## Emphysema

### An Autoimmune Vascular Disease?

Norbert F. Voelkel and Laimute Taraseviciene-Stewart

*University of Colorado Health Sciences Center, Denver*

Emphysema of the lungs – first described by Laennec (1) – is a manifestation of chronic obstructive lung disease, and is almost always caused by smoking (2). Rare causes of emphysema are hypersensitivity pneumonitis (3) and human immunodeficiency virus (HIV) infection (4). Histologically, emphysema is characterized by loss of alveolar septal cells, and it can be centrilobular or panlobular. In extreme cases, the lung is literally vanishing. Modern imaging technology allows both a regional and quantitative assessment of emphysema. Although traditionally thought of as chronic progressive airway disease involving proteolytic injury to lung extracellular matrix, Liebow already recognized in 1959 that the lung vessels were involved (5) as well. Recent data on human emphysema, and in animal studies, demonstrate structural alterations of small precapillary arterioles and endothelial cell (EC) dysfunction (6–9). In addition, there is evidence by Tunel staining for EC apoptosis in these small arterioles (10).

#### THE INVOLVEMENT OF THE ENDOTHELIUM

EC dysfunction had been demonstrated by exposing small pulmonary arteries from patients with emphysema who underwent lung resection to acetylcholine and observing impaired vasodilation when compared with normal lung artery segments of comparable diameter. This test is consistent with EC dysfunction; however, whether this *ex vivo* test reflects *in vivo* pulmonary vascular EC dysfunction remains unknown. The cause or causes of this EC dysfunction are also not understood (8,9). Subsequently, Kasahara and colleagues (10) showed increased apoptosis of ECs in lungs from patients with emphysema, as well as a decrease in the overall lung tissue expression of vascular endothelial growth factor (VEGF) and the VEGF receptor 2 (VEGFR2/FLK-1/KDR). The reduction in the expression of these proteins is likely explained by both a loss of capillary ECs and the impaired gene and protein expression of remaining VEGF-producing lung cells – as judged

by immunohistochemistry of the emphysematous lungs. This begged the question of whether blockade of VEGF receptors can cause lung EC apoptosis and emphysema. Indeed, a single subcutaneous injection of the combined FLT-1/VEGFR1 and VEGFR2 inhibitor SU5416 caused alveolar septal cell apoptosis and emphysema in adult rats (11–13). SU5416 also causes impaired alveolarization in newborn rats (14). Recently, Tang and colleagues selectively ablated VEGF expression in the mouse lung by delivering intratracheal adeno-associated Cre recombinase to VEGF*loxP* mice. They demonstrated that a transient reduction in pulmonary VEGF levels results in emphysema (15).

#### VASCULAR ENDOTHELIAL GROWTH FACTOR IS CRITICAL FOR LUNG TISSUE HOMEOSTASIS

It appears that VEGF is important for lung health. Too much VEGF may cause EC proliferation and angioproliferative pulmonary hypertension (16) (see Chapter 129), and too little VEGF may lead to emphysema (13). In many ways, pulmonary angioproliferative hypertension and emphysema are on opposite ends of a spectrum: EC growth and survival in pulmonary hypertension, and impaired EC growth and apoptosis in emphysema. VEGF has been shown to be expressed in several cell types in the lung, including alveolar type II epithelial cells, Clara cells, fibroblasts, and macrophages. We postulate that the pulmonary microvascular ECs are particularly VEGF-dependent and sensitive to VEGF withdrawal or impaired VEGF signaling. At least in culture, rat pulmonary microvascular ECs produce about 20-fold more VEGF than do rat macrovascular (large pulmonary artery) ECs (17). Whether these *ex vivo* findings reflect the *in vivo* situation of the human lung microvascular cells is unknown.

The survival of lung microvascular ECs depends both on VEGF and an intact VEGF signaling pathway. This has been illustrated recently in a novel autoimmune emphysema model

(18) in which the immunization of adult rats with xenogeneic ECs resulted in the generation of anti-VEGFR2 antibodies. In addition, in this model, T-lymphocytes are required for emphysema development, because immunization of nude, athymic rats with xenogeneic ECs did not cause emphysema. Whether patients with cigarette smoking–induced emphysema have antiendothelial antibodies is unknown. However, this autoimmune model of emphysema provides proof of the concept that an attack of antibodies and immune-experienced T lymphocytes on the lung microvessels can cause emphysema.

