

The obvious fact about computer models for weather forecasting is that they are extremely successful, but only up to a point. The accuracy of a specific forecast declines rapidly with time: Beyond a week, forecasts are not much better than a statement of “typical weather for this time of year in this location.” The models that produce these forecasts require huge data inputs, including measurements of temperature, pressure, wind velocity, partial pressure of water vapor, cloud cover, and length of day. During the 1960s, when computer models were grossly limited by the speed and memory size of the existing computers, it was assumed that forecasts would improve as better computers were available. And although that assump-

tion turned out to be absolutely true, the hard fact is that exponential increases in computer speed and memory produced small, linear gains in the forecast horizon. According to the American Meteorology Society, the accuracy of forecasts made in 1998 more than doubled compared to the forecasts of the 1970s; this stands in sharp contrast to the computers on which the models ran, in which the number of transistors in a processor doubled roughly every *18 months* during that same time (1,2). Specific predictions about the weather are intrinsically difficult because small differences in the initial conditions make ever larger differences in the resulting behavior. Computer forecasting of weather was one of the first fields in which this kind of dependency was studied, resulting in the popular term “butterfly effect,” based on the idea that even an event as small as the flapping of a butterfly’s wings could have large effects on subsequent weather.

If we apply the example of weather modeling to the endothelium, we should first notice the tremendous disparity in the data available for the predictions that we would like to make. In the case of the weather, only one individual – the planet Earth – is measured, moment to moment, by an enormous array of sensors, including satellite photography, radar systems, and ground-based weather stations. In endothelial biology, we have many individuals to observe, including humans, experimental animals, and derived systems such as cell cultures. In any given experiment, we may measure the expression of thousands of genes in several tissues, but only at that single moment in time when a pathology sample is taken or when an animal is sacrificed. Typically, only system parameters, such as heart rate, blood pressure, and the levels of plasma proteins and metabolites, may be measured multiple times in the course of a study. Imagine if this was the type of data available for weather forecasting, treating each individual animal like an entire planet: Meteorologists would have a snapshot – single time point data for the weather on many different earthlike planets – but never a second set of measurements for any planet. On a given planet – Earth, for example – they might have time sequence data, but these would be only for general parameters, such as “mean ocean temperature over time.” The weather models that those forecasters could develop might draw interesting conclusions about climate, but it would be unlikely that they would ever successfully predict “snow in Chicago at 6 PM.”

So the first point is that, in modeling a complex system such as the weather or the endothelium, we need detailed observations over time, preferably observations of the specific system – the individual – for which we wish to make predictions.

The second point is that sharp limits are imposed on the specific predictions that we can make, because the systems we want to model are sufficiently complex that their behavior over time is dependent on small differences in initial conditions. At short time frames, good predictions can be made by determining the effects of dominant factors – straightforward chains of logic can predict the immediate reaction to a perturbation. At medium time frames, sophisticated models can make useful predictions by considering secondary effects

and feedback processes. But in the long term, our attempts to predict or affect biology are at the level of climate.

### THE ENDOTHELIUM IS THE VEGETATION COVERING A VAST TERRAIN

The endothelium is a vast surface – 4,000 to 7,000 m<sup>3</sup> in humans. On that surface, the local conditions control the behavior of the endothelium – and the endothelium alters its local environment in turn. Endothelial cells (ECs) are very plastic, changing their behavior in response to the local conditions.

We can compare this to the land area of our planet: We live on a vast surface on which most areas tend to become vegetated, but the nature of the vegetation depends on the local conditions. Moreover, the growth, resource use, shading, reflectivity, and decomposition of plants in an area continually alter its conditions, making way for further changes in vegetation. For example, if a forest is burned or harvested, it regrows as a succession of species over time, some species successful as early colonizers of open areas, others as later inhabitants of a shaded forest floor. The species and their progression reflect the local climate, topography, and surrounding ecosystems: the sum of many, many individuals growing well or poorly in the prevailing conditions.

In an analogous manner, when the endothelium is damaged or removed in an area of the vasculature, it regenerates by the response of neighboring ECs and/or by the recruitment of endothelial progenitor cells to the site. In both cases, the landscape is populated by dynamic processes in which individual plants or cells grow, colonize, and interact with each other. Given these similarities, I will develop the story of some computer models of vegetation and then return to the endothelium.

A simplistic model of vegetation might predict the flora of an area based on local parameters such as climate, latitude, and geography. This model would essentially be a large table based on ecosystem surveys. Although valuable, such a model merely predicts a typical state for each set of inputs, not the process by which the system achieves that state: It does not provide insight into the response of the system to change or stress. There is no representation of the mechanisms that produce the outcome. And without general mechanisms, it is unlikely to predict the result of novel changes, such as the application of a selective herbicide.

Moreover, these models fail at a level of granularity. If vegetation were composed of perfectly adaptable plants, one might expect smooth transitions as one moves from one climate to another. Each plant would adopt the appropriate intermediate form for the conditions at each point in the transition. But although real plants are quite malleable in their growth and form, discontinuities arise as the dominance of species changes. For any small area in the transition between grassland and forest, we expect to find either a tree, a shrub, or grass. One might handle this in the simple model by treating

the state of that patch of ground as a probability (i.e., 40% of the unit areas are grass, 50% have a shrub, 10% have a tree). But the patterns of growth predicted by random assignment do not match the patterns observed in actual ecosystems. Plants of similar function and species array themselves in a patchy manner, sometimes forming spots, sometimes stripes or loops. In desert areas, shrubs are spaced with characteristic frequencies. These patterns mean that the plants interact, altering the conditions in the adjacent areas of terrain and in their own area. A better vegetation model should therefore represent time, so changes can occur over time. And it should represent each location, describing it with parameters that will allow predictions for the location and its neighborhood.

Cellular automata (CA) are a class of computer models that have been applied to the modeling of vegetation. A CA is perhaps the simplest type of agent-based model (ABM) in which a surface is represented as a grid of squares, and time is divided into a series of *turns*, as in a game. Each square may be considered an *agent*, an entity defined by the values of specific parameters and by the rules for its interaction with other agents in the system. At each turn, each square is assigned new values for its parameters, based on its previous state and the previous states of nearby squares. For example, in a very simple CA, squares might have only one parameter, such as color, and limited values, such as white or black. Their subsequent color is the result of their previous color and the colors of the eight adjacent squares. One set of rules of this sort comprised “the Game of Life,” so named because it had some inspiration in the behavior of cells growing on a surface. Too few or too many neighbors and the cell in the square died; just the right number and a new cell would be generated in an empty square.

These rules were not a serious attempt to model cellular behavior, but “Life” was important because these simple rules produced surprisingly complex behavior: Patterns of black and white could grow, shrink, oscillate, and even move across the grid. Patterns were found that formed stable oscillators that spawned moving progeny at regular intervals. So “Life” seemed very “alive,” even though it was the result of very simple rules. Over the next decades, many researchers developed ideas of emergent behavior – complexity arising from simple rules that specified the interaction of simple components, especially as an approach to explain complex biological behaviors.

Complex biological behavior is daunting: It simultaneously encourages reductionist research to study the mechanisms of component systems and descriptive, statistical studies of larger systems. But emergent behavior viewed in computer models suggests – holds out hope – that some systems demonstrating complexity can be modeled by simple rules, indicating that a manageable number of parameters dominate the behavior.

In that spirit, CA have been applied to a number of biological processes that unfold spatially, including vegetation on a landscape. Rietkerk and colleagues (3) compared the output of a simple CA model to the observed patterns of patchy vegetation in various ecosystems. The model is a two-dimensional grid, in which each square represents an arbitrary area of

Figure 26.1. Changes in patterns produced by the model as the strength of the positive feedback is varied (x-axis) versus the scale of its influence (y-axis).

ground and is colored in proportion to the vegetation in that area. Vegetation in each square changes over time based on two rules: It is both promoted and inhibited by nearby vegetation. The promotion (positive feedback) is stronger at short range, whereas the inhibition (negative feedback) can act over longer distances. Figure 26.1 shows the changes in patterns produced by the model as the strength of the positive feedback is varied (x-axis) versus the scale of its influence (y-axis).

The patterns produced by these rules are in fact similar to observed patterns of vegetation in some ecosystems, as shown in the aerial photograph in Figure 26.2. The hypothesis is that the simple rules produce these recognizable patterns because the rules correspond to dominant processes in these ecosystems: Plants compete for resources and limit each other's growth (negative feedback), but they also alter the local environment in ways that conserve resources (short-range positive feedback). In the case of an arid ecosystem, the critical parameters for the system might be rainfall, soil permeability, and evaporation rate. The future of each square depends on the state of its hydration, which in turn depends on the primary parameters:

- Increased vegetation decreases evaporation and increases permeability.
- Decreased vegetation increases evaporation, but benefits adjacent squares by increasing runoff of rainwater due to decreased permeability.

With sufficient rainfall and moderate temperature, the system tends toward a state of uniform vegetation. Vice versa, with

Figure 26.2. Example of a vegetation pattern in an arid ecosystem.

very low rainfall and high temperatures, all squares become barren. But between these extremes patterns develop that mimic the observed patterns of patchy vegetation at transitions between grassland and desert.

This sounds very appealing, but to consider a model as a theory, we need a better evaluation than “produces patterns that seem similar to observed behavior of vegetation.” For any particular set of data, different rule sets (i.e., different hypotheses) might produce results indistinguishable to the human eye.

To develop the model as a theory requires the development of testable hypotheses, the design and execution of experiments to test these hypotheses, and a comparison of the results with predictions over wide ranges of parameters. Indeed, Rietkerk and colleagues conclude their paper by citing a need to move from qualitative to quantitative prediction. In the world of vegetation, such experiments can be performed. In addition to photographic surveys of vegetation patterns, it is possible to measure rainfall, runoff, permeability, and hydration over time. Moreover, it is possible to perturb these systems – changing water input, removing vegetation, adding artificial shade – and then compare the observed changes to the predictions of the hypothesis.

So how does this type of model apply to the endothelium? ECs generally form an unbroken layer of “vegetation” on the vasculature. Unlike vegetation, only one genotype of EC exists, but many phenotypes exist that the cells adopt in response to their changing environment. One can then imagine the creation of a CA model for the behavior of one or more aspects of areas of the endothelium. In that model, the surface of some segment of the endothelium would be represented as a large grid, each square corresponding to an area roughly comparable to a cell. The granularity of time in the model could

range from fractions of seconds to hours, depending on what aspects of behavior are to be captured. For each “turn,” the status of each square in the grid would be determined by the status of neighboring squares (presence of cells, alignment, shape, expression of certain receptors) and by the climate-like parameters of blood flow, shear stress, cytokines, and lipoprotein levels. It is easy to imagine the use of these techniques to create a model of the endothelium that would generate detailed predictions of multicellular behavior.

But perhaps first we should ask what measurements are available to us. To what extent can we measure the state of a patch of endothelium over time? Can we even come close to the measurements of water movement, temperature, and plant growth that ecologists would make? If our measurements are too crude, too sparse, how can we assess a model that generates many complex predictions? For example, for a given parameter of the endothelium – P-selectin expression – we might ask if our model predicts smooth transitions in time and space. One set of choices in defining the parameters of the model might predict P-selectin expression varying continuously across the surface of the endothelium, whereas another set of choices might predict discontinuous levels of expression, in which individual cells switch abruptly between distinct activation states. To evaluate which choices make a better model, to evaluate *any* model that predicts patterns of P-selectin expression, we must find a way to measure the microscopic variation in P-selectin expression over the surface of the endothelium under varying stimuli. We need enough data so that the model’s predictions can be tested over a wide range of conditions, establishing specific evidence beyond “familiar patterns.” For example, a study might involve imaging layers of cultured ECs for the expression of multiple surface proteins (P-selectin included) and for cell shape and alignment. The imaging would be repeated under variations in flow, after mechanical damage, or following stimulation with cytokines or growth factors.

Recent applications of CA to systems of interacting cells have included models of microvascular growth. Peirce and colleagues (4) developed a model that used over 50 rules integrating epigenetic stimuli, molecular signals, and cellular behaviors to predict microvascular network patterning events. Their model simulates the behaviors of individual cells during new vessel formation, vessel length extension, and recruitment of contractile perivascular cells. Moreover, it produced successful quantitative predictions of changes in vascular density in response to an exogenous growth factor and changes in contractile vessel lengths in response to increases in circumferential wall strain.

Our first two metaphors indicate that systems complex in space and time can be modeled if sufficient measurement is available of the observed system (weather), or by the use of simple rules (CA). However, those models still require extensive datasets to be tested. And our expectations for these models should be limited: Detailed predictions may be inherently difficult when small variations in initial conditions can cause large variations in later behavior.

## ENDOTHELIAL BIOLOGY IS A RULE-BASED SYSTEM

The phrase “rule-based system” conveys an impression of order, but little else. After all, any model is in some sense a set of rules, and the same can be said for any computer program. The more specific meaning of this term is a class of programs characterized by large databases of IF-THEN rules, in which thousands of rules can be manipulated mechanically by algorithms to derive conclusions concerning objects and processes in the real world. In the previous section, we examined ways in which small, simple sets of rules could generate complexity, but now we look for ways to cope with inherently complex models in which there exist many, many genes, proteins, locations, and processes and a large but incomplete body of knowledge specifying their relationships.

Rule-based systems are sometimes optimistically referred to as *expert systems*, when they are intended to emulate the reasoning of human experts. Saying “endothelial biology is a rule-based system” is a way to approach a fundamental idea: Important aspects of biology can be addressed by very large models composed of nonmathematical, qualitative rules. Embracing this metaphor – biology as many abstract concepts linked by many simple rules – permits the development of pragmatic systems in which algorithms manipulate biological knowledge. It is valuable to enable algorithms to reason about endothelial biology because we need a way to pursue biological research, to explore hypotheses and deductions when too many facts and observations exist for any human researcher to grasp or process. Any given deduction made by a biological rule-based system may be simple compared to the insight of a human biologist, but there is power in the straightforward consideration of tens of thousands of deductions at once.

I start my discussion with the most important point: Success is possible. Systems of this kind can be constructed and used with diverse experimental data; they can produce significant scientific insight about the biological changes observed in an experiment and inform the design of subsequent experiments. At Genstruct, Inc., we have developed a working biological rule-based system that has both a very large set of qualitative rules encoding biological information largely derived from the scientific literature (roughly 150,000 cause-and-effect relationships) and a suite of reasoning algorithms that are used to develop hypotheses based on those rules as constrained by the data from specific experiments. This system has been used successfully in both academic and commercial projects, using experimental data from areas as diverse as cancer biology, diabetes research (5), lipid biology, and inflammation studies.

Figure 26.3 shows a causal network that can explain 104 of 694 RNA expression changes observed in an experiment in which the LNCaP prostate cancer cell line was stimulated by a synthetic androgen (6). This network was composed by algorithms that used the RNA expression changes induced by androgen in the experiment to interrogate a causal rule base (Genstruct’s Knowledge Assembly model of human biology). One algorithm selected chains of reasoning – hypotheses – that

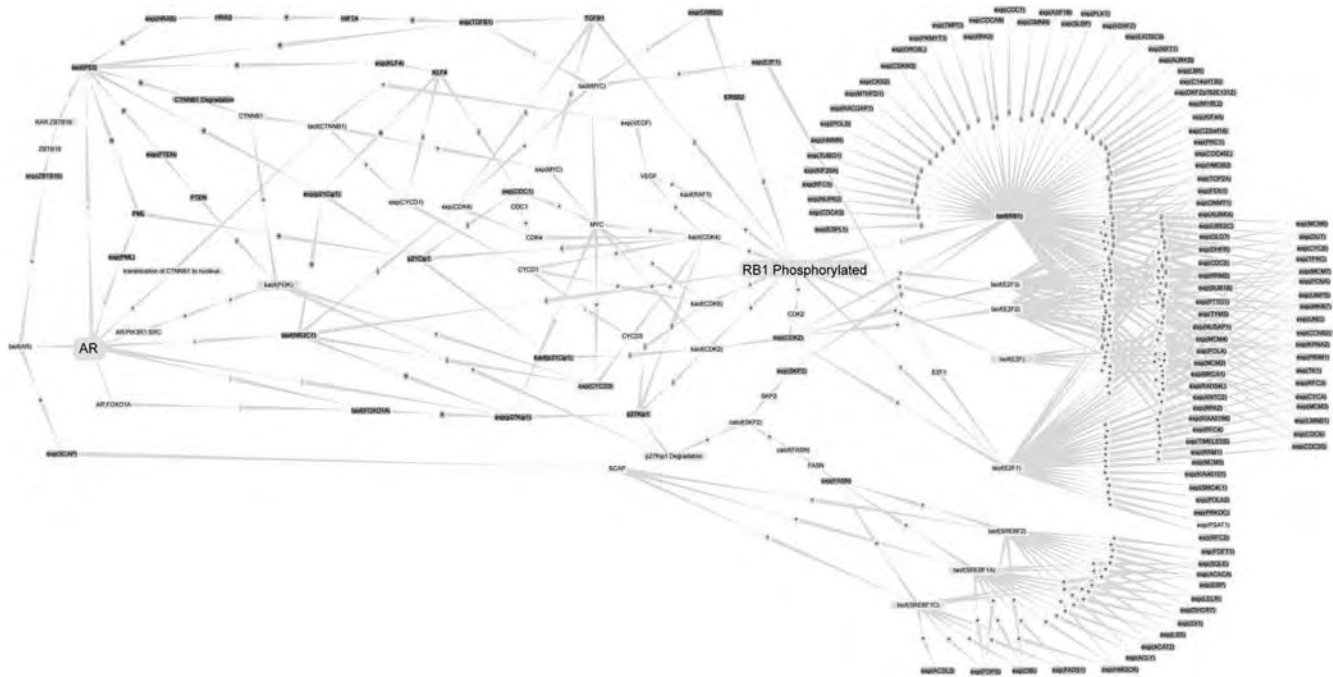

Figure 26.3. Causal network explaining 104 gene expression changes observed in an experiment. The details of the network are not readable at this scale, but its structure makes the important point: A network element toward the left of the diagram representing the experimental perturbation is causally connected to elements representing transcriptional evidence in the fan-like structure at the right of the diagram. Each causal path through this network is a testable hypothesis for a mechanism of action in the experiment.

were explanations of multiple observed RNA expression changes. Another algorithm identified possible causal chains that link those hypotheses to the downstream effects of androgen treatment and of androgen receptor activation. The diagram does not show the entire Knowledge Assembly model; it shows only the small fraction of that model that comprises an explanation of 104 of the gene changes observed in the experiment.

This diagram invites the question “But where are the rules?” The rules are represented by the edges of the graph and the nodes they connect. They express causal relationships, such as “An increase in the amount of phosphorylated retinoblastoma 1 (RB1) causes an increase in the transcriptional activity of E2F1.” Each rule can be represented as an arrow on a pathway diagram, describing the ways in which processes and molecules control each other’s behavior.

Is a biological rule-based system nothing but a giant pathway diagram, drawn in a computable format? In spirit, the answer is “Yes,” but in practice the answer is strongly “No.” The first issue is that in a rule-based system, knowledge must be encoded in a way that precisely preserves all the semantic distinctions necessary to perform the desired inferences. Pathway diagrams, on the other hand, are intended to be read by knowledgeable researchers, to succinctly communicate a manageable number of concepts and relationships in a single page. To that end, they exploit the ability of humans to interpret symbols based on context, to effortlessly shift levels of abstraction, and to bring to bear background information

and unspoken assumptions about the biological system. So one arrow between colored boxes in a diagram may mean “activation of the kinase activity of A by B,” whereas another may mean “increase in RNA expression of C due to the activation of transcriptional activity of D.” A third arrow may mean “X translocates across the plasma membrane due to the activity of channel Y.” One colored box may be labeled “RB1,” meaning the product of a particular gene, whereas another labeled “E2F” refers to the proteins of an entire family of related genes. For an algorithm to use that information – to make inferences similar to the reasoning of a human reader of the diagram – each meaning expressed by the diagram must be represented in a way that captures those essential distinctions.

The second issue is the need for consistency of terminology across all the facts encoded in a rule-based system. Human researchers appreciate consistency, but they are adept at moving between diagrams that use different symbols for the same proteins or diagrams in which the same symbols are applied to genes, proteins, or RNA transcripts depending on the context. But to perform meaningful inference using a rule-based system, each unique biological concept must be represented in the system by a unique and unambiguous term. In this way, biological rule-based systems are less like pathway diagrams and more like circuit diagrams, in which each relationship and component type is well defined. And indeed, an excellent example of the representation of biological rules is Kohn’s molecular interaction map of the mammalian cell-cycle control and DNA repair systems, which encodes over 500 causal

relationships in a precise semantics using a graphic format similar to a circuit diagram (7).

Thinking of assemblages of biological knowledge about the endothelium as rule-based systems rather than pathways, networks, or circuits is an important viewpoint because it forces one to ask critical questions:

- What kind of deductions do I want to make?
- What kind of conclusions could my system potentially draw that would be worth the effort of its construction?
- Would these conclusions be testable?
- Would they advance the knowledge of the biology of the system?

These questions lead to the definition of the discrete semantics that the rules and concepts must express, the nuances that must be encoded, and the distinctions that can be omitted. These semantics distinguish systems that can directly enable the development of scientific hypotheses from those that can support only browsing and searching.

One type of question that a rule-based system can answer is “What if?” If we hypothesize a perturbation to the system, such as a decrease in a process or an increase in the amount of some component, then any rules that use that process or component in their “if” clause can be applied to draw the conclusion in their “then” clause. Those conclusions may then be treated as new perturbations – increases and decreases that are then applied to other terms in the system. This process can be repeated multiple times, propagating changes throughout the system. The result is a list of predicted changes and, for each prediction, a causal chain of events supporting that prediction.

But it may be more useful to ask “What happened?” than “What if?” In today’s endothelial research, enormous datasets are generated routinely by high-throughput technologies such as microarray expression profiling, tissue proteomics, or serum metabolomics. Each individual measurement out of thousands or millions may reveal a state change that reflects the biology of the experiment, and each state change should ideally be explained by the analysis and interpretation of the experiment. However, these changes do not occur independently, but are tightly knit into a causal fabric by the rules of the biological system itself. In practice, when a dataset yields hundreds of state changes between two samples, it is intractable for a human researcher to explore all the possible causes for those changes, let alone search for commonalities. But within a biological rule-based system, it is practical to do just that: to explore the possible causes of every observed state change, the causes of those causes, and so on for multiple iterations. Each possible cause may then be evaluated to determine its fitness as an independent hypothesis, or as part of another clearly defined hypothesis. Clearly, hypotheses whose predictions are highly concordant with the set of observed state changes are among the most interesting; concordance and other parameters can be used to rank and filter

hypotheses, producing a manageable list of detailed hypotheses for review and testing.

In sum, it is valuable to think about aspects of endothelial biology as sets of rules operating on abstract concepts, because finding rules – finding causal relationships – is at the root of the scientific process. Encoding biological facts in a manner that makes them computable requires the explicit choice of clear and consistent terminology and semantics, a process that encourages clarity and completeness in any biological model. When those facts are computable, meaningful inference can be performed over models and datasets too large for any individual researcher to reason about.

## CONCLUSION

Embrace computable metaphors. Think of biological knowledge in terms that can lead to computational models. The biology of the endothelium is too big for the mind of any individual scientist. But when biological knowledge is manipulated by algorithms, larger phenomena can be described, explained, and predicted. Rule-based systems show how many thousands of simple rules can encode biological relationships and use them to perform scientific inference, such as the interpretation of the state changes from a high-throughput experiment. CA demonstrate how small sets of rules, when applied numerous times, can generate complex predictions of biological behavior. Weather modeling is an inspiring success in the practical prediction of the behavior of an enormous system, but it also shows the inherent limits of those predictions. Although the construction of very large computational models is not easy, those models can yield pragmatic results in situations that are otherwise intractable.

## KEY POINTS

- Systems biology, and specifically endothelial systems biology, is the art of defining and implementing computable metaphors, employing diverse computational techniques to generate testable predictions and hypotheses.
- Encoding biological facts in a computable framework facilitates meaningful inference when the models and datasets become too large for the mind of any individual scientist.
- No “free lunch” exists. The effective models of biological systems require the explicit choice of clear and consistent terminology and semantics, the input of many high-quality observations, and are fundamentally limited in their ability to predict specific behaviors of complex systems.
- Practical value can be realized from partial solutions.

### *Future Goals*

- Complex models require comprehensive measurements: to build and test large scale models, systems must be measured in detail and under many conditions.

## Introductory Essay

### Endothelial Cell Input

---

Helmut G. Augustin

*Medical Faculty Mannheim, University of Heidelberg and German Cancer Research Center  
(DKFZ), Germany*

The vascular endothelium lines the inside of all blood vessels. As such, it forms one of the largest internal surfaces that mediates the compartmentalization of the body. The endothelium thereby acts as interface between the blood and the different organs. Structurally, the endothelial layer is diverse and heterogeneous. It is organ and caliber specifically differentiated in a way that best serves the functional needs of the underlying tissue. For example, barrier-forming endothelia such as the brain and lung endothelium are continuous with numerous tight junctions that act as a permeability barrier. The endothelium in the kidneys is continuous, but has numerous fenestrae that facilitate the kidneys' filtration function. Sinusoidal endothelial cells (ECs) are discontinuous, allowing easy entry and exit of fluids and solutes.

The molecular analysis of organ- and caliber-specific EC differentiation is still in its infancy. A number of organ-specific EC molecules have been identified, such as endothelial-specific molecule (ESM)-1 as a marker of lung ECs (1) and the stabilins as markers of sinusoidal ECs (2). Yet, the functional role of such organ-specific EC molecules is not understood. Similarly, several caliber-specific EC molecules have been identified in recent years. EphrinB2 is selectively expressed by arterial (and angiogenic) ECs, whereas EphB4 is preferentially expressed by venous ECs (3). Correspondingly, ephrinB2- and EphB4-deficient mice have essentially complementary embryonically lethal phenotypes characterized by perturbed arteriovenous differentiation (3). The asymmetric arteriovenous expression of ephrinB2 and EphB4 has stimulated research into the identification of EC molecules with arteriovenous asymmetric expression pattern. Some 20 arterial molecules (and much fewer venous-specific EC molecules) have been identified in the last 10 years. Correspondingly, gridlock and COUP-TFII have been characterized as transcription factors controlling arterial and venous EC differentiation, respectively (4,5).

ECs are surrounded by a complex microenvironment that controls the forces acting on the EC layer (Figure 27.1). Luminally, the polarized EC monolayer is exposed to the flow of

blood. Blood flow and blood pressure exert physical forces on the endothelium (shear stress and mechanical strain). Likewise, circulating cells interact with surface molecules of the vascular endothelium (not only leukocytes, platelets, and red blood cells but also metastasizing tumor cells), and molecules in the local or systemic circulation may directly affect EC functions including permeability, coagulation, adhesiveness, and vasotonus. Laterally, ECs are in contact with neighboring ECs through adherens junctions and tight junctions. Cell contact-dependent signaling is well established as controlling many important EC functions. Abluminally, the EC layer is in contact with a caliber- and organ-specific extracellular matrix that is produced by the EC itself as well as by neighboring cells. ECs are abluminally also in contact with mural cells (smooth muscle cells and pericytes), the cell processes of which penetrate the EC extracellular matrix to exert regulatory functions on contacting ECs, particularly those related to the control of EC quiescence.

The vascular endothelium has been conceptualized throughout this book as an input-output device. Signals act on the endothelium (input), are processed within the endothelium (coupling), and enable the endothelium to exert specific functions (output). The input forces acting on ECs can be classified into milieu factors and specific molecular regulators. The mechanistic relationship between the microenvironmental milieu and specific molecular activities is, for most milieu factors, still poorly understood. For example, the identification of the hypoxia regulation of vascular endothelial growth factor (VEGF) expression is among the most important and most cited discoveries in the field of angiogenesis research (6) because it links the milieu factor hypoxia with the induction of gene expression of a key regulatory molecule of the angiogenic cascade. Yet, it took another 10 years to discover the prolyl hydroxylases as the long-sought enigmatic oxygen sensors (7) (Chapter 29). Similarly, the role of biophysical forces in the vascular system (shear stress, mechanical strain) in controlling the molecular repertoire and phenotypic behavior of the vascular

Figure 27.1. EC input. Anatomically, the vascular endothelium forms a cellular system of limited complexity. It is lumenally exposed to biomechanical forces (shear stress, mechanical strain) and interacts with cells in the circulation. Laterally, ECs are in contact with each other through adherens junctions and tight junctions. Abluminally, ECs are in contact with their organ-specific extracellular matrix as well as with mural cells (smooth muscle cells [SMC], pericytes). Nevertheless, this comparatively simple anatomical unit is capable of responding to an enormous plethora of stimuli (*INPUT*) and can exert an array of different effector functions (*OUTPUT*), many of which are related to some of the most devastating human diseases.

endothelium has been solidly established. Yet, a molecular mechanosensor has not yet been identified (Chapter 28).

Milieu factors will eventually translate into the activities of specific molecular regulators. Locally and systemically acting stimulating and inhibiting molecules may act as specific or pleiotropic effectors of EC function. Some peptide growth factors, such as VEGF (Chapter 32) and the angiopoietins (Chapter 39) act almost EC-specifically through the restricted expression of their corresponding receptors by ECs. Other growth factors are pleiotropic in their action. For example, hepatocyte growth factor (HGF) (Chapter 33), the fibroblast growth factors (FGFs) (Chapter 34), and transforming growth factors (TGFs) (Chapter 35) are considered prototypic pleiotropic growth factors because they act on many cell types, but nevertheless exert specific effects on ECs.

Research performed over the last few years has identified intriguing parallels between the formation of neuronal networks and the establishment of vascular networks. Consequently, the neuronal system and the vascular system share a set of fate-determining, guidance signal-mediating, and positional information-transducing molecules. These include semaphorins with their neuropilin receptors (Chapter 37), ephrins and their corresponding Eph receptors (Chapter 38), Robo-Slit molecules (Chapter 40), and Notch molecules (Chapter 41). Mutations of many of these molecules cause specific embryonic lethal vascular phenotypes, reflecting the critical rate-limiting necessity of such guidance- and network-regulating signaling systems for proper vascular assembly.

The inflammatory response program is among the best characterized activation programs of the vascular endothelium. Inflammatory EC activation through tumor necrosis factor (TNF)- $\alpha$  (Chapter 31) or endotoxin (Chapter 46) causes a specific downstream signaling program that leads to the expression of inflammation-associated EC adhesion molecules that facilitate the recruitment of inflammatory

cells. Similarly, a long list of other mediators and regulators of EC signaling and gene expression control EC function. These include opioids (Chapter 50), reactive oxygen species (ROS) (Chapter 42), nucleotides and nucleosides (Chapter 43), advanced glycation products (AGEs) (Chapter 47), complement (Chapter 48), the contact system (Chapter 49), thrombospondin (TSP) (Chapter 36), syndecan (Chapter 44), and sphingolipids (Chapter 45). ECs also are vulnerable to the effects of circulating toxins. Examples are environmental toxins (Chapter 59) and snake venoms (Chapter 51).

Other milieu factors are able to control phenotypic properties and functions of the vascular endothelium through receptor-independent and/or multifactorial mechanisms. These include acid-base metabolism (Chapter 30), hyperthermia (Chapter 52), hyperbaric oxygen (Chapter 53), barotrauma (Chapter 54), deep sea diving (Chapter 55), exercise (Chapter 56), high altitude (Chapter 57), and gravity (Chapter 58).

Contact with neighboring cells similarly contributes to the specific microenvironments that control EC phenotype and function. Neighboring cells can control ECs through direct contact or through paracrine-acting mediators. ECs are in most intimate contact with mural cells (smooth muscle cells and pericytes [Chapters 60 and 61]), which control the quiescent phenotype of the endothelial layer. Likewise, cells in the circulation, such as red blood cells (Chapter 62), leukocytes (Chapter 63), and platelets (Chapter 64), interact with ECs, resulting in bidirectional signaling events. In addition to contacts with abluminally and lumenally contacting cells, ECs also may establish a dialogue with other cell types in select vascular beds. Such interactions include cardiomyocytes in the heart (Chapter 65), hepatocytes (Chapter 66) and stellate cells (Chapter 67) in the liver, and podocytes in the kidneys (Chapter 68).

Examples exist of molecules that contribute both to input and output. Some of these autocrine factors, such as nitric oxide and carbon monoxide, are covered in the section on Output.

Collectively, the vascular endothelium forms an enormously complex input-output system. The relative anatomical simplicity of the vessel wall stands in striking contrast to its remarkable signal transduction capacity and high level of activity. Clearly, the vascular endothelium is functionally involved in some of the most devastating human diseases. These include primary vascular diseases such as hypertension, coagulopathies, ischemic diseases, and atherosclerotic vascular changes. Furthermore, the vessel wall also is involved in many nonvascular diseases including among others tumor growth (tumor angiogenesis) and endocrine disorders (diabetic retinopathy). It may not come as a surprise that more than two-thirds of all human deaths involve the vascular system either directly or indirectly. Thus, a solid understanding of the factors and forces that act on the endothelium – as outlined in the chapters of this section – forms the foundation for a better mechanistic understanding of vascular pathophysiology.

# Hemodynamics in the Determination of Endothelial Phenotype and Flow Mechanotransduction

Peter F. Davies

*Institute for Medicine & Engineering, University of Pennsylvania, Philadelphia*

The movement of blood in the systemic and pulmonary circulations influences every cell of those vascular systems, but its most immediate mechanical effect is on the endothelium. The endothelium is well recognized as a hemodynamic mechanotransduction interface that in turn influences the biology of the vessel and its physiological responses. Furthermore, in arteries, hemodynamic forces are associated with endothelial phenotypes that predispose specific sites to focal atherogenesis. This chapter considers the relationships between hemodynamics and endothelial phenotypes and reviews our current understanding of the broader mechanisms of endothelial mechanosensing and signal transduction as they relate to arterial physiology and pathology. The microcirculation and post-capillary venous return – regions in which flow effects on leukocyte interactions with the endothelium occur in the context of acute inflammation – are considered elsewhere in this volume (see Chapter 114).

## THE ENDOTHELIUM IS HIGHLY RESPONSIVE TO LOCAL HEMODYNAMICS

A feature common to all endothelial cells (ECs) studied in a variety of vascular locations and cell cultures is the ability to respond to local changes of blood flow, particularly to acute and sustained changes of hemodynamic shear stresses that deform the cell (1–4). The endothelia of arteries and heart valves are generally subjected to the highest magnitudes and variations in hemodynamic forces. Arterial hemodynamics has received the most experimental scrutiny, in part because of the correlative relationships that exist between certain hemodynamic characteristics and atherosclerosis. However, models and measurements of flow complexities around the heart valves recently have focused on molecular investiga-

tions of the role of hemodynamics in regulating valve endothelial pathophysiology; both are considered here.

As presented at length elsewhere in this book, ECs play an important role in flow-mediated vasoregulatory control. Acute dilatation and constriction of arteries in response to changes of flow are controlled through endothelial-derived nitrovasodilators, prostaglandins, lipoxigenases, hyperpolarizing factors, and related molecules (1,3). Sustained changes in hemodynamics stimulate the structural remodeling of the arterial wall through a process that is also endothelium-dependent (4) and involves a carefully orchestrated sequence of gene and protein expressions that facilitate major structural adaptation to the new hemodynamic environment. Furthermore, hemodynamics plays a critical role in the arterial circulation at those locations where most vascular pathologies originate and develop their morbidity (5). The localized initiation and development of atherosclerosis and cardiac valve dysfunction are highly influenced by hemodynamics (6).

## HISTORICAL CONTEXT

Until the Renaissance, the prevalent theory of blood movement remained that put forward by the second-century Greek physician Galen, who proposed that blood vessels were discrete noncirculating ebb-and-flow systems supplying the separate fluid compartments associated with the primary organs. During the fifteenth and sixteenth centuries, Versalius and Da Vinci highlighted some of the inconsistencies of the Galen theory (7), but it was not until the early seventeenth century that a complete circulation was demonstrated by William Harvey. However, although it had been recognized for a thousand years that large blood volumes move through complex branching networks, blood vessels were studied from a fluid dynamic

perspective only as passive rigid tubes until well into the twentieth century. During the past three decades, hemodynamic forces and cellular mechanics have become firmly established in most aspects of vascular biology, and in endothelial research in particular.

The relationship between hemodynamics and the geometry of the cardiovascular system was first remarked upon during the sixteenth century by Leonardo Da Vinci, who extrapolated his interest in hydraulics to the anatomy of the human heart (7). While comparing dissected heart valves and arteries to the geometry of natural river systems, he predicted that flow would separate in regions around the valves and branches of the arteries as a matter of (physiological) course. During the nineteenth century, the pathologist Virchow (8) noted that “athero-sclerosis” favored larger arteries, and he made the important distinction that the *cellular* components of the tissue play a prominent role in mediating inflammation. However he did not comment on the role of flow itself in the process. Little further consideration was given to hemodynamics and a metabolically active endothelium, even during the early twentieth century, when a clearly nonrandom distribution of lesions was obvious at autopsy, and the first risk factor for atherosclerosis (hypercholesterolemia) had been identified (9). Renewed interest in hemodynamic patterns in atherosclerosis, but initially not particularly the endothelium, was driven by rheological engineers during the 1960s. The fluid dynamics studies of Caro and colleagues (10) in London, and Fry, Roach, and colleagues in the United States and Canada (11,12) provoked biologists to reconsider the endothelium as an active interface. This coincided with ultrastructural transmission electron microscopy studies that revealed intracellular complexity predictive of the dynamic biology of these cells (13). The isolation and culture of ECs in 1973 (14) led to an appreciation of their structural, functional, and metabolic complexity and facilitated those *in vitro* flow studies performed under controlled conditions that began at the end of that decade (15–17). During the same period, the central role of the endothelium in vascular pathology was established by demonstration of the retention of an intact endothelium during the initiation and development of atherosclerotic lesions, thereby connecting endothelial structure and function to lesion development (18). In pathology, therefore, the link between complex hemodynamics and heterogeneous patho-susceptible endothelial phenotype became evident.

In 1980, Furchgott made the seminal discovery that vascular relaxation is endothelial-dependent (19). It was quickly realized that Schretzenmayer’s observations, made during the 1930s, of acute flow-dependent vasoregulation were mediated by the endothelium (20). The role of the endothelium in flow-regulated vessel remodeling was subsequently demonstrated (4). From the late 1970s onward, devices to impose simulated blood flow over cultured ECs were developed to investigate hemodynamic responsiveness (15–17), and this was paralleled by a renewed appreciation of *in vivo* hemodynamics in relation to lesion location, surgical manipulation, and vascular grafts. These inquiries have continued to the present day, with

the progressive inclusion of the most modern technologies in device engineering, cell and molecular biology, computation, and imaging.

Experimental studies of hemodynamics and the endothelium primarily address two thematic questions related to arteries:

- What role does mechanotransduction play in the localization of atherosclerotic lesions and other cardiovascular pathologies?
- What are the fundamental mechanisms of mechanosignaling and transduction in normal vascular physiological function?

Endothelial mechanotransduction mechanisms are likely to underlie the susceptibility to atherosclerosis and inflammation at those arterial locations where unstable hemodynamics is prevalent and where synergisms of hemodynamics and chemical signaling (cytokines, chemokines) mediate the expression of endothelial adhesion proteins, leukocyte attachment, and cell migration.

## HEMODYNAMIC FORCES

Blood, a complex inhomogeneous mixture of fluid and cells, is imperfectly modeled as a homogeneous Newtonian fluid in most experimental endothelial investigations, an approximation that, despite its limitations, has provided significant insights into endothelial biology. Forces imparted to a vessel by blood flow can be resolved into two principal vectors: (a) blood pressure perpendicular to the vessel wall and (b) shear stress that acts parallel to the vessel surface to create a frictional force at the endothelium, usually expressed as dyn/cm<sup>2</sup> or Pascals (10 dyn/cm<sup>2</sup> = 1 Pascal). Strain is the deformation that results when a stress (force/unit area) acts on a cell or tissue. Thus, both pressure and shear stress result in strain of the vessel wall.

The shear stress varies inversely with the third power of radius. Therefore, shear stresses at high flow in a wide tube (e.g., the aorta) and at lower flow in a narrow tube (e.g., the capillaries) are within a similar range. However, in the larger vessels much greater pulsatility occurs, which results in more variable flow characteristics than in the steadier flow environment of smaller arteries and the microcirculation. Intermolecular attraction between the layers within the fluid is strong, resulting in blood flow as a cohesive body of fluid slowed only by frictional contact with the vessel surface (endothelium); this is pulsatile laminar (or layered) flow. The pulsatility is simply a slowing down or speeding up of laminar flow moving in the same direction throughout each cardiac cycle. In oscillatory flow, which is pulsatile, a reversal of flow occurs during part of the pulse cycle. In arteries, oscillatory flow usually is the result of the bulk flow separating into distinct compartments of undisturbed and disturbed flow as the interfluid molecular interactions are overcome along the interface of separation,

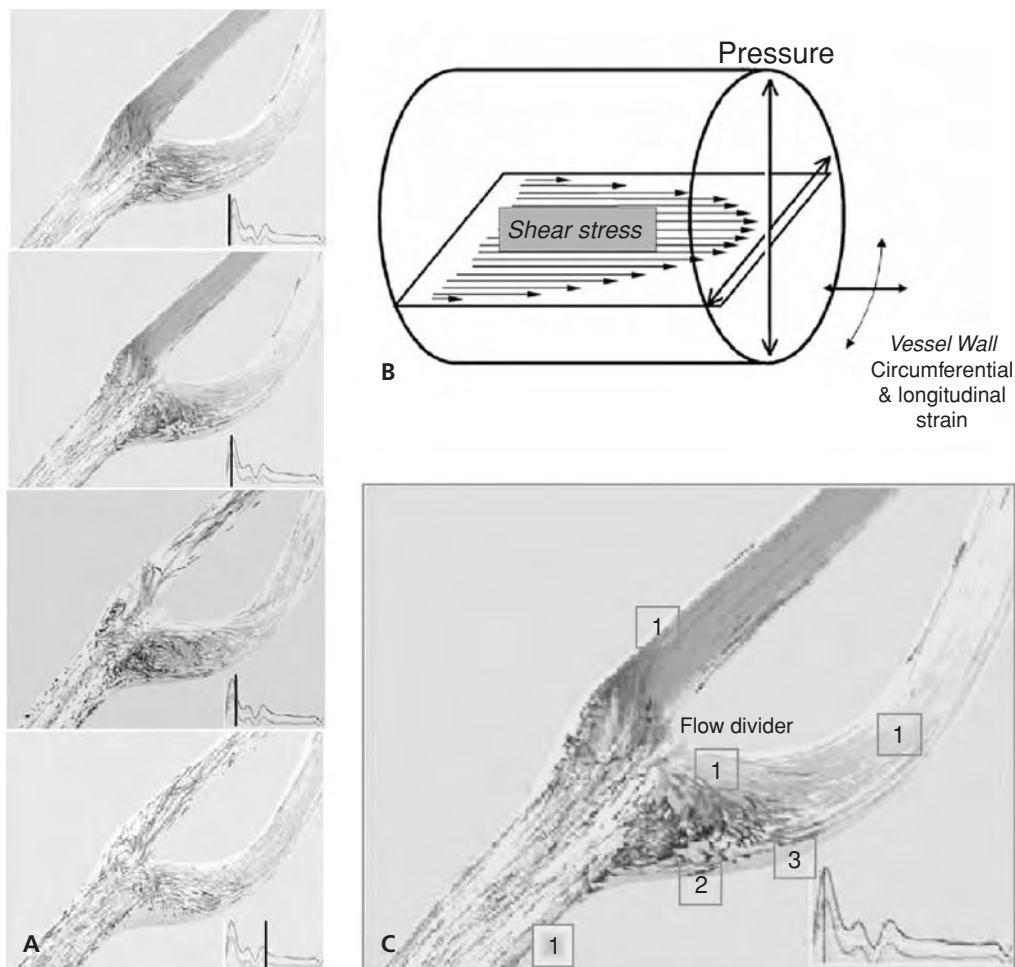

Figure 28.1. Flow characteristics in the normal human carotid artery at the bifurcation into internal and external branches illustrating some spatial and temporal characteristics of the flow. (A) Four frames at progressive points in the cardiac cycle illustrate the transition from unidirectional laminar flow (and shear stress) in the bulbous carotid sinus (panel 1) to the onset (panel 2) and development (panel 3) of complex disturbed flow, including flow reversal beyond peak systole and the restoration of unidirectional laminar flow in the sinus during diastole (panel 4). (B) Resolution of hemodynamic forces into simplified principal vectors of shear stress parallel to the vessel wall and pressure perpendicular to the wall. These stress forces result in cell and tissue deformation (strain) in the endothelium and underlying vessel wall. (C) Enlarged panel from 1A showing spatial separation of flow disturbance. Flow varies in velocity but is laminar and unidirectional at multiple locations (labeled 1). These include the common carotid artery proximal to the bifurcation, the entire lesser branch (internal carotid) artery, the wall of the external carotid artery adjacent to the flow divider, and the distal region of the same branch. In contrast, a transient unstable vortex containing elements of flow reversal (labeled 2) develops in the external carotid artery opposite to the flow divider. Such regions are highly susceptible to the development of atherosclerosis. At 3, the laminar unidirectional flow “reattaches” to the wall beyond the boundary of disturbance. The images in A and C were extracted and modified from a remarkable computational fluid dynamics recording of blood flow in this tissue by Professor David A. Steinman of the Department of Mechanical and Industrial Engineering, University of Toronto (image gallery URL: <http://www.mie.utoronto.ca/labs/bsl/>). Adapted with permission.

an event that requires a considerable input of energy. Such oscillatory disturbed flow in arteries is invariably associated with an encounter with an obstacle (e.g., flow divider of a branch artery; Figure 28.1), or a curvature in the vessel around which the blood following the outer trajectories must travel farther than that of the inner curve (e.g., the aortic arch), or a sudden expansion of the cross-sectional area of the vessel

(e.g., aortic valve stenosis). The instabilities often form a vortex that may remain laminar within its boundaries or, when enough energy is imparted into the separated flow, it may break down to chaos (turbulent flow). Flow separations are difficult to define precisely because, at a single location, not only may they exhibit pulsations, oscillations, secondary helical flows, laminarity, and turbulence, but the characteristics are

changing from millisecond to millisecond throughout the cardiac cycle. Collectively, the term *disturbed flow* commonly is used for such regions. Although the great majority of flow in the arterial circulation is pulsatile, unidirectional, and laminar, the disturbed flow regions are important because they predispose to atherosclerosis. Figure 28.1 outlines these general flow characteristics in a normal human carotid artery sinus.

Whatever the local flow characteristics, the endothelium is the principal recipient of shear stress forces by virtue of its direct contact with the blood flow. Although some transmural interstitial fluid movement acts on the vascular smooth muscle cells (VSMCs) to generate shear stresses, the mixture of VSMC and connective tissues (collagens, elastins, glycosaminoglycans) and four-dimensional fluid movement render it difficult to experimentally estimate the level of shear stresses with high resolution. However, they generally are considered to be low.

In most of the arterial circulation, blood velocity profiles approximate pulsatile laminar flow in a rigid tube. In the capillaries and venules, the flow is steady but subject to upstream

arteriolar vasoregulation that can vary the flow rate considerably, including stasis when blood flow is diverted to other capillary beds. Thus, variations in capillary flow occur with a much longer and more irregular periodicity than in nearby precapillary arterioles.

Flow velocity is maximal at the center of the lumen of larger vessels, remains high across much of the cross-sectional area, and decreases sharply near the vessel surface, where wall shear stress acts at the endothelial surface. Shear stress is in the direction of the flow and is proportional to the fluid velocity and viscosity; in undisturbed laminar flow in the arterial circulation, the endothelium is subjected to pulsatile unidirectional shear stress typically in the range 10 to 20 dyn/cm<sup>2</sup>. Because the cell morphology reflects the hemodynamic environment, most arterial ECs are elongated and aligned in the direction of flow. In contrast, in disturbed flow regions, where pulsatile instabilities generate transient vortices that collapse and reform with each cardiac cycle, the cells exhibit no preferred orientation or alignment. Figure 28.2 illustrates endothelial

Figure 28.2. Flow-mediated EC orientation. In situ EC and nuclear orientation in undisturbed unidirectional laminar flow in the descending thoracic aorta (A,C) and separated disturbed flow (B) adjacent to an intercostal branch of the aorta. Such flow characteristics are associated with arterial branch sites, curvatures, and bifurcations. In B, a region of cell alignment changes abruptly to polygonal cells beyond a line of flow separation (*curved arrows*) that marks the boundary of a disturbed flow region (*double-headed arrow*). In D, the nuclear pattern is representative of a similar disturbed flow region in the inner curvature of the aortic arch.

morphology in regions of different flow characteristics *in vivo*. At high flow velocities and/or heart rate, the complex but predictable disturbed laminar flow in these regions may collapse into chaos (turbulence). Thus, both disturbed laminar flow and nonlaminar turbulent flow depart from the pattern of those unidirectional forces at the endothelium that are characteristic of most other regions, and the ECs at these locations fail to align. From a large number of fluid dynamics studies and *in vivo* measurements, the range of shear stress in the arterial circulation in such regions has been estimated to vary from negative values, through zero values at the edges of flow-separation regions, and up to  $+20 \text{ dyn/cm}^2$ . During episodes of increased cardiac output or hypertension, these values may increase considerably; transients in excess of  $100 \text{ dyn/cm}^2$  have been recorded (15). The spatio-temporal gradients of shear stress in flow disturbance are extraordinarily large compared with sites of undisturbed flow, and the same regions are susceptible to the development of atherosclerosis when experimental risk factors are added. The phenotypic basis of atherosusceptibility at these locations *in vivo* is of great interest.

## HEMODYNAMICS AND ENDOTHELIAL PHENOTYPES

Recently, methods that facilitate the global interrogation of cell structure, function, and tissue organization using high-throughput platforms have been applied to studies of endothelial mechanobiology. Endothelial phenotypes can be defined by “-omics” – techniques such as genomics, proteomics, metabolomics, phenomics, and systems biology that probe the genome, proteome, physiome, and function. These technologies provide valuable insights into endothelial biology through access to large databases managed by specialized statistical and bioinformatics units. The approach embraces a great breadth of information to provide a more comprehensive overview of cell biology as well as the identification of molecular associations leading to focused investigation. In particular, when applied at multiple spatial scales, phenotyping reveals greater endothelial heterogeneity than was previously realized; substantial differences in endothelial phenotype exist not only from vessel to vessel, but also from region to region, and cell to cell within subregions. The convergence of “-omics” with endothelial biology is not only part of the forefront of vascular biology but also is driving multiscale studies of endothelium in an effort to understand the basis of heterogeneity and evaluate its importance in relation both to vascular homeostasis in general and to the hemodynamic influences on vascular function and dysfunction. These efforts are directed *in vitro* and, more recently, *in vivo* and *in situ*.

### Phenotypes and Flow

The endothelial phenotype is malleable and can be considered to be determined by two principal components: (a) an intrinsic

phenotype imprinted genetically during development that defines the essential identity of the cell as endothelial, and (b) elements of the microenvironment that locally modify some characteristics of the intrinsic phenotype. Different vascular beds express specialized morphologies and functions appropriate to their tissue or organ location (e.g., fenestrated endothelium, blood–brain barrier endothelium, discontinuous sinusoidal endothelium, etc.). All retain the essential endothelial features of blood compatibility and express molecular markers of endothelial identity determined during development. Local environmental factors are responsible for much of the plasticity of endothelial structure and function and for the cell heterogeneity that exists within vascular beds (21–23). Separation of these criteria is somewhat artificial, and the programmed and local environmental factors work together to define phenotype. Recently, Chi and colleagues have demonstrated the retention of certain *in vivo* vascular bed–specific endothelial characteristics for several passages in tissue culture (24).

Abundant data show hemodynamic forces to be an important environmental determinant of endothelial phenotype *in vivo*. For example, endothelial gene and protein expressions vary at sites of different hemodynamic characteristics (22–28), and cause–effect relationships between hemodynamics and endothelial nitric oxide synthase (eNOS) expression were recently demonstrated in a coarcted carotid artery mouse model (29). In embryonic development, a venous obstruction increased cardiac shear stress and resulted in altered expression patterns of Kruppel-like factor 2 (KLF2), endothelin (ET)-1, and NOS (30). Furthermore, more than two decades of *in vitro* flow experiments have demonstrated endothelial structural, functional, and adaptive changes associated with shear stress stimuli (1).

### Phenotypes in Undisturbed and Disturbed Flow

Fluid dynamics complexity increases in those regions of transient unstable flow separation associated with branches, bifurcations, and curvatures in the arterial circulation and downstream reattachment (rejoining the main flow). In flow disturbance, the average shear stress is lower but is associated with steep temporal and spatial gradients of shear stress, all within a restricted region of flow disturbance. Occasional turbulence (chaos) as well as disturbed laminar flow impart multidirectional forces to the cells. Consequently, these locations, unlike elsewhere in the arterial circulation, are characterized by an absence of regular EC alignment (see Figure 28.2). Disturbed flow regions correlate closely with susceptibility to pathological change: atherosclerosis in arteries and calcific sclerosis in heart valves. Endothelium at such locations in normal swine (22) and transgenic mice (27) expresses significant differences in gene expression compared with adjacent undisturbed laminar flow regions, and these differences are proposed to be an important influence on susceptibility to, or protection from, pathological change (31).

**Endothelial Multigene Expression in Aorta in Vivo**

Regions of disturbed flow (DF) susceptible to lesion development were compared to regions of undisturbed laminar flow (UF) in the aortic arch and thoracic aorta, respectively, in adult male swine. We profiled gene expression by paired replicate analyses in approximately 10<sup>4</sup> freshly isolated ECs from DF and UF regions of the inner curvature of the aortic arch and middle descending thoracic aorta respectively (Figure 28.3) (22). Total RNA was isolated for nucleic acid amplification, labeling, and microarray analysis. To confirm that the morphologies of the endothelium in each region corresponded to the effects of directional or disturbed nondirectional flow, the endothelial nuclei were stained with fluorescent nuclear Hoechst dye (DAPI). The axial ratio of the cell nuclei, indicative of cell orientation, showed good cell alignment in the region of undisturbed flow. In contrast, no preferential alignment was present in the aortic arch, a region of disturbed flow. Linearly amplified endothelial RNA was used to synthesize labeled DNA probes to screen filter arrays of 13,824 human cDNAs. Dif-

ferential expression between DF and UF regions was validated by real-time reverse transcription PCR (QRT-PCR) sampling of genes. Of the array set, 13.6% (1,880 genes) were identified as differentially expressed in DF ECs compared with the UF site at *p* < .05. The significantly different genes were analyzed for meaningful biological associations. As summarized in Table 28-1, higher proinflammatory cytokine expression occurred in the arch (DF) compared with UF, and with expression of nuclear factor (NF)- $\kappa$ B transcript (but not NF- $\kappa$ B protein), as well as the adhesion factors CD44 and von Willebrand factor (vWF). The expression of adhesion molecules vascular adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1 and -2, P-selectin, and E-selectin (all associated with the early development of atherosclerosis) was no different between regions. Furthermore, profiles of multiple genes with redox-related functions revealed a net *anti-oxidative* phenotype in DF regions indicative of *protection* against reactive oxygen species. The DF region appears to be in a phenotypic state that is primed for inflammation but, in the absence of further risk factors, is physiologically stable – possibly because

Figure 28.3. Anatomical regions of disturbed and undisturbed flow. Disturbed (inner and lateral curvature of the aortic arch) and undisturbed (descending thoracic aorta between intercostal branches) hemodynamic sites in adult swine aorta from which ECs were isolated for the study described in reference 22. An additional undisturbed flow site sampled was the common carotid artery. (Adapted with permission from Passerini AG, Polacek DC, Shi C, et al. Coexisting pro-inflammatory and anti-oxidative endothelial transcription profiles in a disturbed flow region of the adult porcine aorta. *Proc Natl Acad Sci USA*. 2004;101:2482–2487.)

**Table 28-1: Coexisting Proinflammatory and Antioxidant Endothelial Gene Expression Profiles in Disturbed Flow, Atherosusceptible Regions of the Adult Pig Aorta in Vivo**

<b>Proinflammatory phenotype in disturbed flow (DF) in vivo*</b>	
Upregulated	IL-1a, IL-1a receptor, IL-6, IL-8RB, MCP-1, NFkB, Protein C receptor, RAGE
Downregulated	IL-8, IL-10, IL-14, CXCR4, PAF receptor, c-fos,
Unchanged	ICAM-1, PECAM-1, ELAM-1, VCAM-1, ICAM-2, VE-cadherin and other molecules associated with cell-mediated onset of inflammation
<b>Antioxidant phenotype in DF in vivo*</b>	
Upregulated	Heme oxygenase 1, glutathione S-transferase, quinone oxidoreductase, glutathione peroxidase, SOD3. All are associated with antioxidant, protective mechanisms.
Downregulated	Vitamin D <sub>3</sub> -upregulated protein (VDUP-1) (also known as thoredoxin-interacting protein), cytochrome c oxidase, NADH dehydrogenase. Their downregulation is consistent with antioxidant protection. eNOS was also downregulated. NAD(P)H oxidase was unchanged.
<b>Cholesterol balance in DF in vivo*</b>	
Upregulated	ATP-binding cassette A1, ApoA1 regulatory protein, Apo A1, Clusterin (Apo J); most are involved in reverse cholesterol transport.
Downregulated	Apo E, PPAR $\gamma$ , scavenger receptor A, Retinoid X receptor B
<b>Coagulation balance in DF in vivo*</b>	
Upregulated	vWF, Factor XIII (procoagulant), t-PA, and plasminogen (anticoagulant)
Downregulated	PAI-1, urokinase receptor

\*When compared to undisturbed flow.

IL, interleukin; MCP, macrophage chemoattractant protein; RAGE, receptor for advanced glycation end product; CXCR, chemokine receptor; PAF, platelet activating factor; ICAM, intercellular adhesion molecule; PECAM, platelet-endothelial cell adhesion molecule; ELAM, endothelial leukocyte adhesion molecule; VCAM, vascular cell adhesion molecule; VE-cadherin, vascular endothelial cadherin; SOD, superoxide dismutase; Apo, apolipoprotein; PPAR, peroxisome proliferator-activated receptor; vWF, von Willebrand factor; t-PA, tissue-type plasminogen activator; PAI, plasminogen activator inhibitor.

(Adapted with permission from Passerini AG, Polacek DC, Shi C, et al. Coexisting pro-inflammatory and anti-oxidative endothelial transcription profiles in a disturbed flow region of the adult porcine aorta. *Proc Natl Acad Sci USA*. 2004;101:2482–2487.)

of coexisting protective pathways. Thus it meets a definition of athero-susceptible, but not atherogenic. Genes assigned to other mechanisms implicated in lesion development, reverse cholesterol transport, and coagulation, also showed net *protective* profiles in the DF region (see Table 28-1). A delicate balance of pro- and antiatherosclerotic mechanisms may exist

simultaneously in the endothelium of lesion-prone sites to create a setting of net vulnerability to atherogenesis but with protective measures also present. A shift from atherosusceptibility to atherogenesis may occur by *inhibition of the protection*. Thus, disturbed flow characteristics act as a local risk factor for development of atherosclerosis, but they also provide a degree of protection; additional risk factors may overcome the protection. Such a scenario is consistent with the absence of atherosclerosis in the presence of disturbed flow but in the absence of other risk factors. As noted in the section “Endothelial gene expression in heart valves in vivo,” similar protective gene positioning is noted in the undiseased aortic valve (28).

### Gene Clustering by Hemodynamic Location in Vivo

In a follow-up study, we compared endothelial transcript profiles from hemodynamically distinct arterial regions in 15 mature pigs: males and females fed a normal diet, and males briefly fed a high-fat diet (2 weeks) (32). Hierarchical clustering analysis showed preferential grouping of arrays by region over the risk factors of hypercholesterolemia and gender. A set of differentially expressed genes was identified that clearly distinguished regions of disturbed flow from undisturbed flow; however, few differences were observed within the same region based on gender or diet. The results implicated regional hemodynamics as a dominant determinant of endothelial phenotypic heterogeneity underlying atherosusceptibility in vivo.

### Endothelial Gene Expression under Flow in Vitro

Predating the recent in vivo endothelial profiling, candidate flow-sensitive genes were identified in tissue culture (reviewed in 33), and this was quickly followed by microarray analyses of gene expression (33–36). The results, however, are not easily compared to those of in vivo studies that capture the profiles of regions adapted in situ to differential hemodynamic environments. More relevant are two in vitro microarray studies that compared flow conditions analogous to DF and UF. In the first, Garcia-Cardena and colleagues (37) compared differential expression in cultured human ECs subjected to turbulent (TSS) and laminar shear stress (LSS) – analogous to DF versus UF regions in vivo. One hundred genes were identified as differentially expressed (TSS versus LSS) after 24 h (68 upregulated and 32 downregulated). The authors identified a set of genes that was down in LSS but up in TSS as potentially the most pathologically relevant. They considered highly regulated genes of known or putative function in signaling, response to injury, or atherogenesis, and focused on linking the protective effects of LSS to matrix biology and cell cycle.

Using microarrays (588 genes) and subtraction cloning, Brooks and colleagues (38) compared gene expression in cultured human arterial ECs under pulsatile DF conditions with cells subjected to LSS. They identified more than 100 genes as differentially expressed at 24 h, many of which were upregulated genes associated with mechanisms known to be proatherosclerotic, particularly inflammatory molecules, adhesion factors, and oxidation-related molecules. Few genes

**Table 28-2: Principal Endothelial Genes Regulated by Disturbed Flow in Vitro (24 h)**

**Upregulated: Turbulence versus LSS** (From Ref. 37)

TNF receptor stimulating factor 1, CD 1D, exportin, FGF receptor 3, BRCA2, NK tumor recognition sequence, GlcNAc transferase, spastic paraplegia 7, uracil DNA glycosylase, fibrogenic lymphokine, P2X purinoceptor

**Upregulated: Low shear disturbed flow versus modest LSS**

(From Ref. 38)

ICAM-1; PECAM-1; ELAM-1; VCAM-1; ICAM-2; IL-9 receptor; MCP-1; IL-2 receptor  $\alpha$ ; IL-3 receptor  $\alpha$ ; TNF receptor 7; MIP-2 $\alpha$ ; p53; TSP1; integrins  $\alpha$ 3,  $\alpha$ m,  $\alpha$ 6,  $\alpha$ 5,  $\alpha$ v,  $\beta$ 1; VE-cadherin; N-cadherin; thrombin receptor; ET-1; endothelin converting enzyme; glutathione S-transferase; MMP-14; MMP-7; HOX-7; HOX-11; cytochrome P450; alcohol dehydrogenase

**Downregulated: Turbulence versus LSS** (From Ref. 37)

C-termini binding protein-2, translation initiation factor 2, follicular lymphoma variant translocation 1, FOS-like antigen, granulins, KIAA0631 protein, SDF-1, thyroid hormone receptor interactor 7, TPA-inducible protein, cytochrome P450 subfamily V, fibronectin 1, G-proteins  $\beta$ 1 and  $\gamma$ 5, RAGE, thioredoxin reductase, sparc/osteonectin

**Downregulated: Low shear disturbed flow versus modest LSS**

(From Ref. 38)

IL-7; RANTES; IFg; p57kip2; cyclin b1; GADD 153; HSP-40, 47, and 70; LFA-1; PAI-2; SOD-1 and -2; MMP-1 and -8; smad 1; BMP-4; b-myb; estrogen sulfotransferase; 1,4  $\alpha$ -glucagon branching enzyme

LSS, laminar shear stress (steady, undisturbed unidirectional flow); TNF, tumor necrosis factor; FGF, fibroblast growth factor; BRCA, breast cancer genes; MIP, macrophage inflammatory protein; TSP, thrombospondin; ET, endothelin; MMP, matrix metalloproteinase; HOX, homeobox gene; SDF, stromal derived factor; RANTES, regulated on activation, normal T cells expressed and secreted; GADD, growth arrest and DNA damage; HSP, heat shock protein; BMP, bone morphogenic protein

expressed by these in vitro investigations were common to those identified as differentially expressed in in vivo studies of normal arteries. Furthermore, little agreement existed between the two in vitro studies. The reasons may be the nature of the disturbed flow in each study, different cell origins, sensitivities of microarray analysis, or myriad technical considerations. Despite significantly different outcomes however, both these in vitro studies demonstrated that conditions of disturbed flow resulted in significant differential endothelial gene expression compared with conditions of unidirectional steady flow. Principal gene expression differences of interest from these two studies are outlined in Table 28-2.

**Differential Endothelial PKC Activity, Isoform Expression, and Posttranslational Modification at Hemodynamically Distinct Arterial Sites**

As an initial investigation into proteins playing a role in complex signaling networks involved in mechanotransduction,

Magid and Davies (26) focused on protein kinase C (PKC), a family of signaling kinases that have been implicated in a wide variety of cellular processes. The PKC protein family has an endothelial distribution that is affected by flow in vitro (39). Moreover, the expression pattern of PKC isoforms suggest differences between athero-susceptible and athero-protected arterial sites (22). PKC isoforms  $\epsilon$  and  $\zeta$  have been implicated in eNOS (40) and NF- $\kappa$ B signaling (41), respectively. Using arterial endothelial protein lysates, endothelial PKC activities were mapped to DF and UF regions of swine aorta and carotid artery, sites susceptible or resistant to atherosclerosis. Total endothelial PKC activity (all isoforms) in the DF regions was 145% to 240% of that in UF locations, whereas the UF regions were not significantly different from each other. PKC isoforms  $\alpha$ ,  $\beta$ ,  $\epsilon$ ,  $\iota$ ,  $\lambda$ , and  $\zeta$  were expressed in similar proportions in both UF and DF regions, suggesting that differences of kinase activity were not directly attributable to expression levels. The inhibition of members of the “conventional” and “novel” PKC families in the lysates had no effect on kinase activity, which remained different in UF and DF lysates. However, inhibition of PKC- $\zeta$ , a member of the “atypical” PKC family, reduced the DF lysate kinase activity to that of UF levels. Threonine 410 phosphorylation in PKC- $\zeta$ , a proxy for activated PKC- $\zeta$ , was elevated in the DF region, whereas substantially more phosphorylated threonine 560 was present in PKC- $\zeta$  in the UF region, targeting the protein for degradation. These experiments suggest that posttranslational destabilization of PKC- $\zeta$  in the UF region leads to the observed decreased kinase activity compared with the DF site.

**Endothelial Gene Expression in Heart Valves in Vivo**

The aortic valve is another important tissue of multiscale, site-specific endothelial phenotype influenced by hemodynamics. The complex geometry, biomechanics, dynamics, and pathology of the valve endothelium is somewhat understudied in comparison to arterial endothelium. Earlier studies identified morphological and functional differences between aortic side and ventricular side endothelium (i.e., local site specificity), and recent work from this lab has identified site-specific endothelial phenotype heterogeneity (28). During the cardiac cycle, valve endothelium is subjected to complex fluid dynamics that are distinctly different on each side of the leaflet (42). Calcific sclerosis occurs preferentially on the aortic side of the valve leaflet, where greater flow disturbances prevail. Thus, a spatial correlation exists between the localization of calcific lesions and the local biomechanical environment, similar to that observed for athero-susceptible regions in the large arteries. Local environmental factors, including biomechanics, may contribute to differential endothelial phenotypes that define the sidedness of the valve and the focal susceptibility to calcification. Furthermore, recent evidence suggests that valve endothelium may express different biological properties compared with adjacent contiguous endothelium of the ascending aorta (43). Aortic valve disease shows some characteristics of atherogenesis, suggesting that the role of the endothelium also

may be critical for the maintenance of optimal valve function and may influence its dysfunction.

### Differential Endothelial Transcript Profiling from Aortic- Versus Ventricular-Side Aortic Valve

Our group used microarray analyses of endothelial gene expression from either side of normal adult pig valves to identify distinct differential expression patterns representative of the steady state *in vivo* (28). On the aortic versus the ventricular side, 584 genes were differentially expressed *in situ* by the endothelium. Several over-represented biological classifications with putative relevance to endothelial regulation of valvular homeostasis and aortic side vulnerability to calcification were identified. A pattern of gene expression permissive to calcification on the disease-prone aortic-side endothelium was identified. These included osteoprotegerin (OPG; tumor necrosis factor receptor superfamily, member 11b), C-type natriuretic peptide, and parathyroid hormone, each of which has been shown to inhibit cardiovascular calcification and each of which was suppressed on the aortic side of the valve leaflet. Also underexpressed on the aortic side was the transcript for chordin, a secreted protein that inhibits the osteoinductive effects of bone morphogenetic proteins by sequestering them in latent complexes. Aortic valve sections immunostained with an anti-OPG antibody noted a striking differential expression of the OPG protein consistent with the microarray predictions, with strong staining in and around the ventricular-side endothelium, but little expression on the aortic side. However, as was noted in the DF regions of arteries, coexisting putative protective mechanisms also were expressed at a higher level on the disease-prone side. Specifically, the transcripts for several intracellular antioxidative enzymes, including microsomal glutathione S-transferase 2, glutathione S-transferase  $\omega$ -1, and peroxiredoxin 2, were more highly expressed. The lack of differential expression of proinflammatory molecules on the aortic side may protect against inflammation and lesion initiation in the normal valve. These studies implicate the endothelium in regulating valvular calcific sclerosis and suggest that the spatial heterogeneity of valvular endothelial phenotypes may contribute to the focal susceptibility for lesion development.

The above-mentioned recent studies of endothelial phenotype at different locations throughout the circulation represent snapshots of gene and protein expression in complex hemodynamic environments, where the endothelium is known to be subjected to different types of shear deformation. However, it should be remembered that, *in vivo*, the flow not only physically deforms the cells but also transports plasma proteins and chemicals to the tissue and removes metabolic products from it. The influence of such convective transport on endothelial phenotype is difficult to assess *in vivo* but may be considerable when short-lived molecules are released or metabolized at or near the cell surface (e.g., adenine nucleotides from platelets or cleavable peptides such as plasma bradykinin); a change of flow can quickly alter the local concentration in the boundary layer of the endothelium (44). It is unclear how important this indi-

rect contribution to endothelial flow responses is *in vivo*. In *ex-vivo* perfused arterioles, Koller and colleagues (45) demonstrated that vessel diameter changes were similar whether shear stress was increased by flow or by viscosity (in which convective transport remained constant, but shear stress increased at constant flow rate). Their results suggested that the shear stress deformation force dominated any effects of transport, and support the widely accepted view that endothelial mechanotransduction manifested through deformation is the most important hemodynamic mechanism influencing endothelial responses and phenotype.

### MECHANISMS OF FLOW-MEDIATED ENDOTHELIAL MECHANOTRANSDUCTION

Although the importance of *in vivo* hemodynamics experiments, such as mapping cell phenotypes, measuring physiological responses, creating transgenics, and probing *in situ* using immunohistochemistry, cannot be overemphasized, access to the detailed cellular mechanisms of mechanotransduction in intact vessels remains limited. A more manageable approach to the mechanisms is through reductionist experiments *in vitro*.

Success in endothelial culture was quickly followed in the early 1980s by the development of *in vitro* devices that simulate key elements of blood flow characteristics *in vivo*. The adaptation of cone and plate rheological instruments (46) that expose large numbers of ECs to uniform shear stresses (calculated as laminar flow velocities over a nominally flat surface) provided the first direct observations of endothelial morphological, cytoskeletal, and metabolic responses (18,19,47). The subsequent introduction of an extreme form of disturbed flow, turbulent flow, into this system revealed that the flow characteristics (disturbed/undisturbed) were as important as the magnitude of shear stress. In contrast to laminar flow, turbulent flow stimulated endothelial proliferation whether the shear stress was high or low (20).

Most *in vitro* studies of endothelial flow responses compare cells subjected to shear stress with cells maintained in no-flow. Criticism frequently has been directed at this experimental approach because flow stasis does not exist throughout the arterial side of the circulation *in vivo*. Despite this, however, such studies have revealed mechanisms subsequently shown to be highly relevant to the *in vivo* environment, possibly because no-flow comparisons to flow may elicit a higher signal-to-background ratio than do incremental flow rate comparisons *in vitro*, or because no-flow models simulate aspects of the average low-shear stress environment measured in DF regions *in vivo*. More recently, serious attempts have been made to establish more complicated flow characteristics *in vitro* (e.g., steady versus pulsatile versus oscillatory) (48), including the imposition of complex flow profiles from recordings *in vivo* (49). Although the cultured monolayer of endothelium in such experiments is considered to be a homogeneous population of cells, atomic-force microscopy measurements of the

surface topography demonstrate that significant force variations exist between cells when flow is introduced (50). Data derived from such experiments likely reflect an averaging of the cellular response measurements.

Extensive literature is available on in vitro endothelial responses to flow ranging from ion channel activation (very fast) to morphological changes (slow) bridged through the activation of many biochemical pathways involving transcriptional, translational, and posttranslational responses. The reader is referred to several reviews (1,51–53). Below are highlighted some organizational themes of endothelial mechanotransduction that illustrate the complexity of flow-signaling cascades.

### Decentralized Endothelial Mechanotransduction

Throughout the 1980s, flow mechanotransduction was viewed somewhat simplistically as a shear stress-induced deformation event at the apical endothelial surface from which arises biochemical signaling analogous to agonist-receptor signal transduction. The development of tensegrity and other theories of connected tension elements in cells, particularly the contributions of Ingber (see Chapter 192) led to a reconsideration of the spatial distribution of flow forces in the endothelium (51) and the subsequent presentation of a formalized decentralized model based on live cell imaging experiments (1). *The model proposes that, although shear stress acts initially at the apical (luminal) cell surface and immediate biochemical responses located there, surface forces are simultaneously transmitted throughout the body of the cell such that multiple elements, located away from the apical surface may, independently or in concert, transduce the mechanical signals into biological responses* (Figure 28.4). The contributions of each element may vary, and indeed a single element may dominate at a given moment. Note that these statements apply to the transduction event – that is, the site of conversion from a mechanical deformation to a localized biological response. The subsequent downstream mechano-activated biochemical pathways may not remain restricted to the same subcellular site and also may occur later, but they originate there. *Mechanotransduction* is a term that is currently used to include both the force transduction event and the downstream signaling pathways that lead to altered cellular function. Flow induces many different endothelial responses that occur at different times and that may or may not be interdependent. The subcellular spatial relationships of mechanotransduction have been understudied, and those that have been studied suggest complicated distributions and translocations (1,52–54). Examples of spatio-temporal signaling cascades in flow responses are outlined below, but first it is instructive to consider an organizational basis for these mechanisms.