The turnover rate of ECs in the lung is not well understood, nor is the contribution of resident or bone marrow–derived precursor cells. VEGF has been shown to mobilize precursor cells from the bone marrow (19), and it is, in this context, of great importance that these are patients with end-stage emphysema who can have undetectable plasma VEGF levels (20). Commercially available human pulmonary microvascular ECs contain varying numbers of CD34<sup>+</sup> precursor ECs, indicating perhaps that the adult human lung may rely on circulating precursor cells that have been filtered out by the lung (S. Sakao et al., unpublished observations).

Recent reports show high levels of VEGF expression in the airway mucosa of patients with asthma (21,22). High VEGF levels in these patients may be responsible for the hypervascularity of the airways (bronchial circulation) (23) and an increased number of lung parenchyma capillaries (pulmonary circulation) in patients with asthma. This could explain the greater than normal diffusing capacity frequently observed in asthmatics.

It is peculiar that VEGF protein expression is decreased in the lungs from patients with severe emphysema, because these patients are often hypoxemic, and because the lungs are infiltrated with inflammatory cells and lymphocytes known to produce VEGF (24,25). One possibility is that the VEGF promoter region has been modified (26) and has become relatively unresponsive to the transcription-promoting activity of hypoxia-inducible factor (HIF)-1 $\alpha$  and cytokines like interleukin (IL)-1. Why some patients with end-stage chronic obstructive airway disease have unmeasurable levels of plasma

VEGF is also unclear (20); one hypothesis is that the VEGF protein has been trapped by soluble VEGF receptors (27).

## THERAPEUTIC IMPLICATIONS

Drugs that inhibit lung microvascular EC apoptosis would, theoretically, be of value in the treatment of progressive emphysema. The opposite may be true in asthma, where strategies to neutralize the effects of too much VEGF might induce lung vessel EC apoptosis and reduce the hypervascularity.

### KEY POINTS

- Emphysema is also a vascular disease. Lung microvascular EC apoptosis and failure of EC regeneration may be expressions of a failure of the lung structure maintenance program.
- There may be an autoimmune component to progressive emphysema (Figure 130.1), characterized by antiendothelial antibodies and pathogenic T cells. VEGF-trapping by soluble VEGF receptor may explain undetectable plasma levels of VEGF in a subgroup of emphysema patients.

### Future Goals

- To examine animal models of cigarette smoke–induced emphysema and search for anti-EC antibodies

Figure 130.1. Central role of EC injury in pathogenesis of emphysema. Environmental factors and genetic mutations induce EC injury that is associated with oxidant stress and exposure of EC antigens. This results in anti-EC autoantibody production and a new attack on pulmonary microvasculature, leading to endothelial and alveolar septal cell death, lung structural damage, and the development of emphysema.

## Endothelial Mechanotransduction in Lung Ischemia in the Pulmonary Vasculature

Shampa Chatterjee and Aron B. Fisher

*Institute for Environmental Medicine, University of Pennsylvania, Philadelphia*

Ischemia (derived from the Greek *ischein*, to restrain, plus *haima*, blood) is defined as “local tissue anemia due to obstruction of the inflow of arterial blood” (1). *Anoxia* means the absence of oxygen. It has become common to equate ischemia with tissue anoxia. However, although the two conditions commonly coexist, anoxia does not always accompany ischemia, and ischemia has pathophysiological consequences in addition to anoxia. An example of the former is ischemia in the lung, in which continued ventilation provides normal oxygenation to lung cells in the absence of arterial blood flow. (The tissue oxygen [O<sub>2</sub>] supply might actually increase, because O<sub>2</sub> is no longer transported away by the blood.) Nevertheless, anoxia is the major manifestation of ischemia in organs supplied by the systemic circulation. The consequences of ischemia unrelated to anoxia result from loss of the normal endothelial mechanical stimulation – shear stress. These effects have been described only recently. This chapter focuses primarily on events in the pulmonary circulation associated with alterations of endothelial function due to loss of shear stress with ischemia; these events represent altered mechanotransduction.