The finer distinctions within flow-mediated endothelial mechanotransduction might be considered as follows:

1. *Physical deformation.* The displacement of one or more cellular elements required for a flow response. This is the most immediate of events and is required to initiate any subsequent responses. Because the shear stress acts at the apical cell surface, earlier models considered endothelial mechano-sensing systems to be confined to this region; some investigators maintain that view. However, while no doubt remains that signaling elements are located at the apical cell surface (e.g., activation of membrane ion channels [55] or membrane phospholipids [56]), strong evidence suggests simultaneous force transmission by the cytoskeleton (57) causing deformation of cellular elements widely dispersed throughout the cell (with consequent dispersal of mechanotransduction), as outlined in step 2.
2. *Force transmission (mechanotransmission).* The deformation of a connected system under tension – the adherent EC in a confluent monolayer – results in virtually instantaneous transmission of the forces throughout the connected elements. The transmission conduit is principally the cytoskeletal fibers distributed throughout the cell body and the submembranous, spectrin-like cortical cytoskeleton around the cell. Both systems provide rigidity, shape, and structure to the cell and are under tension. Demonstrations of flow-initiated intermediate filament displacement (57), actin filament deformation (58), and directed motion of mitochondria attached to microtubules (59) support the view that apical forces are transmitted to “remote” sites via cytoskeletal displacements. Interference with cytoskeletal structure inhibits flow responses, as defined for various experimental systems. Thus, as proposed in the decentralization model, the actual mechanotransduction event may occur not only at the site of fluid shear interaction with the cell but also at considerable distances (microns) from the apical surface. Furthermore, the deformation effects may extend to adjacent cells, communicated through cell junctional structures (57).
3. *Force conversion to an initial biological response (“true” mechanotransduction).* It follows from step 2 that this critical event may occur at a number of locations simultaneously involving parallel, convergent, or divergent mechanisms and be associated with a variety of different proteins, but all are considered to involve an initial (or simultaneous) physical displacement or deformation in which the plasma fluid forces meet the cell surface. Such an interface is the Holy Grail of mechanobiology because it represents the first step in biological signaling resulting from flow force change. It is therefore the prime target for investigative and/or potential therapeutic intervention. An initial single canonical mechanism has not yet been defined and indeed seems unlikely. Suggested mechanisms include force-induced conformational changes in membrane proteins, physical effects on the lateral mobility of membrane molecules, direct force effects on ion channels, separation of assembled cell–cell oligomeric proteins at junctions, deformation of caveolar structures, and physical inhibition of integrin dynamics and clustering, especially at the basal sites of cell adhesion to extracellular matrices. Physical deformation also may displace local cofactors engaged

Figure 28.4. Decentralized model of endothelial mechanotransduction by shear stress. The cytoskeleton plays a central role in mechanotransmission of tension changes throughout the cell. Examples of direct signaling at the luminal surface (1), junctional signaling (2), and adhesion site signaling (3) are shown. Nuclear deformation also likely results in mechanosignaling (4). The locations are based on direct or indirect experimental evidence, are not mutually exclusive, and are likely interconnected. At 1, deformation of the luminal cell surface, possibly via the glycocalyx. Examples include localized activation of  $K^+$ ,  $Na^+$ , and  $Cl^-$  ion channels, phospholipase activity leading to calcium signaling, and caveolar signaling. At 2, transmission of forces to the intercellular junction protein complexes via the cortical and/or filamentous cytoskeleton. VEGFR2 located at the luminal surface (site 1) or near the junction (site 2) may associate with VE-cadherin,  $\beta$ -catenin, and phosphatidylinositol 3-kinase to phosphorylate Akt and the primary transmembrane protein at this location, PECAM-1. At 3, cytoskeletal force transmission to adhesion sites. Transmembrane integrins bound to extracellular matrix serve as a focus for deformation that results in autophosphorylation of FAK, which binds the SH2 domain of c-Src, a kinase family that phosphorylates paxillin and p130 Cas and leads (via Ras G-proteins) to integrin-dependent activation of MAPK. In a variation of a similar assembly cascade, PYK2 found in multiple locations within the cell contributes to phosphorylation upon translocation to adhesion sites, the cytoskeleton itself, or the nucleus. A second, parallel integrin-mediated pathway involves the activation of Shc, which binds Src family kinases through SH2 domains. Shc phosphorylation leads to Ras-MAPK activity. A third integrin-mediated pathway is via RhoA activation that profoundly influences actin assembly. At (4), recent evidence suggests nuclear deformation or displacement that may result in mechanotransduction, possibly via lamins in the nuclear membrane.

in homeostatic regulation, including soluble and bound forms.

4. *Immediate and downstream signaling responses.* The fastest responses are likely to be closer to the force conversion event than are delayed responses. They include apical membrane ion channel activation, membrane lipid cleavage, membrane fluidity changes, and protein phosphorylation events, all of which lead to signaling pathways. These “immediate” responses occur at multiple locations throughout the EC, including the basal surface and the cell junctions, consistent with decentralized responses. Many different slower downstream events have been reported in response to shear stress *in vitro*. The database does not lend itself to a neat, interpretable series of responses, and indeed it is more likely that multiple parallel responses to flow allow the cell to quickly adapt to the local vascular envi-

ronment. However, compelling evidence suggests the existence of multistep mechanotransduction pathways, and structural elements that are common to most responses.

### The Central Role of the Endothelial Cytoskeleton in Flow Signaling

A unifying component in endothelial mechanotransduction is the cytoskeleton, which in all anchorage-dependent cells is in a state of intracellular tension arising from the association of cytoskeletal elements with each other and with cellular membrane proteins and organelles. When ECs are subjected to flow, the hemodynamic external forces are opposed by intrinsic cytoskeletal tension. Thus, although the apical surface itself is a primary site of deformation, forces communicated throughout the cytoskeleton influence abluminal adhesion

sites, cell–cell junctions, the nuclear membrane, and other organelles. The almost instantaneous displacement of some of these organelles (cytoskeletal filaments, nucleus, mitochondria) can be mapped by two- and three-dimensional imaging in living ECs (57,58). Small areas of cell adhesion to the substratum (close and focal adhesions and their associated integrins) are dynamic, and some of these undergo directional remodeling within a few minutes after exposure to flow, even though the shear stress is acting on the opposite (luminal) side of the cell (1,60). At the luminal surface, Wang and colleagues (59) have demonstrated the transfer of twisting forces across the luminal endothelial membrane via transmembrane integrins and its resistance by cytoskeletal components. At adhesion sites on the abluminal surface, accessory proteins link cytoskeletal elements to integrins that bind extracellular adhesion proteins. Thus, continuity of cytoskeleton structural elements is present throughout the cell. Biochemical pathways associated with adhesion site integrins (reviewed in 52) show that they are important locations for the mechanotransduction elicited by cytoskeletal force transmission.

The cytoskeleton is involved in shear stress mechanotransduction at multiple levels. It determines cell geometry, including the luminal topography and thus the fine distribution of flow-generated surface forces. It maintains cell tension at: (a) adhesion sites, critical locations regulating many aspects of cell function; (b) cell junctions, which regulate contact inhibition of endothelial growth and cell–cell communication; and (c) the nuclear membrane, which may be physically important for gene regulation. It interacts with biochemical pathways throughout the cell, including those regulating its own turnover.

### SPATIO-TEMPORAL COMPLEXITY IN FLOW-MEDIATED ENDOTHELIAL MECHANOTRANSDUCTION

The spatial organization of intracellular signaling may result in the stimulation of multiple parallel, convergent, and/or divergent mechanotransduction pathways. Although the mechanism(s) of initial transduction of a purely mechanical signal is unknown, efforts to understand endothelial mechanotransduction in terms of the generation of second messengers, the activation of transcription factors, and altered gene and protein expression that lead to structural and functional consequences are of great value. Recently, the spatial elements of mechanotransduction are receiving attention, in part because of a better appreciation of the four-dimensional aspects of mechanosignaling pathways (1,57–59). Rather than attempt to list many, often apparently unconnected, flow-induced endothelial responses, it is more instructive to summarize examples in which the experiments permit an integrated spatio-temporal interpretation of flow mechanosignaling. Several investigations have led to proposed mechanotransduction mechanisms that pay attention to the role played by the spatial structure of the cell.

### Protein-Rich Tyrosine Kinase 2

A role for the spatially versatile protein-rich tyrosine kinase (PYK2) in flow mechanotransduction was recently reported (53). This kinase is an example of a molecule that is an important player in multiple signaling pathways, of which mechanotransduction is only one component. PYK2 is spatially interesting because it usually is found in the cytosol but has the versatility to relocate to focal adhesions, the perinuclear cytoplasm, or the nucleus. It also shares homology with focal adhesion kinase (FAK) that is localized to adhesion plaques at the basal side of the cell. In non-ECs it has been shown to exist downstream of G-protein-coupled receptors and able to link G-protein activation to NF $\kappa$ B activation through phosphoinositide 3-kinase (PI3K), the serine/threonine kinase Akt, and I $\kappa$ B kinase. PYK2 is phosphorylated in response to a variety of agonists and hormones and by ion channel activation. In endothelium, it binds Crk-associated substrate p130 (Cas), which itself is tyrosine phosphorylated through a calcium-dependent c-Src activation initiated by flow. FAK and PYK2 share their association with Cas through SH domains. Tyrosine phosphorylation of PYK2 in ECs by shear stress is dependent on the generation of reactive oxygen species (ROS) (53). The obligatory role of intracellular calcium mobilization for PYK2 phosphorylation, mediated through phospholipase C (PLC) activation and inositol triphosphate (IP<sub>3</sub>), showed PYK2 to be a calcium-dependent kinase. Although stimulation of PLC activity by shear stress has been shown to lead to PKC activation, inhibition of PKC directly had no effect on flow-mediated PYK2 phosphorylation, suggesting a PLC-calcium-PYK2 pathway. The correlation of calcium dependence, flow-activation through ROS, and shared SH domain suggests that tyrosine phosphorylation of Cas depends on PYK2 activation. To test this hypothesis more directly, ECs were transfected with a kinase-inactive PYK2, the overexpression of which blocked flow- and ROS-mediated phosphorylation of both PYK2 and Cas. Transfection with a kinase-inactive Src did not inhibit PYK2 phosphorylation, suggesting that Src-dependent Cas phosphorylation occurred downstream of PYK2. Although transfection with a kinase-inactive c-src had no effect on PYK2 phosphorylation by flow, other unknown Src family kinases appear to regulate PYK2 activation, as demonstrated by the effectiveness of the global Src family kinase inhibitor PP2 to inhibit flow-mediated PYK2 activation (53). Both Cas and PYK2 phosphorylation were inhibited by depletion of ROS by the antioxidant N-acetylcysteine and, conversely, were stimulated by superoxide generating agents. Overall, the study links together several elements in mechanical signaling: (a) flow activation of ROS (possibly through G-protein activation), (b) PLC-mediated intracellular calcium mobilization, and (c) Src family kinase (but not c-src)-mediated PYK2 phosphorylation, which appears to be obligatory for p130 Cas phosphorylation.

The protein p130Cas, with which PYK2 associates, is reported to be localized to focal adhesion sites, including association with zyxin and LIM proteins, and is known to

be critical for cell spreading and motility. PYK2 can also physically associate with cytoskeleton linker molecules, such as paxillin. These associations are consistent with its reported localization at adhesion sites, where its autophosphorylation is regulated by FAK through the FAK focal adhesion-targeting domain. Although phosphorylation of PYK2 by flow was unaffected by treatment with the actin microfilament destabilizing agent cytochalasin D, suggesting that an intact actin filament network may not be critical for flow-mediated PYK2 phosphorylation, binding of p130 Cas, FAK, and paxillin to actin microfilaments occurs in response to stretch of L929 cells. Paradoxically, however, PYK2 localizes to the perinuclear region in fibroblasts and becomes exclusively nuclear upon modification of one of its Src homology binding sites, suggesting a possible direct role in the regulation of transcription. The cytosolic distribution and rapid association with structural and adapter proteins suggest a kinase with great versatility of location and function, and highlight the complex interplay between mechanosignaling and other signaling pathways.

### Integrin-Mediated Mechanotransduction

The location and dynamics of abluminal focal adhesion sites were first observed to be responsive to shear stress through the use of tandem-scanning confocal microscopy (60). These observations were followed by demonstrations of the shear-responsive phosphorylation of proteins localized to adhesion sites, including FAK and paxillin. The experiments suggested that shear stress at the luminal surface can stimulate abluminal mechanotransduction at the adhesion sites (1). The physical association of transmembrane integrins with the extracellular matrix (ECM) on the outside of the cell and signaling molecule complexes, linker proteins, and the cytoskeleton inside the cell (61), confer an important role for integrins in the regulation of mechanotransduction.

Shyy and Chien have investigated the role of adhesion site integrins in mechanotransduction (52). They integrated the results of endothelial flow studies with data obtained from platelet activation and growth-factor signaling (both being integrin-mediated). In their proposed mechanism, flow activates integrins, increasing their avidity for the ECM. Integrin activation by many different stimuli is influenced by extracellular or intracellular factors, particularly small GTPases. If activation is blocked with RGD peptides or by monoclonal antibodies against integrin- $\beta$  subunits, typical downstream responses to flow and shear stress are inhibited (e.g., mitogen-activated protein kinase (MAPK) phosphorylation, NF- $\kappa$ B activation). One mechanism of integrin involvement in flow mechanotransduction is proposed to be through the assembly of signaling complexes on the cytosolic side of the membrane, at which integrin-dependent autophosphorylation of FAK leads to its association with the SH2 domain of c-Src, which in turn phosphorylates paxillin and p130 Cas. This mechanism is similar to that of PYK2 phosphorylation (discussed earlier) and results in the assembly of similar molecules. These act as a scaffold to assemble C3G (a guanine nucleotide

exchange factor for Ras G-protein family member Rap1) and adapter protein Crk, which leads to the activation of MAPK. Like PYK2, spatial evidence suggests (using green fluorescence protein [GFP] as a reporter) the recruitment of activated FAK to new focal adhesion sites when ECs are subjected to shear stress, suggesting that the scaffold assembly is likely to be highly compartmentalized to portions of the plasma membrane.

A similar spatial relationship may occur in a second mechanism of integrin activation by shear stress. In this case, the protein Shc is activated and binds Src family tyrosine kinases through SH2 binding. Fyn is one such kinase that, together with its associated caveolar protein caveolin (Cav)-1, binds to Shc, phosphorylates it, and recruits an adaptor protein growth factor receptor binding protein 2 (Grb2). This leads to the activation of the Ras-MAPK pathway prominent in endothelial flow responses.

RhoA also is activated by shear stress through mechanisms that require integrin-ECM binding. Given the association of Rho with the regulation of the cytoskeleton through Rho-associated kinase (ROCK), and LIM kinase via cofilin (62), it is likely that the flow-responsive adhesion site complexes involving integrins are intimately related to the binding of cytoskeletal elements at adhesion sites and cell junctions. Integrins are not restricted to the abluminal surface; flow activation via integrins may occur without the engagement of the ECM. Furthermore, it also has been proposed that nonintegrin mechanisms of Ras pathway activation occur by direct G-protein activation in the plasma membrane, and as a direct result of deformation of membrane lipids without cytoskeletal or integrin involvement (63). The cell must either filter or integrate the spatially and temporally variable signaling events of mechanotransduction.

### Primary Transduction of Shear Through Junctional Mechanosensors

Fujiwara and colleagues (64) first demonstrated the phosphorylation of the endothelial junction adhesion protein platelet-endothelial adhesion molecule (PECAM)-1, its binding to SH2 tyrosine phosphatase, and the subsequent accumulation of signaling molecules at the junction in response to shear stress; they proposed PECAM-1 to be a mechanosensor. Shay-Salit and colleagues (65) demonstrated flow activation of vascular endothelial growth factor receptor 2 (VEGFR2) and its assembly with phosphorylated vascular endothelial (VE)-cadherin,  $\beta$ -catenin, and PI3K, leading to the phosphorylation of Akt-1. Building on these findings, Tzima and colleagues (54) have recently reported that this mechanosensory complex, involving junctional proteins, regulates a subset of mechanotransduction pathways through integrins. In transfection studies of non-ECs, they showed that PECAM-1, VE-cadherin, and VEGFR2 are sufficient to transduce shear stress in the presence of an intact cytoskeleton and its associated proteins. Conversely, their selective inhibition or deletion in ECs inhibited important flow-related transduction; flow-induced activation of VEGFR2 did not occur in *PECAM-1*<sup>-/-</sup> and

*VE-cadherin*<sup>-/-</sup> ECs, nor did pathways dependent on integrin activation. In vivo evidence in support of the mechanism was provided by local regions of endothelial activation (NF-κB nuclear translocation) that correlated with disturbed hemodynamic sites in wild-type mice but were not activated in *PECAM-1*<sup>-/-</sup> mice.

The above examples support the transfer of shear stress forces to the adhesion sites and junctional regions of the cell consistent with a decentralized model of mechanotransduction.

**INVESTIGATIVE AND THERAPEUTIC VALUE**

Other than the acquisition of fundamental knowledge about cell and tissue responses, what is the value of endothelial phenotyping and the pursuit of detailed investigations of mechanotransduction?

Diversity of phenotype is important because it may permit specific therapeutic targeting of endothelium in different vascular beds and, for more refined phenotype biomarkers, targeting of those discrete regions within the arterial system that are susceptible to atherosclerosis. As multiscale studies progress, it may be possible to identify a highly susceptible phenotype for endothelial dysfunction, restricted to a focal location, thus permitting intervention early in the development of pathological change. The interplay of hemodynamics and endothelial phenotype also likely plays a central role in the protective effects of exercise against cardiovascular diseases; a better understanding of the mechanisms involved may be exploitable.

The importance of a comprehensive understanding of mechanotransduction at the single-cell and multicellular levels cannot be overstated. All cells in the body exist in local biomechanical environments that are subject to frequent or occasional change that requires the tissue to adapt accordingly. Although certain mechanoresponse mechanisms are common to many cell types, other such mechanisms are cell- and tissue-type specific. For example, endothelial cells are particularly responsive to flow forces, bone cells to compressive and fluid forces, and other cells to strain. Elucidation of the similarities and differences in these mechanisms will provide a general model for mechanotransduction as well as pathways specific to a tissue, respectively.

**KEY POINTS**

- Flow characteristics and associated hemodynamic forces are regulators of endothelial phenotype with important implications for the physiology and pathology of the cardiovascular system.

- Heterogeneity of endothelial phenotype must be understood over multiple-length scales with a hierarchical organization of endothelial physiology. Global analyses in parallel with candidate gene and protein analyses are being effectively applied to define heterogeneity in vivo and in vitro.
- Hemodynamics is a powerful predictor of vascular pathological susceptibility, initiation, and development. In vitro (reductionist) experiments to determine detailed mechanisms are most valuable when they simulate physiological flow in vivo. Site-specific investigations in vivo are essential to determine the spatial relevance of endothelial phenotype both in the susceptibility to cardiovascular diseases and in the pathogenesis itself.
- Both atherogenesis and calcific sclerosis of heart valves originate focally, not diffusely. If the endothelium is a determinant of focal susceptibility and pathogenesis, short-length scale studies of endothelial phenotype are essential. Therapeutic targets (based on phenotypes) may be highly restricted spatially.
- When hemodynamic forces deform the EC surface, the mechanics are communicated throughout the cell, most directly via the cytoskeleton to cell–cell and cell–matrix adhesion sites and the nuclear membrane. Thus, mechanotransduction is *decentralized*, and the potential exists for multiple mechanosensors remote from the site of interface with blood. In effect, the entire cell is a mechanotransducer.

*Future Goals*

- To refine hemodynamic imaging techniques to resolution levels that match the multiscale biology of endothelial heterogeneity
- To further develop of multiscale high-fidelity cell phenotyping methods at the levels of RNAs (including microRNAs, etc), proteins, and function applied to ever smaller numbers of cells (and eventually single cells) with an emphasis on in vivo expression

# Hypoxia-Inducible Factor 1

---

Gregg L. Semenza

*The Johns Hopkins University School of Medicine, Baltimore, Maryland*

The existence of multicellular organisms is based on the efficient capture of solar energy by plants through photosynthesis, a process by which carbon dioxide (CO<sub>2</sub>) and water are converted into glucose and oxygen (O<sub>2</sub>). These are subsequently utilized by all eukaryotic organisms to generate ATP and, as by-products, CO<sub>2</sub> and water, thus completing the circle of life on our planet (Figure 29.1). The highly efficient recovery of the energy contained within the chemical bonds of glucose through the process of oxidative phosphorylation provides the power necessary to assemble and maintain complex multicellular machines such as *Homo sapiens*, in which more than 100,000,000,000,000 parts (i.e., cells) are assembled and organized into a functional unit (i.e., organism). A requirement for the efficient generation of ATP is the continuous delivery of O<sub>2</sub> to every cell in the body. In postnatal life, this requirement is met through the concerted action of the lungs, blood, heart, and vessels. The lungs of an adult human take in 5 to 6 liters of air per minute or approximately 8,000 liters per day. Within the lungs, O<sub>2</sub> is bound by hemoglobin present within erythrocytes, which are pumped by the heart through blood vessels that represent the transportation infrastructure for O<sub>2</sub> and glucose delivery to the tissues and for the removal of CO<sub>2</sub>, hydrogen ions (H<sup>+</sup>), potassium ions (K<sup>+</sup>), and other toxic metabolites.

Whereas the major blood vessels are generated in a stereotypical pattern during development, the capillaries through which O<sub>2</sub> and CO<sub>2</sub> are exchanged in the tissues develop not through a hardwired program but rather based on physiological signals generated by individual cells. The basis for this signaling involves the ability of every nucleated cell in the body to sense the local O<sub>2</sub> concentration and to respond to imbalances between O<sub>2</sub> supply and demand. Thus, reduced O<sub>2</sub> availability (hypoxia) triggers the production of angiogenic growth factors, which are secreted proteins that bind to cell surface receptors on endothelial cells (ECs) and their progenitors, thereby stimulating the growth of new blood vessels through the processes of angiogenesis and vasculogenesis. It is not clear what factors determine whether new blood vessels in a tissue are generated by angiogenesis or vasculogenesis, although the more severe the hypoxic stimulus (as in a rapidly growing tumor),

the greater contribution of bone marrow-derived progenitor cells (i.e., vasculogenesis) to new blood vessel formation. However, in either case, hypoxia is likely to be a major physiological stimulus for vascularization. Delivery of increased O<sub>2</sub> via these new vessels corrects intracellular hypoxia, thus eliminating the stimulus for angiogenic growth factor production. Blood flow through major vessels can be increased via the process of arteriogenesis, in which the luminal diameter of conduit vessels is increased. These homeostatic mechanisms ensure that each cell in a healthy organism is provided with adequate O<sub>2</sub> to meet its metabolic demands. O<sub>2</sub> levels must be maintained within narrow limits because inadequate O<sub>2</sub> may impair cell function or survival due to ATP depletion, and excess O<sub>2</sub> may impair cell function or survival due to the damaging effect of reactive oxygen species (ROS) on cellular macromolecules. Failure of these homeostatic mechanisms contributes to the pathogenesis of all major causes of mortality in the United States, including heart disease, cancer, stroke, and chronic lung disease, which account for over two-thirds of all deaths annually.

Although hypoxia due to rapidly increasing tissue mass and increasing O<sub>2</sub> consumption is likely to represent a major physiological signal during embryonic and fetal development, in many adults, vessel stenosis due to atherosclerotic plaque formation and rupture leads to ischemia, in which cells are subjected to low levels of O<sub>2</sub>, glucose, and other nutrients and to high levels of CO<sub>2</sub>, K<sup>+</sup>, H<sup>+</sup>, and other toxic metabolites. Although ischemia represents a more complex pathophysiological state, it is the deprivation of O<sub>2</sub> (i.e., hypoxia) that appears to be the major stimulus capable of inducing an adaptive angiogenic response.

## HYPOXIA-INDUCIBLE FACTOR 1 IS A MASTER REGULATOR OF OXYGEN HOMEOSTASIS

Physiological responses to hypoxia occur over a broad time scale. The activity of pre-existing proteins can be modified within seconds as a result of post-translational modification, whereas the synthesis of new proteins requires minutes to

Figure 29.1. Energy trapping and substrate cycling on planet Earth. Solar energy is trapped in the chemical bonds of glucose by photosynthesis in plants and transferred to the high-energy phosphate of ATP during cellular respiration in all multicellular organisms.  $O_2$ , which is generated as a side product during photosynthesis, is required to generate ATP by oxidative phosphorylation.  $CO_2$  and  $H_2O$  are produced as side products.

hours. Often, the expression of new proteins is associated with changes in messenger RNA (mRNA) levels that reflect altered transcriptional regulation. The regulation of gene transcription by hypoxia-inducible factor (HIF)-1 represents the most well-defined molecular mechanism for maintaining  $O_2$  homeostasis in metazoans. HIF-1 was identified through an analysis of the *cis*-acting sequences and *trans*-acting factors required for  $O_2$ -regulated expression of the human *EPO* gene, which encodes erythropoietin. EPO is a glycoprotein hormone that stimulates the proliferation and survival of red blood cell progenitors and thus determines the blood  $O_2$ -carrying capacity. Analysis of the *EPO* gene hypoxia-response element, the *cis*-acting nucleotide sequence that is required for increased transcription of the gene in response to hypoxia, led to the identification (1), biochemical purification (2), and molecular cloning (3) of HIF-1. HIF-1 has been identified in all metazoan species that have been analyzed, from *Caenorhabditis elegans* to *Homo sapiens* (organisms whose cell number differs by more than 10 orders of magnitude). In contrast, HIF-1 is not present in yeast, suggesting that the appearance of HIF-1 represented an adaptation that was essential to metazoan evolution. The battery of genes regulated by HIF-1 is different in each cell type and, for some genes, expression can be induced or repressed by HIF-1 depending upon the cell type (4). Among the critical physiological processes regulated by HIF-1 target genes are erythropoiesis, angiogenesis, and glycolysis, which represent examples of systemic, local tissue, and intracellular adaptive responses to hypoxia, respectively.

HIF-1 is a heterodimeric protein that is composed of HIF-1 $\alpha$  and HIF-1 $\beta$  subunits. The amino-terminal half of each subunit consists of basic helix-loop-helix and PER-ARNT-SIM homology (PAS) domains that mediate heterodimerization and DNA binding. The carboxyl terminal half of HIF-1 $\alpha$  contains two transactivation domains that mediate interactions with coactivators such as cyclic AMP response element-binding protein (CBP) and p300 (5). Coactivators interact with both sequence-specific DNA binding proteins such as HIF-1 and with the general transcription factors associated with RNA polymerase II. Coactivators also have histone acetyltransferase activity that is required to make the DNA embedded in chromatin accessible to the polymerase complex for transcription into RNA.

The HIF-1 $\beta$  subunit is constitutively expressed, whereas the expression and activity of the HIF-1 $\alpha$  subunit are precisely regulated by the cellular  $O_2$  concentration. HIF-1 $\alpha$  accumulates instantaneously under hypoxic conditions and, upon reoxygenation, is rapidly degraded, with a half-life of less than 5 minutes in posthypoxic tissue culture cells (3,6). This represents an overestimation of the half-life, because it includes the time required for  $O_2$  to diffuse out of the culture medium. In isolated perfused and ventilated lung preparations subjected to hypoxia and reoxygenation, the half-life HIF-1 $\alpha$  is less than 1 minute (7). No protein has been shown to have a shorter half-life.

In addition to HIF-1 $\alpha$ , a structurally and functionally related protein designated HIF-2 $\alpha$ , which is the product of the *EPAS1* gene, can also heterodimerize with HIF-1 $\beta$  (8). HIF-1 $\alpha$ :HIF-1 $\beta$  and HIF-2 $\alpha$ :HIF-1 $\beta$  heterodimers appear to have overlapping but distinct target-gene specificities (9,10). Unlike HIF-1 $\alpha$ , HIF-2 $\alpha$  is not expressed in all cell types and, when expressed, can be inactive as a result of cytoplasmic sequestration (11). Although HIF-2 $\alpha$  was originally identified in ECs, it is expressed in several other cell types, including parenchymal cells in kidney, lung, and a variety of carcinomas. A third protein, designated HIF-3 $\alpha$ , also has been identified and a splice variant, designated inhibitory PAS domain protein (IPAS), has been shown to bind to HIF-1 $\alpha$  and inhibit its activity (12).

In mice, complete deficiency of HIF-1 $\alpha$  results in embryonic lethality at midgestation that is associated with dramatic vascular regression due to extensive EC death (13–15).  $O_2$  delivery to cells of the developing embryo becomes limited by diffusion, such that the establishment of a functioning circulatory system is required for embryonic survival beyond embryonic day E(10) in the mouse. In wild-type mouse embryos, HIF-1 $\alpha$  expression increases dramatically between E8.5 and E9.5, whereas embryos that lack HIF-1 $\alpha$  expression die between E9.5 and E10.5 with cardiac malformations, vascular regression, and massive cell death (13–17). Conditional knockout mice lacking HIF-1 $\alpha$  expression in neural cells have marked cerebral atrophy associated with vascular regression (18). Vascularization of tumor xenografts derived from HIF-1 $\alpha$ -null mouse embryonic stem cells also is impaired severely (15,16). The phenotypes of various germline and conditional HIF-1-knockout mice are summarized in Table 29-1.

**Table 29-1: Phenotype of Germline and Conditional HIF-1–Knockout Mice**

<b>Germline knockouts</b>			
<i>Gene</i>	<i>Protein</i>	<i>Phenotype</i>	<i>References</i>
<i>Arnt</i>	HIF-1 $\beta$	Embryonic lethality by E10.5 Vascular and placental defects	65
<i>Epas1</i>	HIF-2 $\alpha$	Embryonic lethality at E9.5–13.5 Vascular defects	66
		Embryonic lethality at E12.5–16.5 Impaired catecholamine production	67
		Survivors develop multiorgan failure	68
<i>Hif1a</i>	HIF-1 $\alpha$	Developmental arrest by E8.5 Embryonic lethality by E10.5 Vascular regression; cardiac defects; Impaired erythropoiesis Neural tube defects	13–17
<b>Conditional knockouts of HIF-1<math>\alpha</math></b>			
<i>Cell Type</i>		<i>Phenotype</i>	<i>References</i>
Breast epithelium		Impaired mammary differentiation and lipid secretion	69
Cardiomyocyte		Altered Ca <sup>2+</sup> flux and reduced myocyte contractility Reduced myocardial vascularization	70
Cartilage		Impaired chondrocyte survival	71
EC		Impaired tumor vascularization, wound healing	55
Intestinal epithelium		Impaired epithelial barrier protection	72
Mononuclear leukocytes		Impaired inflammatory and bactericidal responses	73–74

A variety of other transcription factors have been implicated in the O<sub>2</sub>-dependent regulation of specific genes in specific cell types. For example, in vascular and mononuclear phagocytic cells of the lung, early growth response factor (EGR)-1 has been shown to mediate the hypoxia-inducible expression of tissue factor, intercellular adhesion molecule (ICAM)-1, plasminogen activator inhibitor (PAI)-1, and the cytokines interleukin (IL)-1 $\beta$ , interferon-inducible protein 10 (IP-10), macrophage inflammatory protein (MIP)-2, monocyte chemoattractant protein (MCP)-1, RANTES (Regulated on Activation, Normal T-cell Expressed and Secreted), and vascular endothelial growth factor (VEGF) (19). However, only in the case of HIF-1 has the molecular mechanism by which changes in O<sub>2</sub> concentration are transduced to changes in transcription factor activity been elucidated.

## MOLECULAR MECHANISMS OF OXYGEN SENSING

The O<sub>2</sub>-dependent degradation of HIF-1 $\alpha$  involves ubiquitination and degradation by the 26S proteasome (20). The von Hippel-Lindau tumor suppressor protein (VHL) is required for this process (Figure 29.2), because renal carcinoma cells lacking functional VHL constitutively express HIF-1 $\alpha$  and HIF-1 target genes under nonhypoxic conditions (21). VHL forms a complex with elongin B, elongin C, cullin 2, and RBX1 to form an E3 ubiquitin–protein ligase capable of functioning with E1 ubiquitin-activating and E2 ubiquitin-conjugating enzymes to mediate the ubiquitination of HIF-1 $\alpha$  (22). Proline (Pro) residue 564 is hydroxylated in an O<sub>2</sub>-dependent manner, and this modification is required for VHL binding (23–25). Pro-402 represents a second site of hydroxylation and VHL binding (26). Pro-402 and 564 are each contained within a similar amino acid sequence (LXXLAP; A, alanine; L, leucine; P, Pro; X, any amino acid). HIF-2 $\alpha$  and HIF-3 $\alpha$  expression also are regulated by prolyl hydroxylation and VHL binding (21,26).

Three prolyl hydroxylases were identified in mammalian cells and shown to utilize O<sub>2</sub> as a substrate to generate 4-hydroxyproline at residue 402 and/or 564 of HIF-1 $\alpha$  (26,27). These proteins are homologues of EGL-9, which was identified through genetic studies as the HIF-1 $\alpha$  prolyl hydroxylase in *C. elegans* (26). Alternative designations for the three mammalian homologues include EGLN (EGL-nine homologue), PHD (prolyl hydroxylase domain protein), and HPH (HIF-1 $\alpha$  prolyl hydroxylase) 1–3. The hydroxylation reaction also requires 2-oxoglutarate ( $\alpha$ -ketoglutarate) as a substrate and generates succinate as a side product. Ascorbate is required as a cofactor. The prolyl hydroxylase catalytic site contains an iron (Fe [II]) ion that is coordinated by one aspartate and two histidine residues. Unlike heme-containing proteins, the Fe (II) in 2-oxoglutarate-dependent oxygenases can be chelated or substituted by cobalt (Co [II]), rendering the enzyme inactive. Most importantly, these prolyl hydroxylases have a relatively high  $K_m$  for O<sub>2</sub> that is slightly above its atmospheric concentration, such that O<sub>2</sub> is rate limiting for enzymatic activity under physiological conditions (26). As a result, changes in the cellular O<sub>2</sub> concentration are directly transduced into changes in the rate at which HIF-1 $\alpha$  is hydroxylated, ubiquitinated, and degraded.

Remarkably, HIF-1 $\alpha$  transactivation domain function is regulated by the O<sub>2</sub>-dependent hydroxylation of asparagine residue 803 (see Figure 29.2), which blocks the binding of the coactivators CBP and p300 (28). Factor-inhibiting HIF-1 (FIH-1), which was identified in a yeast two-hybrid screen as a protein that interacts with and inhibits the activity of the HIF-1 $\alpha$  transactivation domain (29), functions as the asparaginyl hydroxylase (30). As in the case of the prolyl hydroxylases, FIH-1 appears to utilize O<sub>2</sub> and  $\alpha$ -ketoglutarate, and contains Fe (II) in its active site, although it has a  $K_m$  for O<sub>2</sub> that is three times lower than the prolyl hydroxylases (31).

Spectroscopic analyses of a peptide from the HIF-1 $\alpha$  transactivation domain complexed with the interacting domain

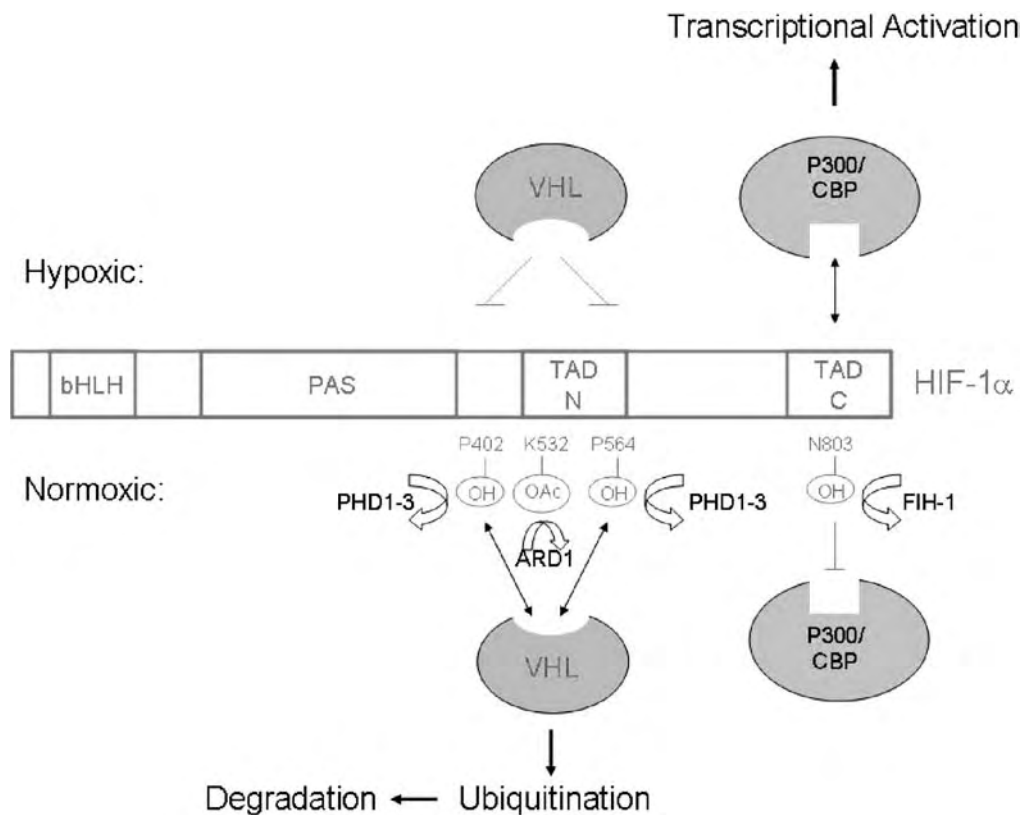

Figure 29.2. O<sub>2</sub>-dependent regulation of HIF-1 activity. O<sub>2</sub> is a substrate for the hydroxylation of HIF-1 $\alpha$ . Residues Pro-402 and/or Pro-564 are modified by the prolyl hydroxylases PHD1–3, leading to VHL-mediated ubiquitination and proteasomal degradation. Asn-803 in the carboxy-terminal transactivation domain (TAD-C) is modified by the asparaginyl hydroxylase FIH-1, which blocks HIF-1 $\alpha$  interaction with the coactivators CBP and p300, thus inhibiting transcriptional activation. HIF-1 $\alpha$  is also post-translationally modified by the acetyltransferase ARD1 at Lys-532, which promotes ubiquitination and degradation of HIF-1 $\alpha$ .

of CBP or p300 revealed that asparagine 803 (Asn-803) is present within an  $\alpha$ -helix buried deep within the protein interface, where it participates in multiple hydrogen bonding interactions that are predicted to stabilize the complex (32,33). Hydroxylation of Asn-803 is predicted to disrupt these protein–protein interactions. Similarly, hydroxylation of proline 564 has been shown to function also as a molecular switch to positively regulate the interaction of HIF-1 $\alpha$  and VHL (34,35). Thus, hydroxylation provides a mechanism for regulating protein–protein interactions, similar to the effect of phosphorylation and other post-translational modifications. However, hydroxylation is unique because the modification occurs in an O<sub>2</sub>-dependent manner, thus establishing a direct link between cellular oxygenation and HIF-1 activity.

#### OXYGEN-INDEPENDENT EXPRESSION OF HYPOXIA-INDUCIBLE FACTOR 1

Humans, like other metazoans, are constant and obligate consumers of O<sub>2</sub>. The more cells present in a tissue, the more O<sub>2</sub> consumed (although the absolute amount of O<sub>2</sub> con-

sumed differs among cell types due to differences in rates of ATP turnover, oxidative phosphorylation, and glycolysis). Thus, when one cell begets two daughter cells, O<sub>2</sub> consumption increases. It is not surprising that major pathways that transduce proliferative and survival signals from growth factor receptors also induce HIF-1 $\alpha$  expression (Figure 29.3) in what can be viewed as a preemptive strategy for maintaining O<sub>2</sub> homeostasis. Proliferating cells express VEGF, which stimulates angiogenesis to provide additional perfusion required to maintain the oxygenation of an increased number of cells. In addition, proliferating cells preferentially utilize glycolytic rather than oxidative metabolism to generate ATP. The concomitant induction of angiogenesis and glycolysis with cell proliferation is mediated in part via the activation of HIF-1.

The increase in HIF-1 $\alpha$  levels in response to growth factor stimulation differs in two important respects from the increase in HIF-1 $\alpha$  levels in response to hypoxia. First, whereas hypoxia increases HIF-1 $\alpha$  levels in all cell types, growth factor stimulation induces HIF-1 $\alpha$  expression in a cell-type–specific manner. The rules governing this specificity have not been elucidated. Second, whereas hypoxia is associated with decreased degradation of HIF-1 $\alpha$ , growth factors, cytokines, and other signaling

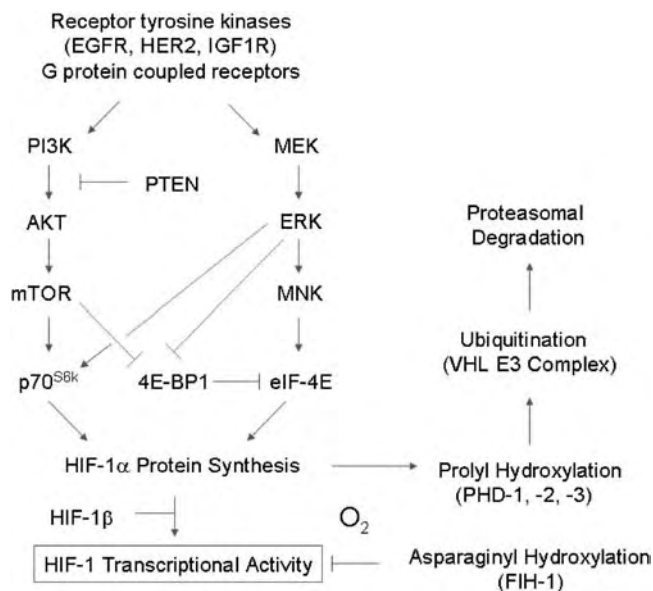

Figure 29.3.  $O_2$ -independent regulation of HIF-1 activity. Activation of receptor tyrosine kinases and G-protein-coupled receptors leads to signal transduction via the PI3K and MAPK (ERK) pathways, leading to phosphorylation of eIF-4E and its inhibitor 4E-BP1, events that increase the rate of HIF-1 $\alpha$  protein synthesis (*left side of figure*), whereas  $O_2$ -dependent regulation of HIF-1 $\alpha$  affects its stability and transcriptional activity (*right side of figure*).

molecules stimulate HIF-1 $\alpha$  synthesis via activation of the phosphoinositide 3-kinase (PI3K) or mitogen-activated protein kinase (MAPK) pathways (36,37). Pulse-chase studies of MCF-7 breast cancer cells stimulated with heregulin demonstrated increased HIF-1 $\alpha$  protein synthesis that was inhibited by treatment with rapamycin, a macrolide antibiotic which inhibits mammalian target of rapamycin (mTOR), a kinase that functions downstream of PI3K and Akt (37). The effect of heregulin was mediated via the 5'-untranslated region of HIF-1 $\alpha$  mRNA (37). The known targets for phosphorylation by mTOR are regulators of protein synthesis (see Figure 29.3). The translation of several dozen different mRNAs are known to be regulated by this pathway, and it is likely that specific sequences in the 5'-untranslated region may determine the degree to which the translation of any particular mRNA can be modulated by mTOR signaling. HIF-1 $\alpha$  protein expression is likely to be particularly sensitive to changes in the rate of synthesis because of its extremely short half-life under non-hypoxic conditions. In addition to effects on HIF-1 $\alpha$  synthesis, activation of the Raf/MEK extracellular signal-regulated kinase (ERK) signaling pathway also has been shown to stimulate HIF-1 $\alpha$  transactivation domain function (38). This effect is due at least in part to ERK phosphorylation of the coactivator p300, with which the transactivation domains interact (39). Unlike hypoxia, which induces HIF-1 $\alpha$  protein stability and transcriptional activity in all cell types, the regulation of HIF-1 activity by growth factor signaling is cell-type specific.

Finally, although great progress has occurred in elucidating the molecular mechanisms by which HIF-1 $\alpha$  protein levels

are regulated, HIF-1 $\alpha$  mRNA expression also is increased in response to hypoxia or ischemia in both experimental animals and humans (7,40,41). In tissue culture cells,  $O_2$ -dependent regulation of HIF-1 $\alpha$  mRNA expression is not observed and thus, the mechanisms underlying this regulation have not been determined. However, HIF-1 $\alpha$  mRNA contains multiple copies of the sequence 5'-AUUUA-3', which has been implicated the regulation of mRNA stability (3).

## HYPOXIA-INDUCIBLE FACTOR 1 REGULATES ANGIOGENIC GROWTH FACTOR EXPRESSION

Ischemic heart disease, a major cause of mortality, is treated by pharmacologic agents, balloon angioplasty, and coronary artery bypass graft surgery. Therapeutic angiogenesis aims to stimulate neovascularization by delivery of an angiogenic factor or its protein-coding DNA sequence. Phase I clinical trials have demonstrated safety, but phase II trials have not demonstrated efficacy. This outcome reflects the complexity of angiogenesis, which involves the temporally and spatially orchestrated expression by multiple cell types of multiple angiogenic factors, including VEGF, angiopoietin 1 (Ang1), Ang2, fibroblast growth factor 2 (FGF2), placental growth factor (PlGF), platelet-derived growth factor (PDGF)-B, transforming growth factor- $\beta_1$ , and others. In ischemic tissue, angiogenic factors are produced by a variety of cell types, including myocytes, fibroblasts, and vascular cells.

VEGF is produced early in the angiogenic cascade and is responsible for the initial activation of ECs. Transgenic expression of VEGF in mouse skin results in increased numbers of blood vessels that manifest excessive permeability, whereas expression of both VEGF and Ang1 results in increased vessels without excessive permeability (42). However, transgenic coexpression of Ang1 in the heart blocks the angiogenic effect of VEGF (43). PlGF plays a critical role in ischemia-induced angiogenesis and has synergistic effects with VEGF in some tissues (44). Synergistic effects of combined treatment with PDGF-BB and FGF2 also have been reported (45). These data suggest that increased expression of a single angiogenic factor is not sufficient for functional vascularization, and that the effects of angiogenic factors are tissue-specific.

HIF-1 plays a critical role in angiogenesis by activating the transcription of genes encoding angiogenic growth factors including VEGF, Ang1, Ang2, PlGF, and PDGF-B (4). HIF-1 directly activates the transcription of the VEGF gene by binding to a hypoxia-response element located approximately 1 kb 5' to the gene (46), whereas it is not known whether regulation of Ang1, Ang2, PlGF, and PDGF-B is direct or indirect.

The regulation of these genes is remarkably cell-type-specific. Ang2 expression is induced by hypoxia in arterial ECs, repressed in arterial smooth muscle cells, and unchanged in cardiac fibroblasts and myocytes, whereas VEGF is induced by hypoxia in all four cell types (4). These results underscore the importance of determining the subset of HIF-1 target genes regulated by hypoxia in a particular cell type. In embryonic

stem cells, *VEGF*, *Ang1*, *PlGF*, and *PDGF-B* mRNA expression was induced by hypoxia, whereas in *HIF-1 $\alpha$* -null cells, the expression of all four mRNA species was markedly reduced under both hypoxic and nonhypoxic conditions (4).

Consistent with the effect of *HIF-1 $\alpha$*  loss of function, infection of cardiac fibroblasts, cardiac myocytes, arterial ECs, and arterial smooth muscle cells under nonhypoxic conditions with AdCA5, an adenovirus encoding a mutant form of *HIF-1 $\alpha$*  that is resistant to O<sub>2</sub>-dependent degradation, induces the same pattern of angiogenic-factor gene expression as that observed in hypoxic cells (4). *HIF-1* can function as either an activator or repressor of *Ang1* and *Ang2* gene expression in a cell-type-specific manner. The molecular mechanism underlying this surprising observation remains to be established. These results are consistent with published data indicating that these factors can either induce or inhibit angiogenesis depending on the cellular context. This remarkable cell-type-specific regulation of gene expression underscores the general principle that *HIF-1* functions as a messenger to the nucleus signaling hypoxia. The response to this signal depends on prior programming of the cell (i.e., the presence or absence of other transcriptional regulators of potential *HIF-1* target genes).

The injection of AdCA5 into mouse eyes in the absence of hypoxia or ischemia induced neovascularization in multiple capillary beds (4), including those not responsive to VEGF alone (47). Lectin and anti- $\alpha$ -smooth muscle actin antibody staining demonstrated that these vessels contain both ECs and smooth muscle cells or pericytes. A link between *HIF-1* expression and VEGF expression in ischemic retina has been well-established in ischemia-induced retinal neovascularization (48). However, the ability of AdCA5 to induce the sprouting of new vessels that extend into the vitreous cavity from the superficial capillary bed, as occurs in patients with diabetic retinopathy, contrasts with the inability of high levels of VEGF alone to do so (47). These studies indicate that increased levels of a single VEGF isoform are not sufficient to cause new vessels to sprout from the superficial vessels. Neovascularization induced by AdCA5 was associated with a dramatic increase in *PlGF* mRNA and protein expression. *PlGF* has been shown to act synergistically with VEGF to stimulate neovascularization, and both factors are required for neovascularization in the ischemic retina (44). Thus, the combined effect of increased *PlGF* and VEGF expression may underlie neovascularization in the superficial capillary bed, induced by the intravitreal injection of AdCA5.

An analysis of gene expression revealed increased expression of *Ang1*, *Ang2*, *PDGF-B*, *PlGF*, and *VEGF* mRNA in AdCA5-injected eyes. These results indicate that *HIF-1* functions as a master regulator of angiogenesis by controlling the expression of multiple angiogenic growth factors, and that adenovirus-mediated expression of a constitutively active form of *HIF-1 $\alpha$*  is sufficient to induce angiogenesis in the nonischemic tissue of an adult animal. These results may provide a mechanistic basis for the observation that transgenic mice expressing a constitutively active form of *HIF-1 $\alpha$*  in the skin manifest increased vascularization without the increased

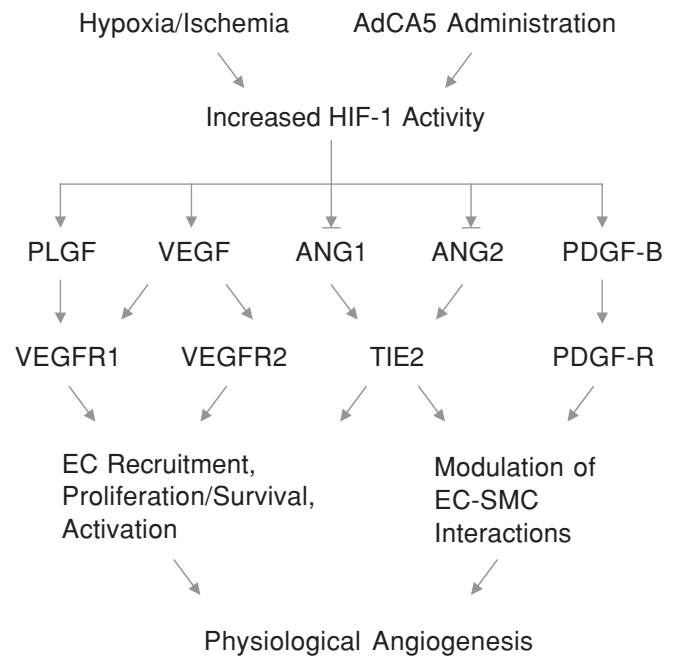

Figure 29.4. Regulation of angiogenic growth factor expression by *HIF-1*. Increased *HIF-1* activity due to either the activation of the endogenous protein in response to hypoxia/ischemia or due to administration of AdCA5, an adenovirus encoding a constitutively active form of *HIF-1 $\alpha$* , induces cell-type-specific changes in the expression of genes encoding angiogenic growth factors. The protein products of these genes bind to receptors on the surface of ECs and smooth muscle cells and activate angiogenic programs in these cells.

vascular permeability observed in transgenic mice expressing VEGF from the same promoter (49). Because *cis*-acting hypoxia-response elements containing *HIF-1* binding sites have not been demonstrated for the genes encoding angiogenic factors (other than VEGF), it remains to be determined whether *HIF-1*-dependent regulation of these genes is direct or indirect. However, whether by direct or indirect mechanisms, the data indicate that *HIF-1* is a pleiotropic mediator of the angiogenic program (Figure 29.4).

Whereas the studies described above provided evidence for the role of *HIF-1* in promoting the growth of microvasculature, as occurs in diabetic retinopathy, they did not address the issue of whether *HIF-1* could promote the remodeling of arteries following the occlusion of a large, conduit vessel. To address this issue, the femoral artery of rabbits was occluded by intravascular coil placement, and the animals received an intramuscular injection of AdCA5 or AdLacZ in the region of the occluded vessel. Two weeks after occlusion, the animals that received AdCA5 showed a significantly greater recovery of blood pressure in the affected limb than did animals that received AdLacZ (50). In addition, perfusion was significantly improved, as determined by angiography, and histological analysis revealed a significant increase in the arterial luminal area in sections of muscle from the affected limb. Thus, in addition to stimulating angiogenesis, *HIF-1* also stimulates arteriogenesis. As in the mouse eye, AdCA5 injection in the rabbit leg

(in the absence of femoral occlusion) induced the expression of mRNAs encoding multiple angiogenic cytokines, including VEGF, PlGF, PDGF-B, MCP-1, and stromal-derived factor 1 $\alpha$  (50).

Two other constitutively active forms of HIF-1 $\alpha$  expressed via either transgenic (49) or gene therapy (51,52) approaches have been shown to increase vascularization during development or in response to ischemia, respectively. Cardiomyocyte-specific expression in transgenic mice of PR39, a peptide that selectively inhibits the degradation of HIF-1 $\alpha$ , also was associated with increased vascularization and protection against ischemia (53). The coordinate activation of VEGF and PlGF and downregulation of *Ang1* mRNA expression by HIF-1 in cardiomyocytes (4) is an interesting finding, as recent studies suggest that these changes in angiogenic factor expression may stimulate both angiogenesis and arteriogenesis/collateralization in the ischemic heart. The demonstration that neovascularization is rapidly induced in AdCA5-injected eyes in the absence of ischemia (4) is noteworthy, because most patients with coronary artery disease do not have ischemia at rest. Further studies are required to determine whether the administration of AdCA5, other modified forms of HIF-1 $\alpha$ , or peptides that inhibit HIF-1 $\alpha$  ubiquitination or degradation may be of therapeutic utility in patients with ischemic cardiovascular disease.

#### CELL-AUTONOMOUS EFFECTS OF HYPOXIA-INDUCIBLE FACTOR 1 IN ENDOTHELIAL CELLS

The studies presented in the preceding sections established the paradigm that O<sub>2</sub> deprivation within the parenchymal cells of each organ induces HIF-1 activity. This leads to the expression of angiogenic growth factors such as VEGF that are secreted and bind to receptors present on the surface of ECs, leading to their activation. This paradigm has undergone an important shift with the recent demonstration that HIF-1 also has critical cell-autonomous functions within ECs.

Gene expression profiles were compared in arterial ECs cultured under nonhypoxic versus hypoxic conditions and in nonhypoxic cells infected with AdLacZ, an adenovirus encoding  $\beta$ -galactosidase, versus AdCA5, which encodes a constitutively active form of HIF-1 $\alpha$  (as described earlier) (54). By analyzing the union of the independently derived data sets, 245 gene probes showed a statistically significant increase in expression of at least 1.5-fold in response to hypoxia and in response to AdCA5. Using the same analytic strategy, 325 gene probes showed a statistically significant decrease in expression of at least 1.5-fold in response to hypoxia and in response to AdCA5. The largest category of genes downregulated by both hypoxia and AdCA5 encoded those proteins involved in cell growth or proliferation. Many genes upregulated by both hypoxia and AdCA5 encoded cytokines, growth factors, receptors, and other signaling proteins. Transcription factors accounted for the largest group of HIF-1-regulated

genes, indicating that HIF-1 controls a network of transcriptional responses to hypoxia in ECs. The infection of ECs with AdCA5 under nonhypoxic conditions was sufficient to induce increased basement membrane invasion and tube formation similar to the responses induced by hypoxia, indicating that HIF-1 mediates the cell-autonomous activation of ECs.

These gain-of-function studies were complemented by loss-of-function studies, in which HIF-1 $\alpha$  expression in ECs was selectively eliminated in mice that were homozygous for a floxed *Hif1a* allele and expressed Cre recombinase from the *Tie2* gene promoter (55). Loss of HIF-1 $\alpha$  expression impaired EC proliferation, chemotaxis, and extracellular matrix invasion. Most strikingly, loss of HIF-1 $\alpha$  expression in ECs resulted in a profound impairment of tumor angiogenesis. All the observed defects were associated with decreased VEGF expression and loss of autocrine signaling via VEGF receptor 2 (VEGFR2) in *HIF-1 $\alpha$ -null* ECs. Thus, both gain-of-function and loss-of-function studies indicate that HIF-1 plays a cell-autonomous role in ECs that is critical for tumor angiogenesis but less critical for angiogenesis during development, which was apparently normal in the *Hif1a<sup>flox/flox</sup>;Tie2-Cre* mice. Although the studies involving these mice suggest that an important function of HIF-1 in ECs is to mediate autocrine VEGF-VEGFR2 signaling, the microarray analysis suggests that this is probably an oversimplification of the large network of gene expression controlled by HIF-1, and it is likely to contribute to many aspects of EC biology.

#### INHIBITORS OF ANGIOGENESIS AND HYPOXIA-INDUCIBLE FACTOR 1 IN CANCER THERAPY

Just as HIF-1 is a candidate target for therapeutic angiogenesis in ischemic cardiovascular disease, HIF-1 appears to be a target (direct or indirect) of many novel antiangiogenic cancer therapies. Many of the novel signal transduction inhibitors that are being tested in clinical trials have antiangiogenic properties that relate in part to their effect on HIF-1 $\alpha$  expression (Table 29-2). These include receptor tyrosine kinase inhibitors such as Herceptin and Gleevec, which block HER2<sup>neu</sup> and BCR-ABL signaling, which leads to HIF-1 $\alpha$  expression in breast cancer and chronic myelogenous leukemia cells, respectively, via activation of the PI3K signal transduction pathway. Overexpression of cyclooxygenase 2 (COX2) has been shown to promote colon cancer angiogenesis. Prostaglandin E<sub>2</sub>, the product of the COX2 reaction, induces HIF-1 $\alpha$  expression via activation of G-protein-coupled receptors and PI3K and MAPK pathways, leading to increased synthesis of HIF-1 $\alpha$  protein (see Figure 29.3). Thus, COX2 inhibitors, such as celecoxib, reduce HIF-1 $\alpha$  levels in cancer cells. The heat shock protein HSP90 is a chaperone for HIF-1 $\alpha$ , and inhibitors of HSP90 induce the degradation of HIF-1 $\alpha$  through a VHL-independent pathway.

To the extent that HIF-1 $\alpha$  synthesis depends on signaling via the PI3K/Akt/mTOR and RAF/MEK/ERK pathways, inhibitors of these pathways will reduce the steady-state

**Table 29-2: Novel Anticancer Agents that Inhibit HIF-1 Activity**

<i>Mechanism of Action</i>	<i>Agent(s)*</i>
Receptor tyrosine kinase inhibitors	<b>Herceptin, Gleevec</b>
Cyclooxygenase-2 inhibitors	<b>Celecoxib</b>
HSP90 inhibitors	Geldanamycin, <i>17-AAG</i>
mTOR inhibitors	Rapamycin, <i>CCI-779</i>
RAF/MEK inhibitors	<i>BAY43-9006</i> , PD98059
HDAC inhibitors	<i>FK228</i> , <i>NVP-LAQ824</i>
Angiogenesis inhibitors	<i>Endostatin</i>
Proteasome inhibitors	<b>Bortezomib</b> , MG132
Topoisomerase I inhibitors	<b>Topotecan</b>
Microtubule-targeting agents	<i>2-methoxyestradiol</i>
Thioredoxin inhibitors	Pleurotin, PX-12
p300 CH1 domain inhibitor	Chetomin
Unknown	PX-478, YC-1

\* Approved drugs are indicated by bold font; drugs in clinical trials are indicated by italics; all others are in preclinical development.

levels of HIF-1 $\alpha$ . Because the inhibition of these pathways is predicted to have protean effects in cancer cells, the extent to which the therapeutic efficacy of agents such as rapamycin can be attributed to its inhibition of HIF-1 is unclear. A recent DNA microarray analysis, which attempted to determine the consequences of mTOR inhibition in a transgenic mouse prostate cancer model, identified two functional groups of genes that were upregulated in neoplasms driven by Akt gain-of-function and downregulated in response to mTOR inhibition. One group consisted of antiapoptotic B-cell leukemia/lymphoma 2 (BCL2) family members and the other group consisted of HIF-1 target genes, principally glucose transporters and glycolytic enzymes (56). Microarray studies have provided evidence that the HIF-1 transcriptome represents a major pathway in ECs that is inhibited by endostatin treatment (57). This is consistent with the data presented in the previous section. Histone deacetylase inhibitors also have been shown to have antiangiogenic effects that appear to be attributable to their inhibition of HIF-1 activity, although their precise mechanism of action in this context has not been delineated. The proteasome inhibitor MG132 has been shown to block both the degradation and nuclear import of HIF-1 $\alpha$  and thus inhibits HIF-1 transcriptional activity. Whether bortezomib (Velcade), a proteasome inhibitor currently in clinical trials, has this same effect remains to be determined.

A cell-based high-throughput screen for the identification of small molecule inhibitors of the HIF-1 pathway using the National Cancer Institute "Diversity Set," a collection of approximately 2,000 compounds selected to represent the

greater chemical diversity of the National Cancer Institute chemical repository, led to the identification of topoisomerase I inhibitor camptothecin and several analogues as inhibitors of HIF-1 $\alpha$  expression (58). Preclinical studies suggest that daily administration of the drug results in significant inhibition of tumor growth and angiogenesis (59). The endogenous angiogenesis inhibitor 2-methoxyestradiol inhibits HIF-1 $\alpha$  expression, an effect that depends on the compound's activity as a microtubule-disrupting agent (60). Thioredoxin is known to interact with and positively regulate HIF-1 activity, and thioredoxin inhibitors also inhibit HIF-1 $\alpha$  expression (61). A screen for low-molecular-weight compounds that block the interaction of the HIF-1 $\alpha$  transactivation domain with the CH1 domain of p300 led to the identification of chetomin as an inhibitor of HIF-1 transcriptional activity (62). Because chetomin binds to p300 rather than to HIF-1 $\alpha$ , it is likely to interfere with the binding of other transcription factors to the CH1 domain. Two low-molecular-weight compounds that potently block HIF-1 $\alpha$  expression, tumor growth, and angiogenesis via unknown mechanisms are PX-478 and YC-1 (63,64). Thus, the understanding of the critical role of HIF-1 in tumor angiogenesis has led to considerable interest in targeting this factor for inhibition as a novel antiangiogenic anticancer therapy.

#### KEY POINTS

- HIF-1 mediates angiogenesis and other adaptive responses to hypoxia.
- HIF-1 controls the expression of multiple angiogenic growth factors.
- HIF-1 controls cell-autonomous responses of ECs to hypoxia/ischemia.

#### Future Goals

- To determine whether increased HIF-1 $\alpha$  expression, as a result of gene therapy or pharmacologic induction, will promote therapeutic angiogenesis
- To determine whether small-molecule inhibitors of HIF-1 will be useful components of novel anticancer therapeutic regimens

# Integrative Physiology of Endothelial Cells

## Impact of Regional Metabolism on the Composition of Blood-Bathing Endothelial Cells

---

Mitchell L. Halperin and Kamel S. Kamel

*St. Michael's Hospital, University of Toronto, Ontario, Canada*

This chapter has a different emphasis from others in this book because it is written from the perspective of integrative physiology. Our objective is to discuss the conditions that endothelial cells (ECs) are exposed to in the body from the luminal side and to raise a number of questions that may influence how vascular biologists think about their subject. In this context, new data may be required to determine whether these are just theoretical considerations or whether they are, in fact, actual perturbations for these cells. If the latter were true, one must consider how these perturbations are dealt with and whether they have an impact on EC function.

Our first task will be to define the composition of blood in the arterial tree. The description will be expanded to veins draining specific regions of individual organs where large differences in blood composition occur. Perhaps the best example of this latter point is the marked difference in the composition of venous blood draining the renal cortex as compared with that draining the hypoxic, hypertonic, and hypercarbic renal medulla.

Rather than focusing on many compounds, we emphasize the major volatile gases (oxygen [O<sub>2</sub>], carbon dioxide [CO<sub>2</sub>], and ammonia [NH<sub>3</sub>]); ions such as hydrogen (H<sup>+</sup>), potassium (K<sup>+</sup>), calcium (Ca<sup>2+</sup>) and citrate; as well as water because of their biological importance and implications for normal cell function. Where applicable, the discussion in each section is divided into three parts. First, we describe the composition of blood in each vascular location. Second, we ask: "What demands might be placed on ECs because of their exposure to the composition of blood in their lumen?" Third, bearing the above in mind, we ask, "What questions should scientists working with ECs consider when they examine endothelial function in vivo and when experiments are performed in vitro?"

### ENDOTHELIAL CELLS IN THE ARTERIAL TREE<sup>1</sup>

ECs in all the arteries are exposed to a similar, if not identical, luminal composition, because these blood vessels serve primarily as conduits of blood. Certain exceptions can be made to this statement, including the pulmonary artery and the efferent renal arteriole. Little exchange of gases and nutrients occurs in arterial segments. Thus, any differences in blood composition between the proximal and distal ends of the artery depend on the degree to which arterial ECs synthesize and release substances into the blood. On the abluminal side of the arterial endothelium, the input is likely similar throughout the arterial tree, consisting of signals derived from extracellular matrix and vascular smooth muscle cells. Arterial blood has all the metabolic constituents needed to support ECs, including a high P<sub>O<sub>2</sub></sub> and a physiologically appropriate P<sub>CO<sub>2</sub></sub> (40 mm Hg).<sup>2</sup>

The relatively high intracellular P<sub>O<sub>2</sub></sub> in arterial ECs has potential disadvantages. O<sub>2</sub> is toxic when it reacts with an electron (e<sup>-</sup>) to form superoxide (O<sub>2</sub><sup>-</sup>) (Equation 1). This O<sub>2</sub><sup>-</sup>, if it is not removed as quickly as it is formed, will rise in concentration and react with a number of reactive groups

- 1 In addressing differences in the composition of blood between and within arteries and veins, it is important to consider variation across space and over time. In arteries, few differences in composition of blood occur in space, but there can certainly be changes over time (e.g., with exercise, or with pathophysiology); in veins, large differences occur across space (in terms of what each organ the vein is draining) and differences also occur in some beds over time.
- 2 Because O<sub>2</sub> is sparingly soluble in water (1), a limitation exists to the diffusion of O<sub>2</sub>. Nevertheless, O<sub>2</sub> diffuses through capillaries to most cells, and the P<sub>O<sub>2</sub></sub> in their mitochondria is only a few mm Hg. Although this is high enough to regenerate ATP at extremely rapid rates because of the high affinity of mitochondrial enzymes that bind O<sub>2</sub> in the electron transport system (2), the low P<sub>O<sub>2</sub></sub> may diminish the formation of superoxide (vide infra).

Figure 30.1. Uncoupling of oxidative phosphorylation. The horizontal structure represents the inner mitochondrial membrane. On the far left, the diffusion of  $H^+$  into mitochondria drives ATP regeneration (coupled oxidative phosphorylation). In the central part of the illustration, only complexes I and II are shown – they pump out  $H^+$  and are linked by the diffusion of coenzyme Q. The semialdehyde form of reduced coenzyme Q reacts with  $O_2$  to produce ROS. The UCP is shown on the right. When ROSs rise and long-chain fatty acids are present, flux of  $H^+$  through UCPs rises and coenzyme Q becomes less reduced, but ATP is not regenerated.

in proteins, lipids, and nucleic acids, which could compromise cell functions (3,4). The chemistry of this type of  $O_2^-$  formation is a nonenzymatic reaction; its rate is directly proportional to the concentration of its substrates. With respect to the concentration of  $e^-$ , when the rate of flux in the electron transport system is not rapid, the state of electron carriers becomes more reduced. The level of one of these electron carriers, the semialdehyde form of coenzyme Q, is most important in this context because, when its concentration and the  $P_{O_2}$  are both high, an accelerated rate of formation of reactive oxygen species (ROS) occurs (Equation 1):

It is important to emphasize that, although low concentrations of ROS have useful physiological functions, high levels of ROS may cause cellular damage (5). Hence, the metabolic pathways that “detoxify” ROS are very important, including catalase and superoxide dismutase. One example will be mentioned to illustrate this point: Uncoupling of mitochondrial oxidative phosphorylation is one mechanism to diminish the rate of production of ROS (Figure 30.1) (6). Mitochondria have uncoupler proteins (UCPs) that can dissipate the large electrical and small  $H^+$  gradient across the inner mitochondrial membrane (3,7). For these UCPs to have a higher conductance for  $H^+$  in the short term, several factors must be present. One stimulus for ROS removal is a higher ROS concentration. In addition, high physiological concentrations of long-chain fatty acids lead to a more rapid  $H^+$  flux (3,4,6,8). One possible reason for this requirement for long-chain fatty acids is deducible from the larger picture of the integrative physiology of prolonged fasting in Paleolithic times (see Chapter 16). In more detail, the  $P_{O_2}$  and the concentration of the semialde-

hyde form of coenzyme Q are both high during prolonged fasting (9). Hence, uncoupling is advantageous to defend against high concentrations of ROS. Having a requirement, however, for long-chain fatty acids ensures that this uncoupling does not lead to the oxidation of glucose, the fuel needed for the brain during early fasting (10). In contrast, after eating a high carbohydrate meal, the level of long-chain fatty acids should be low, and this could increase the risk of damage secondary to ROS accumulation in arterial ECs, especially if other pathways for ROS removal were not proceeding at an adequate rate.

Thus, questions to be addressed by vascular biologists include: “Do arterial ECs have special characteristics to allow them to handle an ongoing oxidative stress?” and “Under what circumstances and/or diseases might the defenses against ROS be diminished?” These considerations apply when experiments are carried out *in vitro*, because the use of a high  $P_{O_2}$  in the incubation system and variations in the fuel mixture used may have implications for the validity of the conclusions drawn in these experimental settings.

## ENDOTHELIAL CELLS IN THE VENOUS TREE

In contrast to arterial blood, the composition of venous blood varies from organ to organ, and at times within different regions of the same organ. Indeed, if one were to compare venous blood in two different organs, large differences would be seen in composition, depending on what that organ extracted from and secreted into the blood of the upstream capillary bed. Some organs have a relatively constant composition of venous blood. Other organs demonstrate significant temporal changes in the composition (e.g.,  $P_{O_2}$  and  $P_{CO_2}$ ) of venous blood.

### Organs with a Relatively Constant Extraction of Oxygen and Formation of Carbon Dioxide

To have a constant composition of  $P_{O_2}$  and  $P_{CO_2}$  in the venous blood, as a general principle, a tight correlation must exist between the biological work of each of these organs ( $O_2$  consumption and  $CO_2$  production) and their rate of blood flow. In three major organs the composition of venous blood remains constant over time, but with very different individual (organ-specific)  $P_{O_2}$  and  $P_{CO_2}$  levels.

#### Brain

The brain has the ability to autoregulate its blood flow, and it also has a metabolic rate that is relatively constant throughout the day (11). Hence, the jugular venous  $P_{O_2}$  and  $P_{CO_2}$  should be relatively constant. Because the brain extracts close to one-third of the  $O_2$  from each liter of arterial blood, the venous  $P_{CO_2}$  is close to 46 mm Hg. This constancy over time is valuable, because certain areas of the brain use changes in their  $P_{CO_2}$  as a signal. The best example is the control of alveolar ventilation via changes in the  $P_{CO_2}$  that are sensed by chemoreceptors.

#### Kidney

The kidneys are the most important site at which a decrease in  $P_{O_2}$  provides the signal for the synthesis and release of the hormone erythropoietin (EPO) (12). Because of the shape of the  $O_2$ -hemoglobin dissociation curve (Figure 30.2), the largest change in the  $P_{O_2}$  per mmol of  $O_2$  extracted from arterial blood (or decrease in the content of arterial  $O_2$ ) occurs when blood is closest to being 100% saturated with  $O_2$ . Moreover, because the signal for the  $P_{O_2}$  should be large, it is important to have the blood flow high enough to ensure that  $O_2$  extraction is quite small per liter of blood. This, in effect, means that kidney cells and renal cortical efferent arterial ECs must exist in an area having a very high  $P_{O_2}$ . As outlined for arterial blood, the pertinent questions are: "Will these cells be more at risk to  $O_2$  toxicity than other venous ECs?" and "Do they possess efficient defense mechanisms to deal with the formation of ROS?"

#### Heart

Myocardial cells extract between 65% and 75% of the  $O_2$  from each liter of blood (13). This strategy provides a number of physiological advantages. First, it is easier to have signals related to a low  $P_{O_2}$  and/or high  $P_{CO_2}$  in the short term. For example, the low  $P_{O_2}$  and high  $P_{CO_2}$  make vasodilatory stimuli more effective. Hence, as soon as a demand occurs for an increased cardiac output, blood flow rises abruptly, and cells may continue to have rapid rates of oxidative metabolism. Second, living in an environment with a low  $P_{O_2}$  can stimulate angiogenesis. This ensures a very rich cardiac blood flow rate and a shorter distance between capillaries and mitochondria, to permit  $O_2$  to diffuse faster.

Because of this high  $O_2$  extraction, cardiac venous ECs exist in a low- $P_{O_2}$  and high- $P_{CO_2}$  environment (10). In exer-

Figure 30.2. Hemoglobin/oxygen dissociation curve. The shaded horizontal rectangle represents the extra  $O_2$  extracted per L when there is a small reduction in the concentration of hemoglobin in blood and the same quantity of  $O_2$  must be extracted. The solid vertical lines indicate the change in arterial  $P_{O_2}$  due to this extra extraction of  $O_2$  per L of blood. There is a larger change in the arterial  $P_{O_2}$  for this increment in  $O_2$  extraction and a much more sensitive signal for the release of EPO when on the flatter portion of the  $O_2$ -hemoglobin dissociation curve (12).

cise, the  $P_{O_2}$  might be even lower and the  $P_{CO_2}$  even higher in coronary sinus blood. Although this low  $P_{O_2}$  diminishes the risk of ROS formation, a disadvantage exists for venous ECs, because they will exist in an environment with a high  $P_{CO_2}$ . If these cells were sufficiently permeable to  $CO_2$ , their  $P_{CO_2}$  would be high. This would drive the bicarbonate buffer system equation to the right, which raises the concentration of  $H^+$  in these cells (Equation 2). This higher concentration of  $H^+$  forces  $H^+$  to bind to intracellular proteins, changing their charge, shape, and possibly function (Equation 3, Figure 30.3) (14).