### LUNG PERFUSION

The lung is perfused by the pulmonary artery, which carries the entire output of the right cardiac ventricle. Because the output of the left and right cardiac ventricles should be equal, perfusion to the lung is equal to the blood flow through the rest of the body. Furthermore, essentially the entire systemic blood flow returns through the venous system to the right side of the heart and thence to the lungs. As a consequence, the lung is a very vascular organ that accounts for approximately 30% of the vascular endothelial cells (ECs) of the body. (This discussion will not consider the bronchial circulation, which arises from systemic vessels and carries normally <0.5% of the cardiac output.) The pulmonary circulation can be interrupted – that is, made ischemic – by embolism, in situ throm-

bolism, compression by a mass, or surgical interruption. In these circumstances, ventilation to the affected lung segment normally would be expected to continue, at least until compromised by edema fluid or loss of surfactant followed by atelectasis (collapse of the lung). Thus, ischemia prior to the secondary responses would not result in decreased tissue oxygenation. This unique property of the lung makes it an ideal organ to separate the consequences of ischemia and reperfusion from the manifestations of anoxia and reoxygenation.

### Lung Tissue Oxygenation

As discussed, cells of the alveolar area of the lung are normally protected from hypoxia because they derive their O<sub>2</sub> from the alveolar space.<sup>1</sup> Although alveolar hypoxia can markedly influence systemic organs through its effect on blood oxygenation, this has insignificant effects on lung cells because alveolar and intracellular Po<sub>2</sub> generally would remain far above the critical Po<sub>2</sub> required to maintain mitochondrial generation of adenosine triphosphate (ATP). In studies using the isolated lung, cellular metabolism was not impaired until alveolar Po<sub>2</sub> was decreased to less than 7 mm Hg (2). These low values may be obtained locally due to impaired blood flow in the presence of focal alveolar edema or alveolar collapse that prevents ventilation of that segment. The lung has been shown to be relatively resistant to the effects of prolonged anoxia, most likely because alternate sources of ATP generation, such as glycolysis, and low rates of energy utilization prevent acute alterations of function (3). The utilization of ATP by lung cells is primarily for routine “housekeeping” functions, without the major energy requirements for muscle activity that are seen with the

1 Although lungs would have higher Po<sub>2</sub> values when compared with other organs, endothelial Po<sub>2</sub> varies depending on the location of the pulmonary vessel. Lung vascular endothelial Po<sub>2</sub> ranges from 40 to 100 mm in venous versus arterial vessels, whereas in other organs it shows the reverse (100–40 mm). Mean lung capillary Po<sub>2</sub> is normally approximately 80 mm, whereas it would be about 50 mm Hg in other organs. Whether lung ECs have greater antioxidant defenses compared to systemic ECs is not known.

heart. Although some functions such as surfactant secretion by lung epithelium and smooth muscle contractibility may be affected by focal anoxia, the effects of anoxia specifically on lung endothelial function are not well defined.

Lung anoxia was demonstrated to inhibit lung clearance of 5-hydroxytryptamine (serotonin), a function of the vascular endothelium; this effect was presumably due to depletion of cellular ATP (4). In endothelium from other organs, compromised O<sub>2</sub> delivery increases EC permeability (barrier function) by reducing the expression of tight junction proteins, in addition to promoting cell surface coagulant properties by suppressing the anticoagulant factor thrombomodulin (5,6). EC "activation" after hypoxia causes the production of proinflammatory mediators, adhesion molecule expression, and leukocyte and platelet adherence to endothelium, with attendant microvascular plugging (7). It is likely that similar events occur in the pulmonary endothelium in areas of focal ischemia. However, the major mechanism for cell injury due to anoxia appears to be the generation of reactive oxygen species (ROS) during the reperfusion period, as described in greater detail in the following sections (8,9).

### Endothelial Mechanotransduction

A crucial insight into EC biology has been the realization that ECs represent a dynamic cell system. One of the important concepts of such dynamic systems is their adaptive response to physiological stimuli. In situ, vascular ECs normally are continuously exposed to the mechanical stimuli associated with blood flow. Thus, understanding the role that physical factors such as shear stress play in EC regulation is of utmost importance (10). Indeed, it is well established that hemodynamic forces generated by the flow of blood along the luminal surface regulate both the structure and function of ECs (11). Physical forces, such as pressure, stretch, and shear stress, act on the vascular wall and specifically on the endothelium, which transforms the mechanical stimuli into biochemical signals (mechanotransduction). Although stretch can arise from the pressure of blood on the vessel and affects both ECs and smooth muscle cells, shear results from the friction of blood against the vessel wall, and it is sensed only by ECs. Although the precise mechanisms of cellular mechanotransduction are yet to be elucidated, studies point to the involvement of stretch- and shear-responsive ion channels and cytoskeletal elements (11,12).