The questions for vascular biologists include: "Are ECs sufficiently permeable to  $CO_2$ ?" and "How do ECs in cardiac veins adapt to this difference in charge on their proteins?" and "Are these ECs more vulnerable to a  $H^+$  load (e.g., during a sprint) because they might not have physiological buffering by their bicarbonate buffer system if their  $P_{CO_2}$  is high?"

### Organs with a Variable Extraction of Oxygen and Thereby Formation of Carbon Dioxide per Liter of Blood Flow

#### Skeletal Muscle

At rest, skeletal muscle extracts a small amount of  $O_2$  per liter of blood flow. The venous  $P_{CO_2}$  in these cells is close to 46 mm Hg, but a large variation occurs in normal

Figure 30.3. Role of EC  $P_{CO_2}$  in the selection of intracellular buffer systems. The aim of buffering is to prevent  $H^+$  from binding to proteins in cells ( $PTN^0$ ) – this can occur if the tissue  $P_{CO_2}$  falls. For this to happen, a low venous  $P_{CO_2}$  must be present. In contrast, if the venous  $P_{CO_2}$  is high, the  $P_{CO_2}$  will be high in ECs, the  $[H^+]$  in these cells will rise, and  $H^+$  will be bound to intracellular proteins ( $H \cdot PTN^+$ ), changing their charge, shape, and possibly their function.

individuals (15). During exercise and in patients with a severe degree of extracellular fluid volume (ECF) volume contraction and metabolic acidosis, muscle cells extract more  $O_2$  from each liter of blood flow; hence, the  $P_{O_2}$  falls and the  $P_{CO_2}$  rises in venous blood (16). This high venous  $P_{CO_2}$  exposes these cells to the risk mentioned earlier for cardiac venous ECs, with a possible titration of intracellular proteins with  $H^+$  (see Figure 30.3).

This raises the following questions for the endothelial biologist: “Are ECs permeable to  $CO_2$ ?” and “Is there a change in their function caused by  $H^+$  binding to ICF proteins?”

### Intestinal Tract

The major feature here is that venous ECs are exposed to all the nutrients absorbed in the intestinal tract, as well as to the products of enterocyte metabolism. A few examples are listed to illustrate the extremes of conditions that these cells face.

**WATER.** When water is ingested rapidly, the concentration of sodium ( $Na^+$ ) in plasma ( $P_{Na}$ ) of arterial blood is  $4 \pm 1$  mmol/L lower than the  $P_{Na}$  in simultaneously drawn peripheral brachial venous blood (17). With respect to potential threats, extrapolating back to portal venules draining the early small intestine (where most of this water is absorbed) implies that the  $P_{Na}$  here might be dramatically lower in this setting. Hence, if these ECs have aquaporin-1 water channels, they could swell acutely and dilute the concentrations of important regulatory molecules in cells. Of great interest, aquaporin-1 also functions as one of the systems that facilitates the diffusion of  $P_{CO_2}$ . Therefore questions arise for the endothelial biologist: “Do these ECs have water channels?” and “Does a large and acute fall in the  $P_{Na}$  in luminal fluid change important properties of these ECs?”

**CITRUS FRUITS.** Two abundant constituents of oranges are  $K^+$  cations and citrate anions. When absorbed, the concentration of  $K^+$  in the plasma ( $P_K$ ) of portal venous blood should rise. With respect to potential threats, if these ECs have  $K^+$  channels that are open in their luminal membrane, the voltage across this membrane will decrease. As a result, one might

expect alterations in voltage-gated calcium ion ( $Ca^{2+}$ ) channels with secondary effects on the concentration of ionized  $Ca^{2+}$  in these cells. Acute episodic changes in this important regulator of metabolism could have important implications for the function of these cells. Therefore, endothelial biologists might ask: “Are there  $K^+$  channels in these cells?” and “Are there changes in the  $[Ca^{2+}]$  in ECs exposed to high  $K^+$ ?”

In a similar “vein,” the absorbed citrate anions chelate  $Ca^{2+}$  in plasma. Therefore, these ECs will be faced with acute falls in the concentration of  $Ca^{2+}$  in venous blood. Again, the endothelial biologist might want to examine what implications this may have for the function of these cells. In fact, episodic absorption and changes in the composition of venous blood-draining enterocytes were the rule in early human evolution because prehistoric diets were rich in fruits and berries (18).

**AMMONIUM.** The liver must be supplied with close to one mmol of ammonium ( $NH_4^+$ ) per mmol of amino acid to permit it to convert amino acids to glucose plus urea (19). The intestinal tract supplies the bulk of this  $NH_4^+$ . The sources of this  $NH_4^+$  are largely glutamine metabolized in enterocytes (20) and the hydrolysis of urea by colonic bacterial urease (21). In fact, the concentration of  $NH_4^+$  in the portal vein is several hundred  $\mu\text{mol/L}$  (19), a concentration of  $NH_4^+$  that is almost an order of magnitude higher than in most other venous systems.

To determine potential threats, it is important to recognize that  $NH_4^+$  and  $NH_3$  do not cross lipid membranes readily. The transport system is recognized as an  $NH_3$  channel (22). Because its outer region has a very hydrophobic area in the luminal membrane of ECs in the portal vein, the apparent  $P_K$  for  $NH_4^+$  falls by close to three units (Figure 30.4). This results in  $H^+$  returning to plasma while  $NH_3$  enters the pore that traverses the plasma membrane. Once  $NH_3$  enters the cytosol

Figure 30.4. Transfer of  $NH_4^+$  from the plasma to the ICF of the EC. The plasma is shown on the top and the ICF compartment of the EC in the portal vein is shown on the bottom of this illustration. The  $NH_3$  channel in the center is greatly exaggerated in size.  $NH_4^+$  diffuses into a hydrophobic area of the mouth of the  $NH_3$  channel where  $NH_3$  is formed. The entry of  $NH_3$  into the cell raises its pH and  $NH_4^+$  concentration.

of ECs, it is converted back to  $\text{NH}_4^+$ , and the amount formed is a function of the local  $[\text{H}^+]$ . In organelles with a high  $[\text{H}^+]$ , if they too had these  $\text{NH}_3$  channels, an enormous concentration of  $\text{NH}_4^+$  would be produced. Hence, it is important to ask: "Do these ECs have Rh-glycoproteins of the classes that form  $\text{NH}_3$  channels (23)?" and "What impact might they have on EC function?"

#### KEY POINTS

- Some demands placed on ECs in the arterial and venous systems related to the composition of arterial and venous blood have been identified.
- With changes in each constituent, potential disadvantages have been identified. Data are needed concerning the pathways for these chemicals to cross EC membranes.
- A consideration of these compositional differences in time and location leads to a number of questions that should be considered when the functions of ECs are investigated in vivo and in vitro.

## Tumor Necrosis Factor

---

Jordan S. Pober

*Yale University School of Medicine, New Haven, Connecticut*

Tumor necrosis factor (TNF) was originally identified as an endogenous mediator of hemorrhagic necrosis of experimental tumors in rabbits. This hemorrhagic necrosis is caused by bacterial products, especially lipopolysaccharide derived from the walls of gram-negative bacteria (1,2). Human TNF protein was purified to homogeneity, and its complete amino acid sequence was determined (3,4); a complementary DNA (cDNA) was subsequently cloned and expressed (4). At the time of cloning, the molecule was renamed as TNF- $\alpha$  to emphasize its close structural relationship to lymphotoxin (LT)- $\alpha$ , then designated as TNF- $\beta$ . (This latter name has gone out of use, so the names TNF and TNF- $\alpha$  are now synonymous, and the designation " $\alpha$ " is superfluous.) Cachectin was independently identified as a mediator of inflammation and as a mediator of cachexia in parasitic infections (2). Following its purification, amino acid sequencing established murine cachectin as identical to TNF (5).

### TUMOR NECROSIS FACTOR FAMILY

TNF and LT- $\alpha$  define the TNF superfamily of secreted and cell-surface proteins that bind to structurally related receptors (the TNFR superfamily) (6). The TNF superfamily is largely confined to vertebrates and probably coevolved with the adaptive immune system, although a single TNF-like molecule recently has been identified in *Drosophila* (6). The largest cluster of TNF superfamily molecules, including both TNF and LT- $\alpha$ , is encoded within the major histocompatibility complex. Knock-out of *TNF* gene in mice leads to abnormal formation of Peyer's patches in the small intestine but otherwise normal development (7).

The primary cellular sources of TNF are leukocytes, especially mononuclear phagocytes, T lymphocytes, and mast cells (8). There is a report that cultured human umbilical arterial endothelial cells (ECs) may synthesize TNF (9), but we have not observed TNF expression under similar conditions by multiple other cultured human ECs types (J. Pober, unpublished observations). Mononuclear phagocytes synthesize TNF largely in response to toll-like receptor microbial

ligands, such as lipopolysaccharide. T cells secrete TNF in response to antigen recognition. Mast cells constitutively synthesize TNF and store it for rapid release following antigen or anaphylotoxin binding. Circulating TNF levels are generally low, less than 1 pg/mL in normal circumstances, but can rise to over 100 pg/mL in settings such as gram-negative sepsis (10). TNF is synthesized as a 24-kDa type II membrane protein and may function as a cell-surface ligand on activated macrophages and perhaps T cells. It is released by proteolysis, predominantly mediated by TNF- $\alpha$  converting enzyme (TACE), a metalloproteinase. The biologically active form of TNF is a homotrimer formed from three 17-kDa processed polypeptides.

### TUMOR NECROSIS FACTOR RECEPTORS

TNF interactions with cellular targets involve binding to either of two cell surface receptors: TNFR1 (CD120a) or TNFR2 (CD120b). Although their external domains are homologous (and define a TNFR superfamily), these two receptors differ significantly in their intracellular domains. Trimeric ligand binding either induces receptor trimer formation or induces conformation changes in preformed receptor trimers, initiating signaling. Both receptors bind TNF (or LT) homotrimers with similar affinities ( $K_d = 1-10$  nM), although TNFR2 may be preferentially activated by the transmembrane form of TNF expressed on activated macrophages. It has been proposed that TNFR2 may capture TNF and pass it to TNFR1, but little direct evidence suggests heterotrimeric receptors containing a mixture of TNFR1 and TNFR2 polypeptides.

Cultured human umbilical vein ECs express both TNF receptors (11). TNFR1 is present on resting ECs, although the majority of receptors are confined to the Golgi apparatus (12). In situ, surface receptors may be concentrated within caveolae, the loss of which results in a diminution of surface expression in cultured ECs (13). Certain signals, such as histamine, result both in mobilization of Golgi receptors to the cell surface and TACE-mediated shedding of receptors from the cell surface (14). (Recall that TACE is the same enzyme that liberates

TNF from the surface of activated mononuclear phagocytes.) TNFR2 molecules, although present in some cultured ECs, are absent from most ECs *in situ* but can be rapidly (within hours) induced in response to TNF (15). TNFR2, when expressed, is primarily a cell-surface protein and, like TNFR1, may be shed following proteolysis by TACE. Soluble TNFRs act as natural inhibitors of TNF signaling (16).

### TUMOR NECROSIS FACTOR SIGNALING

Signaling by TNFR1 involves assembly and disassembly of interacting protein complexes (17,18). The intracellular carboxyl-terminus of TNFR1 contains a protein-protein interaction motif known as a death domain (DD). DDs are found on a subset of TNFR superfamily members in addition to TNFR1 (sometimes called death receptor 1 or DR-1), including Fas (DR-2), DR-3, TNF-related apoptosis-inducing ligand (TRAIL)-R1 (DR-4), TRAIL-R2 (DR-5), and DR-6. Ligand-occupied TNFR1 rapidly (within minutes) recruits an adaptor protein called TNF receptor-associated death domain (TRADD) protein to its cytosolic DD, displacing another DD-containing protein known as silencer of death domains (SODD). The TNFR1-TRADD complex rapidly recruits two other adaptor proteins, receptor interacting protein (RIP)-1 and TNF receptor-associated factor (TRAF) 2. (In some cells, TRAF2 may be replaced by TRAF5.) This signaling complex (sometimes called a signalosome) undergoes three changes within a matter of minutes, namely internalization, dissociation of TRADD-containing complexes from TNFR1, and activation of cytosolic kinases. One such kinase is MEKK-3, a mitogen-activated protein (MAP) kinase kinase kinase (MAPKKK) that phosphorylates and activates the I- $\kappa$ B-kinase complex, leading to activation of nuclear factor (NF)- $\kappa$ B (19). The internalized signalosome also may recruit a different MAPKKK, known as apoptotic signaling kinase (ASK)-1 (20). Binding of ASK-1 leads to activation of kinase cascades that activate c-jun N-terminal kinase (JNK) and p38 MAP kinase (MAPK), which also are known as stress-activated protein (SAP) kinases for their roles in responding to injurious stimuli. ASK-1 recruitment and activation may be facilitated by an adaptor protein known as ASK-1 interacting protein (AIP)-1 (21). AIP-1 and ASK-1 binding to TRAF2 may prevent interactions with MEKK-3, switching signaling from NF- $\kappa$ B to SAP kinases. It is important to note that these signalosome complexes likely are associated with internal membrane structures, but the precise cellular compartments involved are not known.

After a lag period of a few hours, the signalosome further evolves to recruit Fas-associated DD-containing protein (FADD) (22). The recruitment of FADD converts the signalosome to a death-inducing signaling complex (DISC) that binds and promotes the autocatalytic activation of procaspases 8 and 10. Caspase recruitment and/or activation may be blocked by cellular-FLICE inhibitory protein (cFLIP; FLICE is an older name for caspase 8). Activated caspase 8 (or 10) initiates death pathways through proteolytic acti-

vation of caspase 3 and/or through mitochondrial signaling initiated by cleavage of a BH-3 domain-only member of the B-cell leukemia/lymphoma (Bcl)-2 family known as Bid (23). Cleaved Bid binds to Bax on the mitochondrial membrane, triggering release of several death-inducing proteins including cytochrome c, SMAC/Diablo, and apoptosis-inducing factor. The death response initiated by the DISC can be antagonized at several levels by NF- $\kappa$ B-induced proteins such as c-FLIP, Bcl-2, and members of the inhibitor of apoptosis protein (IAP) family. Under normal circumstances, JNK and p38 MAPK activation in response to TNF is transient, but if these signals persist beyond 60 minutes, they can also initiate mitochondrial-dependent death via caspase-independent activation of Bid and its molecular target Bax (24). In summary, the three primary signaling pathways activated by ligand binding to TNFR1 in ECs are NF- $\kappa$ B-mediated gene transcription (involving proteins that are largely antiapoptotic and proinflammatory/procoagulant), SAP kinase-mediated gene transcription (involving proteins that are primarily proinflammatory/procoagulant), and caspase-mediated cell death (which normally is effectively antagonized by NF- $\kappa$ B-induced proteins). However, if NF- $\kappa$ B-induced gene expression is blocked (by drugs or toxins), or if procaspase 8 levels are enhanced (e.g., by interferon [IFN]- $\gamma$  treatments), then TNF may cause EC apoptosis.

Several additional TNFR1-activated signaling responses are less well understood. These include Ras-dependent activation of raf and p42/44 MAPK (25) and phosphoinositide 3-kinase (PI3K)-dependent activation of Akt and its downstream effectors (26). These two potentially progrowth/antiapoptotic responses may involve receptor cross-talk between TNFR1 and other cellular receptors. Cross-talk between different receptors is facilitated by colocalization of different receptors into segregated regions of the plasma membrane, such as those created by cholesterol- or sphingolipid-rich patches, commonly called lipid rafts. In ECs, most lipid rafts are further sequestered into membrane invaginations known as caveolae, which are organized by the cholesterol binding proteins known as caveolins 1 and 2. Caveolae are abundant in ECs *in situ* and, although most ECs rapidly lose their caveolae in culture, these structures are maintained in the immortalized cell line EA.hy.926. Recent studies have shown that TNFR1 is indeed localized to caveolae in this cell line, and that activation of Akt, but not of NF- $\kappa$ B is lost when caveolae are disrupted, consistent with the cross-talk hypothesis (13). Yet another type of response is initiated when ligand-occupied TNFR1 activates neutral sphingomyelinase via a adaptor protein known as factor for activation of neutral sphingomyelinase (FAN) (27); human ECs appear to express little if any FAN and do not seem to activate this pathway (W. Min and J. Pober, unpublished observations). Finally, TNFR1 can activate cytosolic cathepsin B, leading to mitochondria-dependent death responses independent of Bid (28). This response, which may involve RIP-1 (Li and Pober, unpublished observations) is only seen when cathepsin B escapes from lysosomes, a condition observed in human ECs that have been treated with IFN- $\gamma$  (29).

TNFR2 signaling in ECs is less well understood. In some cell types, TNFR2 may directly recruit TRAF2, and receptor overexpression in ECs leads to activation of NF- $\kappa$ B (30). However, it is not clear that this response can be initiated in human ECs by ligand binding. In cultured bovine aortic ECs, TNFR2 signaling may activate PI3K and Akt. This response depends on epithelial/endothelial tyrosine kinase (Etk) and involves cross-talk with the vascular endothelial growth factor receptor 2 (VEGFR2, also known as KDR or FLK-1) (31). The TNFR2-mediated activation of Etk also may be observed in human glomerular ECs in situ (15). TNFR2 signaling via this pathway has been proposed to result in angiogenic responses (32).

Although most TNF responses of ECs may be described as a matter of induced or increased protein expression, some responses involve the reduced expression of proteins. For example, TNF treatment of ECs can reduce expression of the anti-coagulant protein thrombomodulin (33) or the EC enzyme nitric oxide synthase-3 (also known as endothelial or eNOS) (34). The mechanisms of these effects are unclear, but may involve reduced transcription due to diversion of coactivator proteins like CBP/p300 and/or due to mRNA destabilization.

### ENDOTHELIAL CELL PHENOTYPES

At the cellular level, the TNF responses of ECs vary depending on their location within the vascular system. Some proinflammatory proteins, such as the leukocyte adhesion molecules E-selectin and vascular cell adhesion molecule (VCAM)-1, are restricted in their expression to those ECs lining postcapillary venules (35). This may arise from selective inhibition of their transcription by the laminar flow-induced protein Krüppel-like factor 2 (KLF2) in arterial ECs, although it does not explain lack of expression in true capillaries (36). Not all TNF-induced proteins are inhibited by KLF 2, and TNF can induce increased expression of intercellular adhesion molecule (ICAM)-1 as well as major histocompatibility complex (MHC) class I molecules on ECs throughout the vascular system. TNF also causes a rearrangement in the cytoskeleton of ECs, altering cell shape and disrupting cell-cell junctions. These actions increase paracellular leakiness (37). Such changes in EC organization depend on new protein synthesis rather than direct receptor-initiation of signaling responses (38). TNF-induced leakage across the vasculature is being exploited as a means of enhancing the delivery of chemotherapeutic agents to isolated sites of tumor growth, for example, in the limbs (39). At the organ level, TNF responses in ECs lead to leukocyte recruitment and intravascular coagulation (thrombosis) (40), which are the two fundamental mechanisms of host defense. When these responses become systemic (as opposed to local), they can contribute to multiorgan failure and to disseminated intravascular coagulation. IFN- $\gamma$  is a key cofactor in such systemic responses, and it may potentiate both TNF-mediated gene expression and EC death. The potentiation

of gene expression (often called synergy) largely involves the activation of parallel transcription factors (e.g., by IFN- $\gamma$ -mediated signal transducers and activators of transcription [STAT]-1 signaling and TNF-mediated NF- $\kappa$ B signaling) (41), whereas the enhanced EC death may involve potentiation of TNF-activated pathways (e.g., by induction of pro-caspase 8 to exceed the capacity of inhibition by cFLIP) (42) or lysosomal release of cathepsin B into the cytosol, where it may be activated by TNF (29).

### KEY POINTS

- TNF is the prototypic proinflammatory cytokine, and vascular ECs are a principal target of its actions. Anti-TNF therapies are utilized increasingly to control tissue damage, but the efficacy of this approach varies among different inflammatory settings. This variability may relate the activation of different TNF responses in the local ECs. Defining the signaling pathways activated within ECs by TNF may permit more precise therapeutic interventions to reduce inflammation and tissue damage.
- TNF is a pleiotropic inflammatory mediator, synthesized predominantly by mononuclear phagocytes, T cells, and mast cells, that acts on cellular targets by binding to one of two different receptors, commonly designated as TNFR1 and TNFR2.
- Vascular ECs are a principal target of TNF actions and may differentially express TNFR1 and TNFR2.
- TNFR1 signals result in new transcription of proinflammatory and antiapoptotic genes via NF- $\kappa$ B and SAP kinase signaling pathways, and also may activate programmed death through caspase- and cathepsin-dependent signaling pathways.
- The proinflammatory actions of TNF on ECs include expression of leukocyte adhesion molecules and chemokines, as well as expression of procoagulant proteins and induction of vascular leakiness.
- Other cytokines, especially IFN- $\gamma$ , may potentiate TNF actions.
- Locally, such responses contribute to host defense, but systemically may underlie syndromes such as sepsis and multiorgan failure.
- TNFR2 signals may be proangiogenic and may involve cross-talk with VEGFR2.

### Future Goals

- To selectively blockade or stimulate TNFR1 versus TNFR2 responses in specific disease settings to achieve desired therapeutic outcomes
- To protect ECs from TNF-initiated programmed cell death

### VASCULAR ENDOTHELIAL GROWTH FACTORS

#### Background and Discovery

The pioneering observations of Dvorak and his group first showed that tumor ascites fluids from guinea pigs, hamsters, and mice contained an activity that rapidly increased microvascular permeability. The permeability-increasing activity purified from either the culture medium or ascites fluid of one tumor – the guinea pig line 10 hepatocarcinoma – was a 34,000- to 42,000-dalton protein that was distinct from other known permeability factors (1). The vascular permeability factor (VPF) was also secreted by five human tumor cell lines and could be eluted from immobilized heparin. Two tumorigenic (in nude mice) human cell lines were found to secrete at least 14-fold more VPF than their directly matched, nontumorigenic counterparts, suggesting that this factor was important for tumor growth (2).

Later Ferrara and colleagues, and others, isolated a heparin-binding growth factor from the conditioned media of bovine pituitary follicular cells (FCs) and described it as vascular endothelial growth factor (VEGF). This factor was specific for vascular endothelial cells (ECs) and was able to induce angiogenesis *in vivo*. Complementary DNA (cDNA) clones for bovine and human *VEGF* were isolated from cDNA libraries prepared from FC and HL60 leukemia cells, and it was subsequently recognized that VPF and VEGF were encoded by a single gene (3–7).

#### Gene and Splice Variants

The human *VEGF* gene, located on the short arm of chromosome 6, is comprised of eight exons (8) and gives rise to five isoforms containing 121, 145, 165, 189, and 206 amino acids, respectively, that are produced as a result of alternate splicing (9–11). The full transcript encodes a 189-amino acid isoform. A longer molecular species, the 206 isoform, which contains an

additional 17 codons following the 24 codons encoded by exon 6, appears to be expressed only in embryonal tissue (12). The transcript encoding the 165-amino acid form, in which exon 6 is omitted, is expected to generate the 45-kDa peptide following signal peptide cleavage. A fourth transcript, lacking exon 7, encodes a 145-amino acid isoform (11). A shorter transcript, lacking both exons 6 and 7, encodes a 121-amino acid isoform that does not bind heparin, whereas the four larger forms, VEGF-A<sub>145</sub>, VEGF-A<sub>165</sub>, VEGF-A<sub>189</sub>, and VEGF-A<sub>206</sub>, all bind heparin with increasing affinity. VEGF-A<sub>189</sub> and VEGF-A<sub>206</sub> remain cell-associated despite having a signal peptide, whereas the smaller isoforms are secreted (13,14).

#### Vascular Endothelial Growth Factor-Related Genes

The VEGF family currently comprises seven members: VEGF-A (five isoforms as discussed above), VEGF-B (15,16), VEGF-C (17), VEGF-D (18) or VEGF-related protein (VRP), VEGF-E (also called *orf* virus) (19), svVEGF (identified in snake venom) (20), and placental growth factor (PlGF) (21,22). These VEGF-related proteins form glycosylated dimers, which are secreted after cleavage of their signal peptide. They might exist as homo- or heterodimers. They contain the characteristic eight cysteine residues that are highly conserved within the VEGF family. An eighth family member, endocrine-gland-derived vascular endothelial growth factor (EG-VEGF) was recently identified as an angiogenic mitogen selective for ECs of endocrine glands (23).

#### Expression

VEGF is expressed by a variety of normal adult organs including lung, kidney, adrenal gland, heart, liver, and stomach mucosa (24), and by many cell types including megakaryocytes (25,26) peritoneal macrophages, glomerular podocytes (27), glial cells (28), cardiac myocytes, and human placental as well

**Table 32-1: VEGF and VEGF Receptor Knockout and Transgenic Phenotypes**

<i>Knockout</i>	<i>Organism</i>	<i>Phenotype</i>	<i>References</i>
<i>VEGF-A</i> (+/-), (-/-)	Mouse	Embryonic difficulty due to severe cardiovascular defect.	62 63

HCs, hematopoietic cells

as glomerular ECs (29,30). VEGF-A is overexpressed by the vast majority of solid human cancers (reviewed in 3, 31–33) and, increasingly, has been found to be of importance in lymphomas and a variety of hematological malignancies (34–40).

VEGF-A is expressed not only by invasive cancer cells but also by at least some premalignant lesions (e.g., precursor lesions of breast, cervix, and colon cancers); furthermore, expression levels increase in parallel with malignant progression (41–43).

### Regulation

VEGF-A expression is regulated by a number of mechanisms. Hypoxia upregulates VEGF-A expression by stabilizing both hypoxia-inducible factor (HIF)-1 $\alpha$  (thus inducing transcription of the *VEGF-A* gene) and *VEGF* mRNA (44–48). Oncogenes like *src* and *ras*, and tumor suppressor genes such as *p53*, *p73*, and von Hippel Lindau (*VHL*), all play important roles in regulating VEGF-A expression in different tumors (49–51). *VHL* comprises a protein complex that targets HIF-1 $\alpha$  for ubiquitination and proteolysis. Therefore, when *VHL* is absent or mutated, HIF-1 $\alpha$  is stabilized, causing upregulation of VEGF-A (52,53). *p53* and *p73* suppress *VEGF-A* transcription, and thus their deficiency in tumor cells results in increased VEGF-A levels (54–56). Numerous growth factors, cytokines, and lipid mediators upregulate VEGF-A expression in different cells, including epidermal growth factor (EGF), transforming growth factor (TGF)- $\alpha$ , fibroblast growth factor

2 (FGF2), TGF- $\beta$ , keratinocyte growth factor, tumor necrosis factor, interleukin (IL)-1 and IL-6, insulin-like growth factor 1, hepatocyte growth factor (HGF), and prostaglandins E1 and E2 (57–59). VEGF-A also is expressed by steroidogenic cells in response to hormonal stimulation in the adrenal cortex, corpus luteum, and Leydig cells (e.g., the cycling uterus and ovary) (24,60,61).

### Physiological Role

VEGF is such a potent regulator of vascular development that its dosage must be tightly regulated. Disruption of even a single allele of the *VEGF* gene in mice results in embryonic lethality due to severe cardiovascular defects, thus demonstrating the importance of VEGF-A for appropriate vascular development (62,63) (Table 32-1). VEGF is a key regulator of physiological angiogenesis, which is required during wound healing (64,65), ovulation, menstruation (66), and pregnancy (67).

### Pathological Role

High levels of VEGF may lead to pathological angiogenesis in a wide variety of diseases, including chronic inflammation, psoriasis (68), arthritis (69), macular degeneration, diabetic retinopathy (70,71), and tumors. Recent genetic studies have revealed that reduced VEGF levels cause neurodegeneration by impairing neural tissue differentiation and are associated with an increased risk of amyotrophic lateral sclerosis in European populations (72,73). Low VEGF levels have been implicated

in Alzheimer disease and Huntington disease, in which neural perfusion deficits lead to chronic ischemia (74,75).

### Vascular Endothelial Growth Factor and Therapy

VEGF and its functional inhibitors have been used for the treatment of a variety of diseases. Efforts to inhibit VEGF-induced tumor angiogenesis include the development of humanized neutralizing anti-VEGF monoclonal antibodies (76), inhibitory soluble VEGF receptors (66,77,78), antisense VEGF mRNA-expressing constructs (79,80), VEGF toxin conjugates (81), antagonistic VEGF mutants (82), and inhibitors of VEGF receptors (83,84). Avastin, a recombinant humanized antibody to VEGF, was approved by the U.S. Food and Drug Administration (FDA) in February 2004 for use in combination with intravenous 5-fluorouracil-based chemotherapy as a treatment for patients with first-line or previously untreated metastatic cancer of the colon or rectum (85).

The angiogenic properties of VEGF also have been exploited to induce angiogenesis for the treatment of diseases characterized by impaired blood supply. Intramuscular VEGF gene transfer prevented axonal loss and myelin degeneration in a rabbit model of ischemic neuropathy (86), and showed significant improvement in the vascular ankle-brachial index in treated legs in patients with critical lower limb ischemia (87). Successful attempts aimed at the induction of collateral blood vessels in ischemic heart disease and re-endothelization by VEGF recently have been reported (88–90). Collectively, these studies provide sufficient rationale for evaluating the potential therapeutic utility of VEGF.

The remaining part of this chapter focuses on the regulation and function of the VEGF receptors.

## VASCULAR ENDOTHELIAL GROWTH FACTOR RECEPTORS

### Background and Discovery

Several years after the discovery of VEGF as a permeability factor, EC-specific mitogen, and angiogenic cytokine, the search for a putative VEGF receptor was underway. Vaisman and colleagues, using both binding and cross-linking techniques followed by Scatchard analysis, defined two binding sites for <sup>125</sup>I-VEGF on bovine ECs: (a) a high-affinity binding site with a dissociation constant of 10<sup>-12</sup> M and a density of 3 × 10<sup>3</sup> receptors/cell, and (b) a low-affinity binding site with a dissociation constant of 10<sup>-11</sup> M and density of 4 × 10<sup>4</sup> receptors/cell (91). The receptors were shown to have high specificity, because the addition of other growth factors – such as FGF, platelet-derived growth factor (PDGF), EGF, and insulin – were not shown to inhibit VEGF binding.

Simultaneously, other investigators in pursuit of discovery of novel receptor tyrosine kinase (RTK) genes utilized sequences derived from proto-oncogenes or conserved sequences of tyrosine kinases to screen cDNA libraries.

Shibuya and colleagues isolated two novel mammalian kinase genes by weak cross-hybridization with the *v-ras* oncogene (92). One, obtained from a human placenta cDNA library, contained a predicted amino acid sequence of 1,338 residues with seven extracellular immunoglobulin-like domains and a tyrosine kinase domain with a long peptide insertion, indicating that this new gene was closely related to the *fms* family. Consequently, the gene was designated as *FLT* (fms-like tyrosine kinase). It was expressed in several human cell lines derived from placenta, liver, muscle, kidney, and in embryo kidney-derived 293 cells. However, it was undetectable in 20 human tumor cell lines examined. De Vries and colleagues, using oligonucleotide sequences common to tyrosine kinases, isolated a clone identical to *FLT* (93). They demonstrated that, when expressed in COS cells, FLT specifically bound with high affinity to VEGF. Furthermore, *FLT* cDNA, when expressed in *Xenopus laevis*, demonstrated a functional response, with release of calcium upon binding to VEGF. FLT is also designated as FLT-1 and VEGF receptor 1 (VEGFR1).

Similar screening approaches resulted in the discovery of VEGFR2. Mathews and colleagues cloned a RTK cDNA from mouse cell populations enriched for totipotent hematopoietic stem cell and progenitor cells (94). The deduced sequence contained 1,367 amino acids and, similar to FLT, the extracellular region contained seven immunoglobulin-like domains, with a cytoplasmic region containing a long peptide insertion in its tyrosine kinase domain, suggesting that it belonged to the RTK subclass type III. This gene was designated fetal liver kinase 1 (*Flk-1*). Terman and colleagues used polymerase chain reaction (PCR) to amplify DNA segments corresponding to the kinase insert domain of type III RTKs in a human EC cDNA library (95). A clone was isolated with a predicted protein sequence structurally similar to FLK-1, and was designated kinase insert domain-containing receptor (KDR).

Since these initial findings, the known biological functions of VEGF, VEGF-related proteins, and their respective receptors have expanded dramatically to involve a wide spectrum of physiological and pathological entities.

### VEGFR1/FLT-1: Role in Development

Although VEGFR1 was discovered more than a decade ago, the precise function of this receptor is still controversial. In early murine development, VEGFR1 is expressed by embryonic day (E)7.5 in the extraembryonic yolk sac mesoderm (96). A bimodal level of expression was observed during development, with a moderate level of expression during organogenesis (E9.5–E12.5), a very low level of expression during fetal growth (E14.5–E16.5), and a high level of expression in newborn and adult mice. In all tissues examined, which included brain, heart, kidney, and lung, expression was restricted to ECs (97). Studies examining human fetal tissue showed high levels of expression of both VEGFR1 and VEGFR2 throughout the developing endothelia, with the highest levels of expression in the heart, lungs and kidney (98,99); however, careful studies

examining the exact time course have not been carried out in the same detail as in animal models.

Knockout studies reveal a crucial role of VEGFR1 in early angiogenesis. A homozygous null mutation of the *Flt-1* gene in mice results in embryonic lethality at mid-somite stage (E8.5) (100). ECs are present in embryonic and extraembryonic structures, but form abnormal vascular structures. Fong and colleagues subsequently showed that this defect resulted from increased hemangioblastic commitment among mesenchymal cells prior to the formation of blood islands in *Flt-1*<sup>-/-</sup> mice, resulting in increased population density and vascular disorganization (101). These data suggest that FLT-1 plays a critical role in determining cell fate. Others have shown that ECs lacking FLT-1 have a higher rate of cell division than do wild-type controls, suggesting that FLT-1 negatively modulates EC proliferation during embryogenesis (102). In contrast to the full-length receptor, targeted mutation of the tyrosine kinase domain of FLT-1 receptor (TK<sup>-/-</sup>) does not result in embryonic lethality or abnormalities in embryonic development and angiogenesis (103). Furthermore, ECs isolated from FLT-1 (TK<sup>-/-</sup>) animals display a normal mitogenic response to VEGF. These data argue that FLT-1 has an important role in development that is not dependent on the tyrosine kinase domain. Dynamic image analysis of mouse embryonic stem cells suggests that FLT-1 is a positive modulator of vascular sprout formation and branching (104). In the mouse embryo, the absence of FLT-1 resulted in reduced branching of the vascular plexus. This defect was rescued by transgenic expression of soluble FLT-1, suggesting the soluble, rather than membrane-bound form, influences vascular patterning at this stage (104).

#### VEGFR1/FLT-1: Expression in the Adult and Ligands

In the adult, VEGFR1/FLT-1 is expressed primarily on ECs, but also on monocytes/macrophages (105,106), smooth muscle cells (SMCs) (107–110), mesangial cells (111), osteoblasts (112), and hematopoietic stem cells (113). Known ligands for VEGFR1 are VEGF (93), PlGF (114), and VEGF-B (15). VEGFR1 has the highest affinity for recombinant human VEGF, with a dissociation constant (K<sub>d</sub>) of 10 to 20 pM (93) (Figure 32.1). The binding site for VEGF-A and PlGF has been mapped to the second and third Ig-like domains, with loop two being sufficient for VEGF binding (66,115–117). VEGF binding results in weak tyrosine autophosphorylation of VEGFR1 (93,118). VEGFR1 has been considered traditionally as a decoy receptor of VEGF in that it competes for binding and prevents VEGF from interacting with other receptors (77). PlGF has been shown to potentiate the effects of VEGF, which is thought to occur through competitive inhibition with VEGFR1, thus increasing the amount of VEGF available to bind with VEGFR2. Interestingly, the affinity of PlGF for VEGFR1 is somewhat lower (K<sub>d</sub> 170 pM) than it is for VEGF (119,120). Different amino acid residues within the same domains are involved in the ligand–receptor

interface between VEGFR1 and, respectively, VEGF and PlGF (117,121). More recently, a synergism between VEGF and PlGF in pathological angiogenesis has been demonstrated in vivo (122,123). Binding of PlGF by VEGFR1 was shown to result in the transactivation of VEGFR2, and enhanced VEGF-driven angiogenesis. The latter effect was dependent on the tyrosine kinase activity of VEGFR1 (124). The upregulation of specific genes, in response to VEGF and PlGF versus VEGF alone, suggests that unique signaling pathways are involved. Further studies are needed to delineate these pathways and will provide further insight into the role of VEGFR1 in VEGF signaling and biology.

#### Soluble FLT-1

Soluble FLT-1 (sFLT-1), a splice variant of the VEGFR1 that contains the first six Ig-like domains but lacks the transmembrane and cytoplasmic domain, was first identified in conditioned media of human umbilical vein ECs (HUVECs) (77,125). sFLT-1 acts as an antiangiogenic factor by binding to and acting as a sink for VEGF and PlGF, and also in a dominant negative fashion, by forming inactive heterodimers with membrane-spanning VEGF receptors (126). The role of sFLT-1 in physiology and pathophysiology is discussed below.

#### VEGFR2/KDR/FLK-1: Role in Development

During development, VEGFR2 (FLK-1, KDR) is one of the earliest markers for endothelial progenitors (127,128). In mice, FLK-1 is expressed by E7 in the yolk sac mesoderm and proximal lateral embryonic mesoderm, a region fated to become heart. At later stages, FLK-1 expression is restricted to endothelial precursors in the yolk sac blood islands, endocardial tubes, and allantois within the embryo. By E8.5, FLK-1 expression is abundant in the proliferating ECs of vascular sprouts and branching vessels and is later reduced in regions where proliferation has ceased. Within germ layers and organs throughout development, the expression of FLK-1 mirrors that of VEGF.

FLK-1 plays a critical role in embryonic vasculogenesis, angiogenesis, and vascular patterning (129–131). FLK-1-deficient mice show in utero demise between E8.5 and E9.5, and exhibit severe defects in vasculogenesis and hematopoiesis, with lack of mature endothelial and hematopoietic cells and failure to form blood islands (130). In zebrafish, delivery of a VEGFR2 kinase inhibitor at the one-cell stage abolishes axial and intersegmental vessels (ISV), whereas administration at 24 hours inhibits only ISV formation (131,132). These results are consistent with the known temporal sequence of development in the zebrafish, in which axial vessels form first via vasculogenesis, and later, ISV through angiogenesis. FLK-1 also plays a crucial role in vascular patterning. Ambler and colleagues showed that *Flk-1*<sup>-/-</sup> angioblasts, when transplanted into the presomatic mesoderm cavity of quail, fail to migrate to specific embryonic locations, whereas wild-type angioblasts migrate and respond normally to these

Figure 32.1. The VEGF receptor family. The three signaling tyrosine kinase receptors VEGFR1/FLT-1, VEGFR2/KDR/FLK-1, and VEGFR3/FLT-4 consist of seven immunoglobulin-like structures in the extracellular domain, a single transmembrane region, and a consensus tyrosine kinase domain interrupted by a kinase insert domain. Binding of ligand to VEGFR1 promotes the production of proteases in ECs, and the migration of monocytes and macrophages. Binding of ligand and activation of VEGFR2 promotes EC proliferation, migration, and survival. Similarly, ligand binding to VEGFR3 promotes proliferation, migration, and survival in lymphatic ECs (LECs). The receptors neuropilin-1 and neuropilin-2 possess no kinase activity but enhance VEGFR2 signaling. For explanation of the individual neuropilin domains, see Ref 226.

patterning cues (133). These findings demonstrate that FLK-1 has several distinct and overlapping functions throughout development.

### VEGFR2/KDR/FLK-1: Expression in Adult and Ligands

VEGFR2 is the main mediator of the mitogenic, angiogenic, and permeability-enhancing effects of VEGF-A in the adult. It is expressed primarily on vascular ECs (134,135) and endothelial progenitor cells (136). Low levels have been detected in SMCs (110). The ligands for VEGFR2 are VEGF-A (and its isoforms 121, 145, 165) (13), VEGF-C (17), VEGF-D (137), and VEGF-E (138) (see Figure 32.1). VEGFR2 is a 200- to 230-kDa, high-affinity receptor for VEGF-A with a K<sub>d</sub> of 75 to 760 pM (95,120,139) and maps to human chromosome 13q12–13. Upon binding by VEGF-A, VEGFR2 undergoes dimerization and ligand-dependent tyrosine phosphory-

lation. Interestingly, a mutant form of VEGFR2, lacking the Ig-like domains four through seven, was shown to bind to VEGF-A<sub>165</sub> with equal or better affinity as compared to the native receptor, suggesting that these domains may have an important biological function in blocking unwanted signaling events (140). The precise signaling pathways by which VEGFR2 mediates its actions with regards to EC function are discussed later.

### Soluble VEGFR2

A truncated form of VEGFR2 that lacks the C-terminal half of the kinase domain as a result of alternative splicing was reported in normal rat retina (141). More recently, Ebos and colleagues described a soluble VEGFR2 (s-VEGFR2) with an apparent molecular size of 160 kDa, detected in mouse and human plasma (142). This truncated form of sVEGFR2 could be detected in the conditioned media from various EC lines from both human and mouse. More studies are needed to

define the precise biological functions of this newly discovered receptor variant.

### **Role of VEGFR1/FLT-1 and VEGFR2/KDR/FLK-1 in Physiology**

#### ***Wound Healing***

Cutaneous injury initiates a series of events to control hemorrhage. Platelet activation occurs at the site of injury; these platelets secrete several cytokines and growth factors, including VEGF, and subsequently attract circulating neutrophils and monocytes (143). Many cell types contribute to the source of VEGF in wounds, including keratinocytes, macrophages, fibroblasts, ECs, and T lymphocytes (144). Microvascular hyperpermeability induced by VEGF is followed by EC proliferation and migration, which in turn leads to increased angiogenesis at the wound edge (145). At 3 days after wounding, prior to neovascularization, FLT-1 was not detected within the wound, but in ectatic vessels bordering the wound (97). At 7 days, high expression of FLT-1 was observed in large vessels bordering the wound, as well as in small vessels within the wound, representing neovascularization. These data suggest that FLT-1 plays a role in directing new vessel growth and recovery of the endothelium to a quiescent phenotype after neovascularization has occurred.

#### ***Female Reproductive Cycle***

Follicular growth, the development and endocrine function of the ovarian corpus luteum, and cyclic regeneration of the endometrium during the female reproductive years requires a highly regulated angiogenic response (146–148). Menstrual bleeding itself is brought about by tissue breakdown and damage of superficial endometrial vessels, followed by repair of the vessels within 5 days after its onset. *VEGF* mRNA has been shown to be expressed by endometrial stromal cells, significantly increased at the onset of menstruation and mediated by hypoxia, TGF- $\alpha$ , and IL-1 $\beta$ . *VEGF*, *VEGFR1*, and *VEGFR2* mRNA levels were highest, and sFLT levels lowest, during peak EC proliferation in the endometrium (149). *VEGFR2* expression correlated with activation of the receptor, as demonstrated by phosphorylation assays.

#### ***Other Roles of FLT-1***

As mentioned in previous sections, FLT-1 is expressed on several different cell types and organ systems. Other functions mediated by this receptor in response to VEGF demonstrate the complexity of the actions of VEGF at the level of organ system and organism. One well established function of FLT-1 is that it mediates the migration of mononuclear phagocytes across the EC monolayer in response to binding of VEGF-A and PlGF (106). VEGF-E, which binds exclusively to VEGFR2 and induces autophosphorylation, acts as a potent mitogen- and permeability-enhancing factor, but does not stimulate the migration of monocytes, demonstrating that FLT-1 is necessary for the expression of the entire spectrum of VEGF-related events in the adult vasculature (150,151).

Interestingly, LeCouter and colleagues recently showed that selective activation of FLT-1 induced liver sinusoidal ECs to produce HGF and IL-6 (152). This was shown to increase hepatocyte growth but not endothelial proliferation in vitro and in vivo. Additionally, it reduced hepatotoxin-induced liver damage in mice. This study describes a novel role that extends beyond traditional angiogenic mechanisms for VEGFR1 in adult endothelium. It also provides potential new therapies utilizing FLT-1 agonists for the possible preservation of organ function in liver disease.

### **VEGFR1 and VEGFR2 in Pathophysiology**

#### ***Hypoxia-Induced Expression of VEGF Receptors***

Hypoxia is an important stimulus for the expression of VEGF and its receptors in physiologic and pathological processes. Given the heterogeneity of EC and vascular bed phenotypes, it is not surprising that different studies have yielded varying results regarding hypoxic responses. Despite this, some general findings are consistent across studies. With hypoxia, *VEGFR1* is transcriptionally upregulated through the interaction of HIF-1 $\alpha$  with a hypoxia-inducible enhancer element located in upstream promoter of *VEGFR1* (118,153). Both transcriptional upregulation (118,153–155) and increased protein expression (153) have been demonstrated in vitro and in vivo, in a variety of EC types. Interestingly, during development hypoxia is a key stimulatory factor for the formation of vascular tubes. During this process, coordinate upregulation of VEGF-A, VEGF-B, and VEGFR1 (156) is essential for the establishment of normal coronary circulation.

Nilsson and colleagues (157) illustrated the heterogeneity among EC types by characterizing responses to hypoxia in ECs derived from vessels within bovine adrenal cortex, human foreskin, human umbilical vein, human saphenous vein, and human pulmonary artery. Hypoxia induced HIF-1 $\alpha$  in all EC types; however, the related HIF-2 $\alpha$  protein was induced in dermal microvascular ECs, whereas weak or no induction occurred in other EC types. *VEGF-A* was transcriptionally upregulated in all cell types, *VEGFR1* in all cell types with the exception of HUVECs, and *VEGFR2* in dermal microvascular cells alone. Consistent with others studies that have implicated HIF-2 $\alpha$  in the transcriptional regulation of *VEGF-A* and *VEGFR2* genes (158–160), increased gene expression of *VEGF* and *VEGFR2* correlated with clear induction of HIF-2 $\alpha$  in microvascular ECs. With regards to protein expression, hypoxia downregulated VEGFR1 expression at the cell surface in dermal microvascular ECs. Incubation with neutralizing antibodies against VEGF-A during hypoxia prevented downregulation of VEGFR1 receptor expression, suggesting a negative autocrine loop. Additionally, venous ECs were found to transcriptionally upregulate the lymphangiogenic genes *VEGFR3* and both *VEGF-C* and *VEGF-D* under hypoxic conditions (157). Others have reported that the protein expression of VEGFR2 is upregulated in ECs in vitro (107) and in vivo (161) in response to hypoxia. This is thought to

occur through posttranscriptional modification resulting in enhanced mRNA stabilization (162).

### *Preeclampsia*

During normal pregnancy, placental cytotrophoblasts, which help establish the fetomaternal circulation through invasion of the uterine wall, produce and release sFLT-1 into the maternal circulation (163,164). sFLT-1 has been shown to be elevated in pregnant women with preeclampsia (165), a common disorder of pregnancy characterized by hypertension and proteinuria in the third trimester and which is associated with significant morbidity and mortality (see Chapter 161). Elevated plasma concentration of sFLT-1 are detectable about 5 weeks before the manifestation of this disorder (166). Evidence suggests that inadequate invasion of the cytotrophoblasts during placental development results in underperfusion of the placenta (167). Tissue hypoxia stimulates the expression and release of sFLT-1, which binds to VEGF and PlGF, resulting in a functional deficiency of these growth factors. The net effect is attenuation of vasomotor relaxation and angiogenesis, thus promoting a cycle of endothelial dysfunction and increased placental hypoxia. It appears that increased sFLT-1 is due to increased production by cytotrophoblasts, rather than ECs or villous fibroblasts. sFLT-1 may be an important diagnostic tool in this disease and others.

### *Tumor Angiogenesis*

Tumor growth and metastasis is angiogenesis-dependent. The progression from a neoplastic process to carcinogenesis involves an "angiogenic switch" in which tumors, once they have reached a certain size (approximately 2 mm<sup>3</sup>), begin to recruit their own blood supply (168). This occurs through the production of growth factors and cytokines, including VEGF. As mentioned previously, VEGF is overexpressed by the vast majority of solid tumors (31,33) and several hematological malignancies (34–36). Although tumor cells are the main source of VEGF-A, stromal cells and vascular endothelium have been reported to express VEGF-A, albeit at lower concentration, especially at sites of hypoxia (41,169–171). Tumors studied thus far that express a high level of VEGF are supplied by microvessels lined by ECs that overexpress both VEGFR1 and VEGFR2 (31,33,41,42,172–174). The mechanisms involved the upregulation of VEGFR1 and VEGFR2 are not well understood, but experimental evidence suggests that chronic exposure to VEGF is a major determinant of this change in expression. Transgenic mice that overexpress VEGF in the skin under the control of a keratin promoter, or mice injected with adenovirus engineered to overexpress VEGF, were both shown to have upregulation of VEGFR1 and VEGFR2 in the EC of microvessels adjacent to these regions (175). This appears to contradict *in vitro* findings of Nilsson and colleagues (157) but underscores the differences that may exist in culture systems versus *in vivo*.

Angiogenesis-related genes and gene products may serve as prognostic factors in cancer. For example, circulating levels VEGF-A and sFLT-1 (176,177) have been shown to be

potential predictors of clinical outcomes in breast cancer. Cell lines from patients with multiple myeloma have been shown to express VEGFR1 and, in some cases, VEGFR2; in these patients, angiogenic markers such as microvessel density correlate with outcome (178). High tissue expression of VEGF-C and VEGFR2 in ovarian carcinoma portends poor prognosis (179), whereas VEGF-A and VEGFR1 levels are associated with lymphoma progression (180). Numerous receptor tyrosine kinase inhibitors have been developed as antiangiogenic agents and are being studied in preclinical and clinical trials (181). Other strategies have included VEGF-A neutralizing antibodies, toxins, endogenous inhibitors of angiogenesis, and DNA vaccines. Despite these tremendous advances, many questions regarding basic mechanisms governing tumor growth and metastasis remain. Further research focused on the delineation of the molecular determinants and pathways involved will help to identify unique and specific therapeutic targets.

### *Pulmonary Hypertension*

Plexiform lesions, composed of ECs, develop in the lumen of medium and small precapillary pulmonary arteries and are considered to be the characteristic lesion of primary pulmonary hypertension and severe pulmonary hypertension secondary to left-to-right heart shunt, HIV infection, CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, and liver cirrhosis (182). The mechanisms involved bear a striking resemblance to that of tumor angiogenesis (183) in which localized hypoxia stimulates upregulation of VEGF through HIF-1 $\alpha$ . VEGF, VEGFR2, HIF-1 $\alpha$ , and HIF-1 $\beta$  have been shown to be expressed at higher levels within plexiform lesions (184), as compared to unaffected regions within the same lung, or in controls. Upregulation of these factors stimulates an angiogenic response and vascular remodeling that proceeds in a highly uncoordinated fashion. The lesions consist of mass of disorganized capillaries that eventually obliterate the vessel lumen, restricting flow and promoting further progression of the disease. The precise molecular mechanisms have yet to be elucidated, but decreased expression of phosphoinositide 3-kinase (PI3K), src, and Akt within the plexiform lesions, as compared with controls and despite increased expression of VEGFR2, suggests downregulation of important activating signals within these cells (184). This likely results in profound endothelial dysfunction, because these pathways are known stimulate endothelial nitric oxide synthase (eNOS) and prostacyclin production, which are important mediators of vascular tone and function (185).

### *Ocular Microvascular Proliferative Disorders*

VEGF has emerged as a major mediator of intraocular neovascularization in diabetic retinopathy (186,187). Diffuse microvascular disease with resultant capillary closure and tissue hypoxia stimulates the production of VEGF and neovascularization. This leads to increased vascular permeability, tissue edema, hemorrhage, and fibrosis. VEGF production was found not only in retinal ECs, but also in retinal capillary

pericytes, retinal pigment cells, glial cells, and ganglion cells, all of which potentially participate in the pathogenesis of retinopathy. In animal models of ischemic retinopathy, a variety of therapeutic approaches have been explored, including chimeric proteins that bind VEGF (188), monoclonal antibodies (189), antisense oligonucleotides (190), and VEGF receptor tyrosine kinase inhibitors (191). All of these approaches demonstrated a significant reduction in retinal neovascularization, suggesting that this is a promising strategy for this disease.

### *Atherosclerosis and Restenosis*

The specific biological effects of VEGF and its receptors with respect to atherosclerosis and restenosis have yet to be clarified. VEGF-A has been proposed to have several protective effects in the arterial wall including increasing the production of nitric oxide (NO) and prostacyclin (192), reducing low-density lipoprotein oxidation (193), and mediating antiapoptotic effects in the endothelium (194). Conversely, several lines of evidence suggest that angiogenesis and VEGF-A play an important role in atherogenesis. An association between increased vasa vasorum and atherosclerotic plaques in diseased arteries, as compared with normal arteries, has been demonstrated (195). In human coronary arteries, VEGF-A expression was detected in macrophages, SMCs, and ECs within atheromatous plaques, whereas expression within normal coronaries was not detectable (196). Immunostaining for FLT-1 and FLK-1 demonstrated increased expression in aggregating macrophages within these lesions and ECs within microvessels in totally occlusive lesions, but not in normal coronary arteries (196). Furthermore, animals treated with VEGF exhibit accelerated plaque development (197).

Neointimal formation is a major cause of restenosis after coronary intervention (198,199). Neointima formation following coronary interventions arises from a response to arterial injury, which induces a number of changes in the vessel wall that promote vascular SMC proliferation and migration into the site of injury. Angioplasty induces mechanical stretching of the vessel. This disrupts internal elastic lamina and media and denudes the endothelium, subsequently exposing the blood vessel wall to circulating mitogens that promote the release of cytokines from ECs, vascular SMCs, platelets, and inflammatory cells. The vasculoprotective versus the atherogenic and neointima-promoting effects of VEGF-A in arteries is still a matter of debate (200). Increased protein expression VEGF-A and FLT-1 in a porcine model of coronary restenosis has been demonstrated within SMCs of the neointima, and in ECs and macrophages in microvessels around stent struts following stent implantation (201).

Prior studies have suggested that acceleration of re-endothelization can prevent restenosis and inhibit in stent thrombosis (202,203). Local delivery of VEGF after arterial injury has been shown to promote endothelial regeneration, accelerate endothelium-dependent relaxation, and reduce neointimal formation (204). In injury models, VEGF, through its receptor VEGFR1, induces the migration and activation of

monocytes (106), adhesion molecules (205), and monocyte chemoattractant protein (MCP)-1. In vitro experiments have shown that VEGF-A increased the production of matrix metalloproteinases 1 and 9 in human SMCs (109), suggesting a possible role for VEGF-A in enhancing SMC migration. Other investigators have shown that VEGF-A promotes migration but not proliferation of human SMCs, which were shown to express FLT-1 and VEGFR2 (206). Furthermore, VEGF-E, which is known to bind specifically to VEGFR2, induced migration as well (108). Gene transfer of soluble FLT-1 has been shown to prevent neointimal formation after periadventitial injury in mice (207) and to attenuate neointimal formation in animal models after intraluminal injury, with concurrent downregulation of VEGF and inflammatory markers (208). Conversely, phVEGF plasmid-coated polymer stents were shown to improve re-endothelization versus uncoated stents, with reduced neointimal formation in hypercholesterolemic rabbits. Local drug delivery of an antiproliferative agent with drug-eluting stents is a promising strategy for the prevention of restenosis (209). However, this strategy has the potential for impairing endothelial recovery with an associated risk of in-stent thrombosis. Further studies are needed to define the appropriate "VEGF balance" to promote re-endothelization and prevent restenosis.

### **Other VEGF Receptors**

#### *VEGFR3/FLT-4*

VEGFR3, first cloned from human erythroleukemia cells (210), is a highly glycosylated receptor tyrosine kinase, approximately 180-kDa in size. The cDNA was cloned from placental libraries with localization to q35 on human chromosome 5 (211). Two isoforms of VEGFR3 are known: The short form lacks a 65-amino acid sequence found in the cytoplasmic tail of the long form (212). Two ligands are known to bind to VEGFR3: VEGF-C (17) and VEGF-D (137,213). The activation of VEGFR3 leads to protein kinase C (PKC)-dependent activation of extracellular signal-related kinase (ERK)-1 and -2, and activation of protein kinase B/Akt, which supports cell proliferation and survival (214).

#### *VEGFR3 Expression in Development and in the Adult*

Several studies have shown that VEGFR3 is widely expressed on ECs in several species, including human, early in development prior to and during vessel formation (99,135). Unlike VEGFR1 and VEGFR2, VEGFR3 is not expressed in blood islands. As development continues, VEGFR3 is more prominent in developing veins, in vascular networks adjacent to developing skin, and vasculature within the liver. After organogenesis is complete, the expression of VEGFR3 is confined primarily to the endothelium of lymphatic vessels (98). More recent work has shown that, during development, VEGFR3 also is expressed on fenestrated endothelium within cartilage channels, endocrine organs, cells lining sinusoids of bone marrow, endothelial lining the splenic sinusoids, and glomerular capillaries within the kidney (215). In the normal

adult, VEGFR3 is expressed in placenta, lung, heart, and kidney (215) in splenic sinusoid, capillaries of the glomerulus, within the vasa vasorum of the aorta, and in endocrine organs (adenohypophysis, thyroid, parathyroid and adrenal glands) (215).

#### *Role of VEGFR3 in Physiology and Pathology*

VEGFR3 knockout in mice results in embryonic lethality at E9.5. Although vasculogenesis and angiogenesis occur, these embryos possess large, disorganized vessels with defective lumen formation, leading to fluid accumulation in the pericardial cavity and cardiovascular failure, thus demonstrating a critical role of VEGFR3 in cardiovascular development prior to the formation of lymphatics (216,217).

Missense point mutations in one *VEGFR3* allele leads to the inactivation of tyrosine kinase activity and results in chronic lymphedema (218). VEGFR3 has been shown to be expressed in a wide variety of tumors and hematological malignancies including Kaposi sarcoma (219), angiosarcoma (220), hemangiomas (221), lymphangiomas (98), and undifferentiated teratocarcinoma cells, with downregulation of expression upon differentiation (212), and in many human leukemic cells lines (222,223). High expression also is found in the neovasculature of benign and malignant vascular tumors (99), breast cancer (224), and on SMCs in atherosclerotic arteries (110).

#### *Neuropilin*

Neuropilin (NRP), a 130- to 140-kDa membrane glycoprotein, was first identified in the optic tectum of *Xenopus laevis* and subsequently in the developing brain (225). Two NRP genes are known: *NRP1* and *NRP2* (226–228). *NRP1* localizes to neuronal axons (227), but is also abundant on ECs and developing embryonic blood vessels, and is important in normal developmental angiogenesis (62,63) and tumor angiogenesis (229). *NRP1*-knockout mice display abnormal axonal networks, deficiencies in neuronal vascularization, aortic arch malformations, and diminished and disorganized yolk sac vascularization (230). *NRP1* is not a tyrosine kinase receptor, but acts as a coreceptor for VEGFR2, enhancing VEGF-A<sub>165</sub> activity (231) cell survival and migration (232,233).

#### **Signaling Pathways of VEGFR1 and VEGFR2 in the Vascular Endothelium Leading to Biological Responses**

Most of the biological activities of VEGF are mediated primarily by interaction with the two major receptors, VEGFR1 and VEGFR2 (Figure 32.2). At present, the signaling cascades following VEGF interaction with cultured ECs are only partially understood but are known to involve a series of protein phosphorylations. Tyrosine residues known to be phosphorylated on VEGFR1 are Tyr<sup>1213</sup>, Tyr<sup>1333</sup>, Tyr<sup>1242</sup>, and Tyr<sup>1327</sup>. Three SH2 domain-containing proteins bind to the phosphorylation site Tyr<sup>1213</sup> namely, SHP-2, phospholipase C (PLC) $\gamma$ -1, and Grb-2. The site at Tyr<sup>1333</sup> allows binding of PLC $\gamma$ -1 and the adaptor molecules Crk and Nck. Tyr<sup>1242</sup> and Tyr<sup>1327</sup> are

poorly phosphorylated and have not been shown to associate with signaling molecules.

Binding of VEGF or PlGF to VEGFR1 induces cell migration in monocytes (106,234). In ECs, VEGFR1 demonstrates an inhibitory effect on VEGFR2-induced proliferation but not migration (235,236). It is not yet completely clear why VEGFR1 does not induce cell proliferation in response to VEGF, but this could be due to low kinase activity of the receptor resulting from a small number of tightly regulated phosphorylation sites. Accordingly, a repressor sequence has been identified in the VEGFR1 juxtamembrane domain, and replacement of this by VEGFR2 allows VEGFR1 to respond to stimulation by VEGF-A. Furthermore, the repressor sequence may regulate interactions with the phosphatases (237,238). Studies with the receptor chimera of EGF receptor (EGFR) and VEGFR1 (EGLT) or VEGFR2 (EGDR) have suggested a role for PI3K in mediating this inhibitory function through Tyr<sup>794</sup>. Inhibitors of PI3K as well as the dominant negative mutant of p85 (PI3K subunit) reversed the inhibition of proliferation, whereas a constitutive active mutant of p110 introduced the inhibition to HUVEC-EGDR (235).

The binding of VEGF to VEGFR2 results in autophosphorylation of Tyr<sup>951</sup> and Tyr<sup>996</sup> present in the kinase insert domain, Tyr<sup>1054</sup> and Tyr<sup>1059</sup> in the kinase domain, and Tyr<sup>1175</sup> and Tyr<sup>1214</sup> in the C-terminal tail. Phosphorylated Tyr<sup>951</sup> binds VRAP (239), and Tyr<sup>1175</sup> binds Sck (240) and PLC $\gamma$ -1 (241). Binding of PLC  $\gamma$ -1 activates PKC, which in turn activates *ras*. This is followed by the induction of the ERK pathway (p42/44 mitogen-activated protein kinase [MAPK]). ERK then phosphorylates and activates transcription factors in the nucleus. This pathway is important for VEGFR2-mediated DNA synthesis and proliferation (120,242–246).

U73122, a specific inhibitor of the PLC family, inhibited VEGF-stimulated HUVEC proliferation and migration (235). The catalytic activities of PLC- $\beta$ 1, - $\beta$ 2, - $\beta$ 3, and also PLC $\gamma$  were measured in cellular extracts prepared from a HUVEC suspension stimulated with VEGF for 20 or 40 seconds, and 1, 2, and 5 minute. The activity of PLC- $\beta$ 3 peaked at 40 seconds, and dropped to baseline within 1 minute after stimulation, whereas no significant change occurred in the catalytic activity of other PLCs, except PLC $\gamma$ , which started increasing after 1 minute (247). These results indicated that G-protein-regulated PLC- $\beta$ 3, rather than receptor tyrosine kinase-regulated PLC $\gamma$ -1, was mediating the VEGF-induced increase in  $[Ca^{2+}]_i$ . The role of G-proteins in VEGF signaling is novel, considering the receptors that lead to signaling are receptor tyrosine kinases. The ability to block VEGF-stimulated HUVEC proliferation and migration with a Gq-specific antagonist fusion peptide and  $\beta$ -ARK1 minigene suggests the existence of a novel signaling pathway. Inhibition of Gq activation blocked VEGFR2 phosphorylation (248,249). This suggests a unique pathway by which Gq modulates RTK activation. The free G- $\beta\gamma$  subunit activates PLC- $\beta$ 3, followed by an increase in  $[Ca^{2+}]_i$  that results in proliferation and migration of ECs and thus angiogenesis. These results thus suggest that Gq, G- $\beta\gamma$ , and LC- $\beta$ 3 are required for VEGFR2

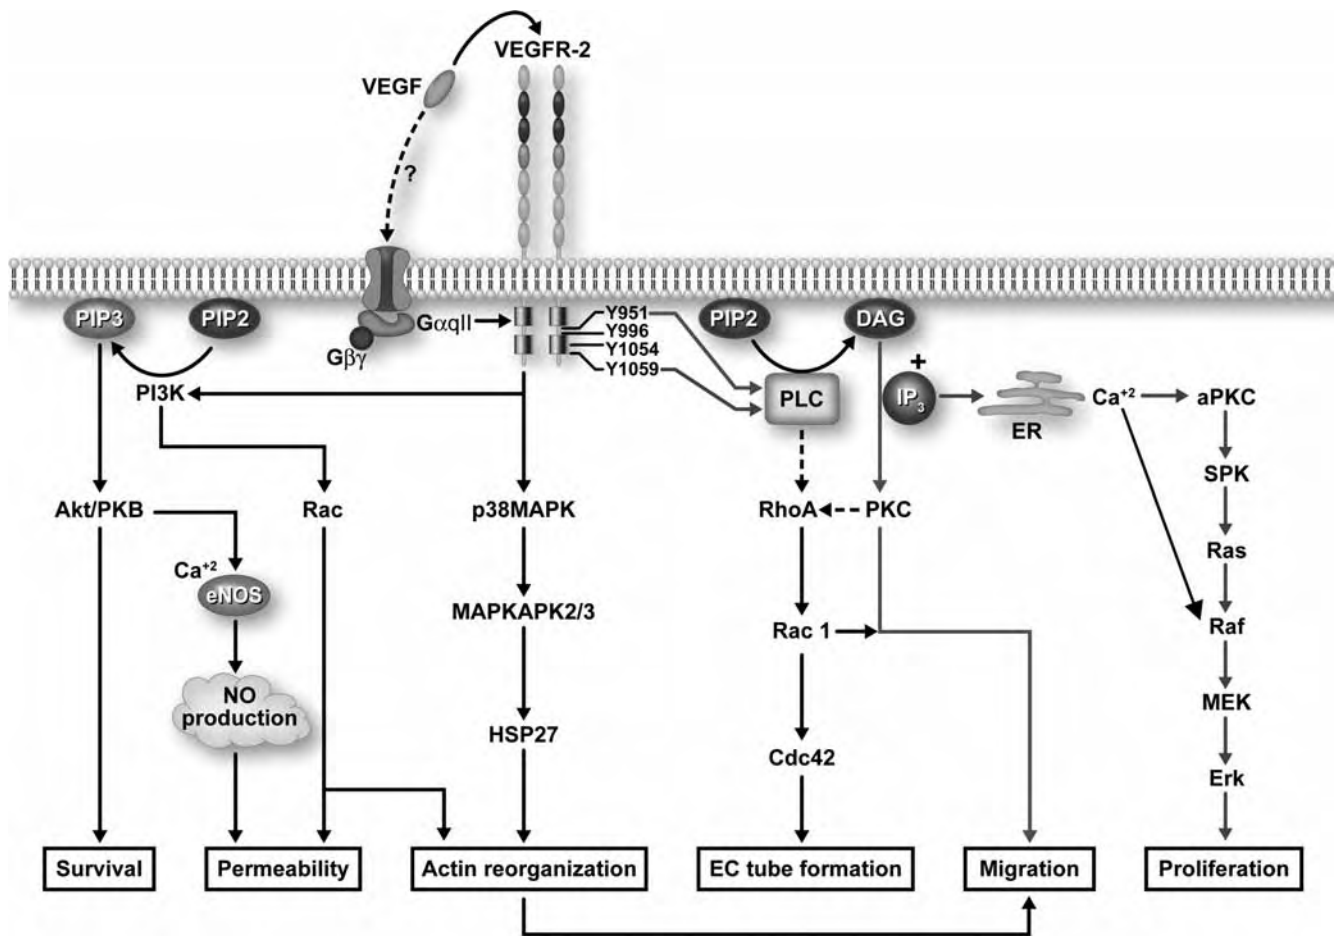

Figure 32.2. Scheme for VEGFR2-mediated signaling. Ligand binding induces dimerization and activation of G $\alpha$ -proteins resulting in autophosphorylation of specific tyrosine residues on the receptor. Several SH2 domain-containing proteins, including PLCs, bind to the tyrosine phosphorylated residues on the receptor, leading to their own phosphorylation and activation. PLC activation results in hydrolysis of membrane phospholipid PIP<sub>2</sub>, which leads to generation of DAG and IP<sub>3</sub>. DAG activates PKCs, whereas IP<sub>3</sub> binds to IP<sub>3</sub> receptors on the ER that results in release from Ca<sup>2+</sup> stores, thus raising the intracellular concentration of [Ca<sup>2+</sup>]<sub>i</sub>. The exact mechanism by which PI3K and p38MAPK are activated by VEGFR2 is not known. Downstream signal propagation from these aforementioned molecules leads to different endothelial functions such as survival, permeability, tube formation, migration, and proliferation. SH2, Src homology-2 domains; PLC, phospholipase C; PIP<sub>2</sub>, phosphatidylinositol (4,5)-bisphosphate; DAG, 1,2-diacylglycerol; IP<sub>3</sub>, inositol (1,4,5)-triphosphate; aPKC, atypical protein kinase C; PI3K, phosphoinositide 3-kinase; p38MAPK, p38 mitogen-activated protein kinase; PIP<sub>3</sub>, phosphatidylinositol (3,4,5)-triphosphate; Akt/PKB, protein kinase B; eNOS, endothelial nitric oxide synthase; NO, nitric oxide; MAPKAPK2/3, MAPK-activating protein kinase-2 and 3; HSP27, heat shock protein 27, ER, endoplasmic reticulum; SPK, sphingosine kinase; Erk, extracellular-signal-regulated kinase; VEGFR2, vascular endothelial growth factor receptor 2; VEGF, vascular endothelial growth factor.

function and indicate for the first time that G-protein can be activated by VEGF (249,250).

SHP-1 and SHP-2, two SH2 protein-tyrosine phosphatases, have been shown to physically associate with VEGFR2 secondary to VEGF stimulation. These molecules are potentially capable of functionally counteracting the endothelial response to VEGF (244). VEGFR2 also activates PI3K, which causes an increase in IP<sub>3</sub> and leads to activation of the PKB (Akt/PKB)-induced survival pathway (251), activation of endothelial nitric oxide synthase resulting in the release of nitric oxide (252–254), and a mediated increase in vascular permeability and migration that is further accentuated by the small GTP binding protein Rac (255). The VEGFR2 pathway

also leads to cell migration and actin reorganization that result from activation of p38 MAPK and focal adhesion kinase (FAK) along with paxillin (245,256,257).

VEGFR2 signaling also regulates tube formation by aortic ECs (258). The Rho GTPases represent an important class of molecules involved in EC morphogenesis. Cdc42 and Rac1 are required for the process of EC intracellular vacuole formation and coalescence that regulates EC lumen formation in three-dimensional (3D) extracellular matrices, whereas RhoA appears to stabilize capillary tube networks. Once EC tube networks are established, supporting cells, such as pericytes, are recruited to further stabilize these networks, perhaps by regulating EC basement membrane matrix assembly. Furthermore,

EC morphogenesis is balanced by a tendency for newly formed tubes to regress. This morphogenesis–regression balance is controlled by differential gene expression of such molecules as VEGF, angiopoietin-2, and plasminogen activator inhibitor (PAI)-1, as well as a plasmin- and matrix metalloproteinase–dependent mechanism that induces tube regression through degradation of extracellular matrix (ECM) scaffolds that support EC-lined tubes (259–262).

## CONCLUSION

The discovery of VEGF and its receptors on ECs initiated a new era of intense research that focused primarily on endothelial biology. However, the subsequent discovery of these receptors on a number of other cell types indicated that highly coordinated complex interactions exist. Furthermore, the variation among VEGF family members with respect to their properties adds to the intricacy of the biology of VEGF and its receptors. These provide new tools that can be utilized to dissect signaling pathways and to develop prognostic markers and potential therapies. Proangiogenic therapy, including gene therapy using VEGF-A, has shown some promise in patients with critical limb ischemia and ischemic heart disease. Antiangiogenic therapy has had some degree of success not only in cancer patients but also in nononcologic disorders such as rheumatoid arthritis, psoriasis, diabetic retinopathy, and age-dependent macular degeneration. Nonetheless, these advances should be viewed with cautious optimism, because such therapy may be associated with significant side effects, including hypertension, thrombosis, proteinuria, and even fatal hemorrhage. Understanding the role of VEGF and its receptors in physiological and pathological processes should lead to the development of targeted therapies with improved efficacy. To achieve maximal therapeutic benefit, the timing of administration must be optimized and the drugs used in conjunction with other treatment modalities, such as chemotherapy and radiotherapy.

Even though the molecular determinants of VEGF actions in the endothelium have been characterized in great detail over the past few years, different areas of VEGF receptor signal transduction still remain to be elucidated. Because both VEGFR1 and VEGFR2 are expressed on the vascular endothelium, it has been difficult to define their respective roles in signaling. This is particularly true for VEGFR1. Nonetheless, the use of chimeric receptor approaches, antisense strategies, and siRNA techniques has shed some light on the distinct signaling properties of these receptors and demonstrates “cross-talk” between the two receptors. Clearly, an emerging paradigm in VEGF receptor signaling has been the shift from VEGF-based linear signaling to “cross-talk” among the different VEGF receptors and the involvement of other receptors such as G-protein–coupled receptors in the initiation of signaling. Although we have shown the requirement of G- $\alpha$ q11 and G- $\beta\gamma$  in the initiation of VEGF-mediated endothelial signaling, many questions remain unanswered, such as: Are these

G-proteins coupled to a receptor at the plasma membrane? If so, then how are they activated by VEGF? Pathways initiated by the VEGF receptors have been well studied, but the molecular determinants causing receptor compartmentalization and endocytosis leading to signaling remain poorly understood. Another important goal is to identify signals relayed from VEGF receptors to the nucleus to generate information required for EC differentiation during angiogenesis and development. Finally, a more in-depth understanding of the regulatory functions of VEGF and its receptors remains essential for realizing potential promising breakthroughs and challenging questions in the pathophysiology of the endothelium.

## KEY POINTS

- VPF/VEGF and its receptors control physiological and pathological angiogenesis.
- The regulation of VPF/VEGF and its receptors is complex and context dependent.

## Future Goals

- To better understand of VPF/VEGF biology to help us design selective targets that can be useful for therapeutics for several pathological states including cardiovascular diseases and cancer

## ACKNOWLEDGMENT

This work is partly supported by NIH grants CA78383, HL072178, and HL70567, and also by a grant from American Cancer Society to DM. We greatly appreciate the secretarial help of Denise Lecy.

## Function of Hepatocyte Growth Factor and Its Receptor c-Met in Endothelial Cells

Xue Wang, Augustine M. K. Choi, and Stefan W. Ryter

*The University of Pittsburgh School of Medicine, Pennsylvania*

Hepatocyte growth factor (HGF), also known as scatter factor (SF), exerts a spectrum of biological activities in epithelial and endothelial cells (ECs), including the stimulation of cell growth or motility, and the promotion of matrix invasion. This chapter introduces the molecular characteristics of HGF/SF and its receptor c-Met, with special emphasis given to the functional activities of this system in the endothelium.