Most prior studies of mechanotransduction have utilized in vitro models in which increased shear elicited changes in EC cytoskeletal alignment, changes in ion conductances, activation of signal transduction pathways, and alterations in gene expression (12,13). It is predictable, then, that the endothelium would respond to the sudden reduction in flow during an ischemic episode. The studies described here, almost all of which are from our laboratory, demonstrate that pulmonary endothelium, along with the endothelium of other organs, responds to an acute decrease in shear stress. Nearly all studies have compared control versus complete absence of flow, which

we have termed *oxygenated* or *nonhypoxic ischemia*, because oxygenation of lung endothelium is maintained during the ischemic period. Studies using graded reduction in flow indicate that effects of altered shear are not observed if the flow rate (i.e., shear) exceeds approximately 10% of the control value (14). Thus, the signaling paradigm presented here represents a response to marked (pathological) alterations in flow and would not be seen during normal physiological flow variations.

### MODELS OF NORMOXIC LUNG ISCHEMIA

We have developed several models for investigating altered mechanotransduction in lung endothelium associated with the acute reduction in shear stress. Each of these models was developed to allow study of altered perfusate flow during adequate cellular oxygenation. All experiments evaluate the change from steady laminar flow; possible effects of oscillatory or turbulent flow have not been evaluated in these models.

#### The Isolated Rat or Mouse Lung

Isolated lung preparations have the advantage of studying an intact system while avoiding variables such as neuroendocrine effects, altered cardiac output, effects secondary to changes in peripheral organs, and other systemic manifestations that accompany in vivo models. A disadvantage of the isolated lung model is the development of pulmonary edema that limits the observation period of ischemia studies to a few hours. Global ischemia is produced by cessation of perfusion. Lungs are continuously ventilated with air (plus 5% carbon dioxide [CO<sub>2</sub>] to maintain pH balance) during the ischemic period. Tissue ATP content measured after 1 hour of ischemia showed no change compared with continuously perfused lungs, confirming adequate oxygenation during the ischemic period (15,16). By contrast, the ventilation of lungs with nitrogen (N<sub>2</sub>) resulted in a marked decrease in lung ATP content compatible with anoxia (17). The effect of ischemia is evaluated using techniques to monitor pleural surface fluorescence or to image the subpleural microvascular endothelium in the presence of various reporter fluorophores (18–20).

#### In Vitro Endothelial Cell Flow-Adaptation Systems

As described earlier, ECs in culture respond to an increase in flow and, within several days, reach a flow-adapted state. We reasoned that the flow-adapted state of cultured ECs would more closely approximate the in vivo condition and might be required to reproduce the changes seen with acute reduction in shear stress in the intact lung. ECs were cultured under flow either in an artificial capillary model or in a specially designed parallel plate apparatus (21). Studies were carried out using bovine pulmonary artery ECs (BPAECs) and rat or mouse pulmonary microvascular ECs (RPMVECs, MPMVECs). Full adaptation required 48 to 72 hours at a shear stress of approximately 5 dynes/cm<sup>2</sup>, and was roughly similar for all cell types.

Several different systems that were tailored for specific situations were utilized.

### *Artificial Capillary System*

The artificial capillary system consists of semipermeable polypropylene hollow fibers, approximately 200  $\mu\text{m}$  in diameter, encased in a sealed cylinder (cartridge) with the ends forming the inlet and outlet ports to allow for perfusion (and exchange of oxygen and medium) (21,22). The system possesses both luminal and side ports that permit either luminal or abluminal flow. The latter allows by-pass of the lumen so that nutrients and oxygenation can be provided in the absence of cellular shear stress. ECs are seeded and grown on the inner surface of the capillaries and subjected to flow-adaptation by circulating cell culture medium through the end ports. For ischemia, the flow is switched to the side ports. Analysis of the medium samples obtained from these chambers using an  $\text{O}_2$  electrode indicates that  $\text{P}_{\text{O}_2}$  with continuous flow is unaltered upon ischemia (23,24). Cells are removed from attachment to the artificial capillaries by trypsinization and then analyzed. The advantage of this model is the simulation of *in vivo* perfusion conditions and the relatively large number of cells that can be obtained for biochemical analysis.