### HISTORY

HGF was originally identified in 1984, in the serum of partially hepatectomized rats as a mitogenic factor for cultured rat hepatocytes (1), and also has been isolated from rat platelets (2), human serum (3), and rat liver (4). This factor was independently discovered as an embryo fibroblast-derived molecule and termed “scatter factor” for its effects on epithelial cell dissociation and motility (5). HGF and SF were later determined to be identical molecules on the basis of functional, structural, genetic, and immunological characteristics (6–8). In the remainder of the chapter, we will refer to the protein as HGF.

### STRUCTURAL AND FUNCTIONAL CHARACTERISTICS OF HGF

The *HGF* gene localizes as a single copy to chromosome 7q11.1–21 in humans, and consists of 18 exons and 17 introns spanning approximately 70 kb (9). HGF originates from a primary transcript of 6-kb as a biologically inactive single-chain precursor molecule of 728 amino acids (pro-HGF) (10–11). The mature form of HGF generated by proteolytic cleavage consists of a 69-kD  $\alpha$ -subunit and a 34 kDa  $\beta$ -subunit (12). The  $\alpha$ -chain contains an N-terminal hairpin loop and four kringle domains, which are 80-amino acid structures stabilized by intramolecular disulfide bridges that mediate protein–

protein interactions (13). The  $\beta$ -chain resembles the catalytic domain of serine proteases but with amino acid substitutions in the active site that render it nonfunctional with respect to protease activity (12–13). Studies on structure–function relationships indicate that the N-terminal hairpin loop and second kringle domains of HGF form a low-affinity binding site for heparin sulfate proteoglycans, whereas the first kringle domain acts as a high-affinity binding site to the HGF receptor, c-Met; thus, these domains are essential for HGF membrane localization and activity. This structural organization highly resembles that of factors implicated in blood coagulation and fibrinolysis, such as plasminogen and prothrombin. The extracellular urokinase-type plasminogen activator (u-PA) complexes with the biologically inactive pro-HGF both in vitro and in vivo, leading to conversion of pro-HGF to mature HGF by the hydrolysis of the Arg494–Val495 peptide bond (14). u-PA cannot act on pro-HGF bearing a mutated cleavage site in vitro. Macrophages provide the primary source of u-PA, which is produced locally in response to environmental stimuli such as tissue injury (14).

In addition to the 6-kb full-length *HGF* transcript, which encodes for the 728-amino acid form of the growth factor, a variety of truncated cDNAs (4.4, 3, 2.2, 1.3 kb) have been cloned (10,15–19). In leukocyte and fibroblast cDNA libraries, a naturally occurring HGF variant arising from alternate splicing of the primary 6-kb transcript was discovered. This transcript encodes a 15-base pair deletion, resulting in a 723-amino acid form, termed dHGF. dHGF bears a five amino acid truncation in the first N-terminal Kringle domain, which alters the solubility and immunological properties of the molecule. dHGF, however, displays similar mitogenic, cytotoxic, and scattering activities as the full-length form of the molecule (15–17). Two additional splice variants of HGF (NK1 and NK2), arising from 1.3- and 2.2-kb transcripts, which contain the N-terminus and one or two intact Kringle domains, respectively, have been described (18–19). Although both variants were initially characterized as antagonists of HGF in vitro, in

transgenic models NK1 acts as a partial agonist, whereas NK2 acts as an antagonist for mitogenic activity (19–20).

HGF is produced by a number of cells of mesenchymal origin including fibroblasts, Kupffer cells, and ECs (21), as well as neutrophils, and cancer cells (22). HGF expression increases in various tissues, including liver, lung, and kidney, in response to tissue injury, and is implicated in tissue repair (21). HGF transcripts are expressed in vascular tissue of rats and humans in vitro and in vivo, including vascular smooth muscle cells (VSMCs) and ECs (23). Analysis of liver-cell populations has revealed that stellate cells are the major source of HGF production. In the lung, HGF also is produced by alveolar macrophages and vascular ECs (24).

### THE HGF RECEPTOR, c-MET

HGF binds with high affinity to its transmembrane receptor, c-Met, which belongs to a family of heterodimeric tyrosine kinases (25). The c-Met receptor tyrosine kinase (RTK) was originally identified as an oncogene activated in vitro after treatment of a human osteogenic sarcoma cell line with a chemical carcinogen, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (26). The human *c-Met* gene localizes to the chromosome 7 band 7q21–q31 and spans more than 120-kb in length, consisting of 21 exons separated by 20 introns. In wild-type cells, the primary c-Met transcript produces a 150-kDa polypeptide that is partially glycosylated to produce a 170-kDa precursor protein. This 170-kDa precursor is further glycosylated and then cleaved into a highly glycosylated extracellular 50-kDa  $\alpha$ -chain, and a 140-kDa  $\beta$ -chain consisting of a large extracellular region, a membrane-spanning segment, and an intra-

cellular tyrosine kinase domain. The  $\alpha$ - and  $\beta$ -chains are linked together by disulfide bonds (26).

### EVOLUTION AND DEVELOPMENT

From limited studies to date, the presence of homologues of c-Met is believed to be restricted to vertebrates, including various species of birds, rodents, reptiles, and fish. No equivalent c-Met homologues were found in worms or flies (27). The HGF/c-Met system appears to serve important functions during embryogenesis, by regulating epithelial and mesenchyme interactions (28). HGF/c-Met signaling has been implicated in the development of various tissues, including the nervous system, muscle, liver, and kidney (27). *HGF*-knockout mice display midterm embryonic lethality due to placental defects (29).

### c-MET SIGNAL TRANSDUCTION

c-Met is expressed in a variety of cells, including epithelial cells and ECs. The downstream signaling pathways activated by receptor–ligand interactions have been elucidated largely from studies in epithelial cells. The activation of signal transduction pathways in response to HGF stimulation is mediated in part by autophosphorylation of specific tyrosine residues within the intracellular region of c-Met (Figure 33.1). Autophosphorylation of tyrosines (Tyr<sup>1234</sup> and Tyr<sup>1235</sup>) located within the activation loop of the tyrosine kinase domain activates an intrinsic receptor kinase activity (27,30–31). Subsequent autophosphorylation of two C-terminal tyrosine residues (Tyr<sup>1349</sup> and Tyr<sup>1356</sup>) of c-Met activates

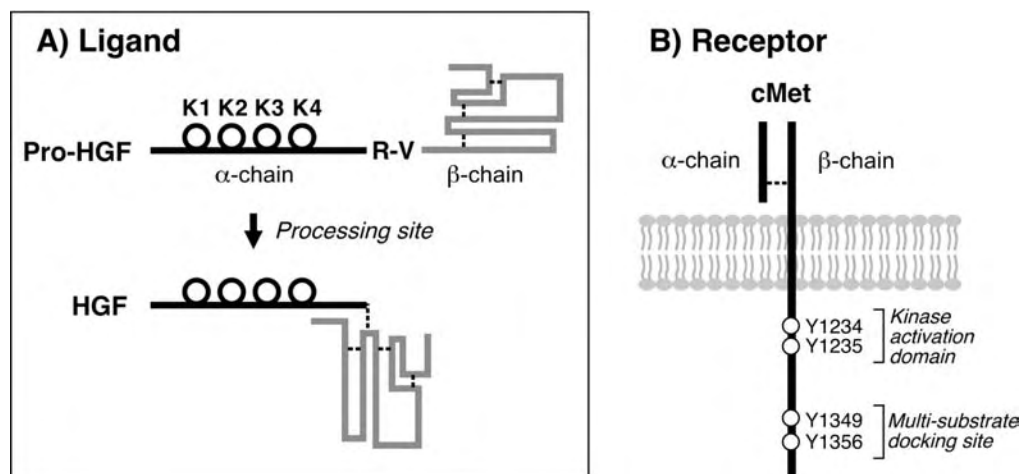

Figure 33.1. Scheme of HGF and receptor c-MET processing. HGF originates from a single-chain polypeptide precursor by proteolytic cleavage of the Arginine 494–Valine 495 peptide bond (R–V). Mature HGF consists of a disulfide-linked heterodimer of a 69-kD  $\alpha$ -subunit and a 34-kDa  $\beta$ -subunit. The  $\alpha$ -chain contains an N-terminal hairpin loop and four kringle domains, designated K1–K4. The HGF receptor c-Met originates from a glycosylated 170-kDa precursor that is cleaved into a highly glycosylated extracellular 50-kDa  $\alpha$ -chain, and a 140-kDa  $\beta$ -chain. The  $\alpha$ - and  $\beta$ -chains are linked together by disulfide bonds. Following stimulation with the ligand, c-Met is autophosphorylated at specific tyrosines (Tyr<sup>1234</sup> and Tyr<sup>1235</sup>) in the tyrosine kinase activation domain and (Tyr<sup>1349</sup> and Tyr<sup>1356</sup>) in the multisubstrate docking site.

Figure 33.2. Activation of the c-Met receptor. Activation of the c-Met receptor tyrosine kinase by binding of the ligand HGF leads to the recruitment of multiple adaptor molecules and activation of signaling pathways leading to functional effects on EC growth and motility as well as other pleiotropic functions.

a conserved multisubstrate docking site (32). Sequences surrounding Tyr<sup>1349</sup> and Tyr<sup>1356</sup> (Y<sup>1349</sup>VHVNATY<sup>1356</sup>VNV) in mouse c-Met form the docking site that binds Src homology-2 (SH2) domain-, phosphotyrosine binding (PTB) domain-, and the c-Met binding domain (MBD)-containing signal transducers (26,32).

The adapter protein Grb2 consists of an SH2 domain sandwiched between two SH3 domains and is well known for recruiting SOS to activated RTKs to induce Ras- mitogen-activated protein kinase (MAPK) signaling (Figure 33.2). In mouse c-Met, the amino acids surrounding phosphorylated Y<sup>1356</sup> (pY<sup>1356</sup>VNV) form a consensus SH2 binding site for Grb2 (pYXN) (33). Mutations in c-Met adjacent to the upstream tyrosine Y<sup>1349</sup> do not significantly affect Grb2 binding; however, mutations of Y<sup>1356</sup> or N<sup>1358</sup> disrupt the Met-Grb2 interaction. Although the Y<sup>1356F</sup> mutation in c-Met disrupts the association of several signal transducers (growth factor receptor-bound protein [Grb]2, phosphoinositide 3-kinase [PI3K], phospholipase C [PLC]- $\gamma$ , and SHP2), the N<sup>1358H</sup> mutation specifically disrupts the Met-Grb2 association. Grb2 also may be recruited to c-Met indirectly via the Shc adapter protein. The PTB domain of Shc can associate with the c-Met

receptor via phosphotyrosines Y<sup>1349</sup> and Y<sup>1356</sup>. Subsequent to c-Met activation, Shc is tyrosine phosphorylated and forms a Grb2 binding site (pY<sup>317</sup>VNV) that is similar to the Grb2 binding site of c-Met (pY<sup>1356</sup>VNV) (33). Therefore, activation of the Ras pathway in response to c-Met stimulation may be the result of the Shc-Grb2-SOS interaction.

Grb2 also has been implicated in recruiting the large adapter protein Grb2-associated binding protein-1 (Gab1) to the c-Met signaling complex. c-Met mutants that contain both Y<sup>1349</sup> and Y<sup>1356</sup> mutations are unable to associate with Gab1, whereas c-Met Y<sup>1356F</sup> mutants, in which Grb2 binding is eliminated, show significantly decreased Met-Gab1 association (27). Therefore, whereas Gab1 may preferentially bind c-Met via a Grb2 linkage, the ability of Gab1 to bind c-Met both directly using Y<sup>1349</sup>, and indirectly via a Grb2 linkage at Y<sup>1356</sup> may allow for a more specific and a higher-affinity interaction. After HGF stimulation, Gab1 becomes strongly tyrosine phosphorylated. Overexpression of Gab1 is sufficient to induce branching morphogenesis in some cell types. Gab1 binds to various signaling molecules including PI3K, PLC- $\gamma$ , and the SHP2 phosphatase (27). Although the p85 regulatory subunit of PI3K can associate directly with c-Met via the multi-substrate binding site, more PI3K activity coprecipitates with Gab1 than coprecipitates with c-Met, suggesting that PI3K, like PLC- $\gamma$ , associates primarily with Gab1 (27).

The adapter proteins of the Crk family consist of SH2 and SH3 domain(s). Gab1/c-Met contains multiple Tyr-X-X-Pro (YXXP) sequences that represent potential Crk family member SH2-binding sites. Both Crk and the related Crk-like (CRKL) proteins bind to phosphorylated Gab1 and thus add an array of signal transducers that become activated on HGF stimulation. Other downstream effectors of Crk include the c-jun N-terminal kinase (JNK). Crk family members can signal through Rac to activate JNK. Dominant-negative forms of Rac block c-Met-mediated JNK activation and raise the possibility of a Met-Gab1-Crk-Rac-JNK signaling pathway (34).

Two other important signal transducers, the Src kinase and the Stat3 transcription factor, also associate with c-Met following receptor activation (35). Src can associate directly with c-Met at Y<sup>1349</sup> and Y<sup>1356</sup>. Similar to other receptor systems, Src activation is important for HGF-mediated cell migration and cell transformation (35). In response to HGF/c-Met stimulation, Stat3 activation and subsequent nuclear translocation/gene transcription is required for branching morphogenesis (35).

#### THE EFFECTS OF HGF/c-MET SIGNALING ON ENDOTHELIAL CELLS

Many studies on HGF signaling have been performed in epithelial cells, which express the HGF receptor c-Met. However, recent studies indicate that HGF/c-Met also plays an important role in vascular cells. mRNAs corresponding to both HGF and c-Met have been detected in ECs and VSMCs of rats, as assessed by reverse transcriptase polymerase chain

reaction (RT-PCR) (23). *HGF* and *c-Met* mRNA also were detected in human aortic ECs (HAECs) and human VSMCs. Cultured ECs and VSMCs of both rat and human produce and secrete immunoreactive HGF (23).

### Scattering and Motility

HGF can promote the “scattering” of a variety of adherent cells, including epithelial cells and ECs, as defined by spatial separation or dissociation and movement in three-dimensional support matrices (36–38). By promoting scattering, HGF activates a cellular differentiation program called “branching morphogenesis,” whereby cells differentiate into branched, tube-like structures (39).

The process of cell scattering can be divided into three phases, namely cell spreading, cell–cell dissociation, and cell migration. Therefore, in order for epithelial cells to “scatter,” the attenuation or dissolution of cell–cell adhesions is required. Under normal conditions, the assembly and maintenance of intercellular junctions is tightly regulated. Disassembly of these junctions occurs during certain physiological and pathological conditions, such as normal development and tumor cell invasion and metastasis. Cell motility plays a key role in both normal physiology and various disease processes. Many studies have shown that HGF/*c-Met* signaling increases the motility of ECs. In bovine retinal microvascular ECs, HGF-induced cell scattering and motility and growth can be blocked by inhibiting protein kinase C (PKC), MAPK, and PI3K (40).

### Angiogenesis

The induction of angiogenesis (formation of new blood vessels) may be an important mechanism that permits tumor cell proliferation and eventually metastasis. Tumor-derived angiogenic factors lead to the growth of new capillaries with fragmented basement membranes, allowing tumor cells to more rapidly enter the circulation. Transfection of breast cancer cell lines with *HGF* cDNA increased tumor outgrowth when implanted into host animals. The increased growth rate of the HGF-transfected tumor cells was attributable to increased tumor angiogenesis (41).

HGF can act as a potent angiogenic molecule by acting directly on vascular ECs in vitro (37,42). HGF stimulation of vascular ECs promotes migration, proliferation, protease production, and invasion. HGF also promotes the expression of angiogenic factors such as vascular endothelial growth factor (VEGF) (43) and decreases the transcription and protein expression of vascular endothelial (VE)-cadherin in human ECs (44). Initial experiments on the angiogenic activity of HGF in vivo demonstrated that the implantation of rabbit corneas with purified HGF promoted neovascularization in vivo (38,45). In the rat diabetic ischemic hind limb model and in rat infarcted myocardium, HGF gene therapy improved blood flow by promoting angiogenesis (46,47). In such models, the proangiogenic effect of HGF was associated with activation of the transcription factor ETS (47).

### Proliferation and Apoptosis

Cell proliferation plays an important role in a variety of physiological processes, including embryogenesis, growth, and wound healing. HGF/*c-Met* signaling can affect both proliferation and apoptosis, depending on the cell context. HGF stimulates vascular EC growth in vitro and in vivo (48). The application of recombinant HGF reduced neointimal hyperplasia in an in vivo balloon injury model of the rabbit iliac artery, by promoting re-endothelialization (49). In cultured murine lung ECs, HGF inhibited hypoxia/reoxygenation-induced apoptosis by blocking both death receptor- (extrinsic) and mitochondria- (intrinsic) dependent pathways (50). Additionally, HGF exerts antiapoptotic action in ECs by modulating several antiapoptotic factors, including Flip and Bcl-X<sub>L</sub> (50).

### Invasion and Metastasis

Tumor cell metastasis requires neoplastic cells to interact with the extracellular matrix (ECM) and to break the barrier to the circulation. The critical event of invasion is the interaction of the neoplastic cell with the basement membrane, which is mainly composed of type IV collagen, laminin, and heparin sulfate proteoglycan. ECM degradation is a highly dynamic event requiring the production of proteinases, namely plasminogen activator and matrix metalloproteinase (MMP). HGF-mediated activation of *c-Met* has been strongly implicated in the promotion of invasion and metastasis through MMP activity in human ECs (51). An HGF-stimulated pathway involving MAPK signaling can upregulate the expression of the serine protease u-PA and its receptor (uPAR) (52), resulting in an increase of u-PA at the cell surface. Certain components of the ECM can be directly degraded by u-PA. More importantly, u-PA cleaves plasminogen into the broader-specificity protease plasmin, which is able to efficiently degrade several ECM and basement membrane components.

### Anti-inflammatory Effects

HGF inhibited the EC expression of the adhesion molecule E-selectin in human EC culture and in rats in response to tumor necrosis factor (TNF)- $\alpha$  treatment (53). The anti-inflammatory effect of HGF in a kidney model was associated with reduced E-selectin–mediated macrophage adhesion to the endothelium and reduced renal macrophage sequestration after TNF- $\alpha$  challenge (53).

## THERAPEUTIC IMPLICATIONS

In the context of tumorigenesis, downregulation *c-Met* has been implicated as a possible therapeutic strategy to reduce tumor cell migration and invasion (30,54–56). This may be achieved through pharmacological application of small-molecule inhibitor compounds, or antagonists such as the

artificial 4-Kringle HGF mutant NK4 (55) or, alternatively, by antisense/hammerhead ribozyme strategies, as illustrated by Davies and colleagues (56).

On the other hand, HGF can be beneficial in limiting tissue and organ damage in a number of models in which inflammatory and/or apoptotic processes are implicated in the injury. For example, HGF inhibits inflammation in various animal models of kidney disease (53). The proliferative effects of HGF on endothelium may be exploited for the treatment of vascular diseases (46,47,49). For example, application of recombinant HGF, which inhibits neointimal hyperplasia after balloon injury, may represent a possible therapeutic strategy for limiting restenosis after vascular injury (49). The proangiogenic effects of HGF in gene therapy approaches have potential therapeutic application in diabetes and myocardial injury (46,47).

#### KEY POINTS

- HGF, through its receptor c-Met, acts as a potent mitogen, motogen, and morphogen in a number of cell types, and plays important roles in EC growth, development, and angiogenesis.
- The mechanism(s) by which HGF/c-Met affect cellular proliferation, apoptosis, and cancer invasion/metastasis remain unclear.
- HGF, by activating its receptor tyrosine kinase c-Met, activates signaling pathways composed of multiple adaptor and effector molecules, including RAS-MAPK pathway, PI3K, and PLC- $\gamma$ .
- The elucidation of critical molecule(s) in HGF/c-Met-signaling pathways is important for understanding the biological function of HGF, and may lead to the development of antiapoptotic, anti-inflammatory, and antiproliferative strategies.
- Modulation of the HGF/c-Met system may have potential therapeutic implications in limiting tumor growth, in organ regeneration, and in the treatment of vascular ischemic diseases.

## Fibroblast Growth Factors

Masahiro Murakami, Arye Elfenbein, and Michael Simons

*Dartmouth Medical School, Hanover, New Hampshire*

### HISTORICAL BACKGROUND

The discovery of fibroblast growth factors (FGFs) in the 1970s arose from observations that a protein with a basic isoelectric point of 9.6, derived from bovine brain and pituitary gland, was able to induce morphological changes in BALB/c 3T3 fibroblast cells (1). Early limitations in purifying the growth factor led to the belief that the FGF derived from bovine brains was a component of myelin basic protein (2). This claim was countered by several reports of nonassociation between the two proteins (3,4), yet the definitive purification did not occur until 1984, when heparin Sepharose chromatography was used to effectively isolate FGFs (5). An acidic fibroblast growth factor (isoelectric point 5.6) was identified several years after the discovery of basic fibroblast growth factor (6–8).

In 1991, when seven FGFs had been identified, a nomenclature committee renamed aFGF and bFGF as FGF1 and FGF2, respectively (9).

### EVOLUTION

In *Caenorhabditis elegans*, two FGF genes (*egg laying defective 17* [*egl-17*] and *lethal-75* [*let-75*]), and one FGF receptor (FGFR) gene (*egl-15*) are identified. The fruit fly, *Drosophila melanogaster*, has three FGF genes, *branchless*, *pyramus*, and *thisbe* and two FGFR genes, *breathless* and *heartless*. Early in evolution, *Fgfs* have undergone a gene duplication expanding from two or three to six genes; thereafter, a second gene duplication occurred during evolution of the early vertebrates, resulting in 22 FGF genes in mice and humans (FGF1–23) (human *FGF15* and mouse *Fgf19* have not been identified in the genome, and mouse *Fgf15* and human *FGF19* are now thought to be orthologous genes [10]). In mice and humans, FGFs range in molecular weight from 17 to 34 kDa and share a conserved amino acid sequence derived from evolutionarily related FGF genes.

In contrast to FGF genes, the *FGFR* gene family has expanded only later in evolution. However, the acquisition of alternative splicing in *FGFRs* has greatly increased their func-

tional diversity, enabling the FGF system's involvement in a variety of biological processes (11). Phylogenetic analyses suggest that the FGF family can be arranged into seven subfamilies (Table 34-1). FGFs within a subfamily have similar receptor-binding properties, tissue expression patterns, and target preferences, possibly providing FGFs with wide functional redundancy.

### OVERVIEW OF FIBROBLAST GROWTH FACTORS

FGFs and their receptors comprise a multifunctional system, the biological effects of which encompass diverse physiological and pathological processes including embryonic development, angiogenesis, wound healing, tissue regeneration, and tumor development (Figure 34.1) (12–14). Most members of the FGF family have an amino-terminal signal peptide and are secreted from cells. Although FGFs 1, 2, 9, 16, and 20 lack signal sequences for processing through the endoplasmic reticulum–Golgi secretory pathway, they are found in the bloodstream, extracellular space, and at the cell surface, implying the existence of a noncanonical secretion pathway. FGF2-induced cell motility is efficiently blocked by addition of neutralizing FGF2 antibody in the culture medium, implying that FGF2 acts through an autocrine, not intracrine, mechanism to promote cell motility (15).

Some FGFs genes (*FGF2* and *FGF3*) transcribe high-molecular-weight isoforms using upstream, in-frame CUG start codons to create FGFs containing an amino-terminal nuclear localization signal (NLS). In the case of FGF1, a molecule that has only one mRNA form, the presence of an amino-terminal NLS ensures its nuclear association, and this sequence is thought to be required for its mitogenic effects (16); a putative second, carboxy-terminal NLS sequence also has been characterized recently for this molecule (17). The FGFs, originally presumed to be exclusive cell-surface ligands, now are understood to have a wider impact on cell signaling events from the cell surface to the nucleus.

Studies detailing the presence and activity of FGFs in the nucleus have revealed that FGFs endocytosed from the

**Table 34-1: FGF Family**

	<i>Receptor</i>	<i>Expression/Target</i>	<i>Function</i>
<b>FGF1 subfamily</b>			
FGF1	All FGF receptors	Mesenchymal, mesodermal, neuroectodermal, EC	Angiogenesis, wound healing, organogenesis
Acidic FGF			
ECGF			
HBGF-1			
FGF2	1b, 1c, 2c, 3c, 4	Mesenchymal, mesodermal, neuroectodermal, endothelial, epithelial cell	Angiogenesis, vasculogenesis, wound healing
Basic FGF			hematopoiesis, neurosurvival, limb and nervous system development, tumor development
HBGF-2			
<b>FGF4 subfamily</b>			
FGF4	1c, 2c, 3c, 4	Limb bud	Bone morphogenesis and limb development, angiogenesis
FGF5	1c, 2c	Hair follicle, primitive ectoderm	Hair growth inhibition
FGF6	1c, 2c, 4	Myogenic lineage	Muscle regeneration or differentiation
<b>FGF7 subfamily</b>			
FGF3	2b	Epithelial cell	Neoplastic transformation and tumor progression, inner ear formation
FGF7 KGF	2b	Keratinocyte Epithelial cell	Epithelial cell growth, morphogenesis of epithelium, reepithelialization of wounds, hair development, and early lung organogenesis.
FGF10	2b	Keratinizing epidermal cell	Embryonic epidermal morphogenesis, brain development, lung morphogenesis, and initiation of limb bud formation; wound healing
FGF22		Hair follicle-keratinocyte, cerebellum	Hair development (?), presynaptic differentiation
<b>FGF9 subfamily</b>			
FGF9	1c, 2c, 3b, 3c, 4	Neuron/glia cell, astrocyte	Motor neuron survival, testicular embryogenesis, lung development
FGF16	2c, 3c	Embryonic brown adipose tissue	Proliferation of embryonic brown adipose tissue
FGF20	1c, 2c, 3c	Normal brain, cerebellum	Survival of midbrain dopaminergic neurons
<b>FGF8 subfamily</b>			
FGF8	(1c), 2c, 3c, 4	Testes and ovaries, adult hindbrain, primitive streak	Midbrain and limb development, organogenesis, embryo gastrulation, and left–right axis determination; tumor growth and angiogenesis
FGF17	1c, 2c, 3c, 4	Cerebellum forebrain, mid-hindbrain junction, developing skeleton and arteries	Central nervous system, bone, and vascular development
FGF18	1c, 2c, 3c, 4	Developing bone	Neurite outgrowth proliferation of the liver and small intestine; skeletal development
<b>FGF11 subfamily*</b>			
FGF11		Neurons	Nervous system development
FGF12		Neurons Developing heart and connective tissue	
FGF13		Neurons, developing heart	
FGF14		Neurons	
<b>FGF19 subfamily</b>			
FGF19	4	Fetal but not adult brain tissue, developing pharyngeal arches	Initiation of inner ear development, cardiac outflow tract alignment
FGF21		Liver	Glucose and triglyceride metabolism
FGF23	3c	Brain, thymus/renal proximal epithelial cell	Inhibits renal tubular phosphate transport

\*FGFs 11–14 (FHF, Fibroblast growth factor homologous factors) lack signal peptides, remain intracellular, and function within cells in a receptor-independent manner. FHF are known to bind to intracellular domains of voltage-gated sodium channels (VGSCs) and to a neuronal MAP kinase scaffold protein, islet-brain-2 (IB2) (106).

Figure 34.1. Schemata of FGF signaling. Active FGFs in the extracellular matrix exist in the monomeric form. They bind with high affinity to their tyrosine kinase receptors (FGFR1–4) and with lower affinity to heparan sulfate proteoglycans (HSPGs), such as syndecans and glypicans. FGF binding to FGFR and HSPG forms a ternary complex that involves the dimerization of FGFR and induces several parallel signaling events primarily through the cytoplasmic tails of FGFR, although certain HSPGs (including syndecan-4) also are able to signal. The complex is endocytosed, and evidence exists for subsequent recycling, degradation, or translocation to the nucleus. The differential effects of nuclear and extracellular FGFs remain incompletely elucidated, as do the roles of nuclear versus cytoplasmic FGF signals in cell proliferation, survival, and migration.

extracellular space, including those lacking a NLS, partially accumulate in the nucleus (18). Whether that results in signaling has not been determined to date. Early insights into the intracellular effects of FGFs were provided by observations that high-molecular-weight FGF2 enables cell survival under low serum conditions irrespective of a functional FGF receptor (19,20). This finding lends credence to the notion that FGFs can signal via an intracrine pathway (perhaps promoting cell survival) that is independent of classically defined FGF pathways.

More recently, low-molecular-weight FGF2 has been shown by nuclear fractionation to activate casein kinase-2, a nuclear protein that modulates cell proliferation, in the cytoplasm and in the nucleus (21). FGF accumulation in the

nucleus also appears to be regulated in a cell cycle-specific manner (22,23). Finally, the nuclear effects of FGFs extend beyond the vascular system, exemplified by the recent observation that tumor cells expressing high-molecular-weight FGF2 have a metastatic advantage over those expressing low-molecular-weight FGF2 (24).

FGFs are broad-spectrum mitogens and stimulate various cellular functions including migration, proliferation, and differentiation (25,26). Some FGFs, especially FGF2, are recognized as cell survival factors that block apoptosis in many cell types, including endothelial cells (ECs) (27). Although it is reported that human umbilical vein ECs express FGF1, 2, 5, 7, 8, 11, 12, 16, and 18 *in vitro* (28), the angiogenic potential of most FGFs is not well characterized. ECs are one of the main

target cell types for FGFs, especially for “angiogenic FGFs” (FGF1, 2, and 5) that have been shown to promote new blood formation *in vivo* and to bind FGFR1IIIc.

The expression patterns of FGFs vary considerably, ranging from nearly ubiquitous (FGF2) to highly restricted within particular cell subsets at specific developmental stages (FGF3, 4, 8, 17, and 19). FGF3, for example, plays a role in mesoderm induction, whereas FGF8 is associated with limb, central nervous system, and cardiac outflow development.

In pathological conditions, the expression of some FGFs is upregulated in inflammatory and angiogenic tissues, including healing wounds and tumors. The cellular sources of FGFs in these settings are thought to be mainly tissue macrophages, ECs, stromal cells, and tumor cells (13).

Several FGFs have been identified as oncogenes by their transforming capacity, and involvement of the FGF system is implicated in the tumorigenesis of several common human cancers including breast, prostate, skin, urothelial, and hematological malignancies (29). In murine mammary cancer, some FGFs are associated with proviral insertions of the mouse mammary tumor virus (MMTV) (30). A detailed analysis of proviral integration sites identified virally activated proto-oncogenes that include members of the *Wnt* and *Notch* gene family and three members of the *Fgf* family: *Int-2/Fgf-3*, *hst-1/Fgf-4*, and *Fgf-8*. Expression of FGF4 (HST) has been reported in human testicular germ cell tumors, including seminomas and embryonal carcinomas (31).

#### FIBROBLAST GROWTH FACTOR SECRETION AND ENDOCYTOSIS

Beyond their role in FGF signaling, heparan sulfate proteoglycans (HSPGs) in particular have been implicated in the process of FGF endocytosis and subsequent nuclear localization (18). Of the HSPGs, syndecans (32) and perlecan (33) have been individually implicated as critical mediators of FGF endocytosis via a ternary complex involving the FGF receptor. Endocytosis of FGF in association with its tyrosine kinase receptors also has been shown to be a requisite step in nuclear translocation. This has been reported to occur in conjunction with the concomitant endocytosis of E-cadherin, a protein most concentrated in the adherent junctions of epithelial cells (34).

Our understanding of FGF signaling complexes and their connection to FGF endocytosis remains relatively tenuous, particularly in the distinction between the effects of FGFs in the nucleus and their classically defined role in tyrosine kinase activation. In addition, FGFs have been shown to localize to the lipid rafts (35) following internalization. It is, therefore, possible that lipid rafts serve to concentrate FGFs and enhance signaling.

FGF release into the extracellular milieu remains an incompletely characterized process, although it has become apparent that FGF secretion likely involves nonclassical routes of export. Of the FGF family, FGF1 and FGF2 secretion has been studied most thoroughly, yet their respective paths from

the cellular cytosol to the outside are entirely unrelated. For example, the release of FGF1 can be induced by particular conditions of stress, including heat shock, which does not affect the secretion of FGF2 (36,37). Likewise, FGF2 secretion is diminished by inhibitors of Na<sup>+</sup>/K<sup>+</sup> ATPase (38), whereas FGF1 release is not similarly affected (39). FGF1 is secreted as a covalently linked homodimer, a state that confers a low heparan-binding affinity on the molecule (40). Consequently, it has been hypothesized that FGF dimer secretion requires an additional step to activate the growth factor in the extracellular space.

Although both FGF1 and FGF2 are presumed to be secreted via translocation across the cell membrane (41,42), plasma membrane-derived exovesicles containing FGF2 also have been isolated (43). It is therefore unclear whether FGFs are released via specific transporters or through vesicular shedding, although in the case of FGF1, the formation of a protein release complex under the plasma membrane argues against intravesicular involvement (41). As in the case of FGF endocytosis and signaling, cell-surface HSPGs have been associated with FGFs undergoing secretion, and they appear to be critical in establishing the complexes required for the FGF release (44).

#### FIBROBLAST GROWTH FACTOR INTERACTION WITH FIBROBLAST GROWTH FACTOR RECEPTORS

FGFs produce their biological effects in target cells in part by signaling via cell-surface tyrosine kinase receptors and in part—at least in the case of FGF2, but probably other FGFs as well—via syndecan-4, a membrane-spanning HSPG (45,46). Four known high-affinity receptors exist for FGFs, FGFR1 through FGFR4. These share 55% to 72% amino acid sequence identity. FGF receptors are transmembrane proteins containing two or three extracellular immunoglobulin (Ig)-like domains, a heparin-binding motif, a transmembrane domain, and intracellular tyrosine kinase domains.

Through alternative splicing, FGFR can produce numerous isoforms. Although the functional significance of every splice variant is not fully understood, of particular importance is the splicing of the carboxy-terminal half of the Ig domain III, with the exception of FGFR4, which determines the binding specificity for different FGFs. As a result of this splicing event, IIIa through IIIc isoforms are generated. Whereas IIIb and IIIc isoforms are type I transmembrane receptor tyrosine kinases, the IIIa splice variant encodes a truncated protein that, because it is secreted and not a transmembrane protein, cannot independently transduce extracellular signals, although it may act to sequester released FGFs and inhibit FGF signaling. This alternative splicing event is regulated in a tissue-specific manner and dramatically affects ligand-receptor binding specificity (47). The expression of the IIIb form is restricted to epithelial lineages, whereas the IIIc form is mainly expressed in mesenchymal lineages. In ECs, the major form of the FGF

receptor is considered to be FGFR1IIIc. However, the expression of the R2IIIc and R3IIIc forms also has been reported (28), with an *in vitro* observation demonstrating that FGFR2 signaling in ECs only contributes to motility through the mitogen-activated protein kinase (MAPK) pathway (48).

#### FIBROBLAST GROWTH FACTOR INTERACTION WITH HEPARIN SULFATE PROTEOGLYCAN

In addition to tyrosine kinase FGFR, the highly complex glycosaminoglycan heparan sulfate has been shown to be critical for FGF function. FGFs' binding to heparan sulfate stabilizes FGFs in the extracellular space and facilitates their binding to FGF receptors, resulting in the formation of dimers and higher-order oligomers. FGFs fail to bind and activate FGFR in cells lacking endogenous heparan sulfate (49,50). Structural studies suggest that heparan sulfate forms a ternary complex with FGF and FGFR by binding to a groove formed by the heparan-binding sites of both the ligand and the receptor (51). The oligosaccharide sequence needed to generate a mitogenic signal with FGF2 appears to require both 2-*O*-sulfated iduronic acid and 6-*O*-sulfated *N*-acetylglucosamine groups (52).

Independent of FGF tyrosine kinase receptors, syndecan-4 can transmit a signal via its cytoplasmic tail in response to FGF2 by activating protein kinase  $C\alpha$  (PKC $\alpha$ ) and potentially other intracellular signaling cascades (45,53). FGF tyrosine kinase signaling is probably not required for these events, but there clearly is a poorly understood interplay between the FGFR and syndecan-4 signaling pathways. The importance of heparan sulfates in FGF2 signaling is such that cellular responsiveness to FGF2 is diminished by the removal of syndecan-4 heparan sulfate chains (46).

#### FIBROBLAST GROWTH FACTOR RECEPTOR SIGNALING

The activation of FGFR leads to phosphorylation on tyrosine residues of FRS2 that in turn results in its binding to FGFR (54). FRS2 serves as a docking protein for the assembly of a signaling complex that includes Grb2, Gab1, and Shp2. This complex recruits the guanine nucleotide exchange factor SOS, through binding to Grb2, and activates Ras, resulting in the activation of MAPK pathways (extracellular signal-regulated kinase [ERK]1/2, p38, c-jun N-terminal kinase [JNK]) (55). FGFR also can activate phospholipase C (PLC)- $\gamma$ , thereby stimulating production of diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP<sub>3</sub>). In turn, this releases intracellular calcium and activates Ca<sup>2+</sup>-dependent PKC (56). However, the functional significance of this pathway is not yet established. Although the MAPK (ERK1/2) pathway is considered to be involved in stimulation of proliferation, p38 and JNK MAPKs are generally associated with inflammatory or stress responses (57). In ECs, p38 MAPK seems to act as an essential mediator

of FGF activity. It is involved in the FGF2-induced tubular morphogenesis of ECs by negatively regulating EC survival, proliferation, and differentiation. Interestingly, inhibition of p38 MAPK increases tube formation, decreases apoptosis, and stimulates DNA synthesis with the concomitant induction of Jagged1 expression (58).

The activation of the phosphoinositide 3-kinase (PI3K)-Akt cell survival pathway seems to be one of the important biological responses induced by FGF2 in ECs. In addition to promoting MAPK pathways, Grb2 recruits the docking protein Gab1, which is tyrosine phosphorylated by FGFR, leading to the recruitment and activation of PI3K (59). Other signaling molecules involved in FGF-driven angiogenesis, especially cell migration and tubulogenesis, are members of the Src kinase family (60,61).

Membrane-associated gangliosides recently have been implicated as modulators of various receptor tyrosine kinases by regulating their ligand binding, receptor dimerization, and receptor subcellular localization (62). FGF interacts directly with a ganglioside (GM1) (K<sub>d</sub> = 3 nM), and FGFR activity is inhibited by both GM3 and GM1. Although it was initially thought that gangliosides can be competitive inhibitors of FGF, a recent study has demonstrated that exogenously added GM1 can restore the ability of heparin sulfate-deficient cells to respond to FGF2 (63). This suggests that gangliosides can act as a functional FGF coreceptor, by presenting FGF to its receptor in a way analogous to that of HSPGs.

Regulation of the FGF signaling system includes feedback systems by which FGF signaling is subjected to fine tuning through a negative or positive feedback loop (64). Members of the Sprouty (Spry), Sef, and MAPK phosphatase families are negative modulators of FGF signaling, whereas positive regulators that promote FGF signaling include the Ets transcription factors Erm and Pea3, low-molecular-weight protein tyrosine phosphatase (LMW-PTP) (65), and the transmembrane protein XFLRT3 (66). Although Spry is thought to be a general inhibitor of Ras-MAPK signaling, it behaves differently depending on the receptor tyrosine kinase that is activated. Overexpression of Spry-1 or Spry-2 in ECs inhibits FGF- or vascular endothelial growth factor (VEGF)-induced proliferation and differentiation by repressing the MAPK pathway.

#### FIBROBLAST GROWTH FACTOR AND VASCULAR FORMATION

Although the ability of FGFs to promote angiogenesis *in vitro* is well established, the degree of FGF contribution to angiogenesis *in vivo* is a more complex issue. In the former case, many studies have shown that various FGFs, including FGF2, stimulate EC chemotaxis and proliferation. In addition, FGFs also can induce ECs to invade a three-dimensional collagen matrix and organize themselves to form characteristic tubules that resemble blood capillaries (67).

However, the demonstration of angiogenic properties of FGFs *in vivo* has been more challenging. Unlike FGFR, it is

possible to knockout many individual FGFs without lethality and, in fact, with little impact. Although FGF1 and FGF2 are known to induce new capillary formation in various *in vivo* angiogenesis models, *Fgf2*<sup>-/-</sup> mice demonstrate a mild delay in wound repair (68), but no alteration in the vessel repair following mechanical injury (69). Moreover, the double knockout of FGF1 and FGF2 failed to show abnormalities in angiogenesis, leaving the distinct role of FGF1 or FGF2 in the vascular development unclear (70). Because FGFs, especially within each subfamily, have similar receptor-binding properties and overlapping patterns of expression, these results may be explained by a functional redundancy of the FGF system.

Although the importance of the FGF system in embryonic development, especially in organogenesis and limb genesis, is well established, its role in vascular system development is much less well understood. The embryonic vasculature forms via a combination of vasculogenesis and angiogenesis. The term *vasculogenesis* refers to the segregation, migration, and assembly of angioblasts (EC precursors) from the mesoderm into the primary vascular plexus, whereas *angiogenesis* refers to the sprouting growth of capillaries from this primary plexus.

*Fgfr1* knockout studies demonstrate that FGF signaling is essential for mesodermal patterning; however, a study using embryoid bodies (EBs) showed that VEGF-induced vascular development is independent of FGFR1, as demonstrated by the induction of capillaries by VEGF-A in the *Fgfr1*<sup>-/-</sup> EBs, contrasting with the results from the *Vegfr2*<sup>-/-</sup> EBs, in which the vascular development was completely arrested (71). Although FGF2 appears to play an important role in the development of the hemangioblast, the common progenitor of hematopoietic and ECs (72), and FGFR1 is expressed by a subpopulation of hematopoietic progenitor cells that give rise to endothelial progenitor cells (73), the expression of FGFR1 in EC precursors does not seem to be required for vascular development. In contrast, hematopoietic development is severely disturbed by the inactivation of FGFR1, with reduced expression of markers for primitive and definitive hematopoiesis (74).

FGF2 bead implantation in somites can induce angioblast differentiation in the epithelial somite, whereas beads lateral to the somitic mesoderm induce the formation of ectopic vessels, which suggests that FGF2 plays a role in the induction of angioblasts and their assembly into the initial vasculature (75). Furthermore, expression of dominant-negative FGFR, capable of blocking the signaling of all FGFRs, in the vasculature of embryonic day (E)9 mouse embryos leads to disrupted embryonic and extraembryonic vasculature (76).

FGF2 appears to promote collateral vessel development (arteriogenesis), which is thought to occur by the growth and remodeling of the preexisting arteries and by *de novo* arterIALIZATION of the capillary network (77). The initiation of arteriogenesis does not seem to be associated with an increased expression of VEGF or hypoxia-inducible genes such as hypoxia-inducible factor (HIF)-1 $\alpha$ , and the speed of collateral development is not accelerated by infusion of VEGF (78). Both angiogenesis and collateral vessel development can occur in the heart as compensatory processes in ischemic heart

disease. An upregulation of the FGF system in collateral development has been reported recently (79), raising the possibility that it plays a role in the process. In support of this hypothesis is the observation that transgenic myocardial expression of FGF1 in mice results in increased vascular branching and coronary arterial density, whereas the capillary density is unchanged (80). In a canine model of myocardial infarction, the administration of FGF2 enhances collateral development, an effect that is not observed in VEGF-treated animals (81). Moreover, administration of FGF2 in a gradual coronary occlusion model in pigs results in increase of coronary flow and reduction in infarct size in the compromised territory, leading to an improvement of cardiac function (82,83).

FGF4 and FGF5 also have been reported to induce neovascularization in experimental animal models of ischemia. The FGF4-mediated response consists mainly of the enlargement of preexisting vessels rather than an increase in capillary density. Adenovirus-mediated FGF4 expression upregulates endogenous VEGF, which may be associated with an increase in vascular permeability (84). In a model of myocardial ischemia, the intracoronary injection of recombinant adenovirus expressing FGF5 was reported to improve regional abnormalities in stress-induced function and blood flow (85).

FGF2 in combination with another angiogenic factor, platelet-derived growth factor (PDGF)-BB, administered in a protein form, synergistically induces vascular networks, which remain stable for more than a year even after depletion of angiogenic factors. The coordination of FGF2 and PDGF-BB appears to enhance both endothelial and vascular smooth muscle cell survival, conferring vascular stability after the withdrawal of growth factors (86). Interestingly, this effect is not observed with combinations of FGF2 and VEGF or PDGF-BB and VEGF.

The evidence implicating FGFs' ability to induce angiogenesis and collateral vessel growth, bolstered by some favorable results in animal studies of myocardial ischemia and peripheral arterial diseases, provides ample motivation to further investigate the functional roles of the FGF system *in vivo* and pursue clinical applications of FGFs as regulators of vascular formation.

## FIBROBLAST GROWTH FACTOR AND VASOMOTOR REGULATION

Nitric oxide (NO) production plays a critical role in mediating vascular remodeling and vasomotor control of collateral vessels following obstruction of the main arterial supply (87).

FGF2 is a potent inducer of NO production and can induce vasodilation of both normal and collateral vessels *in vitro* and *in vivo* (88–90). The vasodilation induced by FGF is not observed in endothelium-denuded vessels or following pretreatment with L-NMMA, an inhibitor of NO synthesis, implying that FGFs modulate blood flow by acting on the endothelium of arteries in an NO-dependent manner

**Table 34-2: FGF Knockout Mice**

<i>Gene</i>	<i>Survival of Null Mutant</i>	<i>Phenotype</i>	<i>References</i>
<i>Fgf1</i>	Viable	None identified	70
<i>Fgf2</i>	Viable	Delayed wound healing, neuronal abnormalities, reduced hypertrophic response in heart, hypotension, decreased vascular smooth muscle contractility	68,69,107–109
<i>Fgf3</i>	Lethal, P0*	Mild inner ear and tail abnormalities	110
<i>Fgf4</i>	Lethal at E4–5	Arrest of growth of inner cell mass	111
<i>Fgf5</i>	Viable	Abnormally long hair	112
<i>Fgf6</i>	Viable	Normal, accelerated differentiation in regenerating muscle	113–115
<i>Fgf7</i>	Viable	Hair follicle growth, ureteric bud growth, fewer nephrons	116,117
<i>Fgf8</i>	Lethal at E7	Gastrulation defect, defects in CNS and limb development	118,119
<i>Fgf9</i>	Lethal, P0	Lung hypoplasia, XY sex reversal	120,121
<i>Fgf10</i>	Lethal, P0	Developmental defects of multiple organs, including limb, lung, thymus, pituitary, and prostate	122–125
<i>Fgf11</i>	NA		
<i>Fgf12</i>	Viable	Disturbed neuromuscular functions	12,106
<i>Fgf13</i>	NA		
<i>Fgf14</i>	Viable	Neurological phenotypes including ataxia and paroxysmal dyskinesia	126
<i>Fgf15</i>	Lethal at E12.5	Malalignment of aorta and pulmonary trunk	10,127
<i>Fgf16</i>	NA		
<i>Fgf17</i>	Viable	Disturbed cerebellar development	128
<i>Fgf18</i>	Lethal, P0	Delay of osteogenic differentiation, impairment of lung alveolar development	129,130
<i>Fgf20</i>	NA		
<i>Fgf21</i>	NA		
<i>Fgf22</i>	NA		
<i>Fgf23</i>	Viable**	Hyperphosphatemia and impaired skeletogenesis	131

CNS, central nervous system; NA, not available.

\*Most of the homozygous mutants die at or soon after birth, but several have survived to adulthood.

\*\*Death at week 13 is observed.

(91,92). The mechanisms underlying FGF-induced NO production seem to involve PKC $\alpha$ . PKC $\alpha$  stimulates NO production by activating endothelial NO synthase (eNOS) (by increasing eNOS phosphorylation at Ser<sup>1179</sup>) in ECs. The overexpression of PKC $\alpha$  in rat femoral arteries results in a significant increase in the resting blood flow (93).

FGF2 is thought to function in the regulation of normal vascular tone. *Fgf2*-knockout mice, although morphologically normal, display decreased vascular smooth muscle contractility, low blood pressure, and thrombocytosis (69). Although

the mechanism of hypotension is not clear, it is thought to be of central origin.

#### KNOCKOUT STUDIES

In striking contrast to the early lethality of both *Fgfr1*- and *Fgfr2*-knockout mice (94–96), the disruption of individual FGF genes in general presented much milder phenotypes, implying possible functional redundancy occurring between

**Table 34-3: FGFR Knockout Mice**

<i>Gene</i>	<i>Mutation</i>	<i>Phenotype</i>	<i>References</i>
<i>Fgfr1</i>	Disruption/null	Growth retardation, defect of mesodermal patterning lethal at E7.5–9.5	94,95
	<i>Fgfr1</i> <sup>-/-</sup> ES chimeras	Defective cell migration through primitive streak, malformation of chimeric limb buds	133,134
	Disruption of $\alpha$ (three-Ig domain) isoform	Distal truncation of limb bud, lethal at E9.5–12.5 due to posterior embryonic defects	135
	Disruption of IIIb	Homozygous mutant mice appeared normal at weaning	136
	Disruption of IIIc	Gastrulation defects	136
	Cartilage/Col2a1-Cre	No obvious defects	137
	Telencephalon/Foxg1-Cre	Malformation of olfactory bulbs	138
	Mid- and hindbrain/En-Cre or Wnt-Cre	Cerebellar and midbrain defects, ataxia	139
	Radial glial lineage/hGFAP-Cre	Hippocampal atrophy	140
<i>Fgfr2</i>	Deletion/null	Lethal at E4.5–5.5; tetraploid rescued embryos show abrogated limb outgrowth and lung development	96,141
	Deletion of IIIb and IIIc	Failure of limb bud initiation and placenta formation lethal at E10.5; tetraploid rescued embryos die at birth without limbs	142,143
	Deletion of IIIb	Agenesis or severe dysgenesis of multiple organs; lethality at birth	144
	Deletion of IIIc	Delayed ossification in the sphenoid region of the skull base, dwarfism in the long bones and axial skeleton	145
	Osteoblast and chondrocyte/Dermo1-Cre	Skeletal dwarfism and decreased bone density	146
	Ureteric bud/Hoxb 7-Cre	Aberrant ureteric bud branching and stromal mesenchyme patterning	147
	Lens/Le-Cre	Impaired lens terminal differentiation, increased apoptosis in lens epithelial cells	148
<i>Fgfr3</i>	Disruption/null	Bone overgrowth and deafness (inner ear defect)	149,150
<i>Fgfr4</i>	Disruption/null	Morphologically normal; decrease of liver function (depleted gallbladders, elevated bile acid pool, and excretion of bile acids)	151,152
<i>Fgfr3/Fgfr4</i>	Cross of FGFR3 and FGFR4 mutants	Dwarfism, lung abnormalities	151

FGFs. FGF knockout studies available to date are summarized in Table 34-2. FGFR knockout studies are summarized in Table 34-3.

### THERAPEUTIC APPLICATIONS

The possible involvement in all three forms of vascular growth – namely vasculogenesis, angiogenesis, and arteriogenesis – positions FGFs as potential therapeutic agents to promote vascular growth in conditions such as ischemic heart

disease and peripheral artery disease. Despite the angiogenic potential seen in animal models, intracoronary delivery of FGF2 protein has failed to provide clear-cut evidence of therapeutic effectiveness, as measured by long-term symptomatic improvement in patients with severe ischemic heart disease. This suggests that the time of exposure and the mode of delivery may be key elements for the success of the therapeutic use of the growth factor (77,97).

In contrast to the single bolus injection, polymer-released FGF2 implanted at the time of coronary artery bypass surgery in the unvascularized myocardium demonstrated a

reduction in the size of the ischemic defect and symptoms after 90 days in the high-dose FGF2 group when compared with the low-dose FGF2 and placebo group (98).

The attempts at FGF gene therapy have not been successful to date. Intracoronary infusion of adenovirus encoding FGF4 in patients with chronic stable angina showed a trend toward increased exercise duration and improved myocardial ischemia in small early studies (99), but a large double-blind, randomized trial failed to show benefits (T. Henry, ACC 2005 presentation).

Moreover, because FGFs are multifunctional, with the ability to modify many biological processes, additional therapeutic applications are being investigated. FGFs are involved in tissue protection by activating antiapoptotic pathways, and in tissue repair after ischemic, metabolic, or traumatic injury (100). After ischemic injury, FGF2 is able to influence neurogenesis in the hippocampus and enhance skeletal muscle regeneration (101,102). Independent of its angiogenic effect, FGF2 recently has received considerable attention with respect to its cardioprotective potential (103).

FGF7 and FGF20 are known to enhance the regenerative capacity of epithelial tissues and protect them from a variety of harmful exposures, such as chemotherapy and radiation for cancer treatment. Clinical trials that treat patients with oral mucositis resulting from chemoradiotherapy for hematologic malignancies demonstrated that FGF7 significantly reduced both the incidence and duration of severe oral mucositis (104).

Targeting the FGF system for inhibition of angiogenesis has a therapeutic potential in cancer, on the premise that tumor progression in general is angiogenesis-dependent. However, increasing evidence suggests that FGFs play crucial roles in tumors of the prostate, bladder, kidney, and testis in a manner independent of their angiogenic effect (105). Other diseases, such as diabetic retinopathy and rheumatic arthritis, also characterized by excessive neovascular formation, are good targets for antiangiogenic therapy. Inhibitors that can be used in the antiangiogenic therapy include endogenous inhibitors, chemical inhibitors, neutralizing antibodies, and soluble receptors.

#### KEY POINTS

- The FGF system is a multifunctional signaling system that has diverse biological activities in early embryonic development, organogenesis, and postdevelopmental pathophysiology.
- FGFs stimulate endothelial proliferation, migration, and differentiation through cell surface tyrosine kinase receptors and syndecan-4. HSPG is an essential component for FGF binding to FGFR and subsequent signaling events. Although FGFs act in an

autocrine manner, high-molecular-weight FGFs that contain NLS and endocytosed FGFs accumulate in the nucleus, with increasing evidence of distinct functional properties.

- FGFs are widely viewed as angiogenic factors; however, their involvement in the processes of vascular formation also may include vasculogenesis and arteriogenesis. Beyond their role in vascular formation, FGFs' participation in vascular tone control, tissue regeneration, tissue protection, and tumor progression also is recognized.

#### Future Goals

- To identify and characterize (a) the secretory pathway of FGFs that lack signal peptides, (b) the function of high-molecular-weight FGFs and nuclear-localized FGFs, (c) the role of individual FGFs, (d) the detailed signaling mechanism of the FGF system, (e) the role of the FGF system in the postdevelopmental physiology and pathology
- To undertake, in the therapeutic angiogenesis, further investigation to understand critical issues for successful therapy: identification of the most effective delivery approach, proper selection of patients, timing and dosage of the angiogenic factor
- To answer the fundamental question: Is augmentation of neovascularization by a single protein or gene in the ischemic tissue a scientifically rational approach?

## Transforming Growth Factor- $\beta$ and the Endothelium

Barbara J. Ballermann

*University of Alberta, Edmonton, Canada*

The discovery that mutations in the genes encoding two endothelium-restricted transforming growth factor (TGF)- $\beta$  receptors – endoglin (1) and activin-like kinase 1 (ALK1) (2) – account for most, if not all cases of the human vascular disorder hereditary hemorrhagic telangiectasia (HHT) (3) firmly established the significance of direct TGF- $\beta$  signaling in endothelial cells (ECs) and in vascular development. Indeed, embryonically lethal vascular phenotypes result from homozygous deletions in no less than eight components of the TGF- $\beta$  signaling system, namely TGF- $\beta$ 1 (4), ALK1 (5), endoglin (6), ALK5 (7), TGF- $\beta$  receptor II (T $\beta$ RII) (8), Smad5 (9), TGF- $\beta$ -activated kinase (TAK)-1 (10), and furin (11) (Table 35-2). TGF- $\beta$ s are key regulators of three-dimensional blood vessel structure, site-specific EC differentiation, and interactions between ECs and their immediate microenvironments. TGF- $\beta$  and other superfamily members, influence ECs through direct activation and through stimuli that result in the release of endothelium-directed mediators from neighboring cells. Moreover, TGF- $\beta$ -elicited EC-derived signals stimulate recruitment and differentiation of pericytes and vascular smooth muscle cells (VSMCs). TGF- $\beta$  pathway activation is necessary for endothelial–mesenchymal transdifferentiation during formation of the cardiac cushion and, consequently, the cardiac valves. TGF- $\beta$  derived from ECs regulates the phenotype of surrounding VSMCs.

More than 40 members of the TGF- $\beta$  superfamily (12), which includes TGF- $\beta$ 1, TGF- $\beta$ 2, TGF- $\beta$ -activated kinase (TAK)-1 and TGF- $\beta$ 3, activins, bone morphogenetic proteins (BMPs), growth differentiation factors (GDFs), inhibin, and muellerian inhibitory substance (MIS), have been identified so far. Pathways for TGF- $\beta$ s, BMPs, and activins, all known to stimulate ECs, are shown in Table 35-1. For all TGF- $\beta$  superfamily ligands, the signaling cascade is triggered by activation of transmembrane receptor serine threonine kinases, causing downstream phosphorylation and activation of Smad signaling molecules, which then translocate to the nucleus to induce or inhibit the transcription of a large number of genes (13). A remarkable array of regulatory molecules and path-

ways (Table 35-1), including ligand traps, ligand enhancers, inhibitory pseudoreceptors, inhibitory Smads, and the regulated activation of the TGF- $\beta$ s, control the location, timing, and degree of activation of these cascades. This chapter emphasizes those components of the TGF- $\beta$  signaling systems that directly or indirectly influence EC functions. A complementary chapter (Chapter 122) focuses on the clinical syndrome associated with loss of TGF- $\beta$  signaling via ALK1 in ECs, HHT.

### TRANSFORMING GROWTH FACTOR- $\beta$ ACTIVATION AND LIGAND TRAPS

#### Activation

All ligands in the TGF- $\beta$  superfamily are produced as propeptides processed by furin-like convertases that cleave mature disulfide-linked homodimeric ligand from the propeptide (Figure 35.1). In the vasculature, the unprocessed pro-TGF- $\beta$  can be secreted and then processed by extracellular furin. Extracellular processing in turn is regulated by the inhibitory action of emilin, a cysteine-rich secreted glycoprotein expressed in the vascular tree (14). In the case of TGF- $\beta$ 1, -2, and -3, once processed, the cleaved homodimer remains noncovalently bound to its own N-terminal propeptide domain, referred to as latency-associated peptide (LAP), rendering the TGF- $\beta$  ligand incompetent to bind to receptor (15) (see Figure 35.1).

Cells release TGF- $\beta$  bound to LAP either as the small latent complex (SLC) or alternatively bound via LAP to latent TGF- $\beta$  binding protein (LTBP) as the large latent complex (LLC) (16). The LAP in the LLC inhibits TGF- $\beta$  activity, whereas the LTBP orchestrates localization of the LLC to specific sites in the extracellular matrix (ECM) and also facilitates activation (see Figure 35.1). Four distinct LTBP genes exist (*LTBP-1* through *LTBP-4*), each capable of giving rise to alternatively spliced short and long transcripts, producing proteins that differ at the C-terminus. Based on *in silico* analysis of serial analysis of gene expression (SAGE) libraries, all LTBPs are expressed

**Table 35-1: TGF- $\beta$  Superfamily Signaling Pathways**

TGF- $\beta$ Cytokine Group Pathway	TGF- $\beta$ s			Activins			Bone Morphogenetic Proteins		
	I	II	III	IV	V	VI	VII		
Type I receptor	ALK1*	ALK5	ALK5	ALK4	ALK3, -6	ALK3, -6	ALK2		
Type II receptor	T $\beta$ RII	T $\beta$ RII	T $\beta$ RII	ActRII, ActRIIB	BMPRII	BMPRII	ActRIIB		
Type III coreceptor	Endoglin*	Endoglin*	Betaglycan	Betaglycan	DRAGON				
Agonist ligand	TGF $\beta$ -1, -3	TGF $\beta$ -1, -3	TGF $\beta$ -1, -2, -3	Activin A	BMP-2, -4	BMP-7	BMP-4, GDF5		
Propeptide ligand trap	LAP	LAP	LAP						
Matrix targeting molecule	LTBP-1, -3, -4	LTBP-1, -3, -4	LTBP-1, -3, -4	LTBP-1					
Physiological ligand activator	Tsp-1 Plasmin?	Tsp-1 Plasmin?	Tsp-1 Integrin $\alpha$ V $\beta$ 6						
Secreted ligand trap	Decorin Biglycan $\alpha$ 2-M	Decorin Biglycan $\alpha$ 2-M	Decorin Biglycan $\alpha$ 2-M	Follistatin $\alpha$ 2-M	BMPER* Noggin/Chordin Gremlin	Sclerostin/USAG-1 Gremlin	BMPER* Noggin/Chordin Gremlin		
Secreted ligand enhancer					TSG	KCP			
Antagonist ligand				Inhibin		Myostatin			
Inhibitory type I-like receptor		BAMBI	BAMBI	BAMBI	BAMBI	BAMBI			
Smad anchor		SARA	SARA	SARA					
Receptor-Smad (R-Smad)	Smad1, -5, ?-8	SMAD2, -3	SMAD2, -3	SMAD2, -3	Smad1, -5, -8	Smad1, -5, -8	Smad1, -5, -8		
Co-smad	Smad4	Smad4	Smad4	Smad4	Smad4	Smad4	Smad4		
Inhibitory-smad (I-Smad)	Smad6	Smad7	Smad7	Smad7	Smad6	Smad6	Smad6		
Endothelium-related function	Vasculogenesis	Growth inhibition	VEGF synthesis		Cardiac cushion		Endothelial precursor Cardiac cushion		
Hereditary vascular disease	Angiogenesis	Apoptosis	PAI-1 synthesis		PAH				
Pathway active in endothelium	Yes	Yes	No	Yes	Yes	No	Yes		
Pathway restricted to endothelium	Yes	Yes	No	No	No	No	No		

\* Indicates those components of the signaling cascades that are highly restricted to ECs.

ALK, activin like kinase; TGF- $\beta$ , transforming growth factor beta; T $\beta$ RII, transforming growth factor type II receptor; ActRII, activin type II receptor; BMPRII, bone morphogenetic protein type II receptor; BMP, bone morphogenetic protein; GDF, growth differentiation factor; LAP, latency associated protein; LTBP, latent transforming growth factor  $\beta$  binding protein; Tsp-1, thrombospondin-1; BMPER, BMP binding endothelial cell precursor derived regulator;  $\alpha$ 2-M,  $\alpha$ 2 macroglobulin; USAG-1, uterine sensitization-associated gene-1; TSG, twisted gastrulation; KCP, kielin/chordin-like protein; BAMBI, BMP activin membrane bound inhibitor; SARA, Smad anchor for receptor activation; HHT, hereditary hemorrhagic telangiectasia; PAH, pulmonary arterial hypertension.

**Table 35-2: Gene Deletions in the TGF- $\beta$  Superfamily Causing Vascular Defects**

<i>Deletion</i>	<i>Function</i>	<i>Vascular Phenotype</i>	<i>References</i>
TGF- $\beta$ 1	Ligand	Defective vasculogenesis and hematopoiesis	4
ALK1	EC restricted type I TGF- $\beta$ receptor	AV shunts; fusion of arteries and veins	5, 101
ALK5	Ubiquitous type I TGF- $\beta$ receptor	Defective yolk sac vasculogenesis	7
T $\beta$ RII	Type II TGF- $\beta$ receptor	Defective VSMC/pericyte recruitment	8, 101
Endoglin (heterozygous)	EC Type III TGF- $\beta$ coreceptor	Mouse model of HHT	185
Endoglin (homozygous)	EC Type III TGF- $\beta$ coreceptor	Defective angiogenesis	6, 101
Smad1	Intracellular signaling molecule	Disorganized allantoic blood vessels	194
Smad3	Intracellular signaling molecule	Vascular inflammation	182
Smad5	Intracellular signaling molecule	Defective yolk sac vasculature	9, 195
TAK1	Smad-independent signaling	Defective yolk sac vasculogenesis, defective VSMC recruitment	10
Furin convertase	pre-pro-TGF- $\beta$ processing	Defective yolk sac vasculogenesis, cardiac abnormalities	11
Emilin	Inhibits activation of pre-pro-TGF- $\beta$ 1 by furin	Excess arterial wall matrix, hypertension	14

in ECs, with the frequencies for LTBP-3 and -4 transcripts being higher than those for LTBP-1 and -2 (B. Ballermann, unpublished observations). The LTBPs contain 17 EGF-like motifs and four eight-cysteine repeats, a domain structure they share with the matrix protein fibrillin (see the later section on Marfan syndrome). LTBP-1, -3, and -4, but not LTBP-2, form disulfide-linked heteromers with LAP and hence bind the SLC (see Figure 35.1). Transglutaminase-2, a protein highly expressed by ECs, catalyses covalent crosslinking of LTBPs to specific binding sites on collagen, fibronectin, and fibrillin-1 (17), thereby sequestering a reservoir of latent TGF- $\beta$  in the ECM, ready to signal upon activation (15). LTBP-2, which does not appear to bind LAP, regulates adhesion of some cells to fibronectin (18).

Release of TGF- $\beta$  from LAP can be achieved by proteases like plasmin and calpain, by transient acidification, chaotropic agents, thrombospondin (TSP)-1, and  $\alpha$ V $\beta$ 6 integrin (19). Activation of TGF- $\beta$  in cocultures of ECs and VSMCs or pericytes (20) was long held to result from plasmin activity (21) similar to the process in blood clots, in which platelets release the SLC from which active TGF- $\beta$  is formed through

cleavage by plasmin (22). The LAP is N-glycosylated at three sites, two of which contain mannose-6 phosphate residues that bind to the mannose-6-phosphate/IGF-II receptor, which in turn facilitates plasmin-mediated activation of TGF- $\beta$  in cocultures of bovine aortic ECs and VSMCs (23). Hence, spatial restriction of TGF- $\beta$  activation in endothelial-pericyte or endothelial-VSMC cocultures may be provided, in part, by association of the LAP with the mannose-6-phosphate receptors on ECs. Plasmin generation is inhibited by plasminogen activator inhibitor (PAI)-1. Because PAI-1 expression is strongly activated by TGF- $\beta$ 1, a shift in the balance of tissue-type plasminogen activator (t-PA)/urokinase-type plasminogen activator (u-PA) to PAI-1 may serve a negative feedback function to dampen TGF- $\beta$ 1 action on ECs by reducing TGF- $\beta$  activation (24). In this regard, activation of ECs by inflammatory cytokines also can result in enhanced PAI-1 release, in turn associated with reduced TGF- $\beta$ 1 activation (25). Nonetheless, because mice deficient in plasminogen do not display a phenotype consistent with TGF- $\beta$ 1 deficiency, it has been argued that plasmin cannot be the physiological activator of TGF- $\beta$ 1 (15). Even so, because the evidence favoring plasmin-mediated

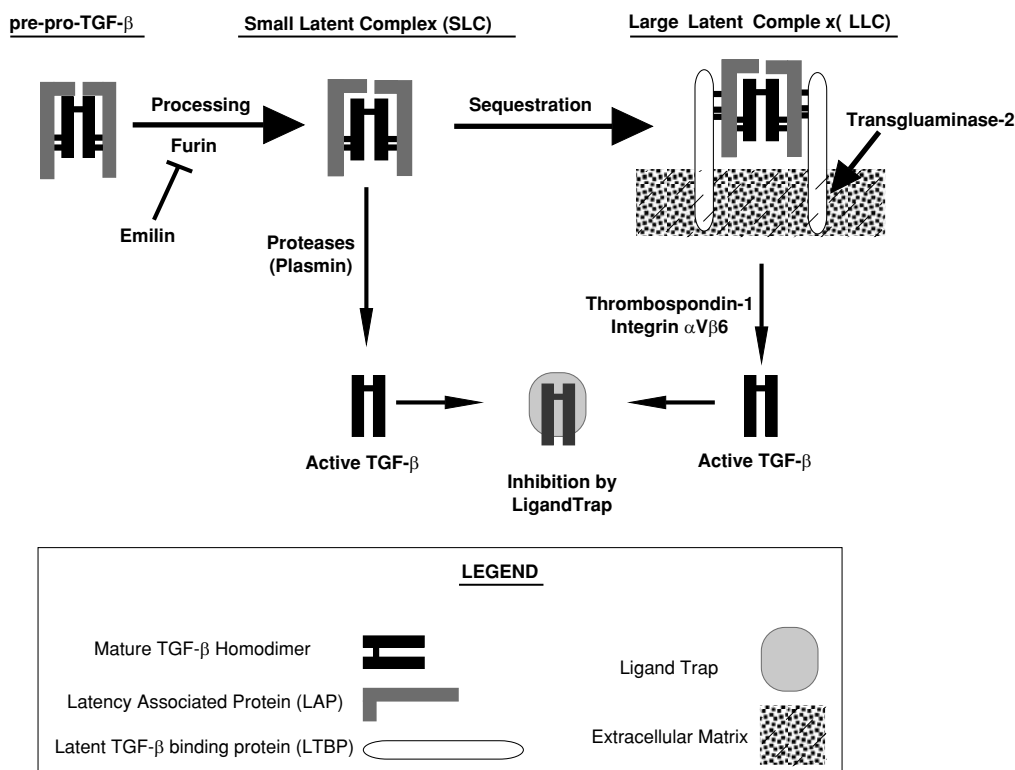

Figure 35.1. Schematic representation of TGF- $\beta$  activation and subsequent silencing by ligand traps. The dual, interacting signaling pathways via ALK1 and ALK5 are unique to endothelium and are described fully in the text.

TGF- $\beta$ 1 activation is plentiful, and deletion of PAI-1 enhances TGF- $\beta$ 1 activation, at least in a model of glomerulonephritis (26), it seems likely that activation of TGF- $\beta$  by plasmin can occur where plasmin is abundant, for example in blood clots, wounds, and inflammatory lesions.

Spatially restricted TGF- $\beta$  activation by LTBP-dependent mechanisms plays a physiologically important role (16,15). Antibodies to LTBP-1 inhibit TGF- $\beta$ 1 activation in endothelial-VSMC cocultures (27) and suppress differentiation of embryonic stem (ES) cells into ECs, a process that is rescued with mature TGF- $\beta$ 1 (28). LTBP-1 is also necessary for TGF- $\beta$ 1 activation by  $\alpha V\beta 6$  integrin in epithelial cells in response to shear stress, suggesting that spatial restriction of TGF- $\beta$  by  $\alpha V\beta 6$  integrin is mediated by LTBP-1, and that activation could result from traction on the integrin-LTBP1-LAP link (29,30). LAP also can associate with  $\alpha V\beta 1$  integrin (31), highly expressed by angiogenic sprouts, but so far  $\alpha V\beta 1$  integrin-dependent TGF- $\beta$  activation in ECs has not been reported.

The extracellular protein fibrillin-1, mutated in Marfan syndrome, binds LTBP-1 (32) and, through this interaction, influences TGF- $\beta$ 1 activation. Fibrillin-1-deficient mice have much higher levels of active TGF- $\beta$ 1 than do controls, resulting in excessive pulmonary apoptosis and abnormal pulmonary septation as well as mitral valve prolapse that is rescued by TGF- $\beta$ 1 antagonism (33,34). It has therefore been suggested

that LTBP-1 linkage of SLC to fibrillin-1 renders TGF- $\beta$ 1 inactive, and that enhanced activation results from absence of fibrillin-1.

TSP-1 probably is the main physiological activator of latent TGF- $\beta$ . TSP-1 is a prominent platelet  $\alpha$ -granule protein also produced by ECs, and is found in the ECM (35). TSP-1 is a powerful inhibitor of EC proliferation and angiogenesis (35). Latent TGF- $\beta$ 1 secreted by bovine aortic ECs is activated by TSP-1 without requiring localization to the cell surface (36). The activation of TGF- $\beta$ 1 by TSP-1 from both SLC and LLC in EC supernatants depends on its association with the LAP (37), and is due a discrete four-amino acid sequence, KRFK, in the type I repeats of TSP-1 (38). Major evidence that TSP-1 is a key physiological activator of TGF- $\beta$ 1 comes from the observation that TGF- $\beta$ 1- and TSP-1-deficient mice have similar phenotypes, that organs of the TSP-1-deficient mice contain very little active TGF- $\beta$ 1, and that their phenotype is rescued by TSP-1 peptides that can activate TGF- $\beta$ 1 (39). Binding of TSP-1 to VLAL domains of both LAP and TGF- $\beta$ 1 in the SLC is mediated by the WSXW region of TSP-1 and is required for TGF- $\beta$ 1 activation (40).

Hence, for TGF- $\beta$  ligands, sequestration in the ECM is orchestrated by LAP and LTBPs, and activation is mediated by TSP-1 and potentially also by matrix-cleaving proteases. Having latent TGF- $\beta$ 1 ready for release by proteases at key sites of tissue remodeling is akin to placing a remodeling sensor into

the extracellular compartment that can then participate in the appropriate angiogenesis and matrix repair processes (15).

### Ligand Traps

For all ligands in the TGF- $\beta$  superfamily, small, secreted proteoglycans act as ligand traps (see Table 35-1). Many are members of the small leucine-rich repeat proteoglycan (SLRP) family (41), and they often contain a conserved arrangement of cysteines that form intramolecular bonds to produce a “cystine knot” (42). These proteins directly bind specific ligands of the TGF- $\beta$  superfamily, inhibiting their interaction with receptors and therefore providing control over ligand activity. For example, the cystine knot proteoglycan decorin binds and inhibits TGF- $\beta$  (43); follistatin is a critical local regulator of activin (44); Noggin, Chordin, Gremlin, Sclerostin, and others bind and inhibit members of the BMP (45) family; and ligand traps in the DAN/Cerberus family bind and inhibit Nodal (46). The ligand trap BMPER (bone morphogenetic protein-binding endothelial cell precursor-derived regulator), which can bind BMP2, -4, and -6, is produced and secreted by FLK-1-expressing EC precursors and can inhibit their differentiation into ECs (47). Expression and secretion of TGF- $\beta$  ligand traps is highly regulated spatially and temporally, serving to regulate the degree of activation of these signaling cascades.

## OVERVIEW OF TRANSFORMING GROWTH FACTOR- $\beta$ SIGNALING

### Signal Initiation

The mature form of nearly all TGF- $\beta$  cytokines contains six to nine conserved cysteine residues that form inter- and intramolecular disulfide bonds. Six of the cysteines form disulfide bonds within each monomer subunit, creating a characteristic “cystine knot” necessary for receptor binding and shared by several other growth factors, for example, platelet-derived growth factor (PDGF) and nerve growth factor (NGF) (48), as well as the ligand traps described earlier. The remainder of the cysteines form intermolecular disulfide bonds that help stabilize the hydrophobic interactions that produce the ligand homodimers (13).

TGF- $\beta$  superfamily ligands bind to type I and type II receptor serine threonine kinases in the context of coreceptors, also referred to as type III TGF- $\beta$  receptors (49,50). The coreceptor betaglycan, expressed by most cells, is required for activation of ALK5 by TGF- $\beta$ 1, -2, and -3, whereas endoglin, expressed predominantly by ECs, promotes activation of both ALK1 and ALK5 pathways by TGF- $\beta$ 1 and -3 in ECs (see Table 35-1). The glycosphospholipid-anchored protein Dragon similarly acts as coreceptor for BMP2 and -4 binding to type II activin receptors (AcR<sub>II</sub> or AcR<sub>II</sub>B) and ALK2, -3, and -6 (51). Coreceptor function has also been ascribed to the soluble proangiogenic and profibrotic EC product connective tissue growth factor (CTGF), which potentiates receptor activation by TGF- $\beta$ 1 (52). Similarly, Cripto potentiates Nodal

binding to AcR<sub>II</sub> and ALK4 (46), and Kielin/chordin-like protein (KCP) increases the affinity of BMP7 for BMPRII as well as ALK2 and ALK6 (53). To what extent each of these coreceptors participates in TGF- $\beta$  signaling in EC remains to be elucidated.

Signaling by the TGF- $\beta$  cytokines is triggered by clustering and activation of membrane-associated receptor serine threonine kinases, grouped into the type I and type II receptor subtypes (13). These receptor serine threonine kinases contain an extracellular ligand binding domain, a single transmembrane spanning domain, and a cytoplasmic serine threonine kinase domain. The type II receptors are constitutively active serine threonine kinases that exhibit ligand family specificity (see Table 35-1). The seven type I receptor serine threonine kinases, also known as ALK, display specificity for ligand families due to their preference for specific type II receptors. The ALKs are inactive in the absence of ligand. Upon ligand-induced clustering with their respective type II receptors, the conserved TTSGSGSG domain (the GS box) of the type I receptors is phosphorylated by the type II receptor serine threonine kinase, resulting in activation of the type I receptor kinase activity (13).

### Signal Propagation

Activated type I TGF- $\beta$  receptor serine threonine kinases transiently associate with a subgroup of Smad proteins (Smad1, -2, -3, -5, and -8), also referred to as receptor Smads (rSmads), through conserved regions in the type I receptors and the rSmad proteins (54). This association facilitates phosphorylation of the rSmads at a conserved carboxyterminal SXS motif. ALK1, -2, -3, and -6 all interact with and phosphorylate Smad1 and -5, and potentially also Smad8, whereas ALK4, -5, and -7 activate Smad2 and -3. Smad2 phosphorylation by ALK5 requires the cosignaling protein SARA (Smad anchor for receptor activation), a FYVE domain protein (55,56). FYVE domains mediate the recruitment of signaling and membrane-trafficking proteins to early endosomes. Once Smad2 is phosphorylated, it dissociates from SARA and associates with Smad4, the common co-Smad required for nuclear translocation of the Smad signaling complex. Binding of Smad2 to SARA (55) and association of SARA with endosomes by the FYVE motif are indispensable for Smad2 phosphorylation by ALK5 (57). The cytoplasmic isoform of the promyelocytic leukaemia (cPML) tumor suppressor also participates in this cascade (58). *PML*<sup>-/-</sup> mouse embryo fibroblasts are resistant to TGF- $\beta$ 1, failing to stimulate the phosphorylation and nuclear translocation of Smad2 and -3 and gene transcription in these cells. The cPML is required for association of Smad2 and -3 with SARA and for the accumulation of SARA and TGF- $\beta$  receptors in the early endosomes. Thus, Smad2 and -3 phosphorylation triggered by TGF- $\beta$  receptor activation probably occurs in early endosomes. Because SARA association is lost upon Smad2 phosphorylation, SARA also may serve to retain inactive Smad2 in the cytoplasm, thus preventing its translocation to the nucleus (59). In this regard, phosphorylation

of Smad2 and translocation to the nucleus of ECs can be induced in a ligand-independent fashion with disruption of endosomes by dominant negative Rab5 (57), strongly suggesting that endosome-controlled retention and release of Smad2 is critical for its function. Whether endosomal mechanisms involving SARA and cPML (or their homologs) are similarly required for all ALK-mediated rSmad phosphorylation, and in particular for the endothelium-restricted phosphorylation of Smad1 and -5 by ALK1, is as yet unknown.

Phosphorylated rSmads interact with the common co-Smad4 to form a heteromeric complex that translocates to the nucleus to positively and negatively regulate transcription of a large number of genes (13). Nucleocytoplasmic shuttling of Smads depends not only on their phosphorylation status but also on nuclear import and export domains in the Smads themselves and their interactions with the nuclear import and export machinery (60–62).

### Signal Termination

Several mechanisms negatively regulate type I TGF- $\beta$  cytokine receptor signaling. As already discussed, several ligand traps prevent interaction of the cytokines with receptor and therefore prevent its activation. Within the cell, type I TGF- $\beta$  receptor phosphorylation is inhibited by FKBP12 (FK506 binding protein 12), which binds to the GS domain of type I receptors, and an inhibitory type-I receptor-like protein named BAMBI (BMP activin membrane-bound inhibitor), which can bind ligand but lacks kinase domain (63).

Activated type I receptors are also regulated through dephosphorylation, proteosomal degradation, and inhibition of Smad phosphorylation by inhibitory Smads. For ALK5, protein phosphatase-1 (PP1) is targeted to the receptor by the PP1 targeting subunit GADD34 in a docking cluster with Smad7 and SARA, returning ALK5 to the unphosphorylated, inactive state (64). Upon activation of type I receptors, inhibitory Smads, Smad6, and -7 interact with type I receptors and interrupt TGF- $\beta$  cytokine signaling via distinct pathways (13). Both Smad7 and Smad6 are strongly induced by laminar shear stress in ECs (65), transcription of Smad7 is strongly induced by TGF- $\beta$ 1 (66), and in ECs both inhibitory Smads are induced by overexpression of constitutively active ALK1 (67). Smad6 is inhibitory primarily to the Smad1 through -5 pathways, whereas Smad7 interferes with activation of Smad2 and -3. Smad6 associates with type I receptors to competitively inhibit binding of rSmads (68), although a role at the transcriptional level also has been described (69). Smad7 similarly associates with type I receptors, and can inhibit binding of rSmads, but it also serves to target its associated receptor for destruction through association with Smurf2. Smurfs are Smad ubiquitin regulatory factors that target Smads as well as Smad-associated proteins, including type I TGF- $\beta$  receptors and SARA for ubiquitination and proteosomal degradation, thus controlling levels of these proteins in the cells (70). Interaction of Smad7 with Smurf2 facilitates ubiquitination by E3 ubiquitin ligase not only of Smad7, but also of ALK5 and SARA and results in

their endocytosis via caveolae, followed by proteosomal degradation.

To sum up, signaling by TGF- $\beta$  cytokines is initiated through type III coreceptor-facilitated binding of the ligand to signaling receptors. Clustering of the signaling receptors brings the constitutively active type II receptor serine threonine kinase into the correct conformational proximity to phosphorylate its principal substrate, the type I receptor. Phosphorylation of rSmads by the type I receptor serine threonine kinase then facilitates association of r- and co-Smads and their translocation to the nucleus, where target genes are activated or silenced. Negative modulation of the signal occurs through inhibitory Smads, dephosphorylation of the type I receptors, and Smurf-regulated ubiquitination and proteosomal degradation of receptors, Smads, and associated proteins.

## TGF- $\beta$ SIGNALING IN THE ENDOTHELIUM

### Two TGF- $\beta$ Signaling Pathways in Endothelial Cells

In vitro, direct stimulation of ECs with TGF- $\beta$ 1 generally inhibits proliferation (71), can induce apoptosis (72), and stimulates migration and assembly of ECs into capillary-like tubes in the presence of ECM (73). Concentration-dependent angiogenic responses to TGF- $\beta$  are observed both in vivo (74,75) and in three-dimensional matrix in vitro (76), with a threshold effect at the lower, and an inhibitory response at the upper end of the concentration range (76). The seemingly contradictory findings that TGF- $\beta$  can both stimulate and inhibit angiogenesis were difficult to explain until the presence of two distinct and interacting signaling cascades were discovered in ECs (77), one stimulating proliferation and migration, the other responsible for blocking these responses. Like most other cells, ECs express the ALK5 type I TGF- $\beta$  receptor; but unlike non-ECs, they also express TGF- $\beta$ -responsive ALK1. Furthermore, ECs express little if any betaglycan and instead use endoglin as their type III TGF- $\beta$  coreceptor (Table 35-1). In ECs, ALK1 and ALK5 elicit distinct, but interacting signals in the context of endoglin.

### Endoglin and ALK1 are Endothelial Cell-Predominant Proteins

Endoglin is a highly glycosylated homodimeric, single transmembrane spanning protein, conserved between species and expressed in a highly restricted fashion by ECs (78,79). Recognition that its structure is highly homologous to betaglycan led to the demonstration that, like betaglycan (80), endoglin serves as a TGF- $\beta$  coreceptor. Unlike betaglycan however, endoglin fails to bind TGF- $\beta$ 2 (50), making ECs unresponsive to TGF- $\beta$ 2. This resistance of ECs to TGF- $\beta$ 2 can be rescued by betaglycan (81). Hence, one function of endoglin in ECs is to constrain their responses to two of the three TGF- $\beta$  isoforms. Endoglin also can interact with activin and BMPs and, in those cases, it couples to ActRII or BMP receptors, respectively (82). The physiological role of

endoglin in activin and BMP signaling is as yet poorly understood.

Expression of ALK1 also is highly restricted to endothelium (83). Both the endogenous *ALK1* promoter (84) and a fragment thereof (85) drive expression of the LacZ reporter only in ECs, with much higher levels in developing and mature arterial, compared to venous and capillary endothelium. This ALK1 expression pattern is essentially identical to that of endoglin (86). TGF- $\beta$ -stimulated Smad1–5 activation also is largely restricted to ECs (77), whereas Smad1–5 in most other cells is phosphorylated in response to BMPs (see Table 35-1).

### ALK1 and ALK5 are Activated by TGF- $\beta$ 1 and -3 in Endothelial Cells

In ECs, Smad1 interacts with ALK1 via a domain unique for type I TGF- $\beta$  superfamily receptors, and is phosphorylated by activated ALK1 (54). Goumans and colleagues (77) showed that ALK1 serves as a receptor for TGF- $\beta$ 1 and -3 in ECs and signals via Smads1 and -5. In non-ECs that lack ALK1, Smad1 and -5 is only responsive to BMP and is not activated by the TGF- $\beta$ s. Still, TGF- $\beta$ 1 and -3 induce not only Smad1 and -5, but also Smad2 phosphorylation in ECs. Taken together with the observations that constitutively active ALK1 phosphorylates Smad1 and -5 but not Smad2 and -3, and constitutively active ALK5 phosphorylates Smad2, but not Smad1 and -5, the data indicate that TGF- $\beta$ 1 and -3 can simultaneously activate two distinct signaling pathways in ECs. These two pathways have distinct biological effects in ECs. For example, by microarray analysis of human umbilical vein ECs overexpression of constitutively active ALK1, but not ALK5, strongly induces Smad6 and Smad7, as well as Id1 and Id2 (67). The kinetics of TGF- $\beta$ 1 and -3 in ALK1–Smad1/5 pathway activation differ from that of ALK5–Smad2/3 pathway activation, the former being activated transiently and inhibited at high concentrations of TGF- $\beta$ , whereas activation of the latter occurs even at high TGF- $\beta$  concentrations and is more sustained (77). The proliferative and migratory response of ECs in response to TGF- $\beta$ 1 and -3 is dependent on ALK1–Smad1/5-mediated Id1 induction, and this set of responses is inhibited by the ALK5 pathway. Interestingly, knockdown of ALK5 strongly inhibits both Smad2 and -3 and Smad1 and -5 responsive promoters in ECs, suggesting that signaling by ALK1 is dependent on ALK5 (77). Indeed, in *ALK5*<sup>-/-</sup> ECs, or in wild-type ECs in which ALK5 expression is knocked down, both TGF- $\beta$ -stimulated Smad2 and Smad1 and -5 pathways are blocked, and Smad1 and -5 signaling cannot be rescued simply by overexpressing ALK1, thus proving that ALK5 is required for ALK1 signaling in ECs (87). By contrast, reduced expression of ALK1 abrogates Smad1 and -5 but not Smad2 activation, showing that ALK1 is not required for ALK5 signaling.

ALK5 and ALK1 are both found in heteromeric complexes with T $\beta$ R2 and endoglin, and their association is strongly induced by TGF- $\beta$  ligand (88). The ALK1 association with endoglin and T $\beta$ R2 does not occur in *ALK5*<sup>-/-</sup> cells, but can be rescued by mutant ALK5 deleted in the Smad2 binding/

activation domain, re-establishing Smad1 and -5, but not Smad2, pathway activation (87). Although ALK5-dependent ALK1 activation does not depend on Smad2 activation, it does require ALK5 kinase activity. These findings strongly support a signaling model whereby ALK1 is activated not only by T $\beta$ R2 but also by ALK5 (Figure 35.2). To add further complexity, ALK1/Smad5 directly inhibit ALK5 pathway activation through an effect that is downstream of Smad2 (87,88). In ECs, therefore, ALK5 is necessary for the activation of the ALK1 pathway, which in turn serves to dampen ALK5 signaling. Conversely, in the presence of high concentrations of TGF- $\beta$ 1, ALK5 signaling predominates, and the ALK1 pathway is suppressed.

### Endoglin Functions as the TGF- $\beta$ Coreceptor in Endothelial Cells

The *endoglin* gene is transcribed as two distinct splicing variants, differing only at the carboxyterminus; the cytoplasmic domain of human short (S)-endoglin being 14 amino acids long, that of long (L)-endoglin 47 amino acids long (78). The cytoplasmic domain of L-endoglin is rich in serine and threonine amino-acid residues that can become phosphorylated by ALK5 and T $\beta$ R-II (89). Endoglin interacts directly with ALK5 and T $\beta$ R2, and in non-ECs lacking ALK1, endoglin potentiates TGF- $\beta$ -stimulated signaling via ALK5 (89). In ECs, endoglin interacts directly with T $\beta$ R2 and ALK1 as well as ALK5, although endoglin seems to prefer ALK1 as its partner over ALK5 (87,88). Endoglin overexpression promotes, and endoglin knockdown abrogates EC proliferation and migration (90). The proangiogenic effect of endoglin has been ascribed, at least in part, to ALK1 pathway-dependent blockade of ALK5-mediated cyclin-dependent kinase inhibitor p15<sup>ink4A</sup> and p21<sup>waf/cip</sup> activation, whereas induction of the proangiogenic transcription factor Id has not been linked to endoglin so far. Hence, endoglin is a necessary component of TGF- $\beta$ -mediated ALK1 signaling in ECs, and endoglin expression determines the growth potential of ECs (90). These findings are consistent with numerous reports of increased endoglin expression in the endothelium of tumor blood vessels undergoing angiogenesis and with inhibition of tumor angiogenesis by antiendoglin antibodies (91).

### Smad-Independent Signals in Endothelial Cells

Activation of TGF- $\beta$  receptors also stimulates signaling via Smad-independent mechanisms (92) that include mitogen-activated protein kinase (MAPK) pathways. TAK-1 (93) activates the stress-activated kinases p38 MAPK through MAP kinase kinase (MKK)-6 or MKK3, and c-jun N-terminal kinases (JNKs) via MKK4. This effect is rapid and does not require Smad phosphorylation (94). In ECs, TAK1 and p38 MAPK activation may play a role in altering monolayer permeability (94), cell-matrix interaction, and apoptosis (95). In non-ECs, TGF- $\beta$ -induced p38 MAPK activation, likely via TAK-1, is involved in activating vascular endothelial growth

Figure 35.2. Schematic representation of TGF- $\beta$  signaling in ECs. The dual, interacting signaling pathways via ALK1 and ALK5 are unique to endothelium and are described fully in the text.

factor (VEGF) expression (96), which indirectly influences EC proliferation. *TAK-1* deletion in mice results in abnormalities of yolk sac vasculogenesis that resemble those seen in ALK1- and endoglin-deficient mice (10), suggesting that TAK1 is a necessary downstream mediator of ALK1 action in ECs. Activation of small GTPases in response to TGF- $\beta$  may play a role in cytoskeletal rearrangements stimulated by TGF- $\beta$ . For example, in cultured pulmonary ECs, activation of the RhoA/Rho-kinase pathway is a component of the TGF- $\beta$  response, and includes myosin light-chain phosphorylation, cytoskeletal reorganization, and reduction in barrier integrity (97). Other TGF- $\beta$ -responsive signaling pathways involving protein phosphatases and the phosphoinositide 3-kinase (PI3K) cascade have been described, but so far insufficient work has been done in ECs to reach any firm conclusions

about their importance in EC biology. Similarly, in T lymphocytes (98), endoglin may participate in signaling through TGF- $\beta$  type I and II receptor-independent mechanisms, but such activity has not been reported in ECs thus far.

#### NECESSITY OF TGF- $\beta$ SIGNALING IN VASCULAR DEVELOPMENT

##### Embryonic Vasculogenesis and Vascular Patterning

During mammalian embryogenesis, endothelial and hematopoietic cells develop from a common “hemangioblast” precursor cell type that is first recognized as FLK-1<sup>+</sup> at embryonic day 7 (E7) in the mouse. The first vascular structures, EC-lined blood islands, appear in the mouse embryo yolk sac at day

E8. In addition, recognizable angioblasts within the embryo mesoderm coalesce into EC tubes that form the primitive cardinal vein and dorsal aorta between E7.5 and E8. The blood islands, primitive dorsal aorta, and cardinal vein are already surrounded by VSMCs by E9.5. The common E7 endothelial/hematopoietic progenitor expresses the VEGF receptor FLK-1 (also known as VEGFR2) but not the transcription factor SCL (FLK-1<sup>+</sup>/SCL<sup>-</sup>), or proteins characteristic for differentiated ECs or hematopoietic cells. These cells then give rise to both EC and hematopoietic lineages through sequential steps first involving upregulation of SCL (FLK-1<sup>+</sup>/SCL<sup>+</sup>) followed by downregulation of FLK-1 (FLK-1<sup>-</sup>/SCL<sup>+</sup>). Loss of both FLK-1 and SCL (FLK-1<sup>-</sup>/SCL<sup>-</sup>) then marks the onset of hematopoietic and EC differentiation. Differentiation of EC and hematopoietic cell lineages can be recapitulated by embryonic stem (ES) cells in vitro stimulated to form embryoid bodies that contain blood islands lined with endothelium and filled with hematopoietic cells. Smad6 overexpression blocks the formation of the earliest FLK-1<sup>+</sup> precursor cell, and application of BMP4, associated with Smad1 and -5 activation, can induce formation of FLK-1<sup>+</sup>/SCL<sup>+</sup> cells (99). Conversely, application of the ligand trap BMPER, which inhibits BMP4 signaling, inhibits differentiation of FLK-1<sup>+</sup> cells into ECs (47). Unfortunately, *BMP4*-null mouse embryos die well before the initial emergence of EC/hematopoietic precursors and are therefore uninformative in regard to EC differentiation. Evidence that TGF- $\beta$  signaling is required for early vasculogenesis comes from the observation that inhibition of TGF- $\beta$  activation by neutralizing LTBP1 antibodies blocks the development of capillary tubes in the ES cell assay (28). In keeping with a predominant effect of TGF- $\beta$  on vasculogenesis, overexpression of TGF- $\beta$ 1 in mouse ES cells stimulates formation of capillary structures in embryoid bodies, but does not alter hematopoietic cell development (100). There also have been many reports of EC assembly into capillary-like structures in response to TGF- $\beta$ 1 in vitro (73,72). Thus, BMP4 signaling is required for the early differentiation of ECs from the FLK-1<sup>+</sup> hemangioblast precursor, and TGF- $\beta$  activation and signaling are necessary for assembly of the ECs into tubes.

In mice deficient in TGF- $\beta$ 1 (4) or T $\beta$ R2 (8), nonvascular development appears normal through E8.5, but development of the early yolk sac vasculature is highly abnormal and leads to embryonic demise in midgestation. Although ECs are present, yolk sac capillaries are markedly distended, they are detached from underlying cell layers, and they contain fewer blood cells than those found in the wild-type embryos (8). In *ALK5*-null mice, a similar defect in yolk sac vasculogenesis is observed, but differentiation of hematopoietic precursors is not affected (7). Finally, mice with EC-restricted deletion of T $\beta$ R2 or *ALK5* show the same disruption in yolk sac vascular architecture and embryonic lethality in midgestation (101) as that in the mice with unrestricted T $\beta$ R2 and *ALK5* deletions. Later in development, vasculogenesis from angioblasts in renal glomerular capillaries also is dependent on TGF- $\beta$ 1 (102).

Endoglin is expressed in the earliest recognizable FLK-1<sup>+</sup>/Scl<sup>-</sup> precursors (103) and in ECs surrounding the blood

islands at E8.5 (86). The ES cells from endoglin-deficient mice (*Eng*<sup>-/-</sup>) display impaired generation of FLK-1<sup>+</sup>/Scl<sup>-</sup> precursors with a marked reduction in myelopoiesis and erythropoiesis but essentially intact lymphopoiesis (103). In *Eng*<sup>-/-</sup> mice, initial differentiation of ECs from mesenchymal progenitors appears normal, although subsequent remodeling of the endothelium into yolk sac blood vessels and their investment with VSMCs is defective (6). Like endoglin, *ALK1* is highly expressed in ECs at the earliest stages of blood island formation and continues to be expressed through embryogenesis into adulthood (104). In *ALK1*<sup>-/-</sup> mice, no discernable defect is apparent in the differentiation of mesenchymal precursors into ECs, and coalescence of ECs to form the early dorsal aorta and cardinal vein occurs normally, albeit with several connecting shunts that eventually fuse to form a single vessel (5). As with *Eng*<sup>-/-</sup> mice, investment of primitive blood vessels with VSMCs is arrested at E9.5. Deletion of *ALK1* in zebrafish similarly results in a highly abnormal blood vessel pattern, with very dilated arteries and veins (105). Hence, endoglin and *ALK1* are not essential for EC formation from precursors or their initial coalescence into blood vessels, but they are necessary for the remodeling of the primitive vessels into distinct arteries and veins and for the normal development of the VSMC layer (5).

#### Defective TGF- $\beta$ Signaling in Endothelial Cells Leads to Defective Vascular Smooth Muscle Cell/Pericyte Recruitment

All blood vessels begin as endothelial tubes that then recruit and stimulate assembly and differentiation of their VSMC/pericyte coat. Data from endoglin- and *ALK1*-null mice indicates that direct TGF- $\beta$  signaling in ECs is required to stimulate the VSMC/pericyte coat recruitment response. Because endothelium-restricted deletion of *ALK5* and T $\beta$ R2 in mice also results in reduced investment of vessels with differentiated VSMCs, TGF- $\beta$  pathway activation in ECs is a key step that directs assembly of the VSMC/pericyte coat.

A key mediator of VSMC/pericyte recruitment is endothelium-derived PDGF-B (106). In the embryo, endothelial expression of PDGF-B is restricted to immature capillary ECs and to the endothelium of arteries undergoing angiogenesis. Proliferating VSMC/pericyte progenitors expressing receptors for PDGF-B are found at sites of endothelial PDGF-B expression (107). Furthermore, recruitment of pericytes to brain, kidney glomerular, and other capillaries is critically dependent on PDGF-B synthesis by ECs and on expression of PDGFR- $\beta$  receptors by the pericyte precursors (106,108). It is known that TGF- $\beta$  strongly induces *PDGF-B* gene transcription in ECs (109) through a process that is Smad3 and -4 dependent (110). Taken together with the findings that PDGF-B stimulates VSMC/pericyte migration and proliferation (106) it seems likely that investment of EC tubes with VSMCs and/or pericytes involves TGF- $\beta$ -dependent PDGF-B synthesis by the developing endothelium. Nevertheless, reduced PDGF-B expression by ECs in mice with defective TGF- $\beta$  signaling

pathways, or rescue of VSMC/pericyte recruitment in these mice by exogenous PDGF-B have not been shown, so it remains to be seen whether reduced or absent paracrine signaling via PDGF-B explains the defect in blood vessel assembly observed with interruption of the EC TGF- $\beta$  signal. Defective nitric oxide (NO) generation by ECs lacking TGF- $\beta$  signaling systems also may contribute to the defect in VSMC/pericyte recruitment. TGF- $\beta$  stimulates expression of endothelial NO synthase (eNOS) by ECs and thereby increases the release of NO locally (111). Both, Smad2 (112) and endoglin (113) are necessary for induction of eNOS expression by TGF- $\beta$ . Furthermore, the TGF- $\beta$ -stimulated assembly of ECs into tubes in vitro can be blocked by L-arginine methyl ester (L-NAME), an inhibitor of NO synthesis (114), NO is a stimulus for angiogenesis in vivo (115), and EC-derived NO induces directional migration of mural cell precursors toward ECs in vitro (116). Again, it is not known whether eNOS expression and NO synthesis are altered in mice with EC-specific TGF- $\beta$  signaling defects, but *eNOS*-null mice do not develop defects in vasculogenesis or VSMC/pericyte recruitment. Hence, reduced eNOS activity in mice with defective TGF- $\beta$  signaling pathways may contribute to, but is not a critical component of this process.

Differentiated VSMCs are characterized by expression of smooth muscle (SM) contractile genes *SM22*, SM-myosin heavy chain (*SM-MHC*), *SM actin*, and *calponin*. These genes are strongly upregulated by TGF- $\beta$ 1 in cultured VSMCs, in pluripotent C3H10T1/2, and neural crest stem cells through a TGF- $\beta$  control element (TCE) that shares sequence similarity with the SP1 recognition site (117) and binds the transcription factor Kruppel-like factor4 (KLF4) (118). So far, an interaction between Smads and KLF4 has not been reported. EC-restricted deletion of T $\beta$ RII or ALK5, or haploinsufficiency of endoglin all are associated with a profound reduction in EC production of TGF- $\beta$ 1, with consequent failure of Smad2 activation in adjacent mesothelial cells (101). Because TGF- $\beta$ 1 stimulates VSMC differentiation, these studies suggest that investment of the early vasculature with VSMCs results, at least in part, from a paracrine TGF- $\beta$  signal that in turn stimulates differentiation of VSMC precursors (101). Findings that deletion of emilin, a furin inhibitor that reduces extracellular activation of TGF- $\beta$ , results in excessive TGF- $\beta$  signaling in the vascular wall, thickening of arterial walls due to excessive matrix deposition, and an increase in the systemic vascular resistance and hypertension in mice (14), strongly support the notion that TGF- $\beta$  plays a central role in blood vessel maturation by defining not only the EC and VSMC phenotypes, but also the volume of matrix in the vascular wall.

Taken together, the current evidence suggests that initial differentiation of ECs from the mesothelial hematopoietic/endothelial precursor requires BMP4-mediated signals, whereas assembly of ECs into nascent blood vessels and normal vascular pattern formation with distinct arteries and veins, as well as the recruitment of VSMCs and pericytes, all requires an intact TGF- $\beta$  signaling cascade. The data furthermore suggest that the ALK5 pathway may be more important than ALK1

signaling for the assembly of ECs into blood vessels, whereas the ALK1 pathway seems critical for the establishment of the normal vascular architecture and proper investment of the blood vessels with VSMCs or pericytes. Vessel assembly and pericyte recruitment also involve indirect actions of TGF- $\beta$  mediated through enhanced PDGF-B and possibly NO synthesis, and TGF- $\beta$  appears to be critical in determining the volume of ECM of the vascular wall.

### Developmental Remodeling Through Endothelial Apoptosis

Remodeling of EC monolayers in vitro in response to TGF- $\beta$  is associated with apoptosis of a subset of the cells (72,119). Apoptosis of ECs in response to TGF- $\beta$  is dependent on p38 MAPK activation (95), has been ascribed to reduced *bcl-2* expression (120), and is associated with reduced expression of the cyclin-dependent kinase inhibitors p21<sup>waf/cip</sup> (121). Similar mechanisms underlie TGF- $\beta$ -induced apoptosis in a number of other cell types, and resistance to apoptosis is thought to contribute, in some instances, to tumor growth (122). The sensitivity of ECs to the apoptotic actions of TGF- $\beta$  is greater than that of VSMCs or pericytes (123). Because endoglin overexpression protects ECs from TGF- $\beta$ -stimulated apoptosis (124,125), and the overexpression of constitutively active ALK5 (but not ALK1) induces apoptosis in human umbilical vein ECs (67), it seems likely the apoptotic response of ECs to TGF- $\beta$  results from activation of the ALK/Smad2/3 pathway. In vivo, TGF- $\beta$ -dependent apoptosis is thought to play a role in renal glomerular capillary morphogenesis. The glomerular capillary bed develops through assembly of capillary cords initially lacking lumens. Because both apoptosis and lumen formation are inhibited by neutralizing TGF- $\beta$  antibody, capillary lumen formation in these capillaries is thought to involve TGF- $\beta$ -dependent removal of superfluous cells by apoptosis (126).

## THE ANGIOGENIC RESPONSE

### In Vitro and Experimental Angiogenesis

Many studies show that TGF- $\beta$  can stimulate assembly of ECs into capillary-like cords in vitro (127), and sprouting angiogenesis with proliferation of cultured ECs in response to TGF- $\beta$  has been described (128). Application of TGF- $\beta$  in vivo, for example, in chick chorioallantoic membrane (129), in rabbit ischemic hindlimb (130), in mice implanted subcutaneously with TGF- $\beta$  impregnated disks (75), or in TGF- $\beta$ 1 producing tumors (74) all result in angiogenesis.

Angiogenesis requires dissolution of the EC basement membrane and the perivascular matrix at the tip of a new vessel sprout (131,132), followed by stabilization of the new vessel and its investment with VSMCs or pericytes. As already discussed above, very strong evidence now suggests that TGF- $\beta$  can stimulate proliferation and migration of ECs at low concentrations and that this signal is carried by endoglin, ALK1,

and Smad1 and -5. The migration response is not well understood but may result, in part, from alterations in the cellular repertoire of integrins, because TGF- $\beta$  increases synthesis of  $\alpha$ 2,  $\alpha$ 5, and  $\beta$ 1 integrins in ECs during angiogenesis (133). TGF- $\beta$  also regulates the process of matrix dissolution via the plasminogen–plasmin system. Both the u-PA and t-PA are essential for in vivo angiogenic responses (134,135). Because PAI-1 is produced in large amounts by ECs stimulated with high dose TGF- $\beta$ 1, suggesting that the angiogenic process is dampened by TGF- $\beta$ 1 via ALK5–Smad2/3 pathway stimulated PAI-1 production (136). The role of the uPA/plasmin system in the process of angiogenesis has, however, been questioned because invasion of fibrin gels by new angiogenic sprouts is not inhibited in *uPA*- or *plasminogen*-null mice. Instead, the potent fibrinolytic metalloproteinase of endothelium, membrane type-1 matrix metalloproteinase (MMP) (MT1-MMP) accounts for the invasiveness of sprouting vessels (131,137). This context is of interest because decorin, a matrix protein that acts as a ligand trap for TGF- $\beta$ , is a substrate for MT1-MMP (137). Degradation of decorin by MT1-MMP would tend to augment availability of TGF- $\beta$  during matrix dissolution. TGF- $\beta$  itself can induce MT1-MMP expression in non-ECs (138), but data for ECs are not yet available. In retinal ECs, TGF- $\beta$  increases the production of MMP-9 (139), and in bovine ECs, the expression of gelatinase A/MMP-2 and B/MMP-9 is upregulated by TGF- $\beta$ 1. It therefore is likely that TGF- $\beta$  participates in the angiogenic invasiveness by augmenting MMP synthesis by ECs at the tip of the sprout, but conclusive work still must be done.

Proliferation of ECs during the angiogenic response is stimulated not only by TGF- $\beta$ , via the ALK1 pathway, but also through VEGF and fibroblast growth factor-2 (FGF2) derived from neighboring cells (140). VEGF synthesis is induced in response to TGF- $\beta$  in several cell types, thus indirectly stimulating angiogenesis (141). Because TGF- $\beta$ 1 acts synergistically with VEGF and FGF2 to promote invasion by angiogenic sprouts (76,142), these mediators act in concert to stimulate growth and invasiveness by angiogenic vessels.

The angiogenic response is followed by a regulated process of vessel stabilization, with investment of the EC tube with VSMCs or pericytes, the formation of basement membrane, and the generation of ECM. The antiproliferative effect of TGF- $\beta$  mediated by ALK5 seems to play a dominant role during this phase of the angiogenic response (143), and the induction by TGF- $\beta$  of PAI-1 may antagonize the invasiveness of already formed vascular sprouts (135). Furthermore, TGF- $\beta$ , acting via ALK5, stimulates synthesis of matrix proteins in most cells, including ECs (144). In cultured pulmonary artery ECs, for example, TGF- $\beta$  stimulates production of type IV procollagen (145), and induction of fibronectin by TGF- $\beta$  seems almost universal (127,146). In addition, TGF- $\beta$  likely plays a central role in the recruitment and differentiation of VSMCs/pericytes during angiogenesis. It seems plausible that the two opposing TGF- $\beta$  signaling systems in ECs, ALK1-Smad1/5 and ALK5-Smad2/3, respectively, orchestrate the initial proliferative and then the resolution phase of the

angiogenic response. Autoinduction of TGF- $\beta$  in ECs (147) may further raise TGF- $\beta$  concentrations to levels at which a predominant ALK5/Smad2/3 response is elicited during the resolution phase.

### Tumor Angiogenesis and the TGF- $\beta$ System

The TGF- $\beta$  signaling cascade, acting via ALK5 in non-ECs, is a major tumor suppressor system. Indeed, Smad4 was first recognized as a tumor suppressor in colon epithelium (148), and many tumors cells, including those derived from breast and colon, harbor somatic mutations that interrupt TGF- $\beta$  signaling (149,150). By contrast, the type III TGF- $\beta$  coreceptor endoglin is strongly expressed in the blood vessels of many tumor tissues (151). Indeed, endoglin seems to be a much better marker for tumor endothelium than are other markers of differentiated endothelium (91). A high microvessel density (MVD) in tumors, as determined by endoglin antibody labeling, is associated with shortened patient survival (91,152). Endoglin is shed into the circulation and, although it is unable to bind TGF- $\beta$  in this form, high circulating endoglin levels in patients correlate with the presence of tumor metastasis (153). Endoglin antibodies have been used to image tumor microvessels in mice (154), dogs (155), and human patients (91). Therapeutic targeting of ECs in tumors using endoglin antibodies in experimental models are positive thus far. For example, synergy between antiendoglin antibodies and cyclophosphamide was observed in SCID mice bearing human tumors (156), and immunoradioisotopes suppress tumor growth in murine models bearing breast and colon carcinoma, without apparent systemic side effects (157). Nonetheless, a provocative paper by Pece-Barbara and colleagues (158) reported that absence of endoglin in ECs derived from *Eng*<sup>-/-</sup> mice resulted in powerful enhancement of TGF- $\beta$ -stimulated Smad1 and -5 phosphorylation and cell proliferation, whereas the presence of endoglin was associated with greater TGF- $\beta$ -mediated suppression of EC proliferation. Hence, it is not clear whether TGF- $\beta$ -mediated signaling in ECs contributes to tumor angiogenesis or not. Still, endoglin is a promising tool for tumor vessel imaging and could potentially serve as a therapeutic target for antiangiogenic therapy in tumors.

### ENDOTHELIAL–MESENCHYMAL TRANSDIFFERENTIATION DURING CARDIAC CUSHION DEVELOPMENT

The vascular tube that eventually forms the heart, also referred to as the atrioventricular (AV) canal, contains an inner lining of ECs surrounded by cell-free cardiac jelly composed of ECM, and an outer layer of myocardial cells. The formation of the cardiac cushions from which the heart valves arise and which is necessary for normal cardiac septation, involves endothelial–mesenchymal transdifferentiation (EMT) of a subset of ECs that then invade and proliferate in the cardiac jelly (159).

During the process of transdifferentiation, the cells begin to express mesenchymal markers, for example tenascin and  $\alpha$ -SM actin, while endothelial markers, for example platelet-endothelial cell adhesion molecule (PECAM)-1, are lost (160). Abnormalities in this process can lead to defective heart valve formation or abnormal septation of the heart. Such defects occur in approximately 1% of human live births and carry with them a high morbidity.

Disruption of TGF- $\beta$  and BMP signaling pathways results in cardiac cushion defects. TGF- $\beta$ 1 and TGF- $\beta$ 3 are highly expressed in the AV canal where the cardiac cushion forms (161–163). In human embryos, T $\beta$ R $\beta$ II and ALK5 are ubiquitously expressed in all cells of the AV canal, with endoglin expression being restricted to the ECs in that region. The high level of endoglin expression is regulated temporally and associated with heart septation and valve formation (164). In the presence of myocardium, TGF- $\beta$ 1 can induce the transdifferentiation of AV canal ECs (161). Also, in AV cushion explants, antibodies directed against T $\beta$ R $\beta$ II, or against TGF- $\beta$ 3 (165), inhibit transdifferentiation. In *endoglin*-null mice, heart development is arrested at E9, and the atrioventricular canal endocardium fails to undergo mesenchymal transformation and cushion-tissue formation (166). Taken together, these observations indicate that TGF- $\beta$ 1 and -3, likely acting directly on the ECs of the AV canal in an endoglin-dependent fashion, induce transdifferentiation of ECs to form the mesenchymal cells of the cardiac cushion.

In the developing mouse, BMP2 and -4 also are expressed in the cells of the developing cardiac cushion, but they are not restricted to the endothelium (167), and BMP2 has a synergistic effect with TGF- $\beta$ 1 on endothelial–mesenchymal transdifferentiation (168). Finally, constitutively active ALK2, but not ALK5, can induce transdifferentiation of AV canal ECs, a process that is inhibited by Smad6 (169). Because Smad6 inhibits Smad1 and -5 but not Smad2 and -3 activation (see Table 35-1), it seems likely that in the ECs of the primitive AV canal, either TGF- $\beta$ 1 or -3 acting on ALK1, and/or BMP2 acting via ALK2, signal the transdifferentiation of the ECs into mesenchymal cells.

Of great interest for this review, patients with Marfan syndrome, due to mutations in the *fibrillin-1* gene, develop cardiac valve abnormalities quite often, most commonly mitral valve prolapse. As already discussed, fibrillin-1 binds LTBPs, and their interaction with LAP play an important role in the local regulation of TGF- $\beta$  activation. In mice with *fibrillin-1* mutations, excess activation of TGF- $\beta$  not only leads to a defect in the lung that is similar to the pulmonary defect observed in patients with Marfan syndrome (33), but they also develop progressive mitral valve prolapse resembling that found in human patients (34). Moreover, a family with Marfan syndrome has been identified in whom mutations in *T $\beta$ R $\beta$ II*, not *fibrillin-1*, produce the disorder (170). It is therefore attractive to speculate that the cardiac and vascular abnormalities in human patients with Marfan syndrome relate to the role of TGF- $\beta$  signaling during the formation of the cardiac cushion or later valve remodeling.

## ROLE OF TGF- $\beta$ IN ATHEROSCLEROSIS

In VSMCs, TGF- $\beta$  signals via the ALK5–Smad2/3 pathway induce differentiation and inhibit proliferation. If the same mechanisms hold in the media of mature blood vessels, TGF- $\beta$  would tend to oppose expansion of the VSMC population and neointima formation. Several lines of evidence support the theory that TGF- $\beta$  indeed acts as a protective cytokine in the mature vascular wall, and that loss of TGF- $\beta$  activity or interruption of TGF- $\beta$  signaling can participate in the formation of atherosclerotic plaques (171). Furthermore, because TGF- $\beta$  tends to inhibit inflammatory cell adhesion and transmigration across the endothelium, and is critically important in suppressing T cell proliferation (172), it may also protect blood vessels from injury by inflammatory cells.

Clonal expansion of VSMC populations in atherosclerotic plaque has been linked to decreased expression and somatic mutation of the *T $\beta$ R $\beta$ II* gene and consequently lower levels of receptor expression (173). Loss of TGF- $\beta$  signaling, as described in tumors, could therefore result in the VSMC proliferation so characteristic in atherosclerotic plaques (173). Moreover, in mice, activation of TGF- $\beta$  from the SCL (see Figure 35.1) is inhibited by high levels of apolipoprotein A and has been linked to VSMC proliferation and development of fatty streaks (171). Also, the human lipoprotein variant Lp(a), which is strongly associated with increased risk of atherosclerosis, can inhibit TGF- $\beta$  activation both in vitro and when overexpressed in transgenic mice (171). Reduced availability of TGF- $\beta$  due to inhibition of activation and reduced T $\beta$ R $\beta$ II receptor expression may therefore contribute to VSMC proliferation in atherosclerosis.

Suppression of inflammation by TGF- $\beta$  also has been postulated to protect the vascular wall from formation of atherosclerotic plaque (171). Deletion of TGF- $\beta$ 1 in mice results in a multifocal, mixed inflammatory cell response, lethal within the first 2 months of life (174), an effect that relates to its role in T-cell differentiation (172). In addition, TGF- $\beta$  acting on ECs suppresses cytokine-stimulated adhesion and transmigration of monocytes (175), T lymphocytes (176), and neutrophils (177). Inflammatory cell adhesion to ECs is reduced at least in part through inhibition of cytokine-stimulated E-selectin expression (178) as well as inhibition of chemoattractant interleukin (IL)-8 (177) and monocyte chemoattractant protein (MCP)-1 (179) expression by TGF- $\beta$ . Little or no effect of TGF- $\beta$  on EC vascular cell adhesion molecule (VCAM)-1 or intercellular adhesion molecule (ICAM)-1 expression has been observed (178,180). Similarly, *P-selectin* gene expression is not changed, but the rapid thrombin-stimulated translocation of Weibel–Palade contents, P-selectin, and von Willebrand factor (vWF) in ECs is markedly suppressed by TGF- $\beta$  (181). Therefore, both the cytokine-stimulated recruitment of leukocytes by chemokines and their initial adhesion to endothelium via E- and P-selectin are generally inhibited by TGF- $\beta$ . It has been postulated that reduced TGF- $\beta$  action, perhaps because of ineffective activation, can lead to more aggressive inflammatory lesions in the vasculature.

In cardiac allografts, which represent an immune-dependent model of atherosclerosis, Smad3 deficiency is associated with accelerated intimal hyperplasia with increased infiltration of adventitial macrophages expressing MCP-1, suggesting that TGF- $\beta$ , acting via Smad3, is important in regulating MCP-1 expression in vivo and that its absence can augment vascular injury in this model (182). Similarly, TGF- $\beta$ 1 exerts a significant cardioprotective effect in a feline model of myocardial ischemia and reperfusion that appears related TGF- $\beta$ 1-mediated inhibition of neutrophil adhesion to the endothelium (183).

Overall therefore, accumulating evidence suggests that TGF- $\beta$  has an anti-inflammatory effect in blood vessels largely due to inhibition of the leukocyte-EC interaction, and that it can inhibit neointima formation through inhibition of VSMC proliferation. Loss of TGF- $\beta$  function in the vessel wall could therefore contribute to the development of atherosclerotic lesions.

## HUMAN HEREDITARY VASCULAR DISORDERS DUE TO MUTATIONS IN HUMAN HEREDITARY TGF- $\beta$ SIGNALING PATHWAYS

### Hemorrhagic Telangiectasia

Hemorrhagic telangiectasia (HHT) is an autosomal disorder in humans also known as Osler-Weber-Rendu syndrome (discussed in detail in Chapter 122). Mutations in the *endoglin* gene located on chromosome 9q34 (1) and in the *ALK1* gene located on chromosome 12.q11 (2) cause HHT-1 and HHT-2, respectively. A number of different mutations for both genes have been reported, all associated with loss of function (3). A third locus for HHT had been proposed but the family in question was later found to have mutations in the *ALK1* gene (3). Patients with *endoglin* mutations develop more pulmonary AV malformations, and they experience epistaxis and telangiectasias earlier in life than do those with *ALK1* mutations (184).

Analysis of mice with heterozygous mutations in *endoglin* serves as a good model for HHT. They develop generalized dilation of veins with an absence of investing VSMCs in more than 70% of vessels, leading to dilation and the characteristic telangiectatic lesions (185). On the 129/Ola or mixed C57BL/6-129/Ola background, heterozygous *endoglin* mutations sometimes are associated with epistaxis, as in human patients (166). The penetrance of the HHT1 phenotype in mice is strongly dependent on the genetic background, thus indicating that several modifier genes influence the function of endoglin in the vasculature (186). Heterozygous mutations in the *ALK1* gene also lead to vascular dysplasia reminiscent of the human disorder (187). These mice display variable penetrance of the phenotype, which consists of vascular lesions in skin and oral mucosa, as well as lesions in the lung, gut, spleen, brain, and liver. Like humans, mice with mutations in *ALK1* gene suffer from gastrointestinal hemorrhage at a much greater rate than expected (187).

The mechanism by which vascular abnormalities develop in humans and in mice with heterozygous *endoglin* or *ALK1* mutations still needs much clarification. Certainly, a simple defect in EC proliferation and migration cannot account for the phenotype, nor can abnormal VSMC/pericyte recruitment. The progressive development of AV malformations implies defective vascular remodeling over time. It has been suggested that a somatic mutation in the normal allele could explain the progressive, focal vascular malformations (3), although this has yet to be confirmed.

### Hereditary Pulmonary Arterial Hypertension

Hereditary pulmonary arterial hypertension (PAH) is a vascular disorder characterized by a progressive reduction in the lumen diameter of pulmonary arteries. This leads to a sustained increase in pulmonary vascular resistance that impedes ejection of blood by the right ventricle and causes subsequent right ventricular failure (188). PAH generally can be ascribed to nongenetic causes. In patients without an identifiable underlying cause for PAH, the term primary pulmonary hypertension (PHH) is also used. The prevalence of hereditary PAH is estimated to be 1 to 2 per 1,000,000 live births, and the disease can be sporadic or familial.

Two independent groups identified heterozygous mutations in the gene encoding the BMPRII (BMP receptor II) as the underlying cause of hereditary PAH (189,190) and, in a substantial portion of patients with sporadic PAH similar mutations of the *BMPRII* gene were observed (191). As is the case with *ALK1* and *endoglin* mutations, incomplete penetrance may result from as-yet-unknown modifier genes. Indeed, in some families with HHT-2 without *BMPRII* mutations, severe PAH has been observed and ascribed to mutations in *ALK1* (192). The observation that mutations in two different but mechanistically related genes, *ALK1* and *BMPRII*, can produce the same clinical phenotype points to TGF- $\beta$  receptors as an important molecular pathway at the origin of pulmonary vascular remodeling. Whereas *ALK1* mutations can lead to hereditary PAH, HHT-2, or both, *BMPRII* mutations appear to lead only to the PAH phenotype. It has been suggested that *BMPRII* mutations are involved mainly in VSMC proliferation and *ALK1* in endothelial or VSM proliferation. Nonetheless, in patients with hereditary PAH, monoclonal expansion ECs from the pulmonary lesions has been shown and suggest that EC proliferation may underlie the compromise in blood vessel lumen in these patients (193).

### KEY POINTS

- The TGF- $\beta$  signaling system is unique in ECs, in that two distinct type I TGF- $\beta$  receptors, *ALK1* and *ALK5*, are activated by two of the three TGF- $\beta$

isoforms, TGF- $\beta$ 1 and TGF- $\beta$ 3. This isoform selectivity is conferred by the endothelium-restricted TGF- $\beta$  coreceptor, endoglin. The two signaling pathways in ECs provide for opposing biological effects: activation of EC development and angiogenesis via the ALK1 pathway, and inhibition of angiogenesis with stabilization of the new vessels through activation of the ALK5 pathway.

- TGF- $\beta$  signaling is essential for normal vascular development because deletion of any component of the cascade in ECs – the convertase furin that cleaves TGF- $\beta$ 1 from its propeptide, TGF- $\beta$ 1 itself, the coreceptor endoglin, T $\beta$ R $\beta$ , both TGF- $\beta$  type I receptors ALK1 and ALK5, as well as Smad1 and Smad5 – all produce major defects in embryonic vascular development resulting in death at midgestation.
- Vascular disorders in human patients are produced by mutations in TGF- $\beta$  and BMP receptor genes. Haploinsufficiency of endoglin or ALK1 is responsible for the human vascular disorder HHT, and haploinsufficiency of BMPRII results in the hereditary form of PAH.
- A unique and highly regulated process of activation controls the spatial and temporal actions of TGF- $\beta$ . The mature form of the three TGF- $\beta$  isoforms remain latent after synthesis through noncovalent association with a portion of their own propeptide, and this latent TGF- $\beta$  is sequestered in the ECM. Defects in TGF- $\beta$  sequestration likely underlie the cardiac abnormalities in Marfan syndrome. The sequestered TGF- $\beta$  serves as a sensor of tissue remodeling during angiogenesis, because it is released in the active form upon matrix dissolution by proteases at the tip of newly forming vessels.

#### Future Goals

- The relatively recent discovery of two TGF- $\beta$  signaling pathways in ECs begs the re-examination of a whole host of EC responses to TGF- $\beta$ , as much of the in vitro work to date has been done with concentrations of TGF- $\beta$  that would tend to activate ALK5 but inhibit the ALK1 pathway. Because ALK1 is so essential in vascular development, this is an important problem to be solved. In this regard, the exact mechanism by which endoglin acts in ECs, and importantly, in tumor vessels, is not well understood at this time.
- The role of sequestered latent TGF- $\beta$  is fascinating and still poorly understood. Biologists often propose that cytokine concentration gradients in tissues produce distinct cellular responses. It seems likely that sequestered TGF- $\beta$  could form such gradients,

depending on the degree of activation during angiogenesis and development. Methods to study the precise spatial and temporal activation of the TGF- $\beta$  system would open new avenues to study vascular development, angiogenesis, and vessel maturation.

- Although much is currently known about prominent EC responses to TGF- $\beta$ , such as proliferation, migration, apoptosis, vessel assembly, and matrix synthesis, and many EC genes positively or negatively regulated by TGF- $\beta$  have been identified, it is evident from the human vascular disorders HHT and PAH that TGF- $\beta$  plays a major role in vessel remodeling throughout life. These long-term effects are not understood at all. Indeed, the three-dimensional patterning of blood vessels seems powerfully influenced by TGF- $\beta$ , but we currently have only a very rudimentary understanding of this process. From work in mice and zebrafish, it is evident that TGF- $\beta$  is required to keep ECs of the venous and arterial beds separate. How this is accomplished, and how TGF- $\beta$  effects differ in distinct EC subpopulations, remain open questions.
- Also, as can be gleaned from the section on atherosclerosis, plausible mechanisms by which TGF- $\beta$  deficiency could play a role in atherosclerotic plaque development exist, but whether they actually participate in human disease remains to be proved. If ineffective TGF- $\beta$  activation indeed leaves the vasculature unprotected, this would open a real opportunity for the development of therapeutic agents that mimic TGF- $\beta$ . On the other hand, if effects of low-dose TGF- $\beta$  have been overlooked so far, who knows what would happen if TGF- $\beta$  or its mimics were used as a therapeutic tool. Conversely, it is known that excess TGF- $\beta$  plays a role in the fibrotic injury response in many organs, and inhibitors of it are being studied as therapeutic tools for those disorders. Will we unmask cardiovascular disease when we begin using such agents clinically? Similarly, in the process of tumor angiogenesis, it is unclear whether inhibition or stimulation of TGF- $\beta$  action would have therapeutic value.
- Selective ALK5 kinase inhibitors already have been produced, but because ALK5 is necessary for ALK1 action, both pathways would be affected in ECs. It seems that development of ALK1 agonists and antagonists will be more relevant for EC biologists, and potentially also as human therapeutic tools.
- Finally, TGF- $\beta$  does not act in isolation. Positive and negative influences by TGF- $\beta$  on other mediators that regulate blood vessels are known, and other mediators influence TGF- $\beta$  synthesis,

activation, and action. Over time, we will develop an ever more complete understanding of the vast array of interacting mechanisms on the vasculature. Bioinformatics tools may well be needed to help predict how a single stimulus might alter the whole network of interacting responses in the endothelium.

#### ACKNOWLEDGMENTS

This work was supported by grant DK50764 from the National Institutes of Health, and by grants MOP641814 and CEG63108 from the Canadian Institutes of Health Research. The author holds a Tier 1 Canada Research Chair in Endothelial Cell Biology.

## Thrombospondins

Sareh Parangi and Jack Lawler

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The thrombospondins (TSPs) are a family of proteins that regulate cellular phenotype and matrix structure during tissue remodeling and genesis (1,2). Of the five proteins that comprise the family, TSP-1 and -2 have been shown to be involved in vascular development and angiogenesis (3,4). The endothelial cell (EC) integrates positive and negative signals for proliferation, migration, survival, and apoptosis during physiological and pathological angiogenesis. TSP-1 and -2 suppress the angiogenic response by inhibiting migration and antagonizing vascular endothelial growth factor (VEGF)-induced survival. In addition, TSP-1 and -2 stimulate apoptotic pathways in ECs (5). The importance of TSP-1 as a negative regulator of angiogenesis is underscored by the fact that genetic mutations that occur in tumor cells often lead to reduced TSP-1 expression (2). Furthermore, a TSP-1-based therapeutic is currently in clinical trials for the treatment of cancer. Although generally an inhibitor of angiogenesis, TSP-1 has been shown to support angiogenesis in some contexts. This seemingly paradoxical effect stems from the fact that various cell types respond differently to the protein. Whereas TSP-1 inhibits EC migration, it supports vascular smooth muscle cell (VSMC) and inflammatory cell migration. Thus, if the induction of angiogenesis occurs in the presence of inflammation, TSP-1 can appear to promote angiogenesis. In addition, the N-terminal heparin-binding domain of TSP-1 assayed in isolation reportedly stimulates angiogenesis (6). These complex responses arise because TSP-1 and -2 are multifunctional proteins with a wide range of cell surface receptors. The cellular response to these proteins in part depends on which receptors are expressed by a given cell type and which receptors are engaged by the various domains of TSP-1 or -2.

### HISTORY OF THE THROMBOSPONDINS

TSP-1 was first identified in 1971 as a 190,000-dalton protein that appeared in the supernatant of thrombin-treated platelets (7). Although it was originally thought to be cleaved from the surface of platelets, it was soon appreciated that the protein was secreted instead from  $\alpha$ -granules as part of the platelet

release reaction (8). Subsequent studies revealed that TSP-1 was synthesized by megakaryocytes as a trimer of identical subunits with a molecular weight of 142,000 (9,10). TSP-1 electrophoreses at an anomalously high molecular weight because it has an unusually high content of aspartic acid. Early studies focused on platelet TSP-1 but, in 1981 and 1982, two groups showed that TSP-1 is synthesized and secreted by fibroblasts and ECs in culture (11,12). These observations led to the cloning and sequencing of full-length human *TSP-1* from an EC cDNA library in 1986 (Table 36-1) (13). The comparison of cDNA and genomic clones that were isolated from murine libraries revealed the existence of TSP-2, a protein with the same domain structure as TSP-1 (14). Genomic cloning of the mucin *MUC-1* led to the identification of mouse *TSP-3*; the isolation of thrombospondins from a frog cDNA library led to the identification of *TSP-4*; and the cloning and sequencing of rat cartilage oligomeric matrix protein (*COMP*) or *TSP-5* resulted in its identification as the fifth member of the thrombospondin gene family (15–17). To explore the functions of the thrombospondins, several groups have determined the expression of mRNA and protein for each family member, and knockout mice have been generated (see Table 36-1). These studies reveal that most tissues express at least one family member, with many tissues synthesizing multiple thrombospondins (see later).

In 1971, Judah Folkman proposed that tumors must induce angiogenesis in order to grow beyond a few millimeters in size (18). To stimulate angiogenesis, tumor cells express growth factors like VEGF to stimulate the growth of capillaries. These observations led to the concept that antiangiogenic approaches could inhibit tumor growth. In 1987, when working with one of the first antiangiogenic compounds, TNP-470, Ingber and Folkman made the observation that whereas TNP-470 inhibited primary tumor growth, it led to the growth of metastases (19). In addition, it was noted that the upregulation of VEGF in pancreatic tumors that form in *Rip-Tag* mice occurs well before the induction of angiogenesis (20). These observations suggested that angiogenesis was being suppressed by naturally occurring inhibitors. In 1990, Noel Bouck's laboratory reported the identification of the first natural

**Table 36-1: Cloning and Sequencing of Full-Length Human TSP-1**

	<i>Cloned</i>	<i>Receptors</i>	<i>Embryo</i>	<i>Adult</i>	<i>EC Signaling</i>	<i>-/- Phenotype</i>
TSP-1	1986	PGs, integrins, CD36, calreticulin, LPR, CD47	Cardiac myocytes, neuroepithelium, cartilage and bone, liver, muscle, various epithelia, capillaries (late)	Platelets, monocytes, lung epithelium, cardiac and skeletal muscle	✓	Pneumonia, delayed wound closure, increased vessel density in some tissues
TSP-2	1991	PGs, integrins, CD36, LRP	Connective tissue, cartilage and bone, heart, kidney, large blood vessels and capillaries (early)	Skin, brain, cardiac muscle, brain	✓	Abnormal collagen fibrils, accelerated wound closure, increased vessel density in some tissues
TSP-3	1992	PGs	Neurons, lung, cartilage, brain	Lung, bone, cardiac muscle	–	Variations in postnatal bone maturation
TSP-4	1993	PGs	Somatic mesoderm, muscle, eye	Cardiac and skeletal muscle	✓	Not published
TSP-5/ COMP	1992	Integrins	Chondrocytes	Cartilage, tendon, ligament, synovium VSMCs (restenosis)	–	None

This table includes data from studies on human, mouse, rat, chicken, cow, and frog.

inhibitor of angiogenesis, TSP-1 (21). This group assayed the ability of culture supernatants from fibroblasts with a mutation in a tumor suppressor gene to inhibit EC migration. N-terminal amino acid sequencing of a protein in the active fraction revealed that a proteolytic fragment of TSP-1 was the key component. The identification of TSP-1 as an endogenous inhibitor of angiogenesis supported the hypothesis that angiogenesis is controlled by a balance between stimulators and inhibitors. Angiogenesis occurs when this balance is shifted in favor of the stimulators. Subsequent studies showed that the nondegraded protein also is active and that the effect is mediated by the interaction of the thrombospondin type 1 repeats (TSRs) with CD36, one of several TSP-1 receptors on the surface of ECs (discussed later) (2,22). Because TSP-2 also contains the TSRs, it is also a potent endogenous inhibitor of angiogenesis. In this chapter, we focus on molecular mechanisms underlying the inhibition of angiogenesis by TSP-1 and -2, and discuss recent data on TSP-1-based cancer therapies. The functions of TSP-3, TSP-4, and COMP are poorly understood, but it is unlikely that they inhibit angiogenesis because they do not contain TSRs. A role for TSP-4 in vascular function has been suggested by the observation that a polymorphism leads to a proline at position 387 instead of the more common alanine. This polymorphism reportedly is associated with an increased risk of early-onset cardiovascular disease (23). TSP-4 has been shown to be expressed by brain capillary ECs and aortic tissue. Although the two forms of TSP-4 do have differential effects on EC proliferation and migration *in vitro*, no clear link is known between TSP-4 and cardiovascular disease at this time (23).

## EVOLUTIONARY CONSIDERATIONS

The five members of the thrombospondin family can be divided into two groups on the basis of their domain and tertiary structure. All the thrombospondins contain type-2 (epidermal growth factor [EGF]-like) repeats, type-3 repeats, and a highly conserved C-terminal domain. The type-3 repeats are composed of low- and high-affinity calcium binding sites that collaborate with the C-terminal to bind as many as 26 calcium atoms per subunit (24). The C-terminal is a 15-stranded concave  $\beta$ -sandwich structure that interacts with the type-3 repeats at multiple points (24). The five proteins differ in that TSP-1 and -2 (subgroup A) contain two domains that are not present in TSP-3, -4, and COMP (subgroup B): (a) a region of homology with procollagen and (b) the TSRs. The TSRs are found in numerous proteins (approximately 100 in the human genome), some of which are involved in the regulation of angiogenesis and axon guidance. The tertiary structure of the two subgroups differs in that the subgroup A proteins are trimers and the subgroup B proteins are pentamers.

Most vertebrates probably express all five TSP genes. Progressive sequence alignment algorithms suggest that the gene duplications that produced these proteins occurred approximately 500,000 years ago, during the vertebrate radiation (16). The primitive chordate, *Ciona intestinalis*, has two TSPs, one similar to the subgroup A and one with the domain structure of the subgroup B TSPs (25). A TSP gene also is found in invertebrate genomes. *Drosophila melanogaster*, *Anopheles gambiae*, and the silk moth *Bombyx mori* have a TSP that has the subgroup B molecular architecture. Like the vertebrate

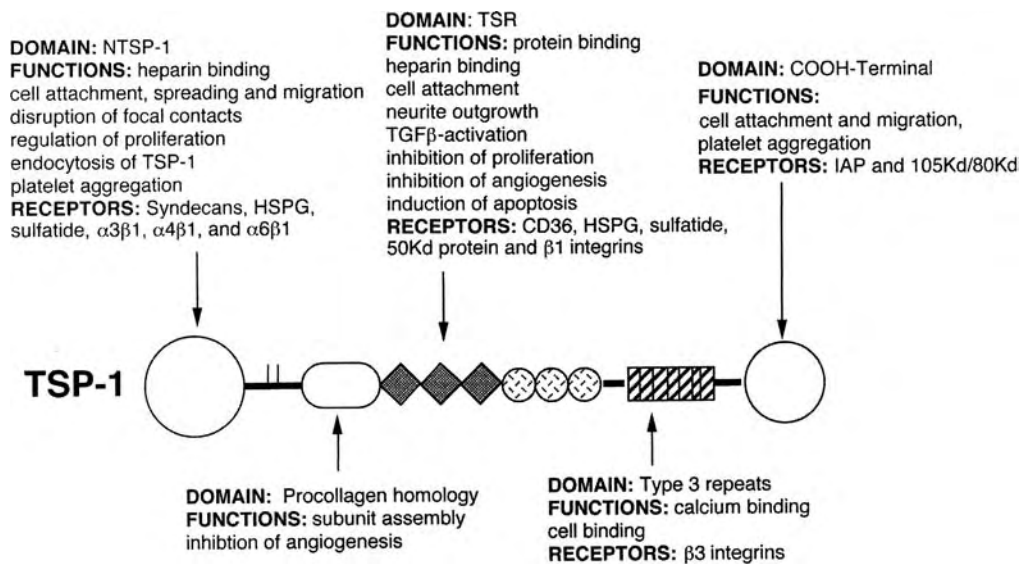

Figure 36.1. A schematic representation of the structural and functional organization of TSP-1.

subgroup B thrombospondins, the *Drosophila* protein is pentameric (26). Interestingly, the *Caenorhabditis elegans* genome does not have a TSP gene.

In TSP-1, the N-terminal and C-terminal domains are similar to each other in terms of both their structures and functions (Figure 36.1). Both domains contain cell binding sites, and antibodies to either domain inhibit platelet aggregation. Thus, the earliest forms of the protein may have been involved in cell-to-cell adhesion or communication. This assertion is consistent with the fact that RGD sequences are present in both the N-terminal and C-terminal domain of insect TSP. The insertion of the four type-2 repeats may have ensured the proper distance between the N- and C- terminal, and the multimerization may have increased valency and thus affinity of the protein for all surface receptors. Early during vertebrate development, a gene duplication may have occurred, with one copy of the gene having the opportunity to acquire new properties. One of the type-2 repeats was replaced by three TSRs by exon shuffling from another gene. Eventually, this new protein gave rise to the modern versions of TSP-1 and -2. The model suggests that the subgroup A TSPs have specialized functions that support vertebrate tissue genesis and remodeling.

#### DEVELOPMENTAL CONSIDERATIONS

The TSPs are widely expressed in developing vertebrates, with most tissues expressing at least one member of the family (see Table 36-1). Northern blot analysis indicates that human adult cardiac muscle expresses all the TSPs except COMP. TSP-4 and COMP are expressed primarily in skeletal muscle and cartilage, respectively. In addition, COMP has been detected in neointimal VSMCs in restenotic vessel walls (27). Only TSP-1 appears to be present in human blood platelets. In tissues that express

multiple TSP genes, distinct temporal patterns of expression are often observed during embryonic development. Whereas TSP-2 is expressed in large vessels and capillaries throughout most of murine development, TSP-1 is only present in capillaries late in vascular development. As a result of the differences in the spatial and temporal patterns of expression of TSP-1 and -2, very limited opportunities may exist for these proteins to compensate for one another. The observation that the phenotype of the *TSP-1* and -2 double null mice is, for the most part, equivalent to the sum of the phenotypes of the *TSP-1* and -2 single knockout mice is consistent with this view (28). However, the two proteins do appear to compensate for each other in the formation of neural synapses; in vitro data indicate that both TSP-1 and -2 can support synaptogenesis, and the number of synapses in the double-null mice is significantly lower than that seen in the wild-type mice (29). The vasculature appears to develop normally in *TSP-1*- and *TSP-2*-null mice; however, increased vessel density in some tissues has been observed (30,31). The single- and double-null mice demonstrate increased vascular density in the same tissues with the extent of the increase in the double-null being equivalent to either one of the single knockouts. For example, vessel density in the iris in the double-null mice is significantly higher than in the wild-type and *TSP-1*-null mice, but not significantly different from that of the *TSP-2*-null mice (31). By contrast, aberrant wound healing in the double-null mice resembles that of the *TSP-1*-null mice and is significantly different from the wild-type and *TSP-2*-null mice (28). This seems to be due to the fact that the TSP-1 is deposited by platelets early in wound healing is essential for normal wound closure. Thus, in tissues in which both proteins are expressed, differences in the spatial and temporal patterns of expression may lead to one of them being more important for the determination of the phenotype.

**Table 36-2: TSP-1 Receptors on ECs**

	<i>TSP-1 Binding Site</i>	<i>Downstream Signals</i>	<i>Function</i>
Calreticulin	NTSP-1	PI3K, ERK	Disrupts focal contact assembly
PGs	NTSP-1, TSRs, TC31		Promotes clearance of TSP-1 and -2
LRP	NTSP-1		Promotes clearance of TSP-1 and -2
Integrins $\alpha 3\beta 1$ , $\alpha 4\beta 1$	NTSP-1		Promotes EC proliferation and angiogenesis
Integrin $\alpha 6\beta 1$	NTSP-1		Promotes EC migration
$\beta 1$ integrins	TSRs	PI3K	Inhibits VEGF-induced migration and adhesion
Integrin $\alpha v\beta 3$	RGD		
CD36	TSRs	Fyn-caspase-3-p38 MAPK	Inhibits EC migration and tube formation in vitro and neovascularization in vivo; promotes apoptosis in vitro and in vivo
CD47	C-terminal domain	G proteins	Supports adhesion and extravasation of immune cells

#### LIGAND-RECEPTOR INTERACTIONS AND DOWNSTREAM SIGNALING

The term *matricellular protein* has been used to describe the TSPs, tenascins, osteopontin, and other proteins (30). Matricellular proteins are predominantly expressed at the interface between the cell membrane and the extracellular matrix. TSP-1 also regulates extracellular proteolysis through direct interactions with plasmin and matrix metalloproteinases (MMPs). To localize TSP-1 at its surface, most cells express a wide array of receptors for the protein (Table 36-2). These include proteoglycans (PGs), sulfatides, integrins, CD36, calreticulin, low-density lipoprotein receptor-related protein (LRP), and CD47. Most of these receptors are widely expressed on ECs; however, CD36 is expressed at low to undetectable levels on large-vessel ECs. Every domain of TSP-1 has a binding motif for at least one cell surface receptor. In many cases, the receptor binding sites have been identified using synthetic peptides, and the authenticity of these sites remains to be established using mutant forms of the intact protein or correctly folded domains.

ECs attach, spread, and form focal contacts on fibronectin-coated tissue culture plates. Addition of intact TSP-1, the N-terminal domain of TSP (NTSP-1), or a peptide designated hep I of TSP-1 (amino acids 19–36 of TSP-1) results in focal contact disassembly and increased EC migration (32). This process may be important during the tissue remodeling that is associated with angiogenesis. Calreticulin reportedly binds to the hep I sequence of TSP-1 (33). Although the majority

of calreticulin is found in the endoplasmic reticulum, some is expressed on the cell surface, where it functions as a receptor for TSP-1. The complex of TSP-1 and calreticulin then associates with LRP and heterotrimeric G-protein to disrupt focal contacts through a pathway that involves phosphoinositide 3-kinase (PI3K), focal adhesion kinase, and extracellular-signal-regulated kinase (ERK)1/2 (34). This appears to be a CD36-independent pathway.

PGs are composed of a core protein and at least one glycosaminoglycan (GAG) chain. Proteoglycans or GAGs have been reported to bind NTSP-1, the TSRs, and the type-3 repeat/C-terminal (T3Cl) domain (1). Because the GAG-binding properties of NTSP-1 and the intact protein are very similar, this domain probably is the predominant GAG-binding site in the intact molecule. NTSP-1 binds to heparin, heparan sulfate, and dermatan sulfate but not chondroitin-4-sulfate. In some cases, specific PGs have been shown to bind TSPs. For example, syndecan-1 and -4, perlecan, and decorin are capable of binding TSP-1 (32).

The binding of NTSP-1 and -2 to LRP mediates their uptake and clearance (35). PGs and LRP may function as coreceptors because the internalization of TSP-1 is inhibited by heparin. Because MMPs can bind to TSP-1 and -2, the uptake and clearance of TSP bound to MMPs occurs through an LRP-dependent mechanism (30). Varying effects of the isolated NTSP-1 on EC behavior have been reported in the presence and absence of growth factors. Vogel and colleagues (36) reported that a recombinant version of NTSP-1 inhibits EC migration toward basic fibroblast growth factor 2

(FGF2). This protein also inhibits the mitogenesis and proliferation of ECs and the binding of FGF2 to heparin (36). Based on these data, the authors concluded that NTSP-1 competes with FGF2 for binding sites on cell surface PGs. By contrast, Taraboletti and colleagues (37) have found that NTSP-1 stimulates angiogenesis in the rabbit cornea in the absence of FGF2. NTSP-1 also stimulates EC invasion through Matrigel by upregulating MMP-2 and -9 and reducing tissue inhibitors of metalloproteinase 2 (TIMP-2) expression (6). Three receptors for NTSP-1 have been reported to mediate the effect of this domain on EC function: syndecan-4, and  $\alpha 3\beta 1$  and  $\alpha 4\beta 1$  integrins. An antibody to syndecan-4 specifically blocks the binding of NTSP-1 to human umbilical vein ECs (HUVECs) (38). In addition, synthetic peptide studies indicate that short sequences in NTSP-1 mediate binding to the integrin  $\alpha 3\beta 1$  (amino acids 190–201) and  $\alpha 4\beta 1$  (amino acids 151–164) (39,40). The interaction with  $\alpha 3\beta 1$  and  $\alpha 4\beta 1$  reportedly stimulates EC proliferation and angiogenesis. The physiological significance of these observations hinges on whether NTSP-1 is produced in vivo in sufficient quantities to elicit proangiogenic effects. The production of NTSP-1 by proteolytic cleavage in human and mouse platelets has been reported (41,42). In addition, the antiangiogenic activity of TSP-1 was first identified in a 140,000-dalton proteolytic fragment produced by cells in culture. Thus, it is likely that some NTSP-1 is produced in vivo by proteolysis.

NTSP-1 also binds to the  $\alpha 6\beta 1$  integrin on human microvascular ECs and HT-1080 fibrosarcoma cells (43). The binding of TSP-1 to  $\alpha 6\beta 1$  supports chemotaxis of human dermal microvascular ECs (HDMECs). The  $\alpha 6\beta 1$  binding site has been mapped to amino acids 87–96 of NTSP-1. A role for  $\alpha 6\beta 1$  in angiogenesis is further established by the observation that antibodies to  $\alpha 6\beta 1$  inhibit tube formation in the Matrigel assay (44). Like  $\alpha 4\beta 1$ ,  $\alpha 6\beta 1$  supports the attachment and spreading of ECs. However, these integrins appear to vary in their level of activation, with  $\alpha 6\beta 1$  displaying greater activity than  $\alpha 4\beta 1$  in HUVECs. It is important to note that the  $\alpha 3\beta 1$ ,  $\alpha 4\beta 1$ , and  $\alpha 6\beta 1$  binding sites of NTSP-1 have been identified using synthetic peptides. The activity of these sites has not been confirmed using site-directed mutagenesis within the context of the correctly folded domain or intact molecule.

$\beta 1$  Integrins also bind to the TSRs and the type-2 repeats of TSP-1 (40). Adhesion of cells that express a single  $\beta 1$  integrin to a recombinant protein containing all three type-1 repeats of TSP-1 (3TSR) is specifically inhibited by an antagonist to that integrin. Adhesion of cells that express several  $\beta 1$  integrins is partially inhibited by each  $\alpha$ -subunit-specific antagonist, and completely inhibited by a combination of these antagonists.  $\beta 1$  Integrins recognize both the second and third TSRs, and each TSR shows pan- $\beta 1$  specificity and divalent cation dependence for promoting cell adhesion. Furthermore,  $\beta 1$  integrins bind in a divalent cation-dependent manner to a 3TSR affinity column. The binding of cells to 3TSR is not inhibited by synthetic peptides that encompass the RFK, WSHWSPW, VTCCG, and GVITRIR sequences, suggesting that  $\beta 1$  integrins bind to a site that is distinct from the CD36 binding site. How-

ever, it is possible that these linear peptides have a much lower affinity than the correctly folded domain and therefore do not compete effectively for binding.

The TSRs reportedly inhibit VEGF-induced HUVEC migration in a  $\beta 1$ -dependent fashion (45). Large-vessel ECs reportedly do not express CD36. Although an antibody to  $\beta 1$ - or  $\beta 1$ -siRNA blocks the ability of 3TSR to inhibit VEGF-induced migration,  $\beta 3$ -siRNA is without effect. Blocking either the  $\alpha 3$  or  $\alpha 5$  integrin subunit prevents 3TSR from inhibiting VEGF-induced HUVEC migration, whereas antibodies to the  $\alpha 2$  and  $\alpha v$  subunits do not have a significant effect. These cells express low levels of  $\alpha 1$  and  $\alpha 4$ , and moderate levels of  $\alpha 6$ . 3TSR-coated beads selectively bind  $\alpha 5\beta 1$  from HUVEC lysates. Although PI3K is essential for TSR-mediated inhibition of HUVEC migration, phospholipase C (PLC)- $\gamma$  and Akt are not required. These data indicate that  $\alpha 5\beta 1$  mediates the inhibition of migration of ECs that lack CD36.