### *Parallel Plate Chamber*

The parallel plate chamber is designed for flow-adaptation of cells that are cultured on a glass slide or cover slip. One chamber with the dimensions of a spectrophotometer cuvette allows the monitoring of real-time fluorescence in cells using fluorescence probes and a spectrofluorometer (23), whereas another chamber can be used on the stage of a microscope for real-time microscopy (24). In these chambers, the  $\text{P}_{\text{O}_2}$  decreases to hypoxic values after 4 to 5 minutes of ischemia; saturation of the perfusate with  $\text{O}_2$  or exposure of the medium to room air can maintain adequate oxygenation for longer periods (23). The advantage of these models is the ability to make measurements in real time without disturbing cells from their attachment to substrate.

## ACUTE ENDOTHELIAL RESPONSE TO DECREASED SHEAR STRESS

### **Generation of Reactive Oxygen Species**

Our initial studies with isolated rat lungs used pleural surface fluorometry to evaluate ROS production with acute cessation of flow. This method uses a light guide against the pleural surface to record light emitted from the cells of subpleural alveoli by various fluorophores (at specific wavelengths). Lungs were preperfused with dihydroethidine, a dye that reacts with superoxide anions to generate a fluorescent congener of ethidium that becomes trapped within cells by intercalation with DNA. With abrupt cessation of flow (ischemia), the pleural surface fluorescence signals showed a marked and relatively rapid (within minutes) increase in ethidium fluorescence, and a parallel decrease in hydroethidine fluorescence,

indicating oxidation of the fluorophore due to generation of ROS (25). Localization of endothelium as the site of ROS generation was determined using a real-time high-resolution digital imaging system that permitted visualization of the subpleural microvasculature by either confocal fluorescence microscopy or with an epifluorescence microscope and commercially available (Metamorph) imaging software. The fluorescent probe for these studies was dihydrochlorofluorescein diacetate ( $\text{H}_2\text{DCFDA}$ ), a ROS-reactive probe that is trapped within cells by deacetylation; oxidation by ROS forms fluorescent dichlorofluorescein (DCF). In ischemia, cellular DCF fluorescence increased, indicating ROS generation. The DCF signal colocalized with fluorescence from the EC marker fluorophore DiI-acetylated low-density lipoprotein (DiI-AcLDL), indicating ECs as a site of ROS generation (18). The third fluorophore used to study ROS generation was amplex red, which fluoresces after reaction with hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) (in the presence of peroxidase). This dye is not taken up by the ECs, and remains in the pulmonary vascular space. Increased amplex red fluorescence with ischemia is compatible with ROS generation (Figure 131.1; for color reproduction, see Color Plate 131.1). The issue of intracellular versus extracellular generation of ROS is discussed later.

ROS generation as an acute response to ischemia also was evaluated in flow-adapted endothelium *in vitro*. Cells cultured under usual conditions failed to show a response to stop flow after a brief period of perfusion. Flow-adapted cells, on the other hand, showed a brisk and reproducible ROS generation, with ischemia as detected by  $\text{H}_2\text{DCF}$  oxidation. The results are compatible with oxidation by  $\text{H}_2\text{O}_2$  arising from dismutation of  $\text{O}_2^{\cdot-}$ . For greater specificity, reduction of ferricytochrome-c (cyt-c) that is inhibitable by superoxide dismutase (SOD) was used to detect  $\text{O}_2^{\cdot-}$ . Reduction of cyt-c was observed within the initial 15 seconds of stop-flow, indicating a rapid generation of  $\text{O}_2^{\cdot-}$ . The rate of  $\text{O}_2^{\cdot-}$  generation calculated from the rate of cyt-c reduction was 6.1 nmol/minutes/ $10^6$  cells, or approximately 70% of the estimated rate of  $\text{O}_2$  consumption (23). This surprisingly high rate of  $\text{O}_2^{\cdot-}$  production indicates a respiratory burst that is similar in magnitude to that observed for polymorphonuclear neutrophils (PMNs). The cyt-c method reflects generation of  $\text{O}_2^{\cdot-}$  into the extracellular space, because the protein probe was added to the medium, and  $\text{O}_2^{\cdot-}$  crosses cell membranes relatively slowly. On the other hand, increased DCF fluorescence primarily reflects intracellular oxidation by  $\text{H}_2\text{O}_2$ . These results are compatible, because  $\text{H}_2\text{O}_2$  arising from dismutation of  $\text{O}_2^{\cdot-}$  can readily cross cell membranes. The dismutation of extracellular  $\text{O}_2^{\cdot-}$  occurs spontaneously and can be catalyzed by extracellular superoxide dismutase.