The interaction of TSP-1 with CD36 plays a significant role in the antiangiogenic activity of TSP-1 both in vitro and in vivo (46–48). In vitro, CD36 mediates TSP-1 inhibition of EC migration and tube formation (46,47). Both GST fusion proteins containing the TSP-1-binding region of CD36 and antibodies against CD36 block the inhibition of EC migration caused by TSP-1. Transfection of CD36 into HUVECs renders them more sensitive to inhibition of migration by TSP-1. Furthermore, molecules that bind to CD36, including collagen, oxidized low-density lipoprotein (LDL), and an anti-CD36 IgM antibody, can also inhibit EC migration (46). Although TSP-1 is a potent inhibitor of FGF2-induced corneal neovascularization in wild-type mice, it is not active in CD36-null mice (48). In addition, upregulation of CD36 in vivo with ligands for peroxisome proliferators-activated receptor- $\gamma$  (PPAR $\gamma$ ) increases the antiangiogenic activity of the TSP-1-based therapeutic, ABT-510 (discussed in the next section) (49). Jimenez and colleagues (48) have shown that TSP-1 activation of a CD36–Fyn–caspase-3–p38 mitogen-activated protein kinase (MAPK) cascade is essential for the antiangiogenic effect of TSP-1, as well as its induction of EC apoptosis (Figure 36.2). Activation of this pathway leads to increased EC expression of Fas ligand, which sensitizes the cells to the increased levels of Fas that are induced by factors that initiate angiogenesis (50). Nor and colleagues (51) have reported that TSP-1 inhibits angiogenesis by decreasing expression of Bcl-2 and increasing expression of Bax. Taken together, the data indicate that the antiangiogenic effect of TSP-1 depends, at least in part, on its ability to induce apoptosis of ECs (48,51).

CD36-independent mechanisms for the induction of EC apoptosis also have been identified (52–54). Guo and coworkers (52) reported that TSP-1 or peptides that comprise TSR sequences induce apoptosis of bovine aortic ECs. As described earlier, recent data indicate that the TSRs can bind to  $\beta 1$  integrins, and this interaction can inhibit EC migration. We have found that CD36, CD9, and  $\beta 1$  integrins form a complex on platelets and ECs (55). CD9 is a member of the tetraspanin family of integrin-associated membrane proteins (56). Although the function of these proteins remains to be

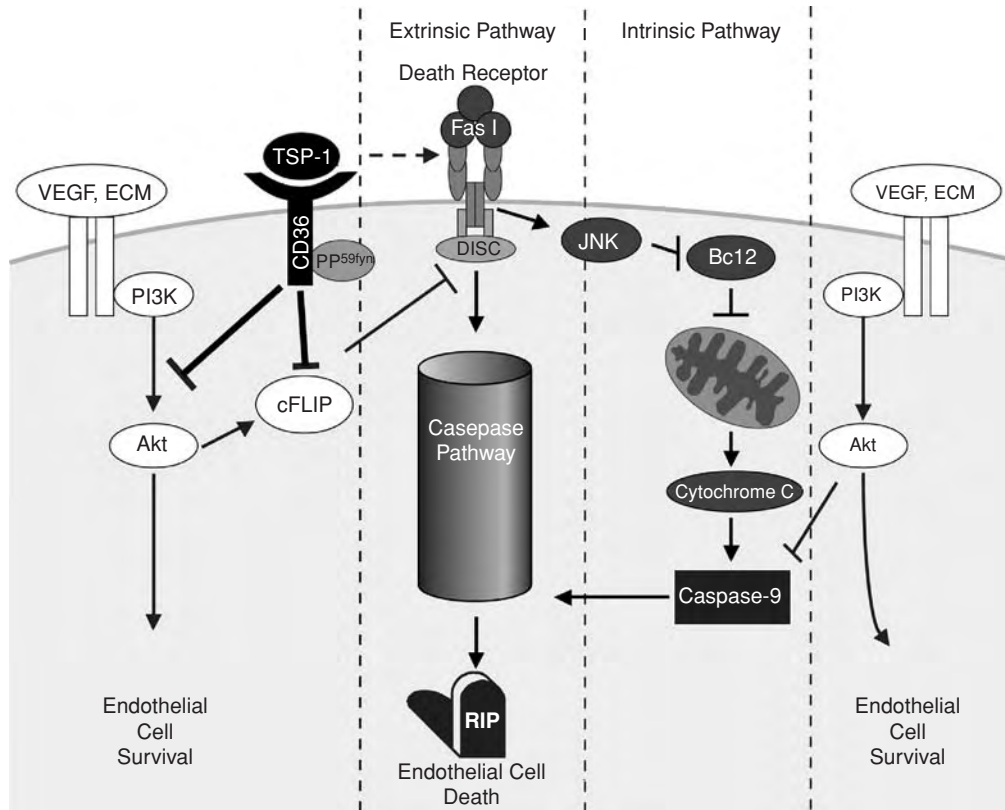

Figure 36.2. TSP-1 affects EC signaling. Complex EC signaling allows for cell survival or cell death. Both VEGF and TSP-1 affect Akt-dependent EC survival pathways as well as caspase-dependent and -independent apoptotic pathways. The balance of VEGF and TSP appears to be important in EC signaling.

fully defined, they appear to form membrane microdomains and modulate integrin function. The TSRs may engage a multi-protein complex to inhibit EC migration and induce EC apoptosis. Increased expression of CD47 also has been reported to correlate with increased EC apoptosis (53). In addition, a peptide that contains the CD47 binding sequence of the C-terminal domain of TSP-1 has been reported to inhibit angiogenesis (54). This peptide inhibits *in vitro* tube formation of brain capillary ECs and FGF2-induced angiogenesis in the cornea. Peptide studies have identified the sequences RFYVVMWK and IRVVM in the C-terminal domain of TSP-1 as binding sites for CD47 (57,58). However, recent structural data indicate that these sequences are not on the surface of the C-terminal domain and therefore are not available to interact with other proteins (24). Although the role of CD47 in TSP-1-induced apoptosis has not been determined, antibodies to CD47 induce apoptosis of B cells derived from patients with B-cell chronic lymphocytic leukemia (59). This apoptotic pathway does not involve caspases.

The molecular cloning of TSP-1 revealed the presence of an RGD sequence within the type-3 repeats. Subsequent studies have shown that the integrins  $\alpha$ IIB $\beta$ 3 on blood platelets and  $\alpha$ v $\beta$ 3 on a variety of cell types bind to the RGD sequence of TSP-1 (60–62). The availability of the RGD sequence is regulated by calcium-dependent and disulfide bond-dependent

structures. An EC surface protein disulfide isomerase reportedly catalyzes disulfide interchange in TSP-1, resulting in the exposure of the RGD sequence (63).

#### EFFECTS ON ENDOTHELIAL CELL PHENOTYPE

Of all five members of the TSP family, only TSP-1 and -2 have been shown to exert influence on EC behavior, including adhesion, migration, proliferation, and apoptosis. The effects of TSP-1 have been well documented in both *in vivo* and *in vitro* models. Although *in vitro* experiments from many laboratories show that TSP-1 modulates adhesion, suppresses migration, inhibits proliferation, and induces apoptosis of ECs (64), some of the data are confusing and conflicting. Some of these disparate findings may be the result of differences in cultured ECs, such as source of origin of the ECs, species, and culture conditions, as well as passage numbers. However, some of the data undoubtedly point to the difficulty in seeing each part of the equation separately in the dynamic balance that controls angiogenesis. This is especially true for the TSPs, when compared to positive regulators of angiogenesis such as FGF1, because they are important regulators of EC function (65).

Under *in vitro* conditions, TSP-1 was shown to inhibit FGF2-induced murine lung capillary EC proliferation as well

as FGF2-induced proliferation of bovine adrenal capillary ECs (see section on Ligand Receptor Interactions) (66,67). However, other studies have demonstrated that TSP-1, in the presence of other factors such as FGF2, lipopolysaccharide, fibrin, and collagen, is capable of stimulating EC proliferation (68,69). TSP-1 inhibited the mitogenic activity of VEGF-A<sub>165</sub> both in the presence and absence of heparin, perhaps due to an interaction of VEGF-A<sub>165</sub> and TSP-1 directly on ECs. The TSRs, the type-3 repeats, and the N-terminal heparin binding domain may have mediated this binding because blocking monoclonal antibodies to these regions significantly inhibited the binding of TSP-1 to VEGF-A<sub>165</sub> (70).

Several authors have shown that TSP-1 increases EC adhesion to plates coated with this molecule, and the addition of a peptide containing the RGD sequence in the type-3 repeats of TSP-1 will inhibit this cellular adhesion (71). The amino terminal also may participate, because adhesion was inhibited by blocking the amino terminal of TSP-1 with the polysaccharide fucoidan (66). TSP-1 regulation of focal adhesions also appears to modulate cell responsiveness to both FGF1 and -2 (72).

Differential effects of TSP-1 on EC migration have been reported. TSP-1 induced EC chemotaxis, which could be inhibited using heparin, fucoidan, or an antibody that binds to the N-terminal domain of TSP-1 (66). However, TSP-1 inhibits VEGF-induced EC migration when it is added to the cells prior to placing them in the Boyden chamber apparatus. This effect could be reversed with anti-TSP-1 or anti-CD36 antibodies (73). In addition, recent work by Short and colleagues (45) has shown that the TSRs, the previously identified antiangiogenic domain of TSP-1, inhibits VEGF-induced HUVEC migration via a CD36-independent pathway. In this study,  $\beta$ 1 integrin activation was shown to be necessary for this TSR-induced inhibition of HUVEC migration. Binding of TSR to the  $\alpha$ 5 $\beta$ 1 integrins outside of their RGD-binding site (since TSR does not contain RGD) resulted in a conformational change that then blocked the activation of PI3K and resulted in inhibition of EC migration (45). Endothelial cord formation also appears to be modulated by TSP-1; cord formation could be increased when anti TSP-1 antibody was added to cultures of both aortic and microvascular ECs (14).

Interestingly, TSP-1 has been reported to induce apoptosis of ECs (see the discussion on Ligand Receptor Interactions and Figure 36.2) (48,52,74). In addition, investigators have shown that the TSRs of TSP-1 are capable of antiangiogenic activity via apoptosis (52). Treatment of mice harboring experimental pancreatic tumors with intraperitoneal doses of 3TSR results in a 2.5-fold increase in EC apoptosis in the tumor (75). 3TSR also induced microvessel EC apoptosis *in vitro* in a CD36-dependent manner, and both the intrinsic and extrinsic apoptotic pathways activate executioner caspase-3 in 3TSR-induced apoptosis (our unpublished observations). Moreover, 3TSR decreased endogenous and VEGF-induced c-Akt activity and induced EC apoptosis in the presence of VEGF. Recombinant type-1 repeats of TSP-1 (3 TSR) have been shown to activate

endothelial caspases between 8 and 12 hours of treatment with an effect similar to Tie2 blockade (76). In these same experiments, PI3K blockade using LY294002 inhibitor resulted in a loss of Akt signaling over 3 hours as well as a gradual increase in TSP-1 expression in the cultured ECs.

TSP also may play an important role in intimal hyperplasia and atherosclerosis. TSP-1 is not present in undamaged subendothelial membranes (77), but injury in the form of balloon angioplasty results in strong TSP-1 staining in the luminal surface as well as the media of the injured vessels within 1 hour (78). TSP-1 may delay healing of the injured endothelium by promoting VSMC proliferation and migration. The presence of anti-TSP-1 antibodies directed against the C-terminal of TSP-1 resulted in decreased neointimal formation in a rat carotid artery injury model (79). VSMCs are induced to migrate in response to TSP-1 through signaling pathways that include PI3K, p21 Ras, ERK-1 and -2, and p38 MAPK (80–82). The C-terminal domain of TSP-1 appears to be predominantly responsible for VSMC migration in these studies (83).

Fewer studies of the effects of TSP-2 on endothelial function exist, given the difficulty in obtaining pure material in sufficient quantities, because it cannot be isolated from platelets, as can TSP-1. A recombinant N-terminal 80-kDa fragment of TSP-2 that contains the procollagen homology domain and three type-1 repeats of TSP-2 was able to inhibit VEGF-induced migration of HDMECs *in vitro* (84). This fragment also inhibited Matrigel tube formation *in vitro*, as well as in an *in vivo* Matrigel assay. No effect of TSP-2 was seen on EC apoptosis.

## DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Despite remarkable progress over the past 25 years in understanding TSP structure and function, the diagnostic or therapeutic potential of these complex multifunctional molecules remains largely untapped. A number of studies have examined plasma levels of TSP-1 expression in patients with tumors. Plasma TSP-1 levels in patients with metastatic gastrointestinal, breast, or lung carcinomas were two- to threefold higher than those in healthy volunteers or in nonmetastatic malignancies (85). A direct correlation was observed between plasma TSP-1 levels and the stage of disease in patients with colorectal or gynecologic malignant tumors (86,87). Larger studies are needed to determine the prognostic value of plasma TSP-1 levels in cancer. The source of plasma TSP-1 in cancer patients has yet to be identified, and could include any combination of platelet, ECs, or tumor cells. Furthermore, high plasma levels of TSP-1 could result in beneficial effects, such as reduction in endothelial proliferation and thus tumor growth suppression at local or metastatic sites, or potentially less beneficial effects, such as increased invasiveness.

Several studies have shown that TSP-1 protein expression is inversely correlated with tumor grade and survival rate in

thyroid, colon, and bladder cancers (88–90). In a study of human thyroid cancers, TSP-1 inversely correlated with the degree of invasion of the primary tumor into adjacent organs and with microvessel count per high power field (MVC) (89). A higher MVC correlated with poorer survival. The ratios of VEGF/TSP-1, VEGF-C/TSP-1, and Ang-2/TSP-1 significantly correlated with a higher microvascular density. Furthermore, the ratios VEGF/TSP-1 and angiopoietin 2 (Ang2)/TSP-1 significantly correlated with the degree of infiltration (91). Interestingly, studies of mouse skin after chronic or acute UVB irradiation also show that the balance of VEGF and TSP-1 expression plays a critical role in the shift from vascular quiescence to a proangiogenic environment (92). This switch results in dermal angiogenesis, a finding that may have potential application in the development of novel medications or topical creams to upregulate skin TSP-1, and thus combat the onset of cutaneous photoaging that results in wrinkles (92). In contrast, breast tumors and cholangiocarcinomas show increased stromal expression of TSP-1 in tumors compared to normal tissue, and in esophageal and gallbladder carcinomas TSP-1 expression directly correlated to occurrence of metastases (93,94). In a study of pancreatic cancer patients, diffuse expression of TSP-1 was significantly correlated with lymph node metastasis ( $p < 0.01$ ), neural invasion ( $p < 0.05$ ), and TNM stage ( $p < 0.01$ ) (95).

Because upregulation of TSP-2 expression in the peritumoral stroma throughout the consecutive stages of chemically induced multistep carcinogenesis in mice has been observed (96), it will be interesting to look at TSP-2 levels in human malignancies. *TSP-2*-null mice display enhanced susceptibility to chemically induced skin carcinogenesis (96). A greater number of papillomas formed in the *TSP-2*-null mice; however, the rate of malignant conversion to squamous cell carcinoma was comparable in the *TSP-2*-null and wild-type mice.

The effects of TSP-1 on tumor growth and angiogenesis are summarized in Figure 36.3. In the tumor microenvironment, TSP-1 inhibits EC function directly through CD36 and probably other cell surface receptors, and indirectly through inhibition of MMP-mediated VEGF mobilization. In addition, TSP-1 can inhibit tumor cell growth and survival through the activation of tumor growth factor- $\beta$  (TGF- $\beta$ ). Inclusion of sequences that are necessary for the activation of TGF- $\beta$  in TSR-based recombinant proteins produced greater inhibition of B16F10 melanoma and A431 squamous cell carcinoma tumor growth (55,97). This effect was abrogated by systemic injections of an anti-TGF- $\beta$  antibody (55). To circumvent the inhibitory effects of TSP-1, the mutations that occur in tumor suppressor genes and oncogenes frequently lead to downregulation of this protein. For example, hyperactivation of Ras and Myc leads to decreased TSP-1 expression

Figure 36.3. Inhibition of tumor growth and angiogenesis by TSP-1. TSP-1 is secreted in tumor tissue by stromal cells and, in some cases, by tumor cells. Through interactions with CD36 and  $\beta 1$  integrins, it has direct effects on the migration and survival of ECs in the vessel wall and in circulating ECs (CECs). TSP-1 also suppresses VEGF activity by inhibiting its mobilization from the extracellular matrix by matrix metalloproteinase (MMP)-9 and by binding directly to it. TSP-1 also suppresses the growth of TGF- $\beta$ -responsive tumors by activating TGF- $\beta$ .

and the acquisition of an angiogenic phenotype (98). These studies have led to the concept that reinstating TSP-1 expression could be used to inhibit tumor progression, and several strategies have been developed to accomplish this goal. Cell-based gene therapy and systemic delivery of synthetic peptides and recombinant proteins have been used to inhibit tumor angiogenesis (50,99,100). In addition, the antiangiogenic activity of low doses of the chemotherapeutic cyclophosphamide is mediated by systematic increases in TSP-1 levels (101,102). Low doses of cyclophosphamide inhibit angiogenesis in Matrigel plug assays performed in wild-type mice, but not in *TSP-1*-null mice (101). Although the efficacy of low-dose chemotherapeutics is diminished in *TSP-1*-null mice, it is equally effective in wild-type, endostatin-null, and tumstatin-null mice (102). The source of increased systemic levels of TSP-1 is unclear. One study presented data indicating that ECs increase TSP-1 expression in response to low-dose chemotherapeutics, whereas another study suggested that the increased TSP-1 is derived from tumor cells and perivascular stromal cells (101,102).

Circulating levels of TSP-2 have been increased by implanting a biodegradable polymer containing fibroblasts that overexpress TSP-2 (99). These increased levels persisted for at least 5 weeks and were sufficient to inhibit experimental squamous cell carcinomas, Lewis lung carcinomas, and malignant melanomas. As expected, these tumors exhibited decreased angiogenesis as measured by decreased tumor vessel size. In addition, systemic treatment of mice with a recombinant protein that contains the N-terminal through the TSRs of TSP-2 inhibits experimental squamous cell carcinoma growth (84).

Systemic delivery of recombinant versions of the TSRs of TSP-1 inhibits the growth of experimental ASPC-1 orthotopically placed pancreatic tumors, B16F10 melanomas, and Lewis lung carcinomas (75,103). Daily doses of 1 to 2.5 mg/kg of recombinant TSR protein inhibits tumor growth by 60% to 80%. For B16F10 melanoma, but not Lewis Lung carcinoma, a portion of the inhibition is associated with activation of TGF- $\beta$  by the TSRs (100). Thus, for tumor cells that retain the ability to respond to TGF- $\beta$ , additional therapeutic efficiency can be achieved with recombinant TSRs that include the TGF- $\beta$ -activating sequence.

A synthetic TSR peptide, designated ABT-510, is currently in Phase II clinical trials for the treatment of cancer (50,104,105). This peptide is a substituted derivative of the sequence GVITRIR, and the two arginine residues are essential for activity. The first phase of clinical trials established that ABT-510 is well tolerated (104). A Phase II trial is currently under way to evaluate the safety and efficacy of ABT-510 for the treatment of soft-tissue sarcoma. The structure of the TSRs suggests that the ABT-510 sequence falls within a positively charged groove that functions as the CD36 binding site (28). In addition, anti-CD36 antibodies reportedly blocked the activity of ABT-510 (106). These data indicate that the antiangiogenic activity of ABT-510 is mediated by CD36. Because CD36 is upregulated by PPAR $\gamma$ , a reagent that activates

PPAR $\gamma$  has been used systemically to sensitize ECs to ABT-510 (107).

In general, it appears that single-agent antiangiogenic strategies will not be sufficient to block tumor growth. Several studies have sought to combine TSP-based therapeutics with other treatment modalities. The combination of downregulation of VEGF by RNA interference and upregulation of TSP-1 significantly delayed fibrosarcoma formation and growth rate (108). Pretreatment with TSP-1 potentiates the effects of radiation by rendering the ECs in D-12 melanoma experimental tumors more likely to become apoptotic (109). Continued delivery of TSP-1 to mice after radiation treatment inhibited the outgrowth of metastases. A combination of TSP-1 with carboplatin also inhibited metastases in human nonseminomatous germ cell tumor xenografts (110).

Further intense investigation of the molecular effects of the TSPs on ECs and tumor cells will undoubtedly yield results that will be directly translatable to the treatment of human diseases such as cancer. Translational research protocols addressing prospectively the use of TSP-1 and TSP-2 as prognostic markers in tumor or plasma samples, as well as treatment of malignancies with TSP-1 or -2 type-1 repeat peptides, will be necessary for further advancement in this area. Thus far, the data point to the fact that TSP-based reagents are well tolerated and effective with little toxicity, but should be combined with other agents to best combat illnesses such as cancer. Ultimately, a complete understanding of the effects of TSPs on the varied cells in the tumor microenvironment will lead to a more targeted use of this protein therapeutically.

#### KEY POINTS

- The five members of the TSP family can be divided into two groups on the basis of their domain and tertiary structure. All the TSPs contain type-2 (EGF-like) repeats, type-3 repeats, and a highly conserved C-terminal domain.
- Of the five proteins that comprise the family, TSP-1 and -2 have been shown to be involved in vascular development and angiogenesis. Only TSP-1 and TSP-2 have been shown to exert influence on EC behavior, including adhesion, migration, proliferation, and apoptosis.
- The interaction of TSP-1 with CD36 plays a significant role in the antiangiogenic activity of TSP-1 both in vitro and in vivo. TSP-1 also acts indirectly through inhibition of MMP-mediated VEGF mobilization. In addition, TSP-1 can inhibit tumor cell growth and survival through the activation of TGF- $\beta$ .
- TSP also may play an important role in intimal hyperplasia and atherosclerosis.

- Several studies have shown that TSP-1 protein expression is inversely correlated with tumor grade and survival rate in certain malignancies.
- Systemic delivery of recombinant versions of the TSRs of TSP-1 inhibits the growth of several experimental tumors including ASPC-1 orthotopically placed pancreatic tumors, B16F10 melanomas, and Lewis lung carcinomas.
- A synthetic TSR peptide, designated ABT-510, is currently in Phase II clinical trials for the treatment of cancer.
- Further intense investigation of the molecular effects of the TSPs on endothelial and tumor cells will open new avenues for therapeutic intervention.

# Neuropilins

## Receptors Central to Angiogenesis and Neuronal Guidance

---

Diane Bielenberg, Peter Kurschat, and Michael Klagsbrun

*Children's Hospital, Harvard Medical School, Boston, Massachusetts*

### HISTORICAL CONTEXT

Neuropilins (NRPs) are type I membrane glycoproteins first described by Fujisawa and colleagues in 1987 as antigens for antibodies that bind to neuropiles and plexiform layers in the *Xenopus* tadpole nervous system (1,2). NRP function was demonstrated 10 years later when these proteins were found to be receptors for the class 3 semaphorins (SEMA). The first class 3 semaphorin identified was chick collapsin-1 (now known as Sema3A), described by Raper and colleagues as an inhibitory axonal guidance signal that collapsed growth cones and repelled axons in chick dorsal root ganglia (DRG) (1–4). Two NRPs (NRP1 and NRP2), and six class 3 semaphorins (A–F) exist (5,6).

Unexpectedly, NRPs were later shown to be regulators of angiogenesis. The first indication came in 1995, when overexpression of *Nrp1* in chimeric mice was associated with vascular defects (7). In 1998, NRP1 was detected in endothelial cells (ECs) for the first time (8). ECs express both NRP1 and NRP2, and these NRPs are functional receptors for vascular endothelial growth factor (VEGF), a potent angiogenesis factor (5). NRPs do not appear to be high-affinity receptor tyrosine kinases but may serve as coreceptors with high-affinity VEGF receptors. A complex of VEGF-A<sub>165</sub>, NRP1, and VEGF receptor 2 (VEGFR2) is formed on ECs that increases VEGF binding and enhances EC chemotaxis (8,9). ECs that express NRPs also bind semaphorins. Plexins (PLXNs), a large family of transmembrane proteins, form complexes with SEMAs and NRPs and function as signaling coreceptors (10). As an example of the effect of SEMA on ECs, SEMA3A inhibits EC migration and sprouting (11), and SEMA3F inhibits tumor angiogenesis and metastasis (12). These findings are discussed in more detail in later sections.

### BIOLOGICAL AND MOLECULAR SIMILARITIES BETWEEN THE NERVOUS AND VASCULAR SYSTEMS

In retrospect, it is not so surprising that similar cues regulate neuronal guidance and angiogenesis and that these two processes have much more in common than was previously thought. Structurally, neurons and blood vessels exist as hierarchically ordered networks. Both neurogenesis and angiogenesis are processes involving a high degree of branching and migration over long distances. Axons sense their environment through their growth cones, sensory structures containing filopodia at the leading tip of the axons. The growth cones react to repulsive and attractive signals in their environment, which ultimately determine axonal direction. Similarly, developing blood vessels have specialized tip cells that resemble axonal growth cones and sense their environment (13). For example, ECs are attracted by VEGF gradients. Thus, path finding (migration to an appropriate target) in both axons and blood vessels is mediated by chemo-repulsive and -attractive signals.

In addition, nerves and blood vessels are in close proximity and follow similar routes of migration. Nerves and blood vessels also are interdependent. For example, nerves are templates for blood vessel branching and arterial differentiation. Arteries, but not veins, are specifically aligned with peripheral nerves in embryonic mouse limb skin (14). These sensory nerves and Schwann cells provide the VEGF needed for arteriogenesis. In another example, DRG are highly vascular. In DRG, capillaries and neurons are in close apposition to each other, and the neurons produce VEGF that is required for capillary survival (15). The proximity of nerves and blood vessels suggests that there may be molecular cross-talk and common cues between nerves and blood vessels. Several proteins, which

were first described as regulators of neuronal migration, have now been shown to guide blood vessels as well. Four pairs of neuronal guidance factors and their cognate receptors have been implicated in angiogenesis. These include Sema/NRP, ephrin/Eph, Slit/Robo, and Netrin/UNC or DCC (13,16). The four receptors are expressed on both neurons and ECs. Thus, it is apparent that a number of ligands and their receptors are involved in the dual regulation of neuronal guidance and angiogenesis.

The congruence of nerve and blood vessel interactions is a rapidly expanding field. The role of ephrin/Eph, Slit/Robo, and Netrin/UNC or DCC in endothelial biology (13,16,17) is covered elsewhere in this volume (see Chapters 38 and 40). This chapter emphasizes the role of NRPs and their semaphorin ligands in developmental and pathological angiogenesis.

### NEUROPILIN STRUCTURE, LIGAND-BINDING SPECIFICITIES, AND FUNCTION

NRP is a 130- to 140-kDa membrane glycoprotein first identified in the optic tectum of *Xenopus laevis* and subsequently in the developing vertebrate brain (1). Currently, two NRP genes are known, designated as *NRP1* and *NRP2* (1,5). Human *NRP1* and *NRP2* map to 10p12 and 2q34, respectively (5). NRPs have five extracellular domains (a1, a2, b1, b2, and c), a transmembrane domain, and a short cytoplasmic domain of 40 amino acids (Figure 37.1). VEGF-A<sub>165</sub> binds to the NRP1 b1b2 domain, whereas SEMA3A binds to both the NRP1 a1a2 and b1b2 domains. SEMA3A and VEGF compete for binding to the NRP1 b1b2 domain (see Figure 37.1) (11). The binding sites on NRP2 for VEGF and SEMA3F have not been identified, but are likely similar to that of NRP1. The NRP c domain is involved in dimerization (1). It is possible that NRP1 and NRP2 can heterodimerize. The cytoplasmic region of either NRP contains no apparent kinase domain, therefore its role in signaling is unclear. Yet, the three most carboxy-terminal amino acids of both NRP1 and NRP2 are serine-glutamic acid-alanine (SEA) and bind a ~40-kDa protein containing a PDZ domain. This NRP interacting protein (NIP) binds members of the GTPase activating protein (GAP) family but its function in ECs and its importance in NRP signaling remain unclear (18). In addition, there are naturally occurring soluble NRP (sNRP) isoforms containing only the a1a2 and b1b2 domains, and these sNRPs are capable of binding ligands (19).

NRP1 and NRP2 share 47% sequence homology and contain similar domain structures, yet their ligand binding specificities are somewhat different (Table 37-1). NRP1 binds SEMA3A, NRP2 binds SEMA3F, and both NRPs bind SEMA3B. Functionally, most NRP/SEMA interactions result in the chemorepulsion of NRP-expressing cells. In the neuronal system, for example, NRP1 is expressed on DRG. SEMA3A binding to NRP1 results in signaling via PLXNs and the repulsion of DRG axons and the collapse of growth cones on the axonal tip of DRG. Neurons in the superior cervical

Figure 37.1. Neuropilins (NRPs) bind semaphorins and VEGF. (1) There are two neuropilins NRP1 and NRP2. NRPs have five extracellular subdomains (a1, a2, b1, b2, c), a transmembrane domain, and a short cytoplasmic domain. NRPs function as homo- or heterodimers (not shown) that bind via the c domain. (2) Class 3 semaphorins are composed of a Sema domain (white), an immunoglobulin loop (black), and a basic domain (gray). Semaphorins bind to NRP via the a1a2 and b1b2 domains. Plexins are transmembrane proteins containing putative cytoplasmic phosphorylation sites. Upon ligand binding, semaphorins, NRPs and plexins form a complex that mediates axon repulsion or growth cone collapse. Semaphorins also inhibit angiogenesis. (3) VEGF binds to NRP through the protein subunit encoded by exon 7 and to VEGFR2 (high affinity receptor) through the protein subunit encoded by exon 4. VEGF enhances angiogenesis by bridging NRP and VEGFR. VEGF can also stimulate neuronal cell survival.

ganglia (SCG) express NRP2 and can be repelled by SEMA3F. In vitro, primary ECs express both NRP1 and NRP2 and can be repelled by both SEMA3A and SEMA3F (discussed in more detail later) (12).

The NRPs also differ in their ability to bind various VEGF family members (Table 37-1). NRP1 binds VEGF-A, VEGF-B, VEGF-E, and placenta growth factor-2 (PlGF2, a splice isoform of PlGF), whereas NRP2 binds VEGF-A and VEGF-C (5,6). VEGF-A binding to NRPs is isoform-specific. VEGF-A<sub>165</sub> binds to NRP1 and NRP2, whereas VEGF-A<sub>121</sub> does not bind either NRP. VEGF-A<sub>165</sub> (containing exon 7) is a heparin-binding isoform, whereas VEGF-A<sub>121</sub> (lacking exon 6 or 7) does not bind heparin. The exon 7 domain of VEGF-A<sub>165</sub> binds to the b1b2 domain of NRP1 (5,8). The exact binding site for VEGF-A and VEGF-C on NRP2 has not been elucidated.

Functionally, NRPs appear to augment ligand-induced signals by acting as coreceptors for other VEGF receptor tyrosine kinases such as VEGFR1 and VEGFR2. Because VEGF-A<sub>165</sub> binds to VEGFR2 via its exon 4 domain, and since coimmunoprecipitation of NRP1 and VEGFR2 is only possible in the presence of VEGF-A<sub>165</sub> ligand, it appears likely that VEGF-A<sub>165</sub> forms a bridge between NRP1 and VEGFR2 (9). ECs that express NRP1 in addition to VEGFR2 show increased chemotactic activity in response to VEGF-A<sub>165</sub> (8). When

**Table 37-1: Ligand-Binding Specificities and EC Expression Patterns for NRPs and PLXN D1**

	SEMA3F	
PLXN D1	SEMA3E*	ECs

\*SEMA3E may signal via an NRP-independent pathway.

NRP1 is inhibited using siRNA in human umbilical vein ECs (HUVECs), VEGF-A–induced mitogenic activity (including tritiated thymidine uptake and phospho-extracellular-signal-regulated kinase [ERK] activation) is decreased (20). NRP1 also regulates VEGF-mediated EC permeability (21). Porcine aortic endothelial (PAE) cells expressing NRP1 and VEGFR2 show decreased transendothelial electrical resistance (a measurement of permeability) in response to VEGF-A<sub>165</sub>, whereas PAE cells expressing NRP1 or VEGFR2 alone do not (21). In addition, blocking of NRP1, but not VEGFR2, using receptor-specific antibodies, attenuated VEGF-A<sub>165</sub>-mediated permeability of human pulmonary artery endothelial (HPAE) cells (21). NRP2's coreceptor functions have not been studied as rigorously as those of NRP1. NRP2 has a similar domain structure to NRP1 and binds VEGF-A<sub>165</sub>, therefore it is suspected that NRP2 may serve as a coreceptor for VEGFR2. It is possible that NRP2 may also act as a coreceptor with VEGFR3, because it binds VEGF-C, whereas NRP1 does not. NRPs also may function independently of other VEGFRs to regulate the attachment and adhesion of ECs to extracellular matrix proteins (20).

### NEUROFILIN EXPRESSION IN ENDOTHELIAL CELLS

NRPs were first found on HUVECs and later on aortic ECs and capillary ECs (5,8,11). NRP expression in blood vessels has been confirmed in vivo in several organs including the skin, heart, kidney, and bone, but its expression is not ubiquitous (5,7,19). In the avian vascular system, blood islands, which are the earliest vascular structures, express both NRP1 and NRP2. However, following differentiation, NRP1 is expressed preferentially in arterial ECs, whereas NRP2 is expressed preferentially in venous ECs (Table 37-1). When quail-chick chimeras

were examined, grafts composed of arterial ECs (expressing NRP1) were found to contribute to both arteries and veins in the host (22). These studies suggest that NRPs contribute toward the determination of vascular identity but are insufficient to determine vascular fate. NRPs are expressed differentially in embryonic blood vessels and lymphatic vessels. For example, NRP2 is expressed primarily in veins and lymphatic vessels (Table 37-1) (13,23). Whether this pattern remains in all adult vessels is unclear, but lymphatic ECs purified from newborn human foreskins express NRP2 and not NRP1 (12).

### NEUROFILINS AND THE VASCULATURE

The importance of NRPs in vascular development has been shown in a series of transgenic mouse studies (Table 37-2) (5,24). Overexpression of *Nrp1* in mice was embryonic-lethal and displayed vascular defects (7). These mice die with various morphological deformities, including excess numbers of blood vessels, dilated blood vessels, frequent hemorrhage, and malformed hearts and limbs. *Nrp1*-knockout mice die in utero at embryonic day (E)12.5 to E13.5. In addition to abnormal axonal networks, these mice exhibited vascular defects throughout the embryo, including abnormal yolk sac and neuronal vascularization (25). Both large and small vessels were disorganized and lacked normal branching, while capillary networks were often missing. The NRP1-deficient mice had major cardiovascular defects including agenesis of the branchial arch-related great vessels, dorsal aorta, and transposition of aortic arches (25). When the *Nrp1* a1a2 domain was mutated (knockin strategy changing seven amino acids in this domain) so that SEMA–NRP1 interactions were abolished but VEGF–NRP1 interactions were retained, blood vessel development was normal in the transgenic mice, whereas axonal path finding and cardiovascular development were not (26). Thus, VEGF–NRP1, but not SEMA3A–NRP1 interactions are necessary for establishing the normal vascular architecture. EC-specific *Nrp1*-null mice (*Tie-2Nrp1*<sup>-/-</sup> mice) have severe vascular and cardiac defects and survive only until mid-to-late gestation (26). NRP2-deficient mice are viable but have increased mortality following birth (27,28). These *Nrp2* mutant mice (with a targeted deletion in the *Nrp2* locus) have disorganized cranial nerves, and axonal guidance defects in the peripheral nervous system and the central nervous system (27,28). The loss of *Nrp2* results in normal development of arteries and veins, but mice display a severe reduction of small lymphatic vessels and a paucity of vascular capillaries (23). These studies suggest that NRP2 is required for the formation of small lymphatic vessels.

Double *Nrp1/Nrp2*-knockout mice die very early (E8.5) and have a more severe vascular phenotype than do either *Nrp1*- or *Nrp2*-null mice (29). These double mutants exhibit avascular yolk sacs and marked growth retardation. The vascular defects included lack of vessel development, capillary formation, and branching. The vascular phenotype of double *Nrp1/Nrp2*-knockout mice resembles that of *Vegf-a*- and

**Table 37-2: Neuropilin-Related Transgenic Mouse Studies**

<i>Genotype</i>	<i>Phenotype</i>	<i>References</i>
<i>Nrp1</i> <sup>-/-</sup>	Embryonic lethal at E12.5–13.5; vascular and axonal defects	25, 44, 45
<i>Nrp1</i> <sup>sema-</sup>	Survive to birth; normal blood vessel development, aberrant axonal path finding	26
<i>Tie-2 Nrp1</i> <sup>-/-</sup>	Embryonic lethal mid to late gestation; dramatic systemic vascular deficiencies	26
<i>Nrp2</i> <sup>-/-</sup>	Viable; abnormal capillaries and lymphatics; neuronal defects; abnormal neural crest migration	23, 27, 28, 46
<i>Nrp1</i> <sup>-/-</sup> <i>Nrp2</i> <sup>-/-</sup>	Embryonic lethal at E8.5; more severe vascular phenotype than either <sup>-/-</sup> alone	29
<i>Sema3A</i> <sup>-/-</sup>	Embryonic lethal; abnormal vascular remodeling; cardiac defects; abnormal neuronal patterning	31, 32
<i>Sema3F</i> <sup>-/-</sup>	Viable; no vascular defects reported; abnormal neural crest migration; abnormal axonal guidance	46, 47
<i>Sema3E</i> <sup>-/-</sup>	Viable and fertile; vascular defects	36
<i>Plxn D1</i> <sup>-/-</sup>	Die after birth; vascular defects	36

*Vegfr2*-null mice, and suggests that *Nrps* are requisite early genes in vascular development.

NRPs contribute to zebrafish vascular development as well (24). Zebrafish genes often are duplicated. There are two *nrp1* (*nrp1a* and *b*) and two *nrp2* (*nrp2a* and *b*) genes (24). During embryogenesis, zebrafish *nrp1* and 2 genes are expressed in neuronal and vascular tissues. During vasculogenesis, *nrp1a* is first expressed by tail angioblasts and, by 48 hours post fertilization (hpf), its expression is found in the major trunk vessels and intersegmental vessels (ISV). When *nrp1* was knocked down using antisense morpholinos (MO), the zebrafish embryos had abnormal connections between the artery and vein, which led to premature return of blood circulation back to the heart (30). Other vascular defects included a lack of circulation in the ISV, in the dorsal longitudinal anastomotic vessels (DLAV), and in the caudal vein plexus. On the other hand, the axial vessels appeared normal, indicating that NRP1 is a regulator of angiogenesis but not vasculogenesis. Results from double knockdown experiments showed that VEGF and NRP1 cooperate in maintaining trunk axial and ISV blood vessel circulation (30).

#### SEMAPHORINS AND THE VASCULATURE

Eight classes of semaphorins are known. Of these, the class 3 semaphorins are secreted proteins capable of binding NRPs (1,2,5,6). Six class 3 semaphorins are known: SEMA3A, 3B, 3C, 3D, 3E, and 3F. Class 3 semaphorins are 100-kDa pro-

teins, originally described as regulators of neuronal guidance capable of repelling axons and collapsing axonal growth cones (Table 37-3). Soon after the discovery of NRP in ECs, semaphorins were found to regulate vascular functions (Table 37-3). SEMA3A inhibited EC migration and sprouting of capillaries from aortic rings (even in the absence of VEGF) (11). The inhibition of EC migration was associated with the depolymerization of F-actin and retraction of lamellipodia, reminiscent of growth cone collapse in neuronal cells. The effects of semaphorins on EC functions may be due in part to competition with VEGF and in part due to direct signaling events via NRPs and PLXNs. SEMA3A and VEGF are competitive inhibitors of one another, possibly due to overlapping binding regions in the NRP1 b1b2 domain (see Figure 37.1). SEMA3A inhibits VEGF-induced EC motility, and VEGF inhibits SEMA3A-induced DRG collapse (11).

Subsequently, SEMA3A was found to inhibit angiogenesis and vascular remodeling in vivo, presumably by inhibiting integrin activation and integrin-mediated adhesion of EC to fibronectin and vitronectin (31). *Sema3A*-knockout mice have variable vascular phenotypes depending on their genetic background. In a 129/SV background, most of the mutant mice died in utero, whereas the few that survived to birth died within the first 3 days due to pronounced hypertrophy of the right ventricle of the heart (32). In a CD-1 background, *Sema3A*<sup>-/-</sup> mice displayed abnormal head and trunk blood vessels. At E9.5, cranial blood vessels of mutant embryos maintained a primitive capillary plexus appearance and were not remodeled (31).

**Table 37-3: Diverse Activities Associated with Neuropilins and Semaphorins**

Cell Type/Activity	SEMA3/NRP*
<b>Neuronal Cells</b>	
Neuronal patterning	SEMA3A/NRP1
Neuritogenesis	SEMA3C/NRP1,2
Cardiac neural crest migration	SEMA3C/NRP1,2
Axonal fasciculation	SEMA3F/NRP2
Collapse of axonal growth cones	SEMA3A/NRP1
Repulsion of axons	SEMA3A/NRP1; SEMA3C/NRP1,2; SEMA3F/NRP2
Neuronal cell survival	SEMA3C/NRP1,2
<b>ECs</b>	
Vascular patterning	SEMA3A/NRP1; SEMA3F/NRP2; SEMA3E/PlexinD1
Inhibition of sprouting	SEMA3A/NRP1
Inhibition of tumor angiogenesis	SEMA3F/NRP2
Inhibition of adhesion/ migration	SEMA3A/NRP1; SEMA3F/NRP2
Repulsion of vascular ECs	SEMA3A/NRP1; SEMA3F/NRP2
Inhibition of lymphatic ECs	SEMA3F/NRP2
<b>Tumor Cells</b>	
Inhibition of proliferation	SEMA3B/NRP1,2; SEMA3F/NRP2
Inhibition of survival	SEMA3A/NRP1
Inhibition of adhesion/ migration	SEMA3F/NRP2
Inhibition of tumorigenicity	SEMA3B/NRP1,2; SEMA3F/NRP2
Inhibition of metastasis	SEMA3F/NRP2
Induction of apoptosis	SEMA3B/NRP1,2
Tumor encapsulation	SEMA3F/NRP2

\*Omission of a *Sema3* family member and its activity may not mean that it does not mediate this function, but rather that it has not yet been tested.

SEMA3F, which signals through NRP2, also inhibits EC function and vascular development (12,31,33). SEMA3F inhibits EC proliferation and ERK1/2 kinase activity in vitro and angiogenesis in vivo (33). In addition to its effects on proliferation, SEMA3F acts as a chemorepellant for vascular ECs and lymphatic ECs (12). When *Sema3F* was overexpressed in ECs of the perineural vascular network in the head of developing chick embryos, vascular remodeling was dramatically inhibited (with a similar phenotype to *Sema3A* overexpression) (31). *Sema3F*-null mice are viable and fertile, and vascular defects have not yet been reported (see Table 37-2). Overexpression of *SEMA3F* in melanoma cells resulted in dramatically reduced tumor angiogenesis in mouse xenograft models (12). To date, other semaphorins (including SEMA3A) have not been investigated in tumor angiogenesis models.

Semaphorins also have been implicated in the regulation of vascular patterning in zebrafish. Zebrafish possess two copies of the *sema3a* gene, *sema3a1* (also known as *sema1a*, *sema3aa*, or *semaZ1a*) and *sema3a2* (also known as *sema1b*, *sema3ab*, or *semaZ1b*) (24). During and after gastrulation stages, angioblasts (vascular endothelial precursors) are located in the trunk ventrally and laterally to the somites. They migrate medially and dorsally along the somites to form the dorsal aorta just ventral to the notochord. Normally, *sema3a1* is expressed by the dorsal and ventral regions of the somites and guides the migration of angioblasts. When *sema3a1* was overexpressed or knocked down in zebrafish embryos, angioblast migration was inhibited, and dorsal aorta formation was retarded (34).

SEMA3E is an unusual member of the class 3 semaphorin family because it is the only member thus far reported to bind directly to a PLXN (see Table 37-1). PLXNs are a large family of transmembrane proteins, which are kinase substrates. They bind NRPs in complex with SEMAs (10). PLXNs are expressed in neurons, ECs, and tumor cells, in a way similar to NRPs. In neurons, signaling via NRP1 is mediated primarily by PLXN A4, and signaling via NRP2 is mediated principally by PLXN A3 (35). Whether this specificity exists in ECs is unknown, but PLXNs are required for semaphorin activity in developmental vascularization (10). PLXN D1 is an unusual member of the PLXN family. Its expression is restricted to ECs. SEMA3E binds PLXN D1 directly and acts as a repulsive cue. In mice, *Sema3E*- and *PlxnD1*-knockouts have similar vascular defects, and SEMA3E appears to regulate vascular patterning by repelling endothelial tip cells (see Table 37-2) (36). SEMA3E-PLXN D1 signaling in this process does not require NRPs, contrary to previous studies showing that class 3 semaphorins need to bind to NRPs for activity (13). In another study, *PlxnD1*<sup>-/-</sup> mice were born in Mendelian fashion, but died within the first day due to congenital heart disease with a perturbed outflow tract (37). Zebrafish *plxnd1* is expressed throughout the vasculature. Knockdown of *plxnd1* in zebrafish results in highly abnormal intersegmental vessels (38). Taken together, these studies demonstrate the importance of PLXN D1 and SEMA3E in proper blood vessel path finding and angiogenesis.

## NEUROFILINS AND SEMAPHORINS IN CANCER

It is now recognized that NRPs are expressed on many cell types, including tumor cells. Initially, NRP1 was discovered in the prostate cancer cell line, PC3, and the breast cancer cell line, MDA-MB-231 (8). Subsequently, NRP1 and NRP2 were found on many tumor types, especially but not limited to those of epithelial origin. These include prostate, colon, pancreas, mammary, skin, bladder, ovarian, and lung carcinomas, as well as melanomas, neuroblastomas, and osteosarcomas (5,6,39). In most tumor cells, NRP1 or NRP2 is the only VEGF receptor expressed by these cells, because VEGFR1 and VEGFR2 are seldom expressed in tumor cells. Therefore, VEGF functional activity in tumor cells is likely mediated through NRPs.

In PC3 prostate tumor cells,  $1-2 \times 10^5$  NRP1 receptors are present per cell that bind VEGF- $A_{165}$  with a Kd of approximately  $2.8 \times 10^{-10}$  M (SEMA3A binds NRP1 with similar affinity). Functionally, VEGF $_{165}$  stimulated tumor cell migration but not proliferation (40). In breast cancer cells expressing NRP1, VEGF- $A_{165}$  promoted chemotaxis and survival (41).

NRP expression has been found to correlate with disease progression in several human cancers (5,6,39). Increased NRP1 expression correlated with advanced disease and high Gleason grade in prostate cancer. In addition, NRP1 was expressed preferentially in metastatic breast tumors and cell lines compared with nonmetastatic tumors and cell lines. Aggressive tumors of the gastrointestinal tract showed elevated expression of NRP1, with highest expression at the invasive leading-edge. NRP1 gene expression was upregulated by epidermal growth factor (EGF) family ligands through the EGF receptor in colon, gastric, and pancreatic cancer cell lines (42). NRP2 was differentially expressed in advanced-stage bladder cancers as compared with early-stage bladder tumors using cDNA microarrays (43).

The consequence of increased NRP expression in tumor cells was directly assessed in rat Dunning prostate cancer cells transfected with NRP1 under the control of a tetracycline-inducible promoter (40). Rats were injected with AT2.1/tetNRP1 prostate carcinoma cells and subsequently given doxycycline in their drinking water to induce NRP1 protein synthesis in the tumor cells. In vitro, the NRP1-overexpressing tumor cells had three- to fourfold increased basal motility as compared with control cells; in vivo, the NRP1-overexpressing tumors were 2.5 to 7 times larger than control tumors and had increased vascularity (microvessel density) and decreased apoptosis (40). In similar experiments, human colon carcinoma cells engineered to express increased levels of NRP1 exhibited enhanced tumor growth and angiogenesis in nude mice (42). In contrast, when prostate cancer cells were transfected with a soluble form of NRP1 (sNRP1, containing the a1a2 and b1b2 domains), the resulting tumors were severely apoptotic and contained mainly damaged and hemorrhagic tumor vessels, ostensibly by inhibiting VEGF function (19).

Because tumor cells broadly express NRPs, it came as no surprise that their ligands, the class 3 semaphorins, play a role in tumor progression (see Table 37-3). SEMA3B and SEMA3F were first isolated from regions of chromosome 3p21.3, commonly deleted in small cell lung cancers (5,6,39). Subsequently, several studies have investigated the role of SEMA3B and SEMA3F as tumor suppressors. Overexpression of SEMA3B in lung and breast cancer cell lines induced apoptosis in vitro. In nude mice, ovarian carcinoma cells expressing SEMA3B resulted in smaller tumors, whereas the same cells overexpressing SEMA3F failed to form tumors. On the other hand, overexpression of SEMA3F in a lung carcinoma cell line (GLC45) did not affect tumorigenicity. Taken together, these results suggest that SEMA3B and SEMA3F may affect the growth of some tumors.

Recently, many tumor cell types, including prostate carcinoma cells, bladder carcinoma cells, and melanoma cells, were found to express SEMA3F mRNA. This expression was downregulated as the cells became increasingly metastatic (12). This observation was consistent with previous reports of weak SEMA3F-immunostaining in advanced-stage lung cancers (6). When SEMA3F was overexpressed in metastatic melanoma cells, it completely inhibited spontaneous metastasis to lymph nodes and lungs (12). The resulting tumors expressing SEMA3F were highly encapsulated and poorly vascularized. SEMA3F expression reduced  $\beta 1$  integrin levels in melanoma cells overexpressing NRP2, thereby inhibiting their adhesion and migration on fibronectin. Because SEMA3F affects multiple steps in the metastatic cascade, including adhesion, invasion, migration, and angiogenesis (12), it might be considered a new member of a metastasis suppressor family, which includes other genes such as KiSS-1, BRMS1, or KAI-1.

In summary, NRP is a receptor that plays a central role in two distinct developmental pathways – angiogenesis and neuronal guidance. Further studies may reveal other receptor/ligand families common to the nervous and vascular systems. The semaphorins may represent a new class of antiangiogenic agents capable of inhibiting tumor angiogenesis by repulsive mechanisms mediated by NRPs. Future studies will be needed to determine whether semaphorins can be used clinically to inhibit tumor angiogenesis and metastasis.

#### KEY POINTS

- Semaphorins and NRPs have a dual role as regulators of angiogenesis and neuronal guidance.
- ECs, neurons, and tumor cells express NRPs.
- ECs bind VEGF via NRPs to promote angiogenesis.
- ECs bind semaphorins via NRPs to inhibit angiogenesis or to guide vascular patterning.

#### Future Goals

- To determine whether semaphorins can be used clinically as antiangiogenic or antimetastatic agents
- To understand the complex signaling networks that govern the regulation of neuronal guidance and angiogenesis through a common receptor, NRP

## Vascular Functions of Eph Receptors and Ephrin Ligands

Helmut G. Augustin

*German Cancer Center, Research Center (DKFZ) and Center for Biomedicine and Medical  
Technology (CBTM), Mannheim, Germany*

Eph receptors comprise the largest family of receptor tyrosine kinases, consisting of eight EphA receptors (with five corresponding glycosylphosphatidylinositol [GPI]-anchored ephrinA ligands) and six EphB receptors (with three corresponding transmembrane ephrinB ligands) (Figure 38.1). They were originally identified as neuronal path finding molecules (1,2). Yet, genetic loss-of-function experiments have surprisingly revealed that EphB receptors and ephrinB ligands act also as critical regulators of vascular assembly and arteriovenous differentiation. This chapter summarizes the current knowledge about the vascular functions of Eph receptors and ephrin ligands and discusses some emerging roles of these molecules in the regulation of vascular homeostasis, leukocyte trafficking, and tumor progression.

### CHARACTERISTICS OF EPH RECEPTORS AND EPHRIN LIGANDS

Eph receptors and their corresponding ephrin ligands are grouped into A and B subfamilies based on distinct structural properties of the ephrin ligands (see Figure 38.1). EphrinA ligands are GPI-anchored peripheral membrane molecules. EphrinB ligands are transmembrane molecules whose cytoplasmic domain is capable of engaging in various signaling activities. The corresponding Eph receptors act as classical transmembrane tyrosine kinases. Correspondingly, the activation of Eph receptors by ephrin ligands is referred to as “forward signaling,” whereas the EphB receptor-mediated activation of ephrinB ligands is designated as “reverse signaling.”

Eph receptors and ephrin ligands were originally described as neuronal path finding molecules. Given that both receptor and ligand are transmembrane molecules, *trans* Eph/ephrin signaling is dependent on the juxtapositional contact of neighboring cells. As such, they elicit propulsive and repulsive activities on outgrowing axons and are, thus, critical mediators of neuronal network formation (1,3,4).

### VASCULAR EPH RECEPTORS AND EPHRIN LIGANDS

Although the Eph/ephrin system was originally identified in the nervous system, gene targeting experiments in mice have revealed important functions during vascular development (5–7) (discussed later). EphrinB2 is an early marker of arterial ECs, and EphB4 reciprocally marks venous ECs (5–8). These genetic experiments have opened a whole new field of research in vascular biology, because EphB4 and ephrinB2 were the first molecules with a clearly defined asymmetric expression pattern in arteries and veins. These findings have subsequently stimulated research focusing on the identification of other molecules with an asymmetric expression pattern in the vascular system. This work has led to a still-growing list of molecules with distinct asymmetric arteriovenous expression patterns that include the arterial markers (DeltaC [zebrafish], Delta-like 4 [Dll4] [mouse], gridlock [zebrafish], vascular endothelial growth factor (VEGF) receptor (VEGFR)-2 [zebrafish], notch1 [mouse], notch3 [mouse], notch5 [zebrafish], tbx20 [zebrafish], BMX [mouse], neuropilin-1 [mouse, chick], and the venous EC markers (neuropilin-2 [mouse, chick], Tie2 [mouse, chick], VEGFR3 [zebrafish, mouse]) (9). Secondly, in addition to having opened the field of arteriovenous differentiation research, the identification of vascular functions of Eph receptors and ephrin ligands also has stimulated work into the study of the functional commonalities between neuronal patterning and vascular patterning. An increasing list of receptor–ligand systems including the Eph/ephrin system, the Semaphorin/Neuropilin/Plexin system, the Robo/Slit system, and the UNC5/Netrin system is being recognized for its capacity to exert distinct guidance functions on neuronal cells as well as on ECs and vascular smooth muscle cells (VSMCs) (10,11).

Prior to the identification of vascular EphB4 and ephrinB2 functions, ephrinA1 (previously called B61) was characterized as a tumor necrosis factor (TNF)- $\alpha$ -inducible gene in

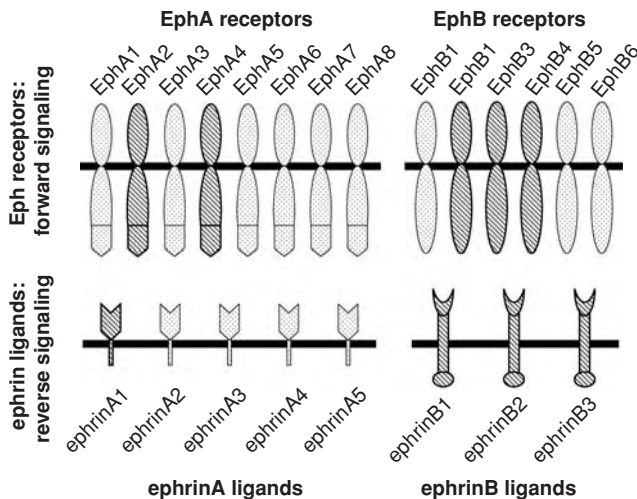

Figure 38.1. Schematic presentation of Eph receptors and ephrin ligands. Eph receptors are classical receptor tyrosine kinases. EphrinA ligands are GPI-anchored peripheral membrane molecules. EphrinB receptors are transmembrane molecules with a cytoplasmic signaling domain. Considerable receptor ligand promiscuity occurs, but little cross-talk between the A and the B subfamilies. Eph receptors and ephrin ligands whose expression has been demonstrated in the vascular system are striped and outlined in bold.

ECs (12). Yet, these early experiments did not lead to a systematic analysis of Eph and ephrin molecules in the vascular system. This is largely due to the fact that research on vascular Eph/ephrin molecules has to this date been hampered by the limited availability of adequate protein reagents to study these molecules.

The hitherto most relevant vascular Eph receptor and ephrin ligand expression data originate from LacZ staining in heterozygous mice in which the  $\beta$ -galactosidase gene is knocked into the endogenous locus (13,14). These studies have substantiated the embryonic reciprocal expression of arterial ephrinB2 and venous EphB4. They also have indicated that vascular EphB/ephrinB expression is not limited to ECs, because LacZ staining also was observed in VSMCs and pericytes. Likewise, these studies have demonstrated intense expression of ephrinB2 by angiogenic ECs in tumor microvessels and during reproductive angiogenesis.

### REGULATION OF ENDOTHELIAL EPH RECEPTOR AND EPHRIN LIGAND EXPRESSION

The asymmetric arteriovenous expression of EphB4 and ephrinB2 has raised the conceptually important question of whether EphB4 and ephrinB2 are intrinsic markers of arterial and venous EC differentiation, or if their expression is controlled by microenvironmental cues. Lineage tracing experiments have provided some evidence that asymmetric EC EphB4/ephrinB2 expression may be established prior to the formation of arteries and veins, suggesting that the Eph/ephrin system may indeed act as a lineage-determining factor in arte-

riovenous differentiation rather than simply representing a set of marker molecules (15). This view recently has been challenged by several lines of evidence. First, cell transplantation experiments in the chick embryo indicate that arterial expression of ephrinB2 is under the control of local microenvironmental cues rather than being a lineage-determined intrinsic property of ECs (16). Indeed, manipulatory experiments in the chick chorioallantoic membrane (CAM) have demonstrated that flow is a major determinant of arterial EC ephrinB2 expression (17). Second, in cell culture studies, VEGF has been identified as a major regulator of ephrinB2 expression in angiogenic ECs (18). These latter studies are consistent with the genetically established role of VEGF as an arterIALIZING molecule (19). Finally, a number of other microenvironmental milieu factors have been shown to induce expression of the arterial marker ephrinB2, including hypoxia (20) and shear stress (21).

Little is known about the expression of Eph receptors and ephrin ligands in the adult. ECs in the adult maintain their asymmetric arteriovenous expression pattern of EphB4 and ephrinB2, suggesting that the EphB/ephrinB system may play a role in controlling vascular homeostasis (13,14). Luminal expression of ephrinB2 by quiescent, polarized ECs in the adult vasculature (18,22) suggests a role of EphB/ephrinB interactions of ECs with circulating EphB receptor-positive hematopoietic cells.

### ROLE OF THE EPH/EPHRIN SYSTEM DURING DEVELOPMENTAL ANGIOGENESIS

Genetic experiments have laid the groundwork for the identification of EphB receptors and ephrinB ligands as mediators of vascular assembly and differentiation (Table 38-1). EphrinB2-deficient mice die around E10.5 as a consequence of a grossly perturbed vascular differentiation and arteriovenous remodeling. These mice are not capable of orchestrating the positioning of arterial and venous ECs and fail to form a properly structured capillary network (5).

EphrinB2 interacts with EphB2, EphB3, and EphB4. *EphB4*<sup>-/-</sup> mice essentially phenocopy the phenotype of ephrinB2-deficient mice, suggesting that the EphB4/ephrinB2 axis is the primary EphB/ephrinB interaction controlling vascular morphogenesis (6,7). Correspondingly, null mice for the other ephrinB2 receptors, *EphB2* and *EphB3*, have no apparent phenotype (6). Yet, a proportion (30%) of *EphB2/EphB3* double null mice have a variable embryonic vascular phenotype, indicating that the EphB4/ephrinB2 interaction is not fully capable of compensating for the loss of EphB2 and EphB3 (6).

Genetic experiments also have provided evidence that reverse ephrinB2 signaling is required for proper arteriovenous differentiation. This was shown by the observation that mice lacking the cytoplasmic domain of ephrinB2 ( $\Delta$ ephrinB2 mice) essentially have the same vascular phenotype as the full-length *ephrinB2*-null mice (8). However, another mouse strain expressing cytoplasmically truncated  $\Delta$ ephrinB2

**Table 38-1: Vascular Phenotypes of Mice with Mutations of Eph Receptors and Ephrin Ligands**

<i>Molecule</i>	<i>Genetic Manipulation</i>	<i>Phenotype</i>	<i>References</i>
EphA2	Deletion	No developmental phenotype; perturbed angiogenic response in ephrinA1-induced postnatal angiogenesis	51
EphB2/EphB3	Simultaneous deletion of EphB2 and EphB3	Embryonic lethality (E11.5) in some double null mice	6
EphB4	Deletion	Embryonic lethality as a consequence of perturbed arteriovenous differentiation; phenocopies <i>ephrinB2</i> -null phenotype	7
ephrinB2	Deletion	Embryonic lethality as a consequence of perturbed arteriovenous differentiation; phenocopies <i>EphB4</i> -null phenotype	5, 6, 8
ephrinB2	Deletion of cytoplasmic domain ( $\Delta$ ephrinB2)	Embryonic lethality as a consequence of perturbed arteriovenous differentiation; phenocopies <i>ephrinB2</i> full length-null phenotype	8
ephrinB2	Deletion of cytoplasmic domain ( $\Delta$ ephrinB2)	No overt developmental vascular phenotype; later defects including cardiac valve maturation	23
ephrinB2	Mutation of cytoplasmic PDZ domain	Lymphatic remodeling defect	24
ephrinB2	Deletion in mural cells	Perinatal lethality; perturbed mural association with microvessels and abnormal association with lymphatic capillaries	26
ephrinB2	Transgenic overexpression (pleiotropically or endothelial)	Neonatal death; perturbed EC – mural cell interactions	27

exhibited a different phenotype, with defects in cardiac valve formation but not in early vascular development (23). Additional support for a critical rate-limiting role of reverse ephrinB2 signaling for the normal development of the vascular system was provided by minimal-mutagenesis mouse genetic experiments of the cytoplasmic domain of ephrinB2. Mice expressing a mutant of ephrinB2 that lacks only the C-terminal PDZ interaction site have no overt arteriovenous assembly defects, but have major defects in lymphatic vessel remodeling (24).

The phenotypic manifestation of ephrinB2 mutations in different cellular compartments (e.g., vascular versus lymphatic) has stressed the need for spatially and temporally restricted genetic manipulations of *ephrinB2*. Recently, *floxed ephrinB2* mice have been generated as a versatile tool to study ephrinB2 functions in specific cell types (25). Breeding these mice to mice expressing *cre* recombinase under the control of the platelet-derived growth factor receptor- $\beta$  promoter was used to genetically ablate ephrinB2 in mural cells (per-

icytes, VSMCs) (26). Mural-cell deletion of ephrinB2 demonstrated a role of ephrinB2 for normal association of mural cells with small-diameter blood vessels, leading to perinatal lethality as a consequence of vascular defects in skin, lung, gastrointestinal tract, and kidney glomeruli as well as abnormal association of VSMCs with lymphatic capillaries (26). Defects of cultured ephrin-B2-deficient VSMCs in spreading, focal-adhesion formation, and polarized migration also indicate cell-autonomous roles of EphB/ephrinB interactions that may result from signalling in *cis* (26).

Transgenic overexpression of ephrinB2 under the control of either the ubiquitously and constitutively active CAG promoter or the EC-specific *Tie2* promoter similarly provided evidence that the EphB/ephrinB system not only is involved in arteriovenous EC positioning, but also in EC interactions with mural cells (27). *CAGp-ephrinB2* transgenic mice show sudden death at neonatal stages from aortic dissecting aneurysms due to defective recruitment of VSMCs to the ascending aorta, indicating that EphB/ephrinB2 signaling

between ECs and surrounding mesenchymal cells is critical for normal embryonic angiogenesis and vessel maturation. The authors concluded from these findings the existence of three distinctly different cellular compartments, namely EphB4-positive cells, ephrinB2-positive cells, and EphB/ephrinB2-negative cells (27).

### ROLE OF THE EPH/EPHRIN SYSTEM DURING TUMOR ANGIOGENESIS

Eph receptors and ephrin ligands do not just regulate the migratory and networking capacity of neuronal and vascular cells. EphB receptors and ephrinB ligands also have been shown to exert positional guidance cues during intestinal epithelial cell migration and differentiation (28). Similarly, circulating leukocytes and bone marrow cells express Eph/ephrin molecules (29,30). A growing list of Eph receptors and ephrin ligands also has been identified in tumors, including colon and lung tumors (31,32). Eph/ephrin expression by tumor cells points toward a potential role of the Eph/ephrin system in controlling malignant cell interactions with the host microenvironment that controls tumor progression and metastatic dissemination. EphA2, as well as its ligand ephrinA1, was found to be expressed by both ECs and various human tumor cells, thereby establishing a microenvironment that stimulates tumor neoangiogenesis by activating EphA2 receptors expressed on angiogenic ECs (32). Blocking of EphA-class receptor activation by competitively acting soluble EphA receptors has been shown to inhibit tumor angiogenesis in two different tumor models (33). Interestingly, stimulation of EphA2 phosphorylation by an EphA2-specific antibody inhibits the malignant behavior of breast tumor cells, indicating that EphA2 signaling may induce different phenotypes in ECs and tumor cells (34).

In contrast to the EphA/ephrinA receptor ligand system (35), much less is known about the functions of the B-class Eph/ephrin molecules during tumor angiogenesis. Several studies, including tumor experiments in heterozygous *ephrinB2* mutant mice expressing LacZ in the *ephrinB2* locus, have demonstrated expression of B-class Eph/ephrin molecules in different tumors and suggested a functional relationship between Eph/ephrin expression and tumor progression (13,36–39). Corresponding functional experiments in an experimental A375 melanoma model indicated that perturbation of bidirectional EphB4/ephrinB2 signaling by overexpression of dominant-negatively acting soluble monomeric EphB4 (sEphB4) dramatically inhibits tumor growth (40). Similar findings have been reported for MCF-7 mammary tumors and SCC-15 squamous cell carcinomas grown in nude mice (41). The observed tumor growth inhibition in these experiments resulted from a combined antiangiogenic and antitumorigenic effect and suggested that EphB/ephrinB interactions may control multiple cell–cell interactions within the tumor and the vascular compartment that collectively control tumor progres-

sion (40). Similarly, complex interactions between tumor cell EphB4 and EC ephrinB2 also have been observed in a breast tumor model in which angiogenic induction through reverse signaling activation of ephrinB2 was shown to be induced by direct cell contact with EphB4-expressing tumor cells (42).

### CELLULAR FUNCTIONS OF EPH RECEPTORS AND EPHRIN LIGANDS IN ENDOTHELIAL CELLS

Little progress has been made in translating the vascular phenotypes of mice with targeted mutations in Eph receptors and ephrin ligands in mechanistic experiments on the cellular level. This is largely due to the limited availability of suitable cellular models to study arteriovenous differentiation, EC positioning, and vascular guidance as it occurs during later stages of (43) the angiogenic cascade.

A number of cell–cell interaction studies involving cells of the vascular system have been performed in recent years. Corresponding to the transgenic overexpression of ephrinB2, coculture experiments of ephrinB2-expressing OP9 stromal cells and para-aortic splanchnopleura revealed a permissive role of stromal-cell ephrinB2 on vascular network formation (43). EphrinB2-positive ECs proliferate in the presence of ephrinB2-positive OP9 cells and actively induce the recruitment and proliferation of  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA)-positive cells. In contrast, stromal cells expressing EphB4 inhibit vascular network formation, proliferation of ephrinB2-positive ECs, and recruitment of  $\alpha$ -SMA-positive cells (43). These findings would suggest that mural-cell EphB4 acts in a negative, repulsive manner on ephrinB2-positive ECs.

Cell–cell interaction experiments with ECs support a model of reverse ephrinB2-mediated propulsive and EphB4-mediated repulsive activities during angiogenesis (44). Activation of EC ephrinB2 promotes adhesion, migration, chemotaxis, capillary network formation, and sprouting angiogenesis. In turn, forward endothelial EphB4 signaling acts in an antiadhesive, antimigratory manner, and inhibits sprouting angiogenesis (44–46). Forward EphB4 activation is associated with rapid receptor turnover, as evidenced by the internalization of the EphB4/ephrinB2 receptor complex on ephrinB2-Fc receptor body binding. Given the angiogenic and arteriogenic expression of ephrinB2, the antagonistic functions of EphB4 and ephrinB2 support an artery-to-vein push-and-pull model of invasive angiogenesis. According to this model, angiogenic activation (e.g., by VEGF induction) is associated with ephrinB2 expression, which supports a proangiogenic and proinvasive phenotype with an artery-to-vein orientation. Surrounding EphB4-positive cells may then guide invasive outgrowth of ephrinB2-positive ECs. In turn, activation of EC EphB4 transduces negative signals and leads to cellular repulsion. Consequently, propulsive and repulsive ephrinB2- and EphB4-mediated effects during capillary network formation limit cellular intermingling and control boundary formation (44).

## EMERGING ROLES OF THE EPH/EPHRIN SYSTEM AS ADHESION REGULATING MOLECULAR SYSTEM IN THE VESSEL WALL

Vascular Eph/ephrin research is still in its infancy. The genetic experiments have focused on the role of EphB receptors and ephrinB ligands as critical determinants of vascular assembly and arteriovenous identity. However, bidirectional signaling through the Eph/ephrin system is increasingly emerging as a rather universal cell–cell interaction and traffic controlling molecular system. Eph/ephrin molecules are expressed by neuronal cells, ECs, VSMCs, epithelial cells, leukocytes, tumor cells, and multiple other cell types. The vascular endothelium forms one of the largest surfaces within the body, acting as a critical interface that controls the trafficking of cells, including the recruitment of circulating leukocytes as well as the metastatic dissemination of malignant tumor cells. As such, Eph receptors in interacting with their ephrin ligands are strategically positioned and suited to either exert direct adhesive functions or to control the adhesive properties of other surface molecules on ECs and interacting cells in the circulation. EphA1- and EphA4-expressing T lymphocytes are capable of binding to EC ephrinA1 (47). Similarly, Eph receptors and ephrin ligands have been shown to support thrombus growth and stability by regulating integrin outside-in signaling in platelets (48). Likewise, EC ephrinB2 has been shown to act as an entry receptor for the Nipah virus (49,50). Thus, further insights into complementary expression patterns of EphB receptors and ephrinB ligands in the vascular endothelium and the multiple cell types interacting with ECs will contribute to the better understanding of the Eph/ephrin system as a cell trafficking and vascular homeostasis–controlling cell–cell signaling system.

## CONCLUSION

Eph receptors and ephrin receptors represent a unique bidirectional signaling system that controls multiple cell–cell interactions in the vascular system that are required for developmental vascular morphogenesis, vascular remodeling, and tumor angiogenesis, as well as for vascular homeostatic maintenance function in the adult.

### KEY POINTS

- Bidirectional signaling through EphB receptors and ephrinB ligands is required for developmental vascular morphogenesis, transducing guidance signals that are associated with arteriovenous differentiation and positioning.

- Vascular positional guidance cues elicited by Eph/ephrin signaling parallel many aspects of neuronal guidance and positioning.
- A-class and B-class Eph receptors and ephrin ligands control tumor angiogenesis and tumor progression by controlling multiple tumor and vascular cell interactions.

### Future Goals

- To undertake the functional analysis of the Eph/ephrin system as a versatile cellular guidance and positioning system controlling multiple cell–cell interactions
- To elucidate the role of endothelial Eph receptors and ephrin ligands as adhesion-regulating molecules of circulating hematopoietic cells and metastasizing tumor cells
- To unravel the differential reverse ephrinB signaling mechanisms in cells of the vessel wall and the analysis of their functional consequences

## Endothelial Input from the Tie1 and Tie2 Signaling Pathways

Daniel Dumont

*The Centre for Proteomic Studies, University of Toronto, Ontario, Canada*

### DISCOVERY OF TIE1, TIE2, AND THE ANGIOPOIETINS

In the early 1990s, numerous groups used an reverse transcription polymerase chain reaction (RT-PCR) approach to identify new tyrosine kinases. This approach, based on the use of degenerate primers complementary to highly conserved regions of the kinase domain, was first described by the lab of Andrew Wilks (1,2). The small RT-PCR fragments produced using this approach and RNA isolated from several sources, such as K-562 cells, embryonic mouse heart tissue, differentiated embryonic stem cells and hematopoietic stem cells (3–10), provided the starting material for the cloning and characterization of many tyrosine kinases including new families of receptor tyrosine kinases (RTK). One of these families has just two members, Tie1 and Tie2. These receptors were first identified by RT-PCR of RNA isolated from the megakaryoblastic cell line K-562 (11). cDNAs coding for these receptors were described in 1992 and 1993, respectively, and were originally named *Tie* (*Tie1*) and *Tek/Hyk* (*Tie 2*) (4,6,11).

The Tie receptors remained orphan receptors until 1996 when angiopoietin-1 (Ang1) was identified as a ligand for Tie2 (12). *Ang1* was cloned using a unique secretion trap cloning method, in which a receptor body was used to probe cells transfected with a cDNA expression library. Subsequent to the identification of Ang1, several other angiopoietins (*Ang2*, 3, and 4) were cloned by low-stringency hybridization (13,14). *Ang3*, which is isolated from mouse, and *Ang4*, which is of human origin, are thought to be interspecies orthologues (14). Both Ang3 and Ang4 bind to and activate Tie2 within their respected species (15).

### EVOLUTIONARY CONSERVATION

Genes for both the Tie1 and Tie2 signaling systems are conserved from fish to humans (16,17), suggesting that these

receptors and their ligands play a pivotal role in the development of the endothelium and hematopoietic systems. Similarly, *Ang1* and -2 have been found in the same lower vertebrates, further emphasizing their importance in vascular development (17,18). Currently, it is not known whether *Ang3* or -4 are found in these lower vertebrates; however, an angiopoietin-related gene, *angiopoietin-like-3*, which is found in humans, was also identified in zebrafish (18), further suggesting that these ligands are important in the biology of blood vessels in diverse organisms.

### ROLE IN DEVELOPMENT

#### Endothelial and Hematopoietic Expression and Function

Expression studies during embryogenesis revealed that the Tie-family of RTKs is expressed in endothelial cells (ECs) (5,9,11,19–21) and in hematopoietic stem cells (8), suggesting that these receptors may play a role in development of the endothelium and in hematopoiesis.

The functions of these receptors in these cell types have been examined with gene-targeted mice. Both Tie1 and Tie2 are needed for embryonic development. *Tie1*-null embryos die around embryonic day (E)13.5 of gestation with marked abnormalities in the vasculature and edema (22,23). In contrast, *Tie2*-null embryos die considerably earlier, around E9.5 of development with defects in the cardiovascular system (23,24). A role in EC survival was demonstrated in *Tie2*-null embryos that were conditionally rescued using a *Tie2*-promoter-driven tetracycline-regulated transgenic system (25). *Tie2*-rescued embryos in which the expression of Tie2 was subsequently silenced had a dramatic increase in apoptotic ECs, suggesting that Tie2 signaling maintains EC survival in vivo (25).

The early embryonic lethality of *Tie2*<sup>-/-</sup> embryos precluded the analysis of the role of this receptor in late stages of

vascular development. To get around this, Puri and colleagues analyzed the ability of *Tie1*- and *Tie2*-null embryonic stem cells to contribute to the vasculature in chimeric embryos and whether any contribution was sustained throughout development (26). *Tie1* and *Tie2* were dispensable in the early phases of vessel development, but *Tie2* was absolutely required for the microvasculature in the adult. Whether this requirement was for all components of microvasculature, capillaries, arterioles, or venules was not determined. Furthermore, similar studies focusing on the development of the hematopoietic lineage revealed that both *Tie1* and -2 were required for postnatal bone marrow hematopoiesis (27).

### Expression and Function in Other Cell Types

As better reagents were developed and as other cell types were examined in more detail, *Tie2* expression was found in other cells including keratinocyte precursors (28), eosinophils (29), neutrophils (30), perivascular mesenchymal cells (31–33), hematopoietic stem cells (34–36) fibroblast-like cells (37), and endometrial epithelial and stromal cells of the endometrium (38). The physiological significance of this expression is not understood; however, as keratinocytes precursor cells differentiate, they downregulate the expression of *Tie2*, suggesting that the expression of *Tie2* in these cells may play a role in the maintenance of an undifferentiated state (28).

### GENE REGULATION

The *Tie1* and *Tie2* genes have been examined to determine the DNA elements in these genes that confer tissue specific expression. Early studies of the *Tie2* gene suggested much of this specificity was directed by a rather large region that was 5' of the coding sequence. These sequences, however, were not sufficient to regulate expression in all ECs in the adult (24). Subsequently, an enhancer element was discovered in the first intron that significantly increased the expression in ECs of the adult (39).

Similar studies were initiated with the *Tie1* gene, and it was found that a smaller region of DNA 5' from the coding sequence was able to direct endothelial expression in the developing embryo and adult (40). Further detailed analysis of these DNA sequences revealed several octamer binding sequences that were thought to be responsible for the endothelial-specific expression (41,42). Ets binding sequences were found within this region. Furthermore, Ets binding sites have been found in both *Tie* promoters, suggesting that the Ets family of proteins play a role in the expression from these promoters in the vasculature (43–47).

Hypoxia is known to drive angiogenesis, suggesting that the expression of many angiogenic factors is controlled by this stimulus. Presently, conflicting results have surfaced regarding the expression of *Tie2* in response to hypoxia (48–52). It is possible that these discrepancies reflect the differences in

experimental paradigms or cell types that have been used. It was recently shown that the 5' end of the *Tie2* mRNA, which is quite long and complex, has an internal ribosome entry site (IRES) that allows for cap-independent translation. This sequence is required for efficient translation of *Tie2* mRNA under the hypoxic state (53), suggesting that *Tie2* expression is enhanced during hypoxia.

ECs are at the interface between blood and the vessel wall and are therefore subjected to hemodynamic stresses. The expression of *Tie1* and *Tie2* was reported to be upregulated by shear (54,55), and the kinase activity of *Tie2* also was elevated (56). This response of *Tie1* expression to shear remains controversial, because one study examining the expression of *Tie1* in cultured ECs found a downregulation (57), whereas another group examining *Tie1* expression in vivo found an upregulation (55). Curiously, the extracellular domain of *Tie1* is cleaved when cells in culture are exposed to shear, and the free *Tie1*-extracellular domain binds to *Tie2* on the EC surface (57). The physiological significance of this is unclear, but it may serve to downregulate *Tie2* signaling and lead to vessel remodeling. ECs also can be subjected to other stresses, including physical or mechanical stress, which has been shown to result in the increased expression of both *Tie1* and *Tie2* (58,59).

In addition, biochemical mediators are thought to play a pivotal role in controlling the expression of numerous angiogenic factors including *Tie2* (60). In 2005, Fathers and colleagues (60) demonstrated considerable *Tie2* expression heterogeneity in xenografts, illustrating that the tumor microenvironment can greatly influence the expression of *Tie2*.

### LIGAND-RECEPTOR INTERACTIONS

Initial studies suggested that Ang1 acts as an agonist of *Tie2* activity, whereas Ang2 behaves as an antagonist (13). However, Ang2, either at higher concentrations in vitro or on exposure of ECs for prolonged periods, also can act as an agonist (61). Whether these experimental conditions recapitulate true endogenous levels or environments encountered by ECs remains to be determined. However, expression of Ang2 systemically using a conditional binary transgenic mouse system suggests that Ang2 may have VEGF-independent activities in certain vascular beds (62). Furthermore, Ang1 and Ang2 are thought to be functionally redundant for lymphatic ECs, but may have this antagonist role in different vascular beds (63,64). The response of ECs to the angiopoietins may depend on the microenvironment or "context" in which the EC finds itself. Table 39-1 summarizes numerous studies examining stimulation of cells in vitro or the growth of tumors in xenograft models. The considerable inconsistencies in the data ultimately suggest that the EC type, growth conditions, and location where a particular tumor is placed in animal xenograft studies have a dramatic impact on effects of the angiopoietins (65).

**Table 39-1: In Vitro and Xenograft Results in Angiopoietin Signaling**

Condition	Outcome
Ang1 in HeLa Cells	Promotes tumor growth in the cervix
Ang1 in A431 Cells	Inhibits tumor growth in skin
Ang1 antisense in HeLa cells	Inhibits tumor growth
Ang2 expression in gliomas	Increased angiogenesis
Ang2 can act as agonist	Promotes cell survival, differentiation
Ang1,2 and VEGF cooption	Ang2 destabilizes, VEGF rescues, Ang1 stabilizes
ExTek	Soluble Tie2 can inhibit tumor growth Inhibition of laser induced retinal neovascularization
Ang2 antibody and peptide-body	Inhibit xenografts growth

In an attempt to circumvent the problem of isolating cells from different organs and to alleviate the known fact that ECs grown in culture lose many of their organ-specific characteristics, research teams have engineered transgenic animals to produce angiopoietins and have found that the vascular beds within different organs do indeed respond differently to these factors, suggesting that context is very important (66,67) (Table 39-2).

*Ang3* and *Ang4* are interspecies orthologues – *Ang3* is murine and *Ang4* human (14,68). In the initial studies of the effect of these ligands using human ECs, it was thought that *Ang4* was an agonist and *Ang3* was an antagonist for Tie2 activation. Recent studies, however, have shown that these ligands exhibit species-specific restrictions in their ability to activate Tie2, and it now seems that both *Ang3* and -4 are agonists (15).

The angiopoietins are multidomain ligands that have a coiled-coiled domain at the amino terminus that is responsible for clustering ligands, and fibrinogen-like domains at the carboxyl-terminus that bind the receptor. The angiopoietins are found as homo-oligomerized proteins held together by disulfide bonds (69–71). This oligomerization is required for the angiopoietins to cluster Tie2 and cause its activation (69,71,72). In fact, monomeric angiopoietin is inhibitory for Tie2 activation (73).

The ligand for Tie1 remains unknown but, under some circumstances, Tie1 and Tie2 heterodimerize, leading to phosphorylation of Tie1. *Ang1*, *Ang4*, or an engineered form of *Ang1*, COMP-*Ang1* (74,75), can enhance this phosphorylation (76). Although there is a basal level of Tie1 stimulation

by angiopoietins in the absence of Tie2, these ligands do not appear to bind directly to Tie1 (76), suggesting that the activation of Tie1 is through an alternative route.

## DOWNSTREAM SIGNALING PATHWAYS

In an effort to uncover the mechanisms of Tie2 receptor signaling, several groups performed yeast two-hybrid assays with a truncated intracellular active kinase region (77–79). This approach proved very successful in identifying binding partners that are now thought to play an important role in Tie2 signaling. These include p85 (the regulatory subunit of phosphoinositide 3-kinase [PI3K]), Grb2, Grb7, Grb14, Shp2, ABIN-2, and Dok-R. Using a candidate-molecule approach, ShcA was also shown to be recruited to Tie2 (80) (Figure 39.1).

PI3K plays an important role in Tie2 receptor signaling. Activation of PI3K by *Ang1* leads to activation of Akt, which promotes EC survival. Akt activation also leads to the phosphorylation of endothelial nitric oxide synthase (eNOS) resulting in the production of nitric oxide (NO) (61,81), an important extracellular signaling molecule. p85 interacts with tyrosine 1100 (Y1101 in humans), a residue that also recruits Grb7 (82). The importance of this site in Tie2-mediated signaling in vivo was demonstrated by genetically engineered mice that carried a mutant form of Tie2 in which tyrosine 1100 was converted to phenylalanine (83). These animals had defects in cardiac and hematopoietic development, whereas pericyte recruitment was unaltered, suggesting that multiple signals emanate from Tie2 and that only certain aspects of Tie2-mediated biology requires signaling through tyrosine 1100. Of further interest is the fact that a mouse mutant that carries a deletion in the catalytic portion of PI3K, p110 $\alpha$ , also exhibits a vascular defect similar to the defect seen in *Tie2*-null embryos (84). Moreover, study of transgenic animals with an activated form of Akt also demonstrated that the development of the vasculature is controlled by a fine-tuning of the signals that emanate from Akt (85). Collectively, these results support an important role for PI3K signaling in vascular remodeling and maintenance.

Dok-R is another molecule that plays a role in Tie2 signaling. Recruitment of Dok-R to phosphotyrosine 1106 on Tie2 is required for *Ang1*-driven EC migration (86,87). Dok-R, upon binding to Tie2, is tyrosine phosphorylated and recruits the signaling molecule Nck, which is bound to the serine-threonine kinase, Pak1 (87). Pak1 initiates a phosphorylation cascade that ultimately results in reorganization of the actin cytoskeleton and in cell migration.

Another molecule thought to play an important role in Tie2 signaling is the ABIN-2 (79). ABIN-2 rescues ECs from apoptosis induced by growth factor deprivation, and a truncated form suppresses Tie2-mediated rescue of this apoptosis, suggesting that ABIN-2 also may play a role in angiopoietin-mediated cell survival (88).

**Table 39-2: In Vivo Models of Angiopoietin Signaling**

<i>Gene</i>	<i>Phenotype</i>	<i>Lethality</i>
<i>Tie2</i> KO	Decreased sprouting	E9.5–12.5
Conditional rescue	Heart development Vessel branching EC survival Recruitment of pericytes Definitive hematopoiesis	
<i>Ang1</i> KO	Endocardial development Trabeculation Recruitment of pericytes	E12.5
<i>Ang2</i> transgenic ( <i>Tie2</i> -promoter)	Endocardial/myocardial Vessel loss	E9.5–10.5
<i>Ang2</i> KO	Lymphatic development Chylous ascites Hyaloid vessel	Partial-P14
<i>Ang1</i> transgenic ( <i>K14</i> promoter)	Large vessels Resistance to VEGF leak	NA
<i>Ang1</i> transgenic ( <i>LAP</i> promoter)	Large vessels in liver ???	NA
<i>Ang1</i> transgenic ( <i>MHCA</i> promoter)	Lack of coronary vessel development	90% dead E12.5–15.5
<i>Ang1</i> transgenic ( $\alpha$ <i>MHC</i> promoter)	Blocks VEGF-induced vessel formation	NA
<i>Ang2</i> transgenic ( $\alpha$ <i>MHC</i> promoter)	Collaborates with VEGF to induce angiogenesis edema and fibrosis	NA
<i>Ang1-CC</i> -transgenic ( <i>MHCA</i> promoter*)	<i>Ang1</i> and <i>Ang2</i> inhibitor. Altered coronary vessel patterning	NA
<i>Tie2</i> -transgenic ( <i>Tie2</i> promoter)	Psoriasis/atopic dermatitis phenotype	NA
<i>Ang1</i> transgenic ( <i>CamK</i> promoter)	Alteration in neuronal processes	NA
<i>Ang2</i> transgenic ( <i>LAP</i> promoter)	Changes in lower vessel growth Increased lymphatic density in gastrointestinal tract Increased congestion in lungs	NA

\*Different MHC promoter. KO, knockout; NA, not available.

As mentioned earlier, other molecules may have a role in Tie2 receptor signaling because they bind to the intracellular domain of Tie2, but the roles of these molecules have not been elucidated.

**EFFECT ON ENDOTHELIAL CELL PHENOTYPE**

**Level of Cell**

*Ang1* protects ECs from apoptosis induced by serum withdrawal, radiation, mannitol, and from detachment (anoikis) (77,82,89), suggesting that this pathway mediates EC survival.

Examination of phosphorylation status of Tie2 in quiescent endothelium in the rat revealed that Tie2 was tyrosine phosphorylated, suggesting that it is active in resting ECs, and that it promotes the survival of resting ECs (89). In support of this role, Jones and colleagues (25) used a conditional rescue of *Tie2* mutant mice to demonstrate that Tie2 provides an important survival signal during the latter stages of embryonic growth. In addition to the antiapoptotic activity of Tie2 signaling, the angiopoietins also induce endothelial tubule formation in vitro. Interestingly, *Ang1* and *Ang2* had similar activities in this assay suggesting that, within this context, these two ligands have similar activities (90).

Figure 39.1. Signaling pathways modulated by Tie2. Proteins known to interact with Tie2 are shown next to the receptor (VE-PTP, ShcA, Grb2, Grb7, Grb14, p85, Shp2, Fes, STAT3, STAT5, ABIN2, and Dok-R).

### Level of Blood and Lymphatic Vessels

Several groups have hypothesized that angiopoietins have an effect on vascular tone through the modulation of NO via the Tie2 receptor signaling, but this role is not well understood (61).

Within the context of tumor angiogenesis, Ang2 seems to provide a destabilizing function that, by antagonizing Tie2 activity, in combination with VEGF, causes ECs within a vessel to detach and to start to migrate toward a chemotactic signal. *Ang2* knockout studies have suggested that this may be the case for the hyaloid vasculature, which during development supplies the lens with nutrients, but regresses after birth. In the *Ang2*-null animal, this regression does not occur (64) (see Table 39-2). Curiously, the rest of the vasculature seemed normal, suggesting that this effect may be very dependent upon the microenvironment of the ECs. Furthermore, the *Ang2*-null animal presents with defects in the developing lymphatics that can be rescued by *Ang1*, thus demonstrating a functional redundancy for these ligands in the lymphatic vasculature.

Several studies that examined the role of these ligands in xenograft tumor growth have yielded contradictory results, suggesting that the context in which the angiopoietins are expressed may dramatically influence the EC response (see Table 39-1).

### Level of Whole Organism

A role for angiopoietin signaling in vascular remodeling has been suggested by the identification of missense mutations in

the *Tie2* gene in several families with inherited vascular malformations (IVMs) (91). The mutated gene encodes a Tie2 receptor with elevated tyrosine kinase activity (91). It is thought this elevated kinase activity in combination with other epigenetic factors results in a defect in the recruitment and/or retention of support cells that ultimately lead to IVMs. Interestingly, one of the mutant Tie2 proteins that was isolated had increased kinase activity and also recruited an additional repertoire of signaling molecules, suggesting that manifestation of the phenotype may be caused by an increase in signaling and/or aberrant signaling (92).

Studies using conditional transgenic mice, in which Ang1 is produced in the liver and delivered systemically, also suggest that angiopoietins play a role in the development of this vascular bed. In these mice, in the absence of any increase in liver size, an increase occurred in the size of the vessels, and remodeling of the liver vasculature was disrupted (93). The response of the ECs in different vascular beds seemed to be different, further supporting the notion that the response of ECs to angiopoietins depends on the context.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

One of the first indications that the angiopoietin signaling system might be a good target for the design of drugs to treat cancer was a xenograft study in which tumors regressed in size when the mice were treated with a soluble form of

Tie2, exTek (94–97). Further studies have suggested that exTek also may decrease the degree of metastasis (98). Furthermore, decreasing available Ang2 with specific antibodies or peptide-bodies resulted in decreased angiogenesis and decreased tumor growth in mice (99). It is not clear whether targeting the angiopoietins will work on all types of tumors because of the context-dependent effect of the angiopoietins on the vasculature.

**KEY POINTS**

- Tie2 signaling plays a pivotal role in the maintenance and integrity of the endothelium.
- Tie2 is expressed on virtually all endothelium.
- The type of endothelium dramatically alters the response of ECs to the angiopoietins.
- To realize the full potential of the angiopoietins signaling system for cancer therapeutics and regenerative medicine, we will need to understand the “context-specific” response of the endothelium in different organ systems to the angiopoietins.

## Slits and Netrins in Vascular Patterning

### Taking Cues from the Nervous System

---

Kye Won Park, Lisa D. Urness, and Dean Y. Li

*School of Medicine, University of Utah, Salt Lake City*

The formation of a functional blood vessel depends on endothelial cell (EC) proliferation and migration, tube formation, and the differentiation and recruitment of vascular smooth muscle cells (VSMCs). Some of the growth factors responsible for vascular development were first identified using cell biological assays that evaluated angiogenic properties. These assays include *in vitro* EC proliferation, adhesion, and migration assays, and *in vivo* aortic ring, chorioallantoic membrane (CAM), and corneal micropocket assays. These studies identified vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), transforming growth factor (TGF)- $\beta$ , angiopoietins, platelet-derived growth factor (PDGF), and their homologues and isoforms, in addition to their multiple cognate receptors (1,2).

Gene targeting experiments demonstrated that many of these growth factors and their receptors are essential for vascular development and provided insight into how sprouting is initiated and a mature network is sculpted. VEGF and its receptors play an essential role in EC proliferation and differentiation. The critical requirement for VEGF at the earliest stage of vasculogenesis is demonstrated by the lack of EC development even in *Vegf* hemizygous mice (3). Once ECs aggregate and undergo tubulogenesis, VSMCs are recruited by PDGF to surround the mature vessel. In the absence of PDGF or its receptors, a subset of vessels fails to recruit VSMCs and pericytes (4). Finally, gene targeting studies have revealed that stabilization and maturation of blood vessels, through the interaction of ECs and VSMCs, is mediated by angiopoietins, TGF- $\beta$ , and extracellular matrix (ECM) proteins (2). Thus, gene ablation experiments have identified which signaling pathways play essential roles in murine vascular development and have delineated the fundamental blueprint for the sequence of molecular events that govern nascent blood vessel formation. Attention has begun to shift from the identification and functional characterization of endothelial growth factors to an appreciation of the molecular mechanisms that *pattern* the mature vascular tree. Recent evidence suggests

that patterning of the vascular system is genetically programmed and that the molecular mechanisms that guide vessel outgrowth are similar to those utilized by the nervous system.

#### DIFFERENTIATION OF ARTERIAL AND VENOUS CIRCUITS

A second level of vascular organization, overlying the primary plexus, is the differentiation and partitioning of separate arterial and venous networks. A functional vascular network requires distinct arterial and venous circuits that only connect via the capillary beds in distal target organs. Whereas it was once believed that hemodynamic forces were responsible for mediating phenotypic differences between arterial and venous ECs (5), evidence has accumulated in the last several years to indicate that genetic programs govern arterial-venous identity prior to the onset of circulation. The ephrins and their receptors, the Ephs, were identified on the basis of their roles in contact-mediated axonal guidance (6). However, the Anderson lab showed that the ligand, ephrinB2, is specifically expressed in arteries, while its receptor, EphB4, is primarily expressed in veins (7). *EphrinB2* and *EphB4* gene-targeted mice show defects in remodeling of the vascular plexus in arterial and venous beds. These data suggest that the ephrin-Eph signaling pathway may function to maintain segregation of arterial and venous domains during angiogenesis via cell-cell interactions, similar to their functions in the nervous system. Indeed, Hellmut Augustin (Chapter 38) describes cellular studies supporting a role for ephrin-Eph signaling in the establishment of capillary arterial-venous network boundaries. Taken together, these studies presaged the existence of genetic pathways that play a role in the patterning of specific arterial and venous EC populations. These observations have since paved the way for studies addressing the molecular nature of vascular guidance.

## VASCULAR GUIDANCE AS A PATTERNING MECHANISM

Once the central vessels and capillary plexi are formed during vasculogenesis, they extend sprouts that must navigate throughout the embryo to nourish all the organs. Large arteries and veins branch into smaller diameter arterioles and venules, respectively, and eventually into the smallest vessels, the capillaries. In addition to a hierarchy of vessels of different diameter, arterial and venous networks must develop in parallel and interconnect in the capillary beds to form a seamless circulation. During embryonic vascular development, vessel trajectories are by no means random; rather, growth is constrained along specific routes. The intricate wiring and predictable trajectories of these vessels suggest that active guidance mechanisms exist to direct this process. It is unlikely that signaling by the vascular growth factors identified to date can account for the complexity of the embryonic vascular pattern. Although vascular mitogens, hemodynamic inputs, hypoxia, and random sprouting and pruning play pivotal roles in sculpting the vascular tree, recent evidence points to the existence of additional genetic programs that guide vessel outgrowth along specific trajectories. A forward genetic screen in zebrafish identified a gene, *out of bounds* (*Obd*), that functions to constrain angiogenic growth. *Obd* mutants exhibit anomalous migration of intersegmental vessels into the adjacent somites, suggesting that a chemorepulsive signal has been lost that normally constrains vessel trajectories between somites. This strongly suggests that vascular patterning is controlled by genetic guidance programs (8). *Obd* recently has been identified by the Weinstein group as harboring a mutation in the locus of the semaphorin receptor, *PlexinD1* (9). These data suggest that, although vascular mitogens such as VEGF have the capacity to stimulate angiogenesis, the growth response can be further refined, both positively and negatively, by other guidance factors in the local environment.

## SHARED NEURAL AND VASCULAR GUIDANCE MECHANISMS

Many similarities exist between vessel and nerve networks at the anatomical and molecular levels. Blood vessels often follow parallel paths to those of nerves, such as the neurovascular bundles that course toward the distal limbs (10,11). Both organ systems must infiltrate all tissues in a highly ordered and coordinated manner, and both employ specialized filopodial extensions on their tip cells to sample their respective microenvironments for directional growth cues. Finally, like the arterial and venous subdivisions of the vascular system, the nervous system is divided into sensory and motor relays that must be precisely coordinated. The directional movement of neuronal growth cones upon exiting the central nervous system is coordinated by multiple genetic programs, which guide the growth cones by integrating a combinatorial code of attractive and repulsive, and long- and short-range cues. The

most extensively characterized classes of proteins that regulate neural guidance are the ephrins, semaphorins, Slits, and netrins, and their cognate families of receptors (12). The strikingly similar repertoire of proteins expressed on vascular ECs and axonal growth cones suggests that the molecular mechanisms that guide axonal path finding also regulate endothelial sprouting and angiogenesis.

### The Ephrin-Eph and Semaphorin-Neuropilin/PlexinD1 Signaling Pathways

The ephrins are membrane-bound ligands for the Eph family of receptor tyrosine kinases. Interaction between receptor-bearing axons and ephrins expressed by surrounding cells mediates contact-repulsion by inducing a collapse of the growth cone cytoskeleton. Wang and colleagues observed that axons expressing Eph receptors are restricted from extending into the caudal half of somites that express ephrin ligands (13). This juxtacrine interaction effectively channels axonal growth through permissive intersomitic corridors. Eph receptors and their ephrin ligands are also essential for organizing arterial and venous domains in the embryonic vasculature (7). This activity is likely a result of reciprocal repulsive cues between arterial and venous ECs that inhibit the fusion of arterial and venous sprouts. Similarly, juxtacrine interactions between intersomitic vessels expressing Eph receptors, and the adjacent somitic mesenchyme expressing ephrin ligands, appear to constrain vessel growth to intersomitic corridors via a repulsive guidance mechanism. Disruption of endogenous Eph/ephrin expression in the somites of mice and *Xenopus* results in aberrant invasion of intersomitic vessels into the developing somitic compartment (14,15), further suggesting that ephrin-Eph signaling may mediate repulsive guidance cues that restrict vessel growth to specific trajectories. Thus, analogous to the role of these factors in nervous system development, complementary ephrin-Eph domains of expression serve to delineate spatial boundaries for permissive growth in the vascular system. These data were among the first to suggest that the nervous and vascular systems may utilize the same array of guidance factors to govern patterning.

Semaphorins are a large family of both secreted and membrane-associated proteins. More than 30 semaphorins have been identified to date that are capable of mediating both repulsive and attractive axon guidance (16). Neuropilins are transmembrane proteins that can mediate semaphorin class 3 repulsive cues in association with plexin receptors expressed on axons. Activation of the neuropilin-plexin complex by semaphorin 3 restricts growth-cone extension to specific paths (17). The semaphorin family and their receptors, the neuropilins and PlexinD1, have been shown to regulate vascular patterning and angiogenesis in addition to their fundamental roles in neural guidance (18). Semaphorins are capable of disrupting the cytoskeleton of vascular ECs, thereby compromising migration and sprouting, analogous to semaphorin-induced axon growth cone collapse (19,20). Mice lacking semaphorin-3A (*sema-3A*) exhibit a gamut of neural and

vascular defects that includes ectopic sprouting of intersomitic vessels into the somites (21). However, these vascular defects exhibit highly variable penetrance and are not observed in some strains. Most recently, Torres-Vasquez and colleagues and Gitler and colleagues reported that the first EC-specific semaphorin receptor, PlexinD1, regulates vascular patterning in zebrafish (*out of bounds* mutant) and mice (9,22). Targeted inactivation of *PlexinD1* in mice results in severe cardiac defects and intersomitic vessel patterning defects. The latter is most likely a result of abrogated signaling from sema-3E, or perhaps sema-3A, ligands that are both highly expressed in the adjacent somites. Gu and colleagues provide compelling evidence that the sema-3E ligand, secreted by the somites, specifically interacts with the endothelial PlexinD1 receptor (23). The activation of this signaling complex transduces inhibitory directional cues to intersomitic vessels. Genetic ablation of *Sema-3E* phenocopies the intersomitic vascular patterning defects in *PlexinD1*<sup>-/-</sup> mice, specifically the ingression of intersomitic vessels into the somitic mesoderm. These data define a new semaphorin signaling pathway that affects vascular patterning.

Neuropilin-1 was first identified as a neuronal cell surface marker and subsequently shown by Klagsbrun and coworkers to be expressed on the surface of vascular ECs (24). In addition to functioning as a nonsignaling accessory receptor to facilitate VEGF binding to VEGF receptor 2 (VEGFR2), neuropilin-1 also binds semaphorins. Evidence for the involvement of neuropilins in vascular development has accumulated substantially in the last several years. In addition to defects in peripheral nerve growth, neuropilin-1-deficient embryos exhibit cardiovascular defects and reduced capillary branching and neural tube vascularization abnormalities (25). Interestingly, Gu and colleagues showed that the sema-3E–PlexinD1 signaling complex functions independently of neuropilin-1 and that sema-3E does not bind neuropilin-expressing COS cells (23). The remaining semaphorin class-3 ligands, with the exception of sema-3B, interact with neuropilin and may function to block the association of neuropilin with the VEGF ligand–receptor complex. The relatively minor vascular defects associated with ablation of sema-3A may reflect the sequestration of neuropilin-1 from the VEGF–VEGFR2 complex, thereby resulting in reduced VEGF signaling.

Thus, many studies have implicated ephrin and semaphorin cues in vascular development over the past decade. These findings immediately begged the question of the potential involvement of the other two primary neural guidance pathways in vascular patterning, namely the Slits and netrins. Most recently, our laboratory and others have addressed this question by analyzing the effects of these factors in cell biological studies, as well as in vivo animal model studies.

### The Slit-Robo Signal Pathway

Three Slit ligands have been identified in mammals, as well as three Roundabout (Robo) receptors that mediate axonal guid-

ance. The Slits are large ECM proteins that control axonal and dendritic branching, regulate the migration of muscle precursor cells, and inhibit neuronal and leukocyte cell migration (26,27). In the nervous system, Slit protein is expressed in the floor plate of the neural tube and has been shown to act predominantly, although not exclusively, as a repellent guidance cue. Slit also is detected in the somites of mouse and zebrafish embryos and likely restricts the sprouting of vessels to the intersomitic corridors (28,29). A fourth member of the Robo receptor signaling pathway recently was identified in zebrafish and mice, dubbed *Magic Roundabout* or *Robo4* (30,31). This Robo receptor is unique among the Robo family due both to its divergent sequence and, more significantly, its expression in embryonic ECs. The identification of a new vascular-specific Robo family member strongly suggests a conserved role for Robo-Slit signaling in vascular development. Moreover, we identified Robo4 on the basis of its altered expression in *Alk1*<sup>-/-</sup> mice, which exhibit severe defects in vascular sprouting (31).

Our laboratory has conducted cell biological studies in adult ECs and heterologous cells overexpressing Robo4. Immunoprecipitation studies revealed binding of Myc-tagged Slit2 to HA-tagged Robo4. Mena, a known effector of Slit–Robo signaling in neuronal cells, also was bound to the Robo4 receptor. It has not been determined whether Slit1 or Slit3 bind to Robo4. Finally, Robo4-expressing HEK cells were decorated with *anti*-Myc antibodies in the presence of Myc-tagged Slit2-conditioned media. In functional assays, we found that Slit2–Robo4 signaling negatively regulates cell migration, but has no effect on proliferation (31). This negative read-out mirrors that of repulsive guidance observed with Slit–Robo signaling in the nervous system. These data led us to hypothesize that Slit–Robo signaling may have an inhibitory effect on vessel sprouting in vivo. Indeed, Robo4 knockdown in zebrafish demonstrated that *Robo4* is essential for vascular development (32). *Robo4* morphants display asynchronous sprouting of the intersomitic vessels from the dorsal aorta, and this defect can be rescued by coinjection of wild-type human *Robo4* mRNA. Characterization of *Robo4*-targeted mice generated in our laboratory is underway to address this hypothesis. Taken together, Slit–Robo signaling inhibits EC migration and may be critical for vascular development. Interestingly, no vascular defects have been reported in *Slit1/Slit2* double knockout (33,34) or in *Slit3*-targeted mice (35), although rigorous examination of vascular development may not have been conducted in these mice.

In contrast to our findings, others report that Robo4 stimulates EC migration in a Slit-independent manner using a soluble truncated Robo4 ectodomain reagent (Robo4-Fc) (36). These investigators observed stimulation of EC migration and proliferation, as well as in vivo angiogenesis, in rodent subcutaneous sponge and aortic ring assays (36). They were unable to detect binding of this ectodomain fusion to any of the three Slit proteins, suggesting that the proangiogenic effect of Robo4 is mediated by an unknown ligand. Taken together, the contradictory results of our two studies may be explained in several

ways. The use of different probe reagents, Robo4-Fc versus Robo4-HA, may affect binding efficiency. Moreover, it is difficult to compare experiments in which Slit activity is assessed directly versus treatment with a Robo4-Fc. Finally, the functionality of these proteins may be contextual and therefore have different activities in different biological assays, depending on the expression of other cell surface receptors.

A second group reports that Slit has a proangiogenic effect mediated by Robo1 (37). They show that Slit2 is expressed by tumor cells and attracts tumor endothelium in *in vitro* assays and in xenografts. It would be interesting to determine if Robo4 is expressed in these tumor cells and if the activity these authors observe may be due to signaling through Robo4 in addition to Robo1. One could envision that treatment with a soluble Robo1 ectodomain protein could compromise signaling via Robo4 assuming they share reactivity to the same Slit ligand. Taken as a whole, the experimental studies on Slit-Robo signaling in vascular development are subject to the reservation that differences in functionality may be ascribed to widely dissimilar cellular contexts and experimental design. Loss-of-function and overexpression studies in animal models will ultimately be informative in regard to teasing apart the various roles of Slit-Robo signaling in vascular development.

### The Netrin-Unc/DCC Signaling Pathways

Netrin 1 and -2 were discovered as chemotropic ligands that attract axons and neuronal cells. Studies by Tessier-Lavigne and his colleagues revealed that netrins attract commissural axons toward the ventral midline of the developing spinal cord (38). Unc5, neogenin, and Deleted in Colorectal Cancer (DCC) receptor families mediate netrin signaling and, depending on the combinations of these receptors expressed on the axon, may induce growth cone extension or collapse. An attractive response toward netrin is mediated by DCC family members. This signal can be silenced by DCC-Robo1 interaction in the presence of Slit (39). The conversion of netrin-attractive activity to a repulsive response also can be achieved by direct interaction between DCC and a second class of receptor, the Unc5h2 receptor (40).

Completing the picture of complementary activities for all four primary classes of axonal guidance factors in the vascular system, recent evidence suggests that this final guidance factor class, the netrins, also plays a role in vascular development. At least three netrin ligands are found in mammals, as well as several receptor partners, including DCC, neogenin, and members of the Unc family of receptors. Several groups have observed EC expression of Unc5h2 receptor in mouse embryos, suggesting that netrins may play a role in early vascular development. To assess the effect of netrin stimulation on ECs, our laboratory conducted assays of migration and proliferation in cultured adult ECs, both human aortic ECs (HAECs) and human microvascular ECs (HMVECs) (41). In all assays (including *in vitro* angiogenic corneal micropocket and tube formation assays), it was found that netrin functioned as a positive angiogenic factor in a

dose-dependent fashion in both EC lines, with activity comparable to VEGF and PDGF. Moreover, *in vivo* chorioallantoic membrane and corneal micropocket assays corroborated these findings. Netrin also induced migration and proliferation of VSMCs. Interestingly, VSMCs, but not ECs, were able to adhere equally well to netrin and fibronectin in our adhesion assays. Reverse transcription polymerase chain reaction (RT-PCR) and Western blot analyses of netrin receptors in VSMCs and ECs suggested that the unique ability of VSMCs to adhere to netrin may be mediated by neogenin, given that it was the only netrin-binding receptor type identified in VSMCs but not in ECs. Furthermore, experiments with a neogenin-blocking antibody abrogated VSMC migration and adhesion to netrin. Surprisingly, none of the canonical netrin receptors were readily detected in our cultured adult ECs, although Unc5h2 is detected in the embryonic vasculature via RNA *in situ* hybridization analyses. These receptors may be expressed at a low level, or an unidentified netrin receptor may exist in adult ECs that mediates the proangiogenic activities we observed. A screen for additional netrin-binding factors is currently underway. Irrespective of the netrin receptor identity, these are the first data to establish netrin as a new angiogenic factor with an activity comparable to VEGF and PDGF. Given these data, one would predict that embryos harboring a hypomorphic allele of netrin 1 would display angiogenic defects. However, examination of *netrin 1* gene-trap mice revealed no obvious vascular abnormalities, owing perhaps to functional redundancy, or to variable potency of netrin on embryonic versus adult ECs.

Reports by others also support a role for netrin in mediating angiogenesis. Examination of vascular development in *Unc5b* (*Unc5h2*)<sup>-/-</sup> mice led Lu and colleagues to conclude that netrin-Unc5b signaling retards vessel growth during embryonic development (42). They confirm that Unc5b is expressed predominantly in the murine arterial embryonic vasculature, particularly in the growing tip cells of vessel sprouts. Ablation of Unc5b in the mouse led to excessive vessel branching, increased tip cell filopodial extensions, and aberrant vessel navigation. Application of netrin to the growing angiogenic front in cultured embryo hindbrains caused filopodial retraction, whereas this response was lost in *Unc5b*<sup>-/-</sup> hindbrains. These authors observed similar effects in cultured human umbilical artery ECs (HUAECs) and in rat aortic ring sprouting assays. Finally, they report increased intersegmental vessel sprouting in *Unc5b* and netrin 1a morpholino knock-down studies in zebrafish. Thus, similar to the Slit-Robo story, there is agreement that netrin signaling modulates vascular guidance, but controversy exists over whether the predominant effect is pro- or antiangiogenic.

How might we reconcile these data? It is possible that the effect of netrin signaling on EC biology may differ dramatically in terms of cultured cells versus vessel guidance in the animal (i.e., although netrin may be a proangiogenic factor for adult ECs, this activity may not model its function during embryologic development). It has been shown that netrin acts bifunctionally in the nervous system depending on the

specific combination of receptors that predominate in the growth cone. If indeed netrin has bifunctional activities in ECs, our data would suggest that an unknown receptor exists that mediates its proangiogenic activity. In regard to the discrepancies in netrin effects on HUAECs, Lu and colleagues employed significantly higher amounts of netrin in their studies, which may account for the different cellular responses (42). Finally, evidence stemming from axonal guidance studies suggests that a cellular response to netrin may be altered depending on the extent of laminin incorporation into the ECM, as well as on the intracellular state (cAMP metabolism) of the target cells (43). In this light, our respective assays may be assessing functionality based on two very different assay conditions – those addressing netrin activity in isolation (cells treated with purified netrin) versus assays using conditioned media from an active netrin-producing monolayer. In summary, it will be important to take cellular context into account in the interpretation of angiogenic and guidance assays utilizing the netrin ligands.

#### FUTURE DIRECTIONS IN VASCULAR PATTERNING

Given the apparent dual roles of guidance genes in both the neuronal and vascular systems, targeted mice that lack specific neuronal guidance genes must be revisited to assess the possible impact of these proteins on vascular development. Mice lacking DCC, neogenin, netrin, Robos, and Slits have been generated and exhibit defects in nervous system development, as reported by many groups. However, examination of these mice for possible vascular defects remains to be investigated. It is entirely possible that vascular defects may be masked due to redundant functions within the gene families, given that all the neuronal guidance factor classes have at least three family members – and up to 30 in some groups. The impact of redundancy on gene function is apparent in ablation studies of the Slit and Robo proteins. *Slit1<sup>-/-</sup>-Slit2<sup>-/-</sup>* double knock-outs exhibited limited neural guidance defects, whereas the commissural axon patterning phenotype most representative of Slit ablation first described in *Drosophila* was observed only after ablating all three murine Slit genes. Similarly, multiple Robo gene ablations will likely be necessary to recapitulate the prototypic *Drosophila* phenotype. Thus, the generation of multiple mutant mice (preferably via endothelial-specific conditional deletion) will be required to assess the roles of all family members in embryonic vascular development. In addition, it will be necessary to address the activity of each member in cell biological assays. Figure 40.1 provides a circumspect comparison of the activities of the four major guidance-cue classes in nervous system and vascular development. Although the data thus far suggest a rough conservation in the inhibitory or attractive activities for these factors between the two systems, this observation must be qualified by the difficulty in deriving a common functional theme given the diversity of assays undertaken by different investigators. This is further challenged by

Ligands	Receptors	Neuronal guidance	Angiogenesis
Netrin Netrin	DCC Neogenin Unc5h1, 2, 3, 4	Attraction Attraction	Netrin1 Netrin3 Unc5h2 Neogenin
Netrin 1, 2, 3	Robo1, 2, 3, 4	Repulsion	Slit2 Robo1 Robo4
Semaphorins	Plexins Neuropilins	Repulsion	Sema3A, 3E, 3C 6D Neuropilin Plexin D1
Class A and B ephrins	Class A and B eph receptors	Repulsion	Ephrin B2 EphB4, B2, B3

Figure 40.1. Four major signaling pathways contribute to neuronal guidance and vascular patterning mechanisms. The netrin, Slit, Semaphorin, and ephrin–Eph signaling pathways either attract or repulse growth cones or, in certain contexts, can be bifunctional (e.g., the netrins). Each ligand and receptor class is comprised of multiple family members. A subset of the factors that were first described in nervous system development has been shown to function in a similar manner during angiogenesis and the patterning of the vascular system. The precise roles of many of these ligands and their cognate receptors in regard to angiogenesis have not been established.

the possibility that a given cue may have a binary function as both an inhibitory and attractive stimulus in different cellular contexts. We have just begun to define the range of activities of these guidance factors, and more extensive studies of function, particularly in animal models, will be required to further refine our understanding of the specific roles of these factors in vascular patterning.

Gaining a better understanding of the activity of guidance factors in vessel outgrowth presents a unique set of challenges for the design of informative “vascular guidance assays.” Nondirected vascular sprouting and directional vascular guidance are difficult to tease apart due to the limited array of vascular assays currently employed. Guidance in the nervous system addresses the extension of a single neuron, whereas guidance in the vascular system depends on both proliferation and migration of the component vascular ECs to generate tubes. Thus, one might envision that some vascular growth factors modulate vessel patterning by regulating survival, while other growth factors and guidance factors affect proliferation and sprouting by providing attractive cues. These two mechanisms may be employed coordinately to guide vessels to an appropriate target. Alternatively, guidance factors may dictate direction only and not regulate proliferation; that is to say, once sprouting is initiated by growth factors, guidance factors may direct vessel trajectory with combinations of attractive and repulsive cues. As an example of this, Lu and colleagues (42) showed that, although vessel navigation was perturbed in *Unc5b<sup>-/-</sup>* mice, the proliferation state and apoptotic indices were similar to wild-type littermates, suggestive of a “pure guidance” role for Unc5b signaling. To address

the function of putative vascular guidance factors, vascular sprouting assays such as the aortic ring assay can be performed with combinations of attractive and repulsive cues. It is anticipated that future studies will utilize modified angiogenic assays to assess whether vessels can be directed to sprout along engineered corridors of cues. Finally, the identification of endocrine gland–selective vascular endothelial growth factor (EG-VEGF) implies that new factors specifically regulating a subpopulation of ECs await discovery (44).

### THERAPEUTIC APPLICATIONS

Without the ability to attract a blood supply, tumor growth is arrested. As such, much attention is being directed to developing new therapeutic strategies aimed at the disruption of vessel growth in cancerous tissue. These strategies have focused on modulating known vascular growth factors, such as VEGF, FGF, and PDGF, and have proven useful in animal and human trials. The realization that neural guidance factors also modulate vascular sprouting significantly expands the number of ligand–receptor signaling pathways available for clinical manipulation. Whether targeting these new factors provides a therapeutic benefit awaits further investigation. Applying repulsive vascular guidance cues to tumor masses may slow the infiltration of new vessels. Alternatively, it may be possible to induce vessel growth toward tissues in ischemic regions by treating with attractive vascular guidance cues or dominant negative receptors that could antagonize repulsive guidance cues. Importantly, attempts to induce vessel formation by providing sustained levels of VEGF alone has, in some cases, led to disorganized vessel formations similar to angiomas, rather than functional vascular networks (45). This stands as further evidence that, in addition to the known vascular cytokines and growth factors, guidance factors will be required for the generation of mature and highly organized vessels in a therapeutic setting. Considerable interest exists in identifying additional positive and negative regulators of vessel growth, because expanding our tool kit of available angiogenic factors will be critical in designing strategies to treat different angiogenic pathological states.

The first steps have been taken toward evaluating the efficacy of these new classes of vascular guidance cues in the therapeutic arena. Recent studies have shown that Slit proteins are expressed in tumor cells, whereas Robo receptors (Robo1 and Robo4) are detected in tumor endothelium (30,37,46). Using a truncated Robo1 soluble receptor, Wang and colleagues observed reduced microvessel density and tumor size in Slit-expressing melanoma xenograft models of tumorigenesis, thereby providing evidence that disruption of Slit–Robo1 signaling can block tumor growth (37). Such studies not only reveal potential strategies for the treatment of different disease states, but also expand our knowledge of the biology of the different angiogenic factors, because their expression levels and activities may vary between tumor types. Thus, clinical observations may, in turn, contribute to biological insight.

### CONCLUSION

Our conceptual framework for understanding the development of the vascular system has been advanced dramatically during the last decade. Elucidating the basic signaling pathways that regulate the activity of the primary components of blood vessels (the ECs) was the first focus. The focus then shifted to understanding the interaction of these cells to form patent vessels and a seamless circulatory network. Most recently, it has become clear that guidance mechanisms are critical for directing this process, and vascular biologists have turned to the nervous system for practical insight. It is clear that the endothelial network is an intricate organ in its own right and responds in a dynamic fashion to specific cues in the environment. Because development makes reiterative use of successful regulatory mechanisms, it is, in hindsight, not surprising that the primary pathways that regulate axonal guidance have been similarly employed by the vascular system to pattern the vascular tree. The same array of ligands and receptors play roles in both systems to pattern these functionally unique, but structurally analogous systems. Finally, although it is clear that the four principal classes of neural guidance factors are shared between the nervous and vascular systems, it is not unrealistic to anticipate that unique molecules may exist to pattern specific subpopulations of ECs. The identification of these activities may similarly provide interesting therapeutic opportunities.

### KEY POINTS

- The vascular and nervous systems share molecular mechanisms that govern complex patterning and functional coordination of their respective networks.
- The intricate organization of mature vascular networks likely requires coordination between vascular mitogens and guidance factors that provide directional information.
- The four well-characterized classes of axonal guidance factors, the Slits, semaphorins, netrins, and ephrins/Ephs, appear to have similar roles as guidance factors in the developing vasculature.

### *Future Goals*

- To elucidate the activities of putative vessel guidance factors, which will require the development of informative vascular guidance assays that can distinguish directionality of growth from general mitogenic stimulation of proliferation
- To identify these new endothelial guidance factors significantly augments the tool kit of available vascular growth regulators; presumably these will provide important targets for therapeutic strategies to

control or engineer vessel growth in pathological conditions

- To overcome redundancy issues and to discern the fundamental roles of these factors in vascular development, it will be necessary to generate animal models in which multiple genes of a given family are ablated
- To determine the extent to which both networks cross-regulate their development and function, given that vessels and nerves exhibit many structural, functional, and regulatory parallels

## *Notch* Genes

### Orchestrating Endothelial Differentiation

---

Yasuhiro Funahashi, Carrie J. Shawber, and Jan Kitajewski

*Columbia University Medical Center, New York, New York*

Vascular development entails multiple cell fate decisions that specify a diverse array of vascular structures, which include veins, arteries, capillaries, lymphatics, and specialized vascular beds of organs. Genetic studies have revealed that Notch plays a central role in the specification of arterial versus venous vasculature. Notch function is critical for remodelling and patterning of the vasculature, suggesting an additional role for Notch in regulating angiogenesis, a multistep process that requires endothelial cells (ECs) to respond to a variety of angiogenic stimuli. Notch proteins are receptors that modulate the ability of cells to respond to external cues, thus making them ideal regulators of angiogenesis. This chapter reviews *in vivo* and *in vitro* studies that have provided insights into Notch functions in the endothelium during development and in postnatal life. These studies show that Notch not only mediates specialization of the endothelium, but also has both positive and negative influences on the process of angiogenesis.

#### **NOTCH AND NOTCH LIGAND GENES**

The study of Notch started in 1917, when the famed geneticist, Thomas Hunt Morgan, first described a strain of *Drosophila* with “notched” wings. Notch genes were first molecularly identified during the 1980s, through genetic analysis of invertebrate organisms *Caenorhabditis elegans* (1) and *Drosophila* (2). Mutations in the Notch genes were described as affecting “cell fate determination,” a process by which cells use molecular signals to specify distinct cellular fates. During the 1990s, the identification of Notch genes expressed in the vasculature (3,4) and both the functional analysis of Notch ligand Jagged1 in mice (5) and Notch gene target gridlock in zebrafish (6,7) began an era of vascular study of Notch. In principle, this period gave birth to studies of the molecular mechanisms of cell fate determination in vascular development, such as during arterial–venous specification.

In multicellular organisms, from worms to humans, Notch signaling regulates a variety of cell-fate decisions. Depending

on the cellular context, Notch has been found to promote differentiation, proliferation, and cell survival as well as to inhibit these same processes (8–10). In mammals, the Notch family consists of four receptors (Notch1–4). Two families of ligands exist for Notch, Jagged (Jagged1 and -2), and Delta-like (Dll1, -3, and -4). Consistent with Notch functioning to regulate cell-fate differentiation via direct cell–cell interactions, both receptors and ligands are cell surface proteins with single-pass transmembrane domains (Figure 41.1).

#### **THE NOTCH MOLECULAR PATHWAY**

The activation of Notch is regulated at the level of receptor proteolysis followed by participation of the intracellular domain of Notch in a transcriptional complex (8,11). As Notch proteins transit to the cell surface, a furin-like convertase cleaves the receptor, at or near the plasma membrane, generating a heterodimeric receptor at the surface (see Figure 41.1). Upon ligand-binding, the cytoplasmic domain of Notch is released from the cell-surface by two sequential proteolytic cleavages. The first cleavage occurs just N-terminal to the transmembrane domain by a disintegrin and metalloprotease domain-like metalloprotease, whereas the second cleavage occurs within the transmembrane domain by the  $\gamma$ -secretase/presenilin complex. The released intracellular Notch peptide (NotchIC) translocates to the nucleus and forms a complex with the CBF, Su (H), Lag-2 (CSL) transcriptional repressor, converting it to a transcriptional activator. The *Hairy/Enhancer of Split* (*HES*) and *HES*-related (*Hey*, also named *CHF*, *HRT*, *HESR*, *gridlock*) genes are the direct targets of Notch/CSL-dependent signaling. The *HES* and *Hey* proteins are bHLH-Orange-domain transcriptional repressors. During neurogenesis and myogenesis, these transcription factors transduce Notch signaling by inhibiting tissue-specific bHLH transcription factors of the *MASH* and *MyoD* families, respectively. The direct targets of *HES*- and *Hey*-mediated transcriptional repression in ECs are unknown.

Figure 41.1. Schematic of Notch and Notch ligands. Two classes of Notch ligands, Jagged and Delta-like, are presented by cells as membrane-bound proteins that are characterized by a cysteine-rich domain, a series of EGF-like repeats, and a DSL domain unique to Notch ligands. Notch is a single-pass transmembrane protein, with the Notch extracellular domain consisting of a series of EGF-like repeats and LNR-lin-12/Notch repeats followed by a furin-cleavage site. The Notch intracellular domain contains protein interaction domains, RAM, Ankyrin repeat, and PEST. The RAM is the CSL binding domain, the ankyrin repeat domain is a protein-protein interaction domain required for Notch function, and PEST a sequence important to target proteins for degradation. The Adam-like convertase cleavage occurs between the LNR and the transmembrane domain, and the  $\gamma$ -secretase/presenilin cleavage occurs within the transmembrane domain.

Notch also signals through a poorly defined CSL-independent pathway.

#### **NOTCH EXPRESSION IN ARTERIAL ENDOTHELIUM AND CAPILLARIES**

During mammalian development, Notch proteins and Notch ligands are dynamically expressed within the developing vas-

culature (12). At embryonic days (E)8 to E9 in mice, Dll4 is expressed in ECs of the dorsal aorta and developing heart tube, while Jagged1 expression begins in the aortic arch arteries and expands to the developing heart. At this same time, Notch4 is expressed in the endothelium of the anterior cardinal vein (13). The vascular expression of other Notch genes during this embryonic stage has not been reported. At E12.5, Notch1 and Notch2 are both expressed in the ECs of the arterial outflow tract, atrioventricular canal, and the aorta. Notch2 expression

also is observed in the pulmonary artery. By the following day, dramatic changes occur in the expression pattern of the Notch family members. In the aorta, Notch2 expression is lost, while Notch1 expression is maintained (14). In addition, Notch4 expression is now present in ECs of the aorta but absent in the vena cava, which develops from the anterior cardinal vein (13,14).

In mouse embryos at stages E12.5 to 13.5, a diverse pattern of expression is also observed for Notch ligands. Jagged1 is coexpressed with Notch2 in the endothelium of the atrioventricular canal and the pulmonary artery. In the ECs of the aorta, both Jagged1 and Jagged2 expression overlap with that of Notch1 and Notch4 (14). Unlike Jagged ligands, Dll4 is no longer expressed in the endothelium of the aorta, but is expressed in the microvascular endothelium of the embryo (15). Expression of Jagged1 is not restricted to ECs, but extends into the surrounding vascular smooth muscle cells (VSMCs) of the aorta (14). In the aortic VSMCs, Jagged1 expression overlaps with that of Notch3 (16,17). From these limited expression studies, it appears that the expression of Notch1, -2, and -4 and Jagged2 are restricted to ECs; and Notch3 to VSMCs; whereas Jagged1 is expressed in both ECs and VSMCs. Several aspects of the expression patterns point to functional redundancies for receptors and ligands.

As embryogenesis proceeds, Notch proteins and ligands become restricted to the developing arterial endothelium. This expression is consistent with zebrafish studies in which Notch signaling was shown to regulate arterial specification of the dorsal aorta (12,18). However, expression of Jagged1 also has been observed in the endothelium of the vitelline veins, portal veins, and the anterior cardinal vein. These observations in mice suggest that Notch may have a function in venous ECs as well as regulating arterial EC differentiation.

In addition to embryogenesis, Notch proteins and ligands have been proposed to function during vascular remodeling and growth in the adult. Both Dll4 and Notch4 are expressed in the vessels of the lung, heart, and kidney of the adult mouse (13,15). It has been proposed that these highly vascularized tissues undergo high EC turnover. In the mature ovary, new blood vessel formation is necessary for follicle growth and maturation. Dll4 expression has been observed in these rapidly developing small vessels and capillaries of the mouse follicles (15). Notch1, Notch4, and Jagged1 also are expressed in the mature and angiogenic vessels of the ovary, although they have unique and overlapping patterns of expression (19). In a murine wound model, an increase in Jagged1 expression has been observed in proliferating ECs, suggesting that Notch may regulate neovascularization during wound repair. Similarly, Dll4 expression is upregulated in the invading vasculature of human tumor xenografts in mice and in the blood vessels in primary cancers of the kidney and breast (15). Thus, the patterns of Notch and Notch ligand expression indicate that Notch signaling may participate in both embryonic and adult physiological angiogenesis as well as pathological angiogenesis.

## MUTATIONS IN NOTCH REVEAL A ROLE IN VENOUS/ARTERIAL SPECIFICATION

In zebrafish and mouse embryos, the observation that Notch and Notch ligand expression becomes predominant in the arterial endothelium suggests that Notch signaling functions to regulate arterial–venous specification. Zebrafish embryos deficient for the Hey2 homologue *gridlock*, or those that ectopically express a dominant negative form of CSL, have coarctation of the dorsal aortae, a failure of the anterior lateral dorsal aortae to merge into a single midline aorta, and shunting between the dorsal aortae and the posterior cardinal vein (20). In these loss-of-function embryos, ECs are recruited to the aortae but do not express the arterial EC marker, ephrinB2. Similarly, *Notch1*<sup>-/-</sup> and *Notch1*<sup>-/-</sup>/*Notch4*<sup>-/-</sup>, *Dll4*<sup>+/-</sup>, *Dll4*<sup>-/-</sup>, *Hey1*<sup>-/-</sup>/*Hey2*<sup>-/-</sup>, *rbpsuh*<sup>-/-</sup> (CSL), and Tek-Cre *Rbpsuh*<sup>fl/null</sup> (endothelial-specific loss of CSL) mouse embryos die around E9.5, and all display arterial vessel defects (20). In these Notch mutant embryos, coarctation of the vitelline arteries, umbilical artery, and dorsal aorta; a loss of arterial branching in the yolk sac vasculature; and arterial venous malformations are all observed. *Notch1*<sup>-/-</sup> and *Notch1*<sup>-/-</sup>/*Notch4*<sup>-/-</sup> embryos also display defects in the anterior cardinal veins, although this defect has been proposed to be secondary to the aortic defects. In contrast to the loss-of-function embryos, the dorsal aortae are dilated in Notch gain-of-function murine embryos, *Flk1-N4/int-3* (21). Expression of arterial markers, such as Connexin37, Connexin40, CD44, and ephrinB2, is reduced or absent in the dorsal aortae of *Dll4*<sup>+/-</sup>, *Dll4*<sup>-/-</sup>, *Hey1*<sup>-/-</sup>/*Hey2*<sup>-/-</sup>, *rbpsuh*<sup>-/-</sup> (CSL), and Tek-Cre *Rbpsuh*<sup>fl/null</sup> murine embryos, whereas the dorsal aortae of *Dll4*<sup>-/-</sup> embryos mis-express the venous endothelial marker, EphB4 (20). Thus, in the embryonic vasculature, Notch signaling functions to suppress the venous fate in the arterial endothelium.

The genes that regulate Notch expression within the vasculature are beginning to be elucidated. In zebrafish, vascular endothelial growth factor (VEGF)-A, through the induction of Notch5 and DeltaC, regulates ephrinB2 expression within arteries (18). Consistent with VEGF-A-induced arterial specification being mediated by Notch, exogenous VEGF-A induced both Notch1 and Dll4 in cultured human iliac arterial ECs (HIAECs) and human femoral arterial ECs (HFAECs), whereas hypoxic conditions induced both VEGF-A and Dll4 in human umbilical vein ECs (HUVECs) (15,18). In mice treated with the VEGF blocking agent VEGF-Trap, Dll4 was found to be downregulated within tumor endothelium (22). Thus, VEGF-A likely regulates arterial specification through the upregulation of both Notch proteins and Notch ligands, which leads to the activation of Notch signaling. A recent study of COUP-TFII suggests that this orphan receptor functions to maintain venous EC identity by repressing Jagged1 and Notch1 expression (23). Loss of *COUP-TFII* in mice correlated with the mis-expression of Notch1, Jagged1, Hey1, and the arterial markers, ephrinB2 and neuropilin 1 (NRP1) within the veins, whereas ectopic endothelial expression of COUP-TFII

resulted in a loss of Notch1, Jagged1, and NP-1 in the arterial endothelium.

### MUTATIONS IN NOTCH UNCOVER VASCULAR REMODELING FUNCTIONS

Zebrafish and murine studies suggest that Notch signaling also may regulate other aspects of vascular development, in addition to arterial–venous specification (12,20). In zebrafish, ectopic sprouting of intersomitic vessels was observed in the *Notch Mindbomb* mutant (*Mib<sup>ta52b/ta52b</sup>*) embryos, in which ligand–Notch signal activation is perturbed, suggesting that disruption of Notch results in defective patterning of microvessels. In addition, gridlock activity was found to be essential during the period of angioblast cell fate determination and migration, suggesting a role for Notch signaling in these processes (24). *Notch1<sup>-/-</sup>*, *Notch1<sup>-/-</sup>/Notch4<sup>-/-</sup>*, *Jagged1<sup>-/-</sup>*, *Dll4<sup>-/-</sup>*, *Rpbsuh<sup>-/-</sup>* (CSL), *Hey1<sup>-/-</sup>/Hey2<sup>-/-</sup>*, or *presenilin1<sup>-/-</sup>/presenilin2<sup>-/-</sup>* mutant mice die in utero between E9.5 and 10.5 and display capillary patterning defects. Expression of an activated form of Notch4 within the endothelium (*Flk1-N4/int-3*) or disruption of *Fbw7/Sel-10*, a negative regulator of Notch signaling, also results in embryonic lethality at E10.5, with vascular patterning defects. Similar to the zebrafish mutants, the intersomitic vessels of these Notch mutant embryos recruit ECs but fail to differentiate into a branching capillary network. These results further demonstrate that branching morphogenesis of the endothelium is exquisitely sensitive to the dosage of Notch signaling. In Notch mutant embryos, this failure in branching morphogenesis may be due to altered EC survival and proliferation. In *Dll4<sup>-/-</sup>* embryos, ECs accumulate at the apical end of the intersomitic vessels, rather than migrating and differentiating to form capillaries. In embryos that have lost one copy of *VEGFR2* and both copies of *presenilin1* (*Flk1<sup>+/lacZ</sup>;PS1<sup>-/-</sup>*), a reduction in capillary sprouting was associated with increased EC proliferation as well as increased apoptosis, suggesting that Notch signaling inhibits proliferation and promotes the survival of angiogenic ECs.

### NOTCH FUNCTIONS DEFINED BY IN VITRO ANGIOGENESIS ASSAYS

Angiogenesis is a multistep process that requires ECs to respond to a variety of angiogenic stimuli. Angiogenesis initiates with the degradation of extracellular matrix (ECM), followed by budding of ECs at sites of active angiogenesis. The ECs then transition to a proliferative mode coincident with the development of new sprouts. The combined steps of budding, proliferation, and migration result in the formation of lumen-containing sprouts. The multicellular sprouts then remodel to form a network of capillary vessels. In vitro angiogenesis assays, using primary ECs have proved useful to model dis-

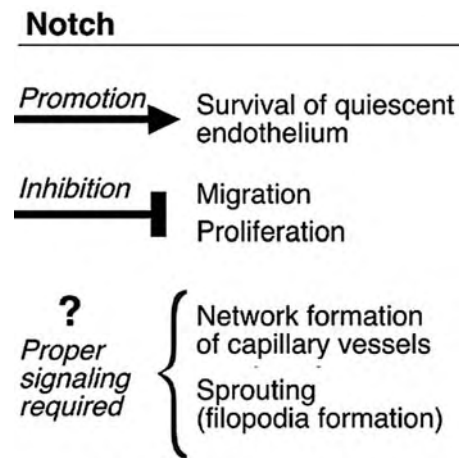

Figure 41.2. Summary of the effects of Notch signaling on distinct steps in angiogenesis, as determined by in vitro assays.

tinct steps of angiogenesis. Using these methodologies, Notch signaling has been described as both a positive and negative effector of angiogenesis (Figure 41.2).

Activation of Notch signaling inhibits proliferation of human primary ECs (25–27). Notch signaling inhibits mitogen-induced expression of p21<sup>Cip1</sup> and delays cyclin D–cdk4–mediated retinoblastoma (Rb) phosphorylation. In ECs, upregulation of p21<sup>Cip1</sup> is necessary for nuclear localization of cyclin D and cdk4, resulting in the phosphorylation of retinoblastoma protein (Rb). Thus, Notch might use such a mechanism to inhibit EC proliferation, because an activated form of Notch is not able to induce cell-cycle arrest of immortalized ECs expressing SV40 T antigen, which inhibits the phosphorylation of Rb (28). Notch signaling also may function in the regulation of contact inhibition, because confluent cultures of ECs exhibit Notch signal activation (28). Notch signaling also controls EC apoptosis (26,29). In immortalized ECs, inflammatory-mediated cell death by lipopolysaccharide (LPS) is inhibited by Notch signal activation, accompanied by inhibition of the proapoptotic c-jun N-terminal kinase (JNK) pathway and upregulation of antiapoptotic bcl-2 protein (29). Notch signaling inhibits the migration of both human primary and immortalized ECs (25,30). The action of Notch against migration of immortalized EC line is detected in collagen-coated, but not fibrinogen-coated plates, possibly via regulation of  $\beta 1$  integrin signaling (30).

The role of Notch in endothelial morphogenesis, such as angiogenic sprouting and network formation of capillary vessels, is still controversial. Activation of Notch signaling can promote budding of HUVECs into the underlying collagen matrix (31). However, activation of Notch signaling in human immortalized dermal microvascular ECs decreased endothelial sprouting (30). In three-dimensional (3D) collagen gels, Notch signaling is activated during network formation of HUVECs, whereas a dominant negative form of Notch inhibits network formation (27). Either ectopic expression of activated Notch1 or overexpression of HES1, one of the primary

**Table 41-1: Vascular Expression/Phenotypes of Notch Proteins**

<i>Receptor/ Ligand</i>	<i>Cultured ECs</i>	<i>E8.5–9.5</i>	<i>E11.5–12.5</i>	<i>E13.5</i>	<i>Knockout Phenotype</i>
Notch1	Induced by VEGF in arterial ECs Induced by VEGF and bFGF in venous ECs	ND	ND	Aorta	Lethal at E9.5; defects in yolks sac plexus, placental labyrinthine, intersomitic vessels, and arterial EC specification; collapsed dorsal aorta; pericardial swelling
Notch2		ND	ND	Heart outflow tract	50% lethal at E16.5; pericardial effusion and widespread hemorrhaging. 50% viable lack of glomerular capillary tufts or glomerular capillary aneurysms; defects in hyaloid vessels
Notch3		ND	ND	Arterial VSMCs	Viable; adult-onset arteriopathy associated with failed arterial VSMC differentiation, VSMC and EC death
Notch4	Induced by VEGF and bFGF in venous ECs	E9.5 – Anterior cardinal vein ECs		Aortic, aortic tract and pulmonary artery, capillary ECs	Viable; augments Notch1 loss-of-function phenotype
Jagged1		E9.5 – Aortic arch arteries	E12.5-Aortic and aortic arch, pulmonary, coronary, and intervertebral artery ECs and VSMCs	Aortic ECs and VSMCs	Lethal at E10.5; defects in yolk sac plexus, cranial vasculature
Jagged2				Aortic ECs	Viable; no vascular defects reported
Dll4	Induced by VEGF or bFGF in arterial ECs	E8.5 – ECs of dorsal aorta umbilical artery and heart tube. E9.5 – ECs of aorta, umbilical artery, mesenteric arteries, intersomitic vessels, and yolk sac	E11.5-ECs of arteries	Capillary ECs	Lethal at E9.5; haploinsufficient; defects in yolk sac plexus, intersomitic vessels, cranial vasculature, and arterial EC specification; coarctation of dorsal aorta; pericardial swelling; AV malformations

Dll1 and Dll3 are not expressed in the vasculature, and knockout mice do not have vascular defects.  
ND, No data.

targets of Notch signaling, also enhances network formation of human iliac artery ECs (26). Moreover, overexpression of HESR1 (Hey1), a primary target gene of Notch signaling, or inhibition of HESR1, blocks network formation of capillary-like vessels of primary adipose ECs (25). It is clear that these diverse results, carried out in different types of ECs, require further clarification. It is important to consider that these findings may be highlighting the necessity of the proper levels of Notch signaling to regulate endothelial morphogenesis during angiogenic progression. In support of the concept that proper Notch activity is required for vascular development

is that fact that either endothelial-specific deletion or activation of Notch signaling causes vascular remodeling defects and embryonic lethality (20,21,32).

It may be that the most direct links between Notch and angiogenesis come from the finding that Notch functions downstream of VEGF-A signaling (18,22,26). An intriguing example of such a connection may be apparent in retinal vasculature. VEGF-A functions to induce angiogenic sprouting via the production of filopodia at the tip of ECs (endothelial tip cells) (33). Dll4 is strongly expressed in the tip ECs of the developing retinal vascular plexus (34). As VEGF-A induces

both Notch1 and Dll4 expression in cultured ECs (26), VEGF-A might induce Dll4 expression to initiate angiogenic sprouting. Therefore, Notch signaling might assist in determining the site for angiogenesis initiation in the growing vasculature, in concert with VEGF-A. However, it remains to be determined how Notch signaling participates in defining the tip cell phenotype and in the regulation of sprouting.

## NOTCH AND ENDOTHELIAL/VASCULAR DISEASE

In humans, misregulation of Notch signaling is clearly linked to disruption of vascular integrity. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an adult-onset arteriopathy caused by mutations within the EGF-like repeats of Notch3 (12,20). In CADASIL patients, dysregulation of Notch3 function results in reduced adhesion and death of arterial VSMCs, leading to recurrent strokes and (ultimately) death. This syndrome is consistent with Notch3 expression being restricted to VSMCs during embryogenesis and in the adult (16,17,34–38) (Table 41-1). The human CADASIL phenotype has been recapitulated in transgenic mice that express the CADASIL Notch3 R90C mutation in VSMCs. Ten-month-old transgenics that express Notch3 R90C display an impaired flow- and pressure-induced arterial dilation as well as compromised cerebrovasculature (39,40). These phenotypes were associated with VSMC regression and death, suggesting Notch3 function is essential for VSMC adhesion-dependent survival. In fact, constitutive activation of Notch3 in rat aortic VSMCs correlated with the induction of cFlip, an antagonist of Fas-dependent apoptosis (41). Recent analyses of *Notch3*<sup>-/-</sup> mice also indicate that Notch3 function is essential for the differentiation of arterial VSMCs (42,43).

Dysregulation of Notch4 signaling has been implicated in a human vascular homeostasis syndrome. In patients with mutations in *cerebral cavernous malformation 1 (CCM1)* and a *CCM1*-knockout mouse model, development of thin-walled, hemorrhaging vessels in the brain correlates with a decrease in Notch4 expression in both arterial endothelial and VSMCs (44). Finally, retrospective analysis of Alagille patients, a complex developmental disorder with characteristic organ-specific vascular defects caused by mutations in *Jagged1*, revealed a significant mortality from anomalous vasculature, and that up to a third of patients' deaths correlated with the presence of defective, aneurysmal arteries.

### KEY POINTS

- Vascular development entails multiple cell fate decisions in which Notch might be involved. Arterial-venous differentiation is one such cell fate decision in which Notch is a key regulator.

- Notch has been observed to have both pro- and antiangiogenic functions; thus, a proper balance or timing of Notch activity may be required during angiogenic sprouting and vascular remodeling.
- Notch also functions in vascular homeostasis and possibly in interactions between VSMCs and ECs. Human mutations in human *NOTCH3* and *JAGGED1* or reduction of *NOTCH4* expression are linked to hereditary vasculopathies.

### Future Goals

- To define the interaction between Notch signaling and that of other known angiogenic cascades, such as the VEGF/VEGF receptor pathway
- To identify other cell fate determination steps that occur during vascular development and endothelial differentiation that utilize Notch signaling as a regulator
- To explore further roles for Notch in pathologies of the human vasculature, such as tumor angiogenesis
- To determine the mechanisms by which Notch functions as both a pro- and antiangiogenic regulator, and determining its role in sprouting angiogenesis

## Reactive Oxygen Species

---

Kaikobad Irani

*Cardiovascular Institute, University of Pittsburgh Medical Center, Pennsylvania*

The endothelium plays a pivotal role in vascular homeostasis. Its strategic location between the vascular wall and the circulation allows it to serve as a bridge between these two compartments. A dynamic interaction exists between the endothelium and hormonal and cellular mediators, both from the circulation as well as from the vascular wall. This same strategic location of the endothelium also makes it a prime target for injury in the setting of vascular disease.

Accumulating evidence suggests that oxidative stress, by resulting in a maladaptive endothelial cell (EC) phenotype, is one of the common means by which conditions such as hyperlipidemia, hypertension, advanced age, hyperhomocysteinemia, and diabetes, all of which are associated with an increased risk of vascular diseases, lead to a dysfunctional endothelium. However, the term *oxidative stress* is loosely used and applied, and it would be simplistic to conclude that oxidants or reactive oxygen species (ROS) always play a pathophysiological role in the endothelium.

### HISTORICAL PERSPECTIVE

ROS have been regarded historically as deleterious due to free radical-induced oxidation and damage of macromolecules such as DNA, proteins, and lipids. More recently, however, it has been appreciated that ROS can exert more subtle modulatory effects. This evolution in our understanding of the roles of ROS is exemplified by the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a source of ROS in many cell types. The NADPH oxidase was first described in professional phagocytic cells (macrophages and neutrophils) of the innate immune system, where it is responsible for generating a large amount of the ROS superoxide as part of the oxidative burst during the process of phagocytosis (1). In this capacity, the NADPH oxidase and the ROS generated by it has long been associated with pathophysiological outcomes such as injury of cardiovascular tissue perpetrated by infiltrating neutrophils in the setting of ischemia–reperfusion. In contrast to this injurious role of ROS generated by the NADPH oxidase in phagocytes, the role of ROS derived from the NADPH oxidase (and

homologues of it) in nonphagocytic cells can be more appropriately described as one of physiological signaling. This latter function of ROS as biologically relevant signaling intermediaries is primarily mediated by chemically reversible, post-translational modifications of specific amino acid residues on proteins that result in changes in protein function. A classical example of this is the progressive oxidation of specific cysteine residues by  $H_2O_2$  to give rise to sulfenic acid, sulfinic acid, and sulfonic acid derivatives (2), which can mediate discrete and diverse regulatory outcomes.

### DEFINING REACTIVE OXYGEN SPECIES AND OXIDATIVE STRESS

ROS are oxygen-based molecules that are characterized by their high chemical reactivity and are generated by all aerobic organisms. In health, ROS generation is counteracted by enzymatic and nonenzymatic antioxidant systems that scavenge or reduce ROS levels, thereby maintaining reduction-oxidation (redox) homeostasis in cells and tissues. Perturbation of this balance secondary to an increase in ROS production and/or a decrease in antioxidant reserve leads to a state of oxidative stress.

By definition, ROS are chemical species containing oxygen atoms with unpaired electrons that may be charged or uncharged. The unpaired electrons render the molecule unstable, allowing the ROS to react with electrons, other chemical species, or macromolecules such as proteins and nucleic acids. Molecular oxygen serves as the primary electron acceptor yielding the superoxide anion. Subsequent univalent reductive steps can lead to the generation of a whole range of ROS (Figure 42.1). The distinct physical and chemical properties of each of these ROS determine its toxicity as well as its suitability as a signaling intermediary.

ECs and, for that matter, almost all cell types have multiple mechanisms for the production and removal of ROS. Multiple enzymatic systems can convert molecular oxygen to superoxide ( $O_2^-$ ). Those notable in the endothelium are xanthine oxidoreductase, NADPH oxidases, uncoupled endothelial

Figure 42.1. Chemical derivation of main reactive oxygen species.  $\text{O}_2$ , molecular oxygen;  $\text{e}^-$ , free electron;  $\text{O}_2^-$ , superoxide;  $\text{H}_2\text{O}_2$ , hydrogen peroxide; SOD, superoxide dismutase; MPO, myeloperoxidase; Cat, catalase; GPX, glutathione peroxidase;  $\text{H}_2\text{O}$ , water; HOCl, hypochlorous acid;  $\text{Fe}^{2+}$ , ferrous ions;  $\text{OH}^-$ , hydroxyl radical.

nitric oxide synthase (eNOS), the cytochrome P450-based enzymes, and mitochondrial respiration. Other mechanisms for the generation of ROS include: (a) catalytic conversion of other ROS, such as  $\text{H}_2\text{O}_2$  by dismutation of  $\text{O}_2^-$ ; (b) conversion of  $\text{H}_2\text{O}_2$  to hypochlorous acid (HOCl); and (c) reduction of ROS by transition metals such as the ferrous ion to the highly reactive hydroxyl ( $\text{OH}^-$ ) radical. As an example of ROS removal, hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) is enzymatically converted to water ( $\text{H}_2\text{O}$ ) by glutathione peroxidase (GPX) and catalase (see Figure 42.1).

### SOURCES OF REACTIVE OXYGEN SPECIES IN THE ENDOTHELIUM

ROS may be produced within or without the endothelium, and may exert both autocrine and paracrine effects.