### *Nicotinamide Adenine Dinucleotide Phosphate Oxidase as the Pathway for $\text{O}_2^{\cdot-}$ Generation with Ischemia*

Video imaging of the pulmonary microvasculature in the intact lung detected increased ROS-associated fluorescence within 2 to 4 seconds after abrupt cessation of perfusion; this fluorescence continued to increase during the subsequent

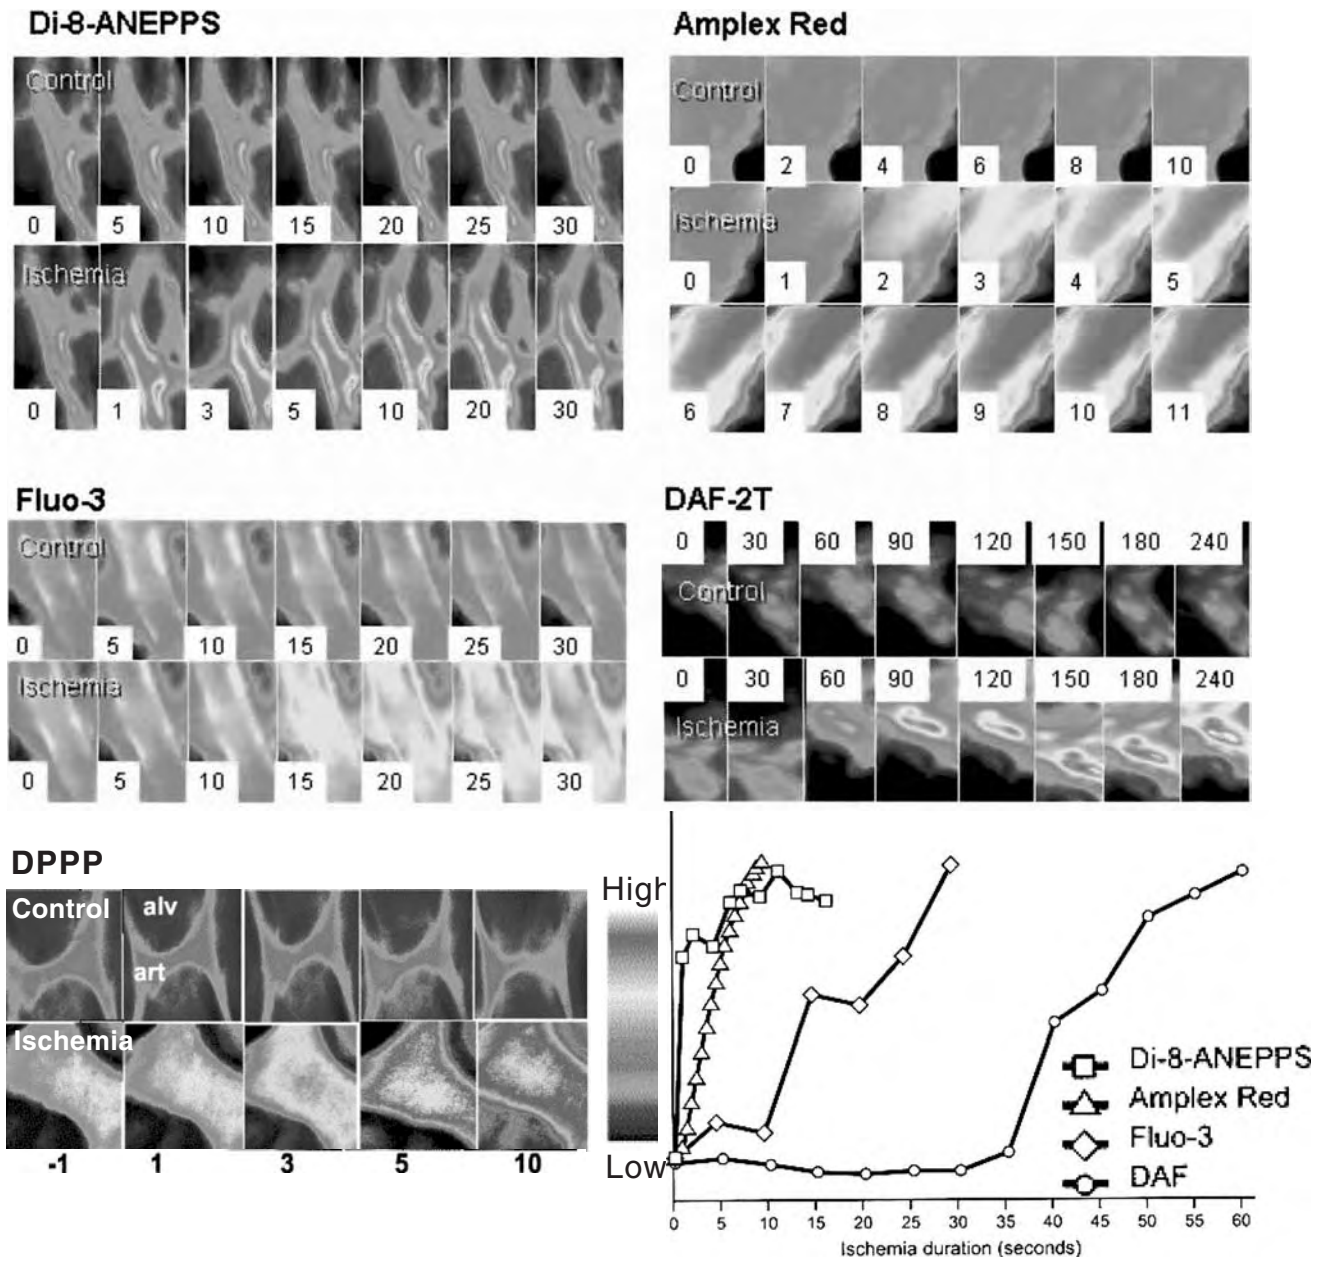

Figure 131.1. Fluorescence imaging of subpleural microvascular ECs in the isolated rat lung. Each set of images represents a control perfusion period followed by ischemia. Images are in pseudocolor. The number on each panel indicates time in seconds (minutes for DPPP), either during the control observation period or after cessation of perfusion. (Top left): Imaging for cell membrane potential using the fluorophore di-8-ANEPPS. (Top right): Imaging with Amplex red for the appearance of H<sub>2</sub>O<sub>2</sub> in the intravascular space. (Middle left): Imaging for intracellular Ca<sup>2+</sup> with fluo-3. (Middle right): Imaging for NO with diaminofluorescein (DAF). (Bottom left): Imaging for lipid peroxidation using the hydroperoxide probe DPPP. The preset scale indicates the pseudocolor scale used in all these images. (Bottom right): Timing of fluorescence changes in membrane potential, ROS generation (Amplex red), intracellular Ca<sup>2+</sup> (Fluo-3), and NO generation (DAF) with ischemia, as determined by imaging techniques in the isolated rat lung. The y-axis represents arbitrary units. DAF, diaminofluorescein; DPPP, diphenyl-1-pyrenylphosphine. For color reproduction, see Color Plate 131.1.

30-minute observation period (19). Using flow-adapted cells, ROSs were produced into the extracellular space, suggesting a plasma membrane source. Allopurinol, an inhibitor of xanthine oxidase, had no effect on ROS production with ischemia, unlike its known effects in reperfusion injury. However, near

total inhibition of the generation of ROS with ischemia resulted from the flavoprotein inhibitor, diphenyleneiodonium (DPI). This agent has been widely used as an inhibitor of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase pathway of ROS production in phagocytic cells.

ECs are known to possess a plasma membrane NADPH oxidase-like enzyme system that resembles the  $O_2^-$  generating enzyme complex of PMNs (18,26–28). Mice with knockout of gp91<sup>phox</sup> (*gp91<sup>phox</sup>-/-*), the membrane flavoprotein component of NADPH oxidase in PMN, failed to generate ROS with lung ischemia, providing additional evidence that phagocyte-type NADPH oxidase is responsible for endothelial ROS generation with lung ischemia (18).