#### Nonendothelial Sources

As the interface between flowing blood and the vascular wall, the endothelium is exposed to ROS produced in both luminal and abluminal compartments. The classical example of a blood-borne source of ROS external to the endothelium is circulating cells of the innate immune system. In conditions in which macrophages and neutrophils have infiltrated the vascular wall (such as in an atherosclerotic plaque), their proximity to the endothelium allows the membrane-permeable ROS produced within them to affect endothelial function. When activated, infiltrating neutrophils and macrophages (which now form part of the vessel wall) are rich sources of  $\text{H}_2\text{O}_2$  and, because they express the enzyme myeloperoxidase, also can produce large quantities of another cell-permeable ROS, hypochlorous acid (HOCl) (3). On the abluminal side of the endothelium, vascular smooth muscle cells (VSMCs) and adventitial fibroblasts can generate ROS (4).

#### Endothelial Sources

Although the endothelium is subject to influence by diffusible ROS produced in neighboring cells, it is itself endowed with

Figure 42.2. Major oxidant and antioxidant systems in endothelial cells. several enzymatic systems with the capacity to generate ROS (Figure 42.2).

#### The NADPH Oxidase(s)

Phagocytic cells such as neutrophils and macrophages express a multimolecular oxidase that transfers an electron from NADPH to molecular  $\text{O}_2$  to generate  $\text{O}_2^-$ , which plays an important role in the innate immune response (1). The *phagocyte oxidase* (phox) comprises a heterodimer flavocytochrome consisting of a 22-kDa unit ( $\text{p}22^{\text{phox}}$ ) and a glycosylated 91-kDa unit ( $\text{gp}91^{\text{phox}}$ , also termed NOX2 for NADPH oxidase). In addition to this membrane-associated catalytic core, four cytosolic subunits ( $\text{p}40^{\text{phox}}$ ,  $\text{p}47^{\text{phox}}$ ,  $\text{p}67^{\text{phox}}$ , and the small GTPases Rac1 or Rac2) are essential for the regulation of oxidase activity. Although initially thought to be limited to phagocytes, it is now appreciated that many components of this oxidase (including the catalytic NOX2 flavoprotein) are expressed in nonphagocytes. For example, NOX2,  $\text{p}47^{\text{phox}}$ ,  $\text{p}22^{\text{phox}}$ , and  $\text{p}67^{\text{phox}}$ , and the ubiquitous  $\text{pac}1$ , are all expressed in ECs (5–10). Although ECs may express a functional phagocytic NADPH oxidase, the regulation of oxidase activity is likely to be different than that in phagocytes. In ECs, the oxidase generates constitutive low levels of ROS even in the absence of extrinsic stimulation (in contrast to phagocytes, in which ROS production is an all-or-none phenomenon), but can increase ROS production in response to specific stimuli. This might be because in ECs, unlike in phagocytes, NOX2 is present in a preassembled complex with its regulatory components (9,11).

The observation that NOX2 is not ubiquitously expressed led to a search for homologues of NOX2, adding new members to the NOX family. The first of these, *NOX1*, was originally cloned from a colon cDNA library, and is expressed mainly in colon, VSMCs, and prostate (12–14). Since then, several other homologues, *NOX1*, -2, -3, -4, and -5, and *Duox1* and -2 (for *dual oxidase*, because they possess a second N-terminal peroxidase homology domain), have been cloned, and been

shown to have tissue-specific expression. In addition to NOX2, ECs express NOX1 and NOX4, albeit at much lower levels (7,15).

Endothelial NOX activity is subject to regulation by many physiologic and pathophysiological stimuli, and this activity mediates diverse EC phenotypes. Vascular endothelial growth factor (VEGF), a potent angiogenic agent that specifically targets ECs, leads to a NOX2-dependent increase in ROS levels in ECs (16,17). This effect is important for VEGF signaling, vis-à-vis EC proliferation and migration (16,17). In addition, VEGF induces antioxidant defenses in ECs, such as the expression of manganese superoxide dismutase (MnSOD) in mitochondria, which also depends on the activation of NOX (18). NOXs also are activated by cytokines such as tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-1 $\beta$ , and may play a part in survival mechanisms when ECs are challenged with these stimuli (19,20). Both angiotensin II and endothelin-1 also activate endothelial NOX (10,21), which may be an important mechanism for the endothelial dysfunction seen in heart failure. Endothelial NOX activity also is stimulated by high insulin (22) or glucose (23) and by advanced glycation end products (24), as well as by oxidized low-density lipoprotein (LDL) (25,26), which may contribute to diabetes- and hyperlipidemia-associated endothelial dysfunction. Environmental stressors such as ischemia (27), hypoxia-reoxygenation (28), and nutrient deprivation (29) also have been reported to upregulate endothelial NOX activity, implicating endothelial NOXs in ischemic and postischemic vascular dysfunction. Finally, laminar and oscillatory shear enhance endothelial NOX activity (30).

#### *Endothelial Nitric Oxide Synthase*

eNOS is responsible for the production of nitric oxide (NO), a reactive nitrogen species that exerts many effects on the vascular system that counteract those of ROS. However, under certain circumstances, eNOS can paradoxically become a source of ROS by transferring an electron to molecular oxygen rather than its usual substrate, L-arginine, resulting in the generation of superoxide (31,32). This process, termed *uncoupling*, occurs when there is paucity or oxidation of tetrahydrobiopterin (BH4), a cofactor for eNOS (31,33,34). Interestingly, ROS derived from NADPH oxidase(s) can themselves lead to oxidation of BH4, thereby uncoupling eNOS and further promoting superoxide generation. This is an example of a positive feedback loop between ROS and different enzymatic sources. The uncoupling of NOS has been implicated as a source of ROS in atherosclerosis (35), hypertension (36), hypercholesterolemia (37), and diabetes (38).

#### *Xanthine Dehydrogenase/Xanthine Oxidase*

Catalysis of xanthine to urate by xanthine oxidase (XO) results in the generation of superoxide (39). XO is derived from oxidative conversion of xanthine dehydrogenase (XDH). XO is expressed on the luminal side of the endothelium, and its activity is upregulated – both at a transcriptional and posttranscriptional level – by inflamma-

tory stimuli such as interferon (INF)- $\gamma$  (40) or in response to phagocyte adhesion to the endothelium (41). Furthermore, observations that the inhibition of XO improves the endothelial dysfunction seen with hypercholesterolemia (42,43), smoking (44), and in atherosclerosis (45), imply that XDH/XO is an important source of endothelial ROS in these pathologies. In addition, exposure of the endothelium to oscillatory shear augments conversion of xanthine hydrogenase to XO (46).

#### *The Mitochondria*

Mitochondria make a significant contribution to overall ROS production in the endothelium. Mitochondria generate superoxide as a by-product of electron transport during ATP synthesis. Under normal physiological conditions, up to 2% of consumed molecular oxygen is converted to superoxide by the mitochondria. This fraction is increased by specific stimuli and under certain pathological conditions. Similar to the functional interaction between NADPH oxidase-derived ROS and eNOS uncoupling, there exists an amplification loop in which ROS generation in the mitochondria leads to NADPH oxidase activation (47).

Mitochondrial ROS generation is increased in response to many stimuli and has various effects. EC death, whether due to cell detachment or cytokines such as TNF- $\alpha$ , is associated with an increase in mitochondrial ROS generation (19,48). Both hypoxia and hyperoxia lead to an increase in mitochondrial-derived ROS in ECs (49,50). In addition, hypoxia followed by reoxygenation also increases the mitochondrial generation of ROS (28,51). Interestingly, mitochondrial ROS also play a part in the proinflammatory response of the endothelium to mechanical forces (52–54). With regards to known clinical cardiovascular risk factors, both diabetes and oxidized LDL are associated with an increase in mitochondrial ROS flux (55,56), whereas LDL, which is inversely related to cardiovascular risk, suppresses mitochondrial generation of ROS (57). Indeed, an increase in mitochondrial superoxide production due to hyperglycemia can lead to activation of proinflammatory and biochemical pathways associated with vascular complications of diabetes, and normalization of mitochondrial ROS production prevents hyperglycemic damage in vascular ECs (58). Finally, leptin, a satiety hormone reported to be elevated in patients with insulin resistance, leads to an increase in mitochondrial ROS generation, which mediates leptin-induced inflammatory response of ECs (59). Thus, it is becoming increasingly apparent that the mitochondria are a rich source of ROS in ECs, and that these ROS mediate primarily proinflammatory signals, particularly in response to metabolic abnormalities such as those seen in diabetes and insulin-resistance syndromes.

#### **CYTOCHROME P450**

The cytochrome P450 (CYP) family are flavoprotein enzymes that can oxidize a variety of substrates using NADPH and O<sub>2</sub> as cofactors and, in the process, also can produce ROS

such as  $O_2^-$  and  $H_2O_2$  (60). CYP2, a member of this family, is expressed in ECs and converts arachidonic acid to epoxyeicosatrienoic acids, which have vasodilatory properties (61). CYP2 also has been identified as a source of ROS in ECs (62). Because of the potential to generate both vasodilators and ROS, it is not entirely clear whether CYP2 plays a salutary or detrimental role in endothelial function. Nonetheless, CYP2 impairs endothelium-dependent vasorelaxation and promotes the expression of EC leukocyte adhesion molecules (62). The cholesterol-lowering statins reduce endothelial CYP2 activity (61), whereas oxidized LDL downregulates its expression (63).

### Antioxidant Systems in Endothelial Cells

The endothelium is endowed with several antioxidant systems that play an important part in regulating not only the quantities of specific ROS, but also the compartmentalization of these ROS (see Figure 42.2). These antioxidant systems can be broadly divided into two categories.

#### Enzymatic Systems

Enzymatic systems within ECs that act on ROS include superoxide dismutases (SODs), glutathione peroxidases, catalase, heme oxygenase (HO), and the thioredoxin/thioredoxin reductase system. The predominant SOD in ECs is copper-zinc SOD (CuZnSOD or SOD1) (64). The importance of CuZnSOD in maintaining redox homeostasis in ECs is illustrated by the endothelial dysfunction seen with genetic knockout or pharmacologic inhibition of this enzyme (65,66). The physiologic role of SOD1 is evident by the fact that it is upregulated in response to laminar shear forces (67). SOD2 or MnSOD is primarily expressed in the mitochondria and is upregulated in response to physiologic agents such as VEGF (18). Finally, the heparan sulfate-bound extracellular SOD (ecSOD or SOD3), expressed on the EC surface, is also important in maintaining the vascular redox balance, because mice lacking this enzyme are prone to angiotensin II-induced hypertension (68).

The HO system consists of HO-2 and an inducible form (HO-1). HO-2 is constitutively expressed in ECs (69), whereas HO-1 is transcriptionally induced by hypoxia, NO,  $H_2O_2$ , heme, oxidized LDL (69), and other stimuli. Both enzymes, by generating bilirubin and biliverdin from heme, increase the antioxidant capacity of cells.

ECs also express catalase and GPX, both of which catalytically convert  $H_2O_2$  to water. GPX utilizes the thiol glutathione (GSH) for this reaction, which in turn is oxidized to a disulfide form (GSSG). GSH then is regenerated from GSSG by glutathione reductase.

Thioredoxin (TRX), a ubiquitously expressed low-molecular-weight selenoprotein, possesses antioxidant properties. The thioredoxin/thioredoxin reductase system is an important antioxidant defense in ECs (70). TRX, by virtue of a critical dithiol motif (C-X-X-C) modulates the redox state of important cysteine residues in a number of proteins and transcription

factors. For example, in ECs, TRX binds to and inactivates apoptosis signal-regulating kinase 1 (ASK1) (71). TNF- $\alpha$ -induced ROS target the di-thiol motif of TRX, leading to dissociation of TRX from ASK1 and promoting EC apoptosis (71). The C-X-X-C motif also can act as a direct antioxidant. Levels of reduced TRX are replenished in the cell by TRX reductase.

Interestingly, the reductive activity of TRX also is regulated by NO, through the S-nitrosylation of a distinct cysteine residue (72). This modification may be an important mechanism for the antioxidative properties of the HMG-CoA reductase inhibitor (statin) class of clinical pharmaceuticals (73). TRX, because of its dithiol CXXC moiety, can act both as a direct antioxidant and also maintain thiol residues in many protein and transcription factors in its reduced form (70).

#### Nonenzymatic Systems

ECs possess a full armamentarium of chemicals that, through direct scavenging of ROS, participate in redox homeostasis. These include the aforementioned GSH, TRX, and heme by-products, as well as vitamins A and C (74,75).

### TISSUE- AND VASCULAR BED-SPECIFIC DIFFERENCES IN ENDOTHELIAL REACTIVE OXYGEN SPECIES

It is well recognized that ECs from different vascular beds have different properties (76). This difference also extends to ECs from macrovessels versus microvessels (77). However, a dearth of information exists about whether there exist differences in primary mechanisms of ROS generation, ROS elimination, or both in ECs from different tissues, ECs from venous versus arterial beds, and in ECs from large versus small vessels. Nevertheless, studies do show differences in the activity of endogenous enzymatic sources of ROS between ECs from macro- and microvessels, and tissue-specific differences in endothelial expression of receptors for ligands that induce ROS. For example, experimental evidence shows that cultured microvascular ECs have significantly higher NADPH oxidase activity than do human umbilical vein ECs (8), suggesting that mechanisms of ROS generation do differ in ECs of different origin and implying that such differences may contribute to the different properties of these cells. Similarly, expression of chemokine receptors on ECs that mediate chemokine-stimulated ROS production varies greatly between tissues (78).

#### THE ENDOTHELIAL RESPONSE TO REACTIVE OXYGEN SPECIES

Cultured ECs and the intact endothelium exhibit varied responses when challenged with ROS, whether they are derived from internal enzymatic sources or externally.

### Impaired Endothelium-Dependent Relaxation

Perhaps the best-studied response of the endothelium to an increase in ROS flux is its ability to govern vasorelaxation. Endothelium-dependent agonists such as bradykinin and acetylcholine, changes in oxygen tension, and hemodynamic forces all affect vessel diameter and blood flow (79,80). This effect is mediated predominantly by eNOS-derived NO. Impairment of endothelium-dependent vasorelaxation is a striking manifestation of many vascular disorders including hypertension and atherosclerosis (81,82). An increase in ROS (in particular superoxide), derived from within the endothelium or without, by chemically reacting with endothelium-derived NO to form the secondary species peroxynitrite (which itself is highly reactive) leads to a decrease in its availability (83,84) and impaired endothelium-dependent vasorelaxation.

### Inflammation

The endothelium can be transformed from an antiinflammatory surface to one that is proinflammatory. This change, a feature of atherosclerosis, is induced by a variety of inflammatory stimuli including cytokines such as TNF- $\alpha$  and IL-1 $\beta$  and oscillatory shear forces, and involves the expression of endothelial-leukocyte adhesion molecules such as vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 (85,86). That antioxidants suppress the expression of these adhesion molecules on ECs suggests that ROS mediate this response.

### Angiogenesis

Because of the important role of ROS in EC migration, proliferation, organization into primitive tube-like structures *in vitro* (87), as well as the expression of the angiogenic factor VEGF in tumor cells (88), it follows that ROS are likely to be involved in the *in vivo* growth of new blood vessels. Indeed, ROS, in particular those generated by NOX2, do mediate signaling and angiogenesis induced by VEGF (17,89). Because angiogenesis plays a prominent role in the development of atherothrombosis, ROS within ECs also may contribute to the progression of atheromatous lesions by this mechanism.

### MOLECULAR TARGETS OF REACTIVE OXYGEN SPECIES WITHIN ENDOTHELIAL CELLS

ROS have long been known to target macromolecules such as lipids and nucleic acids. This "oxidative damage" has been well recognized as a marker – if not the cause – of cellular injury induced by ROS. However, as a role for ROS as "second messengers" has emerged in recent years, so has the understanding that they can target specific classes of intracellular proteins, many reversibly.

### Tyrosine Kinases

The role of ROS as intracellular second messengers involved in receptor tyrosine kinase-mediated signaling was first shown in platelet-derived growth factor (PDGF)-treated VSMCs (90). A large body of evidence has shown that ROS serve a very similar role in other cell types by linking the membrane event of ligand-induced receptor tyrosine kinase activation to effectors of such receptors. The addition of H<sub>2</sub>O<sub>2</sub> to ECs mimics ligand-induced receptor tyrosine kinase by leading to phosphorylation of the PDGF receptor (91). ROS, particularly those derived from NOX2, also participate in phosphorylation of the VEGF tyrosine kinase receptor KDR (17). Moreover, through activation of the epidermal growth factor (EGF) receptor tyrosine kinase, H<sub>2</sub>O<sub>2</sub> also stimulates c-jun N-terminal kinases (JNKs) (92) and eNOS (93) in ECs. "Transactivation," or ligand-independent activation of receptor tyrosine kinases, now has been described to occur in response to a number of other stimuli (94).

Because transactivation of receptor tyrosine kinases in ECs by ROS involves tyrosine phosphorylation of these kinases, this prompted a search for tyrosine-kinase targets of ROS capable of phosphorylating receptor tyrosine kinases. Several studies suggest that such kinases may be, in fact, of the nonreceptor variety. For example, the Src tyrosine kinase is responsible for H<sub>2</sub>O<sub>2</sub>-induced tyrosine phosphorylation of the EGF receptor in ECs (92). In addition, endogenous ROS triggered in ECs subjected to fluid shear forces or cyclic strain stimulate activity of Src kinase and other Src-related tyrosine kinases, such as the proline-rich tyrosine kinase Pyk2 (95,96). Src kinase activation stimulated by VEGF, and in response to ligation of ICAM-1 in ECs, also is mediated by ROS (97,98). Finally, the addition of exogenous sources of ROS can activate p125 focal adhesion kinase (FAK) (99).

### Tyrosine Phosphatases

One means by which ROS may lead to tyrosine phosphorylation is their likely effect on tyrosine phosphatases. Tyrosine phosphatases tonically inhibit tyrosine kinases, both of the receptor and nonreceptor variety. All tyrosine phosphatases share an active site that includes an oxidant-sensitive cysteine residue (100). Oxidation of this cysteine residue can occur in cells (101) and *in vitro* (102). This provides an attractive molecular mechanism by which H<sub>2</sub>O<sub>2</sub> and other ROS can result in the tyrosine phosphorylation of a host of cellular proteins. Indeed, in ECs, chemical inhibition of tyrosine phosphatases mimics VEGF-induced signaling mediated by ROS (103). In concert with this observation, the overexpression of low-molecular-weight protein tyrosine phosphatases (LMW-PTP) in ECs enhances stimulated cell migration (104). Furthermore, the inhibition of the specific tyrosine phosphatases src homology-2-containing protein-tyrosine phosphatases-2 (SHP-2) prevents Src kinase activation induced by cross-linking of ICAM-1 (98). Consistent with this, SHP-2 is inactivated in ECs treated with H<sub>2</sub>O<sub>2</sub> (105).

### Serine/Threonine Kinases

The mitogen-activated protein kinase (MAPK) family is the largest family of serine/threonine kinases. This family consists of three kinase subfamilies: the extracellular-signal-regulated kinases (ERKs), the JNKs, and p38 mitogen-activated protein kinase (MAPK). All the MAPKs share a common T-X-Y motif, and their activation is generally dependent on phosphorylation of the threonine and tyrosine residues in this motif.

MAPKs are activated in ECs in response to a variety of stimuli and, in many cases, this activation depends on ROS. The inflammatory stimulus TNF- $\alpha$  requires ROS to stimulate p38MAPK-mediated IL-8 production in ECs (106). Furthermore, the direct addition of H<sub>2</sub>O<sub>2</sub> stimulates p38 MAPK activity in ECs (107). JNKs also are activated by H<sub>2</sub>O<sub>2</sub> (92), and vasculoprotective stimuli such as laminar flow suppress ROS-stimulated JNK activation (108). In contrast, certain anti-inflammatory exogenous stimuli, such as atrial natriuretic factor (ANP), also lead to an increase in intracellular ROS and JNK activity in ECs (109). Interestingly, this increase in JNK activity requires the induction of mitogen-activated protein kinase phosphatase (MKP)-1 (109), suggesting that a dephosphorylation event is required to trigger JNK activity, and that JNK has a role in the anti-inflammatory effect of ANP in ECs.

Finally, ERK activation in ECs subjected to various stimuli, including laminar flow (110) and cyclic strain (111), is mediated by ROS. ERK activation in ECs in response to H<sub>2</sub>O<sub>2</sub> has been shown to lead to an increase in endothelial NO production by stimulating endothelial NOS activity (112), suggesting a counter-intuitive, yet important role of ROS in promoting endothelial function.

### THERAPEUTIC IMPLICATIONS

With the central role that ROS play in endothelial pathophysiology, the potential is great for ameliorating endothelium-dependent manifestations of diseases such as hypertension and atherosclerosis by manipulating ROS. Unfortunately, this potential has been largely unrealized. Clinical trials using antioxidant vitamins in patients at risk of cardiovascular disease have shown no benefit in reducing cardiovascular events (113). This reality suggests that ROS play a much more complex role in endothelial biology than previously imagined. The myriad sources, functions, effects, and targets – only a fraction of which are known and reviewed here – and many of which may be disease-specific, attest to this. This complexity demands that therapies to manipulate endothelial ROS must be finely targeted at the molecular level in order to be successful.

### CONCLUSION

The endothelium is uniquely poised both as a sensor and regulator of ROS production in the vascular wall. Endothelium

from different vascular beds may have different capacities to achieve these functions, which may be suited to their own specific location.

### KEY POINTS

- Endothelial ROS are produced by a number of intracellular enzymatic sources that are subject to regulation by many different environmental, chemical, and mechanical stimuli.
- Endothelial ROS levels also are determined by the endothelium's endogenous antioxidant defenses.
- Endothelial ROS can have various effects on endothelial function, both physiological and pathophysiological.
- The endothelium attempts to maintain redox homeostasis.
- Redox homeostasis is perturbed in many cardiovascular disease states.

## Extracellular Nucleotides and Nucleosides as Autocrine and Paracrine Regulators within the Vasculature

---

Silvia Deaglio and Simon C. Robson

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The normal vascular endothelium provides a barrier that separates blood cells and plasma factors from highly reactive elements of the deeper layer of the vessel wall. It maintains blood fluidity and flow by inhibiting coagulation and platelet activation and promoting fibrinolysis (1). These properties are governed by important, specific thromboregulatory mechanisms that include the release of prostacyclin (2), the generation of nitric oxide (NO) (3), and the expression of heparan sulfate (4), together with the expression of natural anticoagulants such as tissue factor pathway inhibitor or thrombomodulin and fibrinolytic mechanisms involving tissue plasminogen activator (1). These properties of the endothelium and antithrombotic pathways are addressed elsewhere in this volume. This chapter focuses on those key biological activities of the vasculature that have been identified recently and shown to be ectonucleotide catalysts that generate the respective nucleosides through phosphohydrolysis (5,6).

Extracellular nucleotides (e.g., ATP, ADP, UTP, and UDP) are released by leukocytes, platelets, and endothelial cells (ECs) in the blood, where they serve as extracellular signals (7). These mediators bind the multiple type-2 purinergic/pyrimidinergic (P2Y1–14 and P2X1–7) receptors on platelets, endothelium, vascular smooth muscle cells (VSMCs), and leukocytes (8). The 15 defined and characterized P2-receptors of the P2Y and P2X families have different specificities and have been shown to transmit signals from extracellular nucleotides, as discussed later. These receptors trigger and mediate short-term (acute) processes affecting cellular metabolism, NO release, adhesion, activation, and migration together with other more protracted developmental responses, such as cell proliferation, differentiation, and apoptosis (9–11).

These P2-receptor-mediated effects are closely modulated by ectoenzymes, termed *ectonucleotidases* (e.g., ecto-ADPases, ecto-ATPases), which bind and then hydrolyze

extracellular nucleotides, ultimately to the respective nucleosides (that in turn activate a series of adenosine or P1 receptors) (6,11). The dominant ectoenzymes or ectonucleotidases of the vasculature are characterized more fully as the ectonucleoside triphosphate diphosphohydrolases (E-NTPDases) of the CD39 family. This important biological property expressed by the endothelium and associated cells is responsible for the regulation of extracellular levels of nucleotides (5,12–15).

Extracellular nucleotide stimulation of purinergic/pyrimidinergic (P2) receptors is associated with activation of platelets, leukocytes, and ECs, and may culminate in vascular thrombosis and inflammation *in vivo*. This chapter considers extracellular nucleotide or purinergic/pyrimidinergic signaling and its associated nucleoside-mediated effects, and chiefly addresses the role of the ectonucleotidases of the vascular endothelium and accessory cells in modulating these signals (6).

### HISTORICAL PERSPECTIVES

Over 70 years ago, Drury and Szent-Györgyi (16) first described the circulatory effects of injected purine nucleotides and nucleosides – ATP and adenosine – on the cardiovascular system. The concept of a purinergic signaling system, using extracellular nucleotides and nucleosides as mediators, was introduced by Burnstock approximately 30 years ago, as an initial hypothesis dealing with neurotransmission (17). Subsequent work detailed how extracellular nucleotides could serve as extracellular messengers that modulate exocrine and endocrine systems, the vasculature and hemostatic mechanisms, and musculoskeletal, immune, and inflammatory cells, as reviewed in Burnstock and Knight (11).

Figure 43.1. The two families of membrane-bound P2-type receptors that recognize extracellular nucleotides. Representative elements of the two families of nucleotide type-P2 receptors are depicted here. P2X are “rapid” ligand-gated ion channels permeable to  $\text{Na}^+$ ,  $\text{K}^+$ , and also  $\text{Ca}^{2+}$  (subtypes P2X1–7). P2Y are the “slow” metabotropic receptors (P2Y1–14) and are seven-transmembrane  $\text{G}_q$ - or  $\text{G}_i$ -protein linked receptors.

Initially, this concept was controversial, in that it was unclear how such commonplace metabolites and ubiquitous intracellular components could be specifically involved in selective extracellular signaling. However, given the protean roles of nucleotides in the intracellular compartment, it seemed plausible that these chemicals also could function as extracellular mediators. Theoretically, these pathways also could be employed to provide nucleosides and other substrates for intracellular biochemical salvage pathways, which would provide for the rapid resynthesis of nucleotides and avoid redundancy of nucleoside biosynthetic pathways in endothelium. Such a dual role would require the origination of inter-related proteins to shuttle these purine and pyrimidine compounds between the extra- and intracellular compartments and to provide for specific recognition and ultimate clearance. Furthermore, nucleotide-mediated cellular signals might well be coordinated in a manner analogous to that described for the acetylcholinesterase system, as would occur during neurotransmission (18). Hence, in purinergic responses, there might well have evolved regulatory steps at the level of nucleotide release, receptor expression and/or desensitization, and phosphohydrolysis of the nucleotide mediators to the specific derivatives.

Indeed, subsequent studies demonstrated that each of the following factors is involved in mediating the specificity of purinergic/pyrimidinergic signaling: (a) the derivation or source of the extracellular nucleotides (7,8,19); (b) the expression of specific receptors for these molecular transmitters (or the nucleotide and nucleoside derivatives) (20–23){8521}<sup>1</sup> (Figure 43.1); and (c) the existence of ectonucleotidases that dictate the cellular responses by hydrolyzing the nucleotides (to nucleosides) (6,15,24).

Table 43-1: Biochemical Names of Bases, Nucleosides, and Nucleotides

	Base	Nucleosides (= Base + Pentose)	Nucleotides (= Nucleoside + Phosphates)
Purines	Adenine	Adenosine	AMP, ADP, ATP
	Guanine	Guanosine	GMP, GDP, GTP
Pyrimidines	Cytosine	Cytidine	CMP, CDP, CTP
	Thymine	Thymidine	TMP, TDP, TTP
	Uracil	Uridine	UMP, UDP, UTP

### NUCLEOSIDES AND NUCLEOTIDES AS PRIMORDIAL SIGNALING MOLECULES AND MEDIATORS: BIOCHEMISTRY AND EVOLUTIONARY RELEVANCE

Nucleosides are glycosylamines made by attaching a nucleobase to a pentose sugar ring. Examples of these include cytidine, uridine, adenosine, guanosine, thymidine, and inosine (Table 43-1). Nucleosides can be phosphorylated by specific kinases in the cell and produce nucleotides. Typically, nucleotides are considered the monomeric, structural unit of those nucleotide chains that form nucleic acids (RNA and DNA). Nucleotides also play important roles in cellular energy transport and transformation (nucleoside triphosphates such as ATP are the energy-rich end-products of the majority of biochemical energy-releasing pathways), in enzyme regulation, and as intracellular second messengers.

Cellular injury causes a release of nucleosides and nucleotides. Hence, it is possible that purinergic/pyrimidinergic signaling evolved as a sensor for environmental stresses and that later, receptors for neuroactive agonists in more advanced vertebrates may have evolved from external chemoreceptors. In this respect, organization of the purinergic/pyrimidinergic system presumably involved a stepwise evolution of new gene families, gene duplication, and conservation of adaptive genes to facilitate the specificity of nucleotide metabolism and responses. This would involve the development of the many P2 and adenosine P1 receptors, and the various ectonucleotidases such as diadenosine polyphosphate hydrolases, the CD39/NTPDase family, nucleotide pyrophosphatases/phosphodiesterases (E-NPP), 5'-ectonucleotidase, alkaline phosphatases, NAD-glycohydrolase, CD38/NAD and nucleosidase activity, and adenosine deaminase.

NTPDases, in particular, might be able to serve as molecular switches at the membrane, each having differing functions according to the context of the signal. Such complexities must have been dictated by the ubiquitous nature of the signaling molecules (e.g., ATP). This situation concerning extracellular nucleotide signaling can be suitably contrasted with the

1 Molecular Recognition Section of National Institutes of Health <http://mgddk1.niddk.nih.gov:8000/nomenclature.html>.

Figure 43.2. Proposed and speculative mechanisms for nucleotide-mediated signaling and linked integrin activation. The P2Y2 nucleotide receptor contains the integrin-binding domain arginine-glycine-aspartic acid (RGD) in the first extracellular loop, suggesting that this G-protein-coupled receptor might interact directly with the vitronectin receptor, the  $\alpha v \beta 3$  integrin (1). Interactions between P2Y2 and endothelial integrins (e.g.,  $\alpha v \beta 3$  and the ectonucleotidase CD39/NTPDase1) with other membrane proteins in a macromolecular complex may be important for coordinating P2Y2-mediated responses triggered by nucleotides (2), as discussed in the text. Specifically, nucleotides can induce expression of the  $\alpha v \beta 3$  integrin, and positively influence avidity and affinity of the receptor with matrix proteins such as vitronectin in vascular endothelial matrix tissues via interactions with the P2Y2 receptor, as modulated by CD39/NTPDase1. Ligation of the integrins by vitronectin and other matrix proteins results in “outside-in” signaling and post-ligand binding alteration (3). Whether any potential direct signaling components of CD39 modulate these cellular activation responses remains speculative at this time.

unique specificity of peptide hormones or vasoactive factors, which often are designated for single, defined receptors (25,26).

Thus, the potential of these and other surface-located enzymes involved with nucleotide metabolism would also extend to ADP-ribosylation and phosphorylation of extracellular proteins (27).

### EXTRACELLULAR NUCLEOTIDES IN THE VASCULATURE

The metabolic roles of nucleotides are well established. Over the past decade, extracellular nucleotides have been increasingly recognized as important mediators of a variety of processes, including vascular inflammation and thrombosis, with varying impacts in different experimental systems and models of human disease (6). At least in part, vascular biology can be understood by considering endothelial and accessory cells as having a certain degree of plasticity and behaving as adaptive input-output devices. Input arises from the extracellular milieu and may include biochemical signals triggered by extra-

cellular nucleotides (or nucleosides) and the resulting biomechanical responses that are transduced by adhesion receptors in response to P2-mediated signals, such as the affinity changes in integrins (Figure 43.2). The output is manifested as alterations in cellular phenotype, such as in activation responses, and includes a number of structural and functional changes implicated in diverse pathophysiological processes and thrombotic disease.

Adenosine- and ATP-mediated effects have been implicated in the local control of vessel tone as well as in vascular cell migration, proliferation, and differentiation. As an example, ATP may be released from sympathetic nerves and result in a constriction of VSMCs through effects mediated by P2X receptors. In contrast, ATP released from ECs during changes in flow (shear stress) or following exposure to hypoxic conditions activates the P2Y receptors expressed by these cells as well as VSMCs. This activation occurs in an autocrine and paracrine manner and releases NO, resulting in vessel relaxation as a purinergic event. Any nucleotide released will be ultimately hydrolyzed to adenosine and will result in vasodilatation via the effects of VSMC adenosine P1 receptors. P2

**Table 43-2: Purinergic Receptors Expressed by the Vasculature**

<i>Receptor</i>	<i>Agonist</i>	<i>Cell Type</i>	<i>Phenotype/Effects</i>
<b>P1 Adenosine/AMP</b>			
A1	Adenosine	Nerves, cardiac cells	Cardiac rate, preconditioning
A2a	Adenosine	Immune cells, platelets and ECs	Vasodilatation and renin effects Anti-inflammatory and antithrombotic
A2b	Adenosine	Mast cells, platelets	Vasodilatation
A3	Adenosine	Mast cells	Janus-like and varied Cell proliferation and apoptosis
<b>P2 ADP, UDP, ATP, ATP, and UDP-glucose</b>			
P2Y1	ADP	ECs, platelets, stem cells (mouse)	Platelet activation Apoptosis
P2Y2	ATP/UTP	ECs/VSMCs	Vasodilation
P2Y4	UTP/ATP	?ECs/VSMCs	Calcium mobilization
P2Y6	UDP	VSMCs	Calcium mobilization
P2Y11	ATP	ECs

P2X4	ATP	ECs	EC activation and calcium mobilization
P2X7	ATP	ECs, monocytes	Apoptosis, EC activation responses

receptors also appear on vascular cells and are thought to be associated with changes in cell adhesion and permeability (11).

These cellular processes and nucleotide-triggered events are modulated during angiogenesis and influence the development of atherosclerosis and restenosis following angioplasty (11,28–31).

#### RELEASE OF NUCLEOTIDES WITHIN THE VASCULATURE

Extracellular nucleotides, and potentially nucleosides, are continuously released from cells (e.g., following the exocytosis of ATP/UTP-containing vesicles, facilitated diffusion by putative ABC transporters, or by poorly understood electrodiffusional movements through ATP/nucleotide channels). It has been shown that rates of increase are higher in injured or stressed cells (7,32–35). Several mechanisms account for the presence of nucleotides or nucleosides in plasma (36). As alluded to earlier, these include aggregating platelets, degranulating macrophages, excitatory neurons, injured cells, and cells undergoing mechanical or oxidative stress resulting in lysis, selective permeabilization of cellular membranes, and exocytosis of secretory vesicles, such as from platelet-dense bodies (7,37). It is important to note here that many processes of arterial vascular injury are associated with the release of adenine nucleotides that exert a variety of inflammatory effects on the endothelium, platelets and, leukocytes (7,19).

#### PURINERGIC RECEPTORS IN THE VASCULATURE

P1 (adenosine) receptors can be differentiated from P2 (ATP/ADP) receptors by direct pharmacological and molecular means (Table 43-2). The endogenous ligand adenosine (and potentially inosine at A3 receptors) activates adenosine receptors.<sup>2</sup> Adenosine signaling and uptake inhibits many intracellular ATP-utilizing enzymes, including the adenylyl cyclase systems. To date, four subtypes of P1 receptors have been cloned – namely A1, A2A, A2B, and A3 – with substantial interspecies differences (20–23). A pseudogene also exists for the A2B adenosine receptor (ENSG00000182537) with 79% identity to the A2B adenosine receptor cDNA coding sequence but which is unable to encode a functional receptor. The adenosine receptors are classified according to their affinities for adenosine and variant coupling to adenylate cyclase (23).

P2 receptors bind extracellular nucleotides and initiate cellular signaling. Burnstock and Kennedy originally distinguished between two major types of P2 nucleotide receptors, the P2X and P2Y subtypes, again based largely on pharmacological criteria (38). These are expressed by the endothelium, VSMCs, platelets, and leukocytes. Further studies of transduction mechanisms followed by cloning of both P2X and P2Y

2 The nomenclature is determined by the NC-IUPHAR Subcommittee on Adenosine Receptors.

receptors have been carried out, resulting (in 1994) in a new nomenclature system that is generally accepted (8) (see Figure 43.1 and Table 43.2).

In summary, two main families of nucleotide receptors exist (Table 43-2): P2X and P2Y. P2X are "rapid" ligand-gated ion channels permeable to Na<sup>+</sup>, K<sup>+</sup>, and also Ca<sup>2+</sup> (subtypes P2X1–7) (21). The P2X receptors (nomenclature determined by the NC-IUPHAR Subcommittee on P2X Receptors) are putative trimeric transmitter-gated channels, with two putative transmembrane domains, in which the endogenous ligand is ATP. In P2X receptors, structural features should be the initial criteria for nomenclature. The relationships of many of the cloned receptors to endogenously expressed receptors have not been established to date. Functional P2X receptors exist as polymeric transmitter-gated channels. The native receptors may occur as homopolymers (e.g., P2X1 in VSMCs) or heteropolymers (e.g., P2X2:P2X3 in nervous tissues). P2X7 receptors have been shown to form functional homopolymers that initiate pores permeable to low-molecular-weight solutes.

P2Y are the so-called "slow" metabotropic receptors (P2Y1–14) (20).<sup>3</sup> P2Y receptors (provisional nomenclature as agreed by NC-IUPHAR Subcommittee on P2Y Receptors) are activated by the endogenous ligands ATP, ADP, UTP, UDP, and UDP-glucose. These receptors are seven-transmembrane G<sub>q</sub>- or G<sub>i</sub>-protein linked receptors that initiate signal transduction coupled to activation of phospholipase C (PLC) or to inhibition of adenylate cyclase, respectively (20) (see Figure 43.1). The relationship of many of the cloned receptors to endogenously expressed receptors is not yet fully established. To prevent additional problems with the accepted terminology, it is recommended that terms such as "UTP-preferring (or ATP-) P2Y receptor" or "P2Y1-like" be used until further classifications can be applied. For example, P2Y7 is not a true nucleotide-receptor but rather encodes a leukotriene receptor; P2Y8 is an LPA receptor, and no functional data exist for P2Y10. Finally, the recently proposed and described P2Y15 receptor is not a genuine P2 receptor in that it recognizes dicarboxylic acids (39).

The distribution of the families of validated receptors in the vascular system and elsewhere, using their pharmacological properties, recently has been collated exhaustively and defined in depth by Burnstock and Knight (11). P2X1, P2Y2, and P2Y6 are the most highly expressed P2 receptors in VSMCs, and they mediate the contractile and mitogenic actions of extracellular nucleotides. P2X4, P2Y11, P2Y1, and P2Y2 are the most highly expressed P2 receptors in ECs (11).

In the blood, extracellular nucleotides/nucleosides can influence cardiac function, vasomotor responses, platelet activation, thrombosis, and inflammatory processes (19,35,40, 41). ATP and ADP appear to regulate hemostasis through the activation of platelet P2 receptors, most notably P2Y12

and P2Y1. P2X1 is rapidly desensitized and likely important under very high shear stress. ADP is a major platelet-recruiting factor originating from platelet-dense granules during activation, whereas ATP derived from the same sources has been considered a competitive antagonist of ADP for platelet P2Y receptors and a putative agonist for P2X1 receptors (7,37,42). ATP (and UTP) also stimulate endothelial P2Y1 and P2Y2 receptors to release prostacyclin (PGI<sub>2</sub>) and NO, two vasodilators and inhibitors of platelet aggregation (43–47). This latter protective action of ATP may limit the extent of intravascular platelet aggregation and help localize thrombus formation to areas of vascular damage (45,48,49).

Interestingly, the P2Y2 nucleotide receptor contains the integrin-binding domain arginine-glycine-aspartic acid (RGD) in the first extracellular loop, suggesting that this G-protein-coupled receptor might interact directly with an integrin. Subsequent work by Erb and colleagues has detailed that this RGD sequence is required for P2Y2-mediated activation of G<sub>o</sub>, but not G<sub>q</sub> signaling pathways. Further work has indicated that interactions between P2Y2, integrins such as the vitronectin receptor  $\alpha v \beta 3$ , and other membrane proteins may be important for coordinating P2Y2-mediated responses (50) (see Figure 43.2). Other, more recent work has detailed that P2Y2 and possibly P2Y4 receptors mediate the vascular responses important during inflammation and upregulate integrins crucial in angiogenic responses (51).

In addition, ATP also stimulates P2X receptors to cause plasma membrane permeabilization, induction of apoptosis, organic anion transport, and stimulation of Ca<sup>2+</sup> mobilization (19,52). The active form of ATP that causes membrane permeabilization is a fully ionized tetrabasic ion (or ATP<sup>4-</sup>) that interacts with the unique multimeric P2Z/P2X7 receptors known to be expressed on the endothelium and monocyte-macrophages (53). In fact, this nucleotide is a relative inhibitor of NTPDases, because these are divalent cation-dependent enzymes (54) (S.C. Robson, unpublished observations). Such P2X7 receptors also are stimulated by ATP- $\gamma$ -S but are unresponsive to UTP (35,55). Activation of P2X7 receptors can induce cellular activation and apoptosis (55,56).

Pathways of nucleotide-mediated signaling are further complicated by P2-receptor desensitization phenomena. Thus, adenine nucleotides may also directly limit the ADP-mediated reactivity of platelets (19,37,57,58). As in other members of the G-protein-coupled receptor family, some P2Y receptors readily undergo agonist-induced desensitization (59). This may involve phosphorylation of the receptor by multiple protein kinases (10). For unclear reasons, P2X- and P2Y-type receptors differ widely with respect to desensitization rates. Rapidly desensitizing receptors and/or channels (P2Y1, P2Y2, P2X1, and P2X3) may be contrasted with slow desensitizing receptors such as the P2Y6, P2X2, and P2X7 receptors (the last very important in inflammatory reactions). P2X4 is intermediate in this regard (60). Resistance to ATP and other nucleotides in the vasculature also may be explained by downregulation or absolute deficiencies of defined P2 receptors on cell membranes, because cell intracellular transduction

mechanisms differ, or by the presence of ectonucleotidases that hydrolyze the nucleotide mediators (61).

Select examples exist of how the differential expression of P2-receptors affects pathological outcomes. Saphenous vein, internal mammary, and other arteries have been used for coronary grafting and bypass surgery. Levels of endothelial P2Y2 receptors are comparable in all three vessels, but endothelial P2X4 receptors are expressed at much higher levels in the saphenous vein samples (11). P2X4 receptors are involved in calcium influx into ECs, they modulate blood vessel contractility, and they are upregulated in situations involving intima proliferation. These P2X4 receptors possibly play a more significant role in the higher frequency of restenosis in vein grafts, as reflected by the susceptibility of saphenous grafts to the development of atherosclerosis (62).

A novel role for P2Y2 receptors in atherosclerosis also has been suggested, because this receptor and the potential agonists (either ATP or UTP) induce EC vascular adhesion molecule (VCAM)-1 expression and consequent intimal hyperplasia in animal studies (63). Recent data indicate that this P2Y2 nucleotide receptor also can transactivate receptor tyrosine kinases in human coronary artery ECs (HCAECs) to generate inflammatory responses, which is considered associated with atherosclerosis (64). These long-term (trophic) effects of extracellular nucleotides in VSMC or EC proliferation and the linkage to ectonucleotidases in associated vascular lesions suggest the exploration of therapeutic strategies in relation to atherosclerosis and vascular inflammatory conditions associated with transplantation (15,65).

#### **ECTONUCLEOTIDASES AND THE NUCLEOSIDE TRIPHOSPHATE DIPHOSPHOHYDROLASE (NTPDase/CD39 FAMILY)**

Ectonucleotidases are a subset of ectoenzymes that hydrolyze extracellular purine and pyrimidine nucleotides (15,24). As

detailed previously, these enzymes differ from intracellular nucleotidases in molecular structure and are also distinct from alkaline phosphatases and ecto-5'-nucleotidase; the latter are enzymes capable of releasing phosphate from a large variety of organic compounds, including the hydrolysis of nucleotides (66,67). These ectoenzymes are ubiquitous, broadly distributed in tissues, and well defined at the biochemical level. However, because specific inhibitors are not available, their pathophysiological relevance has remained largely elusive. The recent development of genetic techniques to modulate the levels of defined members of these families promises to advance our understanding of the biology of the purinergic/pyrimidinergetic system.

One important function of ectonucleotidases might be the modulation of P2-receptor-mediated signaling by the removal of extracellular ATP, ADP, and related nucleotides. The ultimate generation of extracellular adenosine not only abrogates or terminates nucleotide-mediated effects but also activates adenosine receptors, with often opposing pathophysiological effects. Ectonucleotidases also produce the key molecules for purine salvage and the consequent replenishment of ATP stores within multiple cell types. Indeed, although nucleotides appear not to be taken up by cells, their dephosphorylated nucleoside derivatives interact with several specific transporters to enable membrane passage. The regulated dephosphorylation of extracellular nucleotides by ectonucleotidases may be critical for appropriate purinergic/pyrimidinergetic signaling and metabolic homeostasis (6,15,24,59).

CD39 was characterized originally as an activation marker, identified on B cells, monocytes, subsets of activated NK cells, and T lymphocytes (68–70). Once the enzymatic function of CD39 was elucidated, work proceeded on genes that share considerable sequence identity, including the five apyrase conserved regions (71,72). Some of these eight enzymes are membrane-attached, with external-oriented active sites, whereas others are soluble (73–75) (Table 43-3). The most prevalent ectonucleotidases expressed by vascular cells (e.g.,

ECs, pericytes, VSMCs, and adventitial cells) are members of the CD39 family. These members include NTPDase1/CD39, ecto-ATPase and ecto-ADPase, and CD39L1/NTPDase2 (Table 43-3) (74,75).

NTPDases are subject to multiple post-translational changes that influence both tertiary and quaternary structure and that have major implications for enzymatic function (72,76). Interestingly, the structures of CD39 and P2X receptors appear remarkably similar (20,74), and both can form multimers (i.e., tetramers) (77,78).

The endothelial membrane-expressed CD39/NTPDase-1 is the major ectonucleotidase in the vasculature (59). Other NTPDases associated with the vasculature are the cell-associated ecto-ATPases (CD39L1 or NTPDase-2) and soluble ecto-ADPases (CD39L2 or NTPDase-6; akin to the monocyte-expressed CD39L4 or NTPDase-5) (66,79,80). The ectoenzyme CD39/NTPDase1 can be shown to efficiently bind and hydrolyze extracellular ADP (and ATP) to AMP; the product AMP does activate select P1 receptors, but is preferentially hydrolyzed to adenosine by the ubiquitous CD73 and ecto-5'-nucleotidases. This phosphohydrolytic reaction limits the platelet activation response, which depends on the autocrine and paracrine release of ADP with activation of specific purinergic receptors (5,12,81). In contrast, CD39L1/NTPDase2, a preferential nucleoside triphosphatase, activates platelets by converting the competitive antagonist (ATP) of platelet ADP-receptors to the specific agonist (ADP) of the P2Y1 and P2Y12 receptors. In keeping with these biochemical properties, CD39 is mainly expressed by ECs and VSMCs, where it serves as a thromboregulatory factor. In contrast, CD39L1 is associated with the adventitial surfaces of muscularized vessels, microvascular pericytes, and stromal cells, where it could potentially serve as a hemostatic factor (82).

#### OTHER ECTOENZYMES IN THE VASCULATURE

NTPDases of the CD39 family are  $\text{Ca}^{2+}/\text{Mg}^{2+}$ -dependent ectonucleotidases that hydrolyze nucleoside 5'-triphosphates and nucleoside 5'-diphosphate (6,15,66). This ectonucleotidase chain initiated by NTPDases is terminated by ecto-5'-nucleotidase (CD73; EC 3.1.3.5) (83).

Adenosine deaminase (ADA; EC 3.5.4.4) is another ectoenzyme that binds to CD26 and is involved in the generation of inosine from adenosine. Together, CD73 and ADA closely regulate local and pericellular extracellular and plasma concentrations of adenosine (26,84).

The CD38 family of ectoenzymes also is involved in recycling extracellular nucleotides by metabolizing NAD through the generation of cyclic ADP ribose and ADP ribose (85). The surface expression levels of CD38 are tightly regulated in vivo in response to inflammatory signals (86). Furthermore, a clear role for CD38 in the interactions taking place between circulating lymphocytes and the vessel wall was recognized several years ago (87). The latter finding was the starting point of

the search for an EC-bound ligand, which culminated in the identification of platelet-endothelial cell adhesion molecule (PECAM)/CD31 as a counter-receptor for CD38 (88).

The CD38 paradigm is also representative of a more general trend involving several nucleotide-metabolizing enzymes (89). CD38 and CD157 (a member of the CD38 family) also may serve as receptors, controlling intracellular signaling pathways apparently independently of the ectoenzymatic activity. The two functional activities might represent two separate evolutionary developments resulting in the final multifunctional molecule. Phylogenetic studies support the view that the enzymatic activity is the "older" conserved function, whereas at a later point CD38 may have acquired membrane anchorage and the ability to function as a receptor (90).

These common traits also involve localization in membrane lipid microdomains and the physical and functional association with partners specialized in signal transduction (91–93). It has been shown recently that the  $\text{NH}_2$  terminus of the molecule CD39 is physically associated with components of the Ras signaling pathway. These data suggest that receptor-like function also might have been acquired by this ectonucleotidase.<sup>4</sup>

#### HOMEOSTASIS

Depending on the repertoire of receptors and signaling components, P2 and P1 receptors influence those cellular pathways crucial for homeostasis. Although in regard to nucleotide receptors, platelet P2Y12 has received the most attention for its role in ADP-mediated thrombosis, recently obtained evidence suggests that P2Y1, P2Y2, and P2X4 in vascular ECs, VSMCs, and monocytes are important receptors in the mediation of vascular responses. Nucleotide-mediated effects are in turn modulated by ectonucleotidases, as discussed earlier.

The various biological functions of these P2 and adenosine receptors, together with NTPDases, may be influenced by differential expression in various vascular beds, certain unique biochemical characteristics and the effects of their relevant substrate nucleotides, or by products on various receptor subtypes expressed in the local environment. It has been proposed that, in concert with the nearly 20 described P2 or P1 or adenosine receptors, combinations of NTPDases have the capacity to terminate signaling, alter specificities of the response, or even generate signaling molecules (e.g., ADP) from precursors (e.g., ATP) (6). However, little is currently known of the structural or functional associations of NTPDases with one another or with P2-receptors. It is proposed that, under certain conditions, NTPDases may protect the integrity of any future response by preventing receptor desensitization reactions (59,94). In contrast, coexpression of ectonucleotidases

4 AASLD meeting 2004; Wu Y, Sun X, Keiichi Enjyoji K, Robson SC. CD39 Interacts with Ran Binding Protein M (RanBPM) to directly modulate Ras activation and cellular proliferation in liver regeneration following partial hepatectomy. *Hepatology* 2004;135:40, 222A.

may be essential for the survival of cells that express P2X7 receptors, because these receptors do not readily autoregulate by desensitization responses and can induce apoptosis (56).

## PATHOBIOLOGY

To test these how extracellular nucleotide-mediated signaling influences pathophysiological events, we and others have developed and validated several techniques to manipulate CD39 expression in the vasculature and study effects under conditions of inflammatory stress. For example, we have globally deleted *Cd39* in mice. The mutant mice null for this dominant ectonucleotidase exhibit major perturbations of P2-receptor-mediated signaling in the vasculature and immune systems (6,95,96).

These phenomena manifest as hemostatic defects, thromboregulatory disturbances, and heightened acute inflammatory responses with a failure to generate those cellular immune responses that are associated with vascular endothelium, monocyte, dendritic cell, and platelet integrin dysfunction (28,67). The therapeutic potential of NTPDase1 to regulate P2-receptor function in the vasculature and to mitigate against thrombotic or inflammatory stress has been further established. This has been studied by the generation of CD39 transgenic mice (15,97), the use of adenoviral vectors to upregulate CD39 in cardiac grafts (98), and the use of soluble derivatives of CD39 and apyrases (14,99). All these studies show beneficial effects for the overexpression of NTPDases within the vasculature, or by their pharmacological administration (14,15).

Other mutant mice models are summarized in Table 43-4.

## THERAPEUTICS

Platelets are known to express P2Y1, P2Y12, and P2X1 receptors. The Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) and Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) studies have provided definitive evidence that clopidogrel and ticlopidine, antagonists of the platelet P2Y12 receptor, decrease the clinical sequelae of recurrent strokes and myocardial infarcts, especially when combined with aspirin (100,101). More recently developed drugs hold even greater promise. MRS 2500, a potent, highly selective antagonist for the human P2Y1 receptor, also has been shown to have substantive antiaggregatory potential for platelets (102). Synergism occurs in the inhibition of ADP-induced platelet activation via the P2Y1 and P2Y12 receptors, and also for antithrombin approaches using P2Y receptor inhibition or ectonucleotidases (15,103,104). A synergistic interaction also occurs between ATP and norepinephrine in stimulating platelet aggregation, which suggests a prothrombotic role for ATP in stress (14).

Genetic variations occur in P2Y1 and P2Y12 receptor DNA in apparently normal subjects; these variations may explain

**Table 43-4: Mutant Mice Models of Pertinent Purinergic Receptors and Ectoenzymes**

<i>Genetic Model</i>	<i>Phenotype (Vascular)</i>	<i>References</i>

variations in the platelet responses and possibly individual variation in atherothrombotic risk and bleeding manifestations. These discoveries also may provide a basis for the understanding of interpatient variation and complication rates in response to standard doses of antiplatelet drugs (105).

The beneficial effects of administered NTPDases have been determined in several animal models of vascular inflammation (99,106). Exogenous infusions of soluble NTPDases were able to rescue *cd39*-null mice from toxicity induced by ischemia-reperfusion injury and after stroke induction (96,107). Clinical studies of these soluble thromboregulatory factors are planned (15,108,109).

### KEY POINTS

- Purinergic signaling by extracellular nucleotides impacts on vascular injury and inflammation and is modulated by the CD39/NTPDase family of ectonucleotidases.
- Extracellular nucleotide-mediated events, with inflammatory stress and/or immune reactions, have

important consequences for platelet activation, thrombogenesis, angiogenesis, vascular remodeling, and the metabolic milieu of the vasculature.

- Modulated, distinct NTPDase expression appears to regulate nucleotide-mediated signaling in the vasculature.
- Current pharmacological interventions to block platelet microthrombi are associated with limited therapeutic success, adverse clinical events, and bleeding.
- Available experimental data suggest that therapeutic modalities targeting nucleotide-mediated platelet activation and the evolution of rational drug delivery systems may facilitate control of the thrombotic component of inflammatory vascular disease while preserving adequate hemostasis.

#### Future Goals

- To determine whether increased CD39/NTPDase1 expression as a result of gene therapy or pharmacological induction will provide effective treatment modalities for vascular thrombotic disorders, atherosclerosis, and the vascular inflammation seen in transplant-related diseases, such as rejection
- To study selective P2-receptor inhibitors and effects in thrombotic human disease and the disorders tabulated above
- To determine whether targeted inhibition of CD39/NTPDase1 expression or pharmacological blockade using small molecule inhibitors will provide a useful component of novel anticancer and antiangiogenesis regimens
- To determine the biology of the other vascular NTPDases of the CD39 family

## Syndecans

Eugene Tkachenko, John M. Rhodes, and Michael Simons

*Dartmouth Medical School, Hanover, New Hampshire*

Proteoglycans consist of negatively charged sulfated unbranched glycosaminoglycan (GAG) chains that are covalently attached to transmembrane- or membrane-anchored proteins. Such proteins carrying various GAG chains are referred to as *core proteins*. GAGs consist of a repeating disaccharide unit. The major GAGs are hyaluronic acid, dermatan sulfate, chondroitin sulfate (CS), heparan sulfate (HS), and keratin sulfate. Different GAG moieties are found on different core proteins, including syndecans, glypicans, betaglycan, lumican, and perlecan. This chapter discusses the syndecan family of core proteins.

Syndecans are a family of transmembrane proteins that perform several distinct functions (Table 44-1). By virtue of their wide expression and their ability to interact with a large number of ligands, ranging from circulating growth factors to extracellular matrix (ECM) proteins, syndecans can integrate and coordinate various cellular signaling inputs. Furthermore, they can activate specific signaling cascades and induce profound changes in cell structure and behavior. This ability to integrate and modulate various signaling inputs, as well as to signal in their own right, has earned this family of cell surface receptors the name “tuners of transmembrane signaling” (1).

In addition, due to shedding of their extracellular domains that include large HS and CS chains, syndecans have the ability to alter the protein and water context of the surrounding ECM, greatly affecting storage, distribution, and transport of many extracellular proteins.

### SYNDECAN STRUCTURE

The syndecan family in all vertebrates is composed of four genes (syndecan-1, -2, -3, -4). Each syndecan possesses a protein core which, in its extracellular domain, has attachment sites for three to five HS and/or CS chains (Figure 44.1). Among different syndecans, the chains are structurally diverse and their exact composition determines the extent of interactions with various HS- or CS-binding proteins. This structural diversity results from a series of post-translational modifications in which newly synthesized chains are modified by

epimerization of glucuronic to iduronic acid residues and sulfation of the C2 position of glucuronic and/or iduronic acid (for further details Ref. 2).

Various combinations of enzymes involved in post-translational chain modifications produce unique binding motifs that selectively recognize different extracellular proteins. Thus, a specific combination of sulfotransferase-mediated 2-*O* and 6-*O* sulfation is necessary for synthesis of the fibroblast growth factor 2 (FGF2)-binding site, whereas 3-*O*-sulfotransferase 1 activity is needed for generation of the antithrombin-III-binding site. These modifications can play an important biological role as demonstrated, for example, in the case of 2-*O*-sulfotransferase (2-OST) deficiency, which results in marked abnormalities in FGF signaling, whereas augmentation of 2-OST expression leads to enhanced FGF responsiveness (3). It has been generally assumed that HS and CS chains lack preference for different syndecans. However, a recent study has suggested that HS and CS chains on syndecan-1 and syndecan-4 are structurally different (4). Another layer of complexity has been added by the discovery of HS-specific 6-*O*-sulfatases (Sulf 1 and Sulf2), which can act extracellularly and have the ability to modify heparin binding growth factor signaling (5).

The syndecan core protein is composed of an extracellular, single-span transmembrane domain and a short intracellular domain. The extracellular domains are widely divergent in their amino acid composition among the four syndecans but all have the nucleation sites for attachment of HS and/or CS chains. In contrast, the transmembrane domains of syndecans are highly conserved. A unique feature of these domains is their high affinity for self-association. In fact, all syndecans probably exist as homo- and heterodimers, with higher-order aggregates forming upon binding to partner proteins.

The cytoplasmic domain in all syndecans has three distinct regions – conserved regions 1 and 2 (C1 and C2) and a variable region (V). The C1 domain is virtually identical in all four mammalian syndecans. It is involved in syndecan dimerization and has the ability to bind several intracellular proteins including ezrin, tubulin, Src kinase, and cofilin (6,7). The highly conserved C2 domain contains a

**Table 44-1: Syndecan Family**

Syndecan	Expression	Cell Signal	
		Intermediates	Function
S-1	Epithelial and mesenchymal tissues; VSMCs	Syntenin, synectin, synbindin, and CASK	Inhibition of cell growth; cell-cell and cell-ECM interactions; establishing of epithelial cells polarity; role in ephrin signaling
S-2	Epithelial, mesenchymal, and neuronal tissues	Syntenin, synectin, synbindin, and CASK	Stimulation of cell growth; important in vascular development (zebrafish); capillary sprouting; regulation of TGF- $\beta$ signaling; role in ephrin signaling
S-3	Neuronal and MSK tissue	Syntenin, synectin, synbindin, and CASK	Inhibition of cell growth; feeding behavior control; role in muscle differentiation
S-4	All cells	Syntenin, synectin, synbindin and CASK; PKC $\alpha$ , Src, syndesmos, ezrin	Stimulation of cell growth; control of postnatal angiogenesis, mediation of FGF2 signaling; cell spreading, cell migration, and focal adhesion formation

PDZ2-binding site that can bind four syndecan-interacting PDZ domain-containing proteins: syntenin, synectin, synbindin, and CASK (8–11). The specificity of binding of the various syndecans to these PDZ-binding partners has not been established.

The V domain is, as its name implies, highly heterogeneous among the four syndecans. In syndecan-4, the V-region sequence includes a phosphatidylinositol-(4,5)-bisphosphate (PIP<sub>2</sub>) binding site that is involved in syndecan-4 dimerization, in which two syndecan-4 cytoplasmic domains are linked by two PIP<sub>2</sub> molecules in antiparallel fashion (see Figure 44.1) (12).

### SYNDECAN EXPRESSION

Syndecan-1 is expressed predominantly in epithelial and mesenchymal tissues; syndecan-2 in cells of mesenchymal origin, neuronal and epithelial cells; syndecan-3 almost exclusively in neuronal and musculoskeletal tissue; and syndecan-4 in virtually every cell type (6). Although endothelial cells (ECs) express both syndecan-2 and -4, syndecan-4 is the predominant species in adult ECs. Growth factors and

mechanical stress play an important role in the regulation of syndecan expression. Thus, in aortic vascular smooth muscle cells (VSMCs), FGF2 induces syndecan-4, but not syndecan-1 or -2 expression. Likewise, mechanical stress is a prominent inducer of syndecan-4 expression in VSMCs during arteriogenesis (13). A number of inflammatory conditions such as acute myocardial infarction (14) or wounds (15) also are associated with increased syndecan-4 expression in VSMCs and endothelium. One interesting mediator of syndecan expression is an inflammatory cell-derived peptide, PR39, that has a unique ability to markedly upregulate syndecan-1 and -4 expression in vitro and in vivo in a number of cell types (16).

### THE ROLE OF SYNDECANS IN DEVELOPMENT

Several syndecans play an important role in the development of the vascular system. Exposure of zebrafish embryos to syndecan-2 morpholino oligonucleotides resulted in suppression of intersegmental vessels, although formation of dorsal vessels (aorta, cardinal vein) was not affected (17). Furthermore, application of moderate doses of syndecan-2 and vascular endothelial growth factor (VEGF) morpholinos demonstrated synergistic inhibition of angiogenesis, whereas coexpression of syndecan-2 and VEGF-A<sub>165</sub> resulted in an increase of vessel formation compared with VEGF alone (17). These results suggest that syndecan-2 potentiates VEGF-induced capillary sprouting, but the precise mode of interactions between syndecan-2 and VEGF has not been established.

Homozygous disruption of syndecan-4 expression in mice leads to frequent thrombus formation in the vessels of the placental labyrinth, resulting in high embryo loss and suggesting a role for syndecan-4 in blood clotting (18). The adult *syndecan-4*<sup>-/-</sup> mice have impaired skin wound healing that is thought to be secondary to defective angiogenesis (19) and demonstrate increased sensitivity to lipopolysaccharide-induced shock.

### SYNDECAN-DEPENDENT SIGNALING

Syndecans engage in signal transduction in several distinct ways. Due to the ability of their HS and CS chains to bind growth factors, thereby restricting their presence to the membrane surface and facilitating their subsequent interactions with corresponding high-affinity receptors, syndecans can serve as coreceptors for these growth factors. Indeed, inhibition of HS chain synthesis grossly affects signaling (the role of CS chains in syndecan-dependent signaling has not been established). For example, heparinase treatment of cultured VSMCs decreases their responsiveness to FGF2 (20), whereas heparinase treatment in vivo inhibits angiogenesis (21). Similarly, a homozygous deletion of 2-OST results in mice that die perinatally because of the complete failure of kidney formation (22), whereas a knockdown of the 6-O-sulfotransferase in *Drosophila* severely perturbs tracheal development (23),

Figure 44.1. Syndecan structure. *Upper panel.* Cartoon representation of the vertebrate syndecan structure. *Lower panel.* NMR structure of the syndecan-4 dimer in the presence and absence of PIP2. Note that interaction with PIP2 results in reorientation of PDZ-binding domains.

an FGF-dependent process. Deletions of other genes involved in HS biosynthesis have equally profound phenotypic effects.

In addition to HS chain-dependent signaling, syndecans can initiate signaling via their protein core domains by activating a variety of intracellular signaling pathways, including mitogen-activated protein kinase (MAPK), Src, Rac1, and protein kinase C (PKC) $\alpha$ . Each of the syndecans has its own characteristic biology that will be briefly reviewed in the following sections.

In approaching syndecan-mediated signaling it is useful to think of syndecan-1 and -3 as one subfamily and syndecan-2 and -4 as another. This reflects both the homology of variable domains between corresponding syndecans as

well as functional similarities. Thus, although expression of both syndecan-1 and -3 is associated with the inhibition of cell growth, that of syndecan-2 and -4 is associated with its stimulation.

#### SYNDECAN-1

Syndecan-1 plays a role in the regulation of cell-cell and cell-ECM interactions. Because its expression is predominantly limited to the cells of ectoderm-derived tissues, it is not clear how important a role it plays in the vascular system, although its expression in certain types of VSMCs and endothelium

during inflammation has been noted. In epithelial cells, down-regulation of syndecan-1 expression results in loss of cell polarity, associated with a reduced level of E-cadherin on the cell surface, suggesting involvement in the epithelial–mesenchymal switch during development and in wound healing (24). Overexpression of syndecan-1 leads to the increased shedding of its ectodomain, which results in inhibition of FGF2-induced proliferation due to sequestering of the growth factor (25). Consequently, mice overexpressing syndecan-1 have delayed dermal wound repair (26).

Syndecan-1 plays an important role in the regulation of inflammation, as suggested by increased leukocyte–endothelial interactions in *syndecan-1*-null mice. It also plays an important role in chemokine gradient formation for the transendothelial and transepithelial migration of neutrophils (27).

Syndecan-1 also plays a role in regulating ephrin signaling in venous–arterial differentiation. During this process, EphB4 is expressed in venule endothelium and a homozygous disruption of EphB4 or one of its ligands, ephrinB2, results in fatal vascular defects. Activation of EphB4-positive ECs causes upregulation of syndecan-1 (28), resulting in suppression of FGF2 signaling.

### SYNDECAN-2

Syndecan-2 is the predominant syndecan expressed during embryonic development. In adult cells, it is involved in regulation of transforming growth factor (TGF)- $\beta$  signaling. Unlike other syndecans that bind to growth factors via HS and CS chains, syndecan-2 directly binds TGF- $\beta$  via a protein–protein interaction. Furthermore, syndecan-2 coimmunoprecipitates with the TGF- $\beta$  as well as with the type III TGF- $\beta$  receptor (betaglycan) and expression of a syndecan-2 mutant with a truncated cytoplasmic domain results in impaired response to TGF- $\beta$  (29).

Similar to syndecan-1, syndecan-2 also may play a role in ephrin signaling. Cell surface ephrin–Eph signaling in ECs induces clustering of syndecan-2 and recruitment of cytoplasmic molecules, which leads to localized actin polymerization via Rho family GTPases, N-WASP, and the Arp2/3 complex (30).

### SYNDECAN-3

Syndecan-3 does not play an important role in the vascular system. However, it plays an important role in skeletal muscle differentiation. A knockout of syndecan-3 results in expression of myogenin, a master transcription factor for muscle differentiation, and in accelerated skeletal muscle differentiation and myoblast fusion. Syndecan-3 also appears to be involved in the regulation of hedgehog signaling by means of proper spatial and temporal regulation of Indian hedgehog (Ihh) (31).

### SYNDECAN-4

Syndecan-4 has become the most extensively studied member of the syndecan family, and it plays an important role in vascular biology due to its ability to modulate FGF2 signaling, regulate cell migration via cross-talk with  $\beta$ 1 integrin, and control adhesion via cytoskeletal modifications (7). Some of these functions are probably shared with other syndecans, but most derive from the presence of syndecan-4-specific cytoplasmic V domain.

Syndecan-4 directly initiates a number of intracellular signaling events including activation of PKC $\alpha$ , Src, and Rac1. The initiation of syndecan-4 signaling is prompted through the clustering of its extracellular domains by a ligand that can be a soluble growth factor, a matrix protein such as fibronectin, or an antibody. The importance of this signaling pathway is further emphasized by the fact that introduction of a syndecan-4 construct with the mutated PDZ or PIP<sub>2</sub> binding regions that, respectively, eliminated syndecan-4 ability to bind PDZ proteins or PIP<sub>2</sub>, inhibited FGF2- but not serum-induced EC growth, migration, and the ability to form vascular structures on Matrigel (32).

Although it is clear that syndecan-4 can modulate FGF2 signaling via its cytoplasmic tail interactions, the precise mechanism of this effect is uncertain. A sustained activation of FGF2 signaling requires internalization and perhaps nuclear transport of the ligand. Syndecan-4 plays an important role in FGF2 endocytosis in ECs that proceeds in a clathrin- and dynamin-independent fashion, requires syndecan-4-dependent activation of Rac1, and strongly resembles macropinocytosis (33).

A unique feature of syndecan-4 signaling is activation of PKC $\alpha$  in the absence of Ca<sup>2+</sup>. This ability of syndecan-4 to activate a calcium-dependent PKC, first shown by Oh and colleagues, requires core-protein multimerization and the presence of PIP<sub>2</sub> (34). This event depends on dephosphorylation of the Ser<sup>183</sup> site in its cytoplasmic domain (32), whereas its phosphorylation markedly reduces its affinity for PIP<sub>2</sub> (35) and prevents PKC $\alpha$  activation in vitro and in vivo (35). Remarkably, PKC $\delta$  phosphorylates the Ser<sup>183</sup> site, thus setting up a system that allows one PKC to regulate the activity of another (Figure 44.2) (36).

The molecular details of syndecan-4-dependent PKC $\alpha$  activation have not yet been established. The results of yeast two-hybrid screening demonstrated that although a full-length PKC $\alpha$  weakly bound the variable domain of syndecan-4 (4V), the PKC $\alpha$  constructs that lack the pseudosubstrate region or that encode only the whole catalytic domain interacted more strongly (37). A mutation of Tyr<sup>192</sup> in the syndecan-4 cytoplasmic domain abolished this interaction (37). Interestingly, the corresponding binding site in the catalytic domain of PKC $\alpha$  (amino acid sequence 513–672) encompasses the regulatory autophosphorylation sites implicated in control of PKC activation and stability (37). On the other hand, in vitro surface plasmon resonance studies suggested that binding affinity of a full length PKC $\alpha$  to the

Figure 44.2. Syndecan-4-dependent modulation of PKC activity. Under normal circumstances, the Ser<sup>183</sup> site is phosphorylated by PKC $\delta$ . Exposure to FGF2 results in dephosphorylation of the site, which in turn allows syndecan-4 oligomerization, binding of PIP<sub>2</sub>, and activation of PKC $\alpha$ . Any signal that would activate PKC $\delta$  would impair syndecan-4 dependent PKC $\alpha$  activation.

syndecan-4 cytoplasmic domain is very low in the absence of PIP<sub>2</sub> (35).

Syndecan-4 colocalizes with PKC $\alpha$  in focal adhesions, suggesting a role in cell adhesion, spreading, and stress fiber formation. Indeed, studies in cultured fibroblasts have shown that overexpression of syndecan-4, but not of a mutant lacking its cytoplasmic domain, specifically increases the level of endogenous PKC $\alpha$  and enhances the translocation of PKC $\alpha$  in the plasma cell membrane in general and in the membrane raft fractions in particular, and increases the activity of membrane PKC $\alpha$  (38).

### CELL ADHESION AND THE CYTOSKELETON

One of the important roles played by syndecans is the modulation of cytoskeletal rearrangements. For example, syndecan HS binding to fibronectin leads to cell spreading, and overexpression of syndecan-4 results in cell flattening as well as increase in focal adhesion formation and a decrease in cell migration in fibroblasts (39). In contrast, *syndecan-4*-null fibroblasts plated on fibronectin exhibit enhanced lamellipodia formation and increased level of Rac1 (40) and low Rho (41) activities, compared with wild-type cells. Interestingly, in ECs also plated on fibronectin, clustering of syndecan-4 constructs by antibodies results in upregulation of Rac1 activity (33). These differences in Rac activation might be due to the differences in syndecan-4 localization following binding to matrix versus soluble ligand. In this way, growth factors might modulate cell-matrix interactions by removal of the syndecan component via endocytosis (33).

In VSMCs, shear stress causes syndecan-4 dissociation from the focal adhesions (13). Overexpression of syndecan-4 blocks this dissociation and also results in reduced mechanical stress-induced cell migration. This observation suggests that syndecan-4 might be involved in regulation of VSMC migration during arteriogenesis.

Syndecan-4, but not syndecan-1 or -2, coimmunoprecipitates with CXCR4. This syndecan-4/CXCR4 complex is likely a functional unit involved in chemokine stromal cell-derived factor (SDF)-1 binding that may play a role in SDF-1-dependent stem cell recruitment, a process that can be involved in angiogenesis, atherosclerosis, and vascular repair, among other processes.

Finally, syndecans may regulate the cytoskeleton via their interactions with members of the ezrin-radixin-moesin (ERM) family. The ERM proteins have NH<sub>2</sub>- and COOH-terminal domains that associate with the plasma membrane and the actin cytoskeleton, respectively. Association of syndecan-2 with actin cytoskeleton through ezrin binding was observed in COS-1 cells following expression of a constitutively active form of RhoA (42). Thus, ezrin provides RhoGTPases with a regulated link between syndecan-2 and actin. The ezrin binding motif is identical between syndecan-2 and -4, implying the possibility of syndecan-4/ezrin interactions (42).

### CONCLUSION

Syndecans are a family of four single-span transmembrane proteoglycans with a divergent amino terminal extracellular domain decorated with heparan and chondroitin glycosaminoglycans and a conserved intracellular domain. These proteins modulate signaling shown to be critical in angiogenesis and development.

### KEY POINTS

- Signaling of heparin-binding growth factors via syndecans is mediated primarily via the structural diversity of their glycosaminoglycan chains. This diversity is governed by changes in the pattern and sulfation of the GAG's "building-block" monosaccharides.
- Syndecan-1 is primarily limited to cells of ectoderm-derived tissues, where it is involved in regulation of cell-cell and cell-matrix interactions. It also plays an important role in the regulation of inflammation and in chemokine gradient formation in the transendothelial and transepithelial migration of neutrophils, as revealed by *syndecan-1*-null mice experiments. Ephrin signaling in venous-arterial differentiation is regulated partially by syndecan-1, because activation of EphB4 causes upregulation of syndecan-1 and thus suppressing FGF2 signaling.
- Syndecan-2 is expressed in mesenchymal and epithelial as well as neuronal tissues but mainly during embryonic development. Direct protein-protein