In PMNs, ROS generation requires the assembly of the NADPH oxidase complex by translocation of at least four cytosolic protein components (p47<sup>phox</sup>, p67<sup>phox</sup>, p40<sup>phox</sup>, p21rac1) to the plasma membrane, where they associate with the cytochrome b558 heterodimer (gp91<sup>phox</sup> and p22<sup>phox</sup>) (29,30). Although the precise details of NADPH oxidase assembly in pulmonary ECs are still under investigation, the components of the oxidase appear to be similar to those in PMNs; other flavoprotein components (the NOX proteins) may be present in addition to gp91<sup>phox</sup>, but that remains to be determined. PR-39, an inhibitor of src homology (SH)-3 groups that blocks NADPH oxidase assembly in PMNs, also inhibited ROS generation by lung endothelium in response to ischemia, indicating that assembly of the oxidase is required for maximal rates of  $O_2^-$  production (18). In PMNs, the transmembrane protein gp91<sup>phox</sup> transfers electrons across the plasma membrane to generate superoxide anions in the extracellular space. Extracellular generation of  $O_2^-$  with ischemia also occurs with flow-adapted ECs in culture, as indicated by our observations using exogenous ferricytochrome-c.

#### **Membrane Depolarization Is the Activating Signal for Reactive Oxygen Species Generation**

Several previous observations led us to investigate changes in membrane potential as the initiating event for activation of NADPH oxidase. First, ion channel events leading to alteration in membrane potential are among the earliest responses to onset of flow. Second, local changes in membrane potential have been associated with NADPH oxidase activation in PMNs, although this issue is complicated by the response of the proton pump to extracellular transfer of electrons. To study membrane potential in intact lungs, they were preperfused with a membrane potential-sensitive dye, bis-oxonol or di-8-ANEPPS. These dyes localize in the plasma membrane where, in the depolarized state, increased rigidity of the bilayer results in better dye alignment and higher fluorescence yield. The monitoring of EC fluorescence from the pleural surface in real time revealed that cessation of flow caused membrane depolarization, as evidenced by the increase in the bis-oxonol fluorescent signal (16). For video imaging, the faster response dye, di-8-ANEPPS, was used (Figure 131.1). Rapid sampling showed a gradual increase in fluorescence within the first 1 to 2 seconds that then stabilized (19). Thus, the change in membrane potential appeared to precede activation of NADPH oxidase. Additional evidence that change in membrane potential could initiate ROS generation was obtained by perfusing lungs and treating cells with high potassium ( $K^+$ ), which resulted in membrane depolarization and ROS generation. Perfusion of

**Table 131-1: Mouse Phenotypes**

<i>Gene</i>	<i>Survival of Null Mutant</i>	<i>Phenotype</i>
<i>K<sub>IR</sub>6.2</i>	Viable	Glucose intolerance
<i>gp91<sup>phox</sup></i>	Viable	Abnormalities in host defense and inflammation

the intact lung or treatment of flow-adapted ECs with increasing concentrations of  $K^+$  showed that flow cessation results in EC membrane depolarization equivalent to that observed with approximately 12 mM KCl. In accord with the Nernst equation and assuming an initial EC membrane potential of  $-65$  mV, the decrease in membrane potential with flow cessation is approximately 20 mV (19).

#### ***K<sub>ATP</sub> Channels Are Responsible for Endothelial Cell Membrane Depolarization with Ischemia***

Depolarization of the pulmonary microvascular endothelium with  $K^+$  indicates that  $K^+$  channels are, at least in part, responsible for the resting cell membrane potential. Based on inhibitor/agonist studies, we postulated that the  $K_{ATP}$  channel is an important determinant of cell membrane polarization and the subsequent ischemic response.  $K_{ATP}$  channels are composed of an inwardly rectifier pore-forming protein ( $K_{IR}6$ ) and a regulatory subunit, a sulfonylurea receptor (SUR). The presence of  $K_{IR}6.2$  and SUR1 subunits has been identified in rat and bovine pulmonary vascular ECs (Table 131-1). Pretreatment of the lungs with cromakalim (or its L-isomer, lemakalim), a  $K_{ATP}$  channel agonist, blocked membrane depolarization in ischemia (19) and prevented ROS production. Conversely, perfusing lungs with glyburide, a  $K_{ATP}$  antagonist that binds to the SUR, caused depolarization and ROS production during continued flow (i.e., in the absence of ischemia) (16). These results indicate that channel closure leads to membrane depolarization, which results in ROS generation. Lungs and ECs from mice with knockout of  $K_{IR}6.2$  (*K<sub>IR</sub>6.2<sup>-/-</sup>*) showed a significantly diminished response to ischemia, with a lesser change in membrane potential and lesser ROS production compared with wild-type mice (31,32). We conclude that  $K^+$  channel inactivation resulting in membrane depolarization is the earliest event following cessation of flow, and that this event is linked to ROS production through activation of membrane-localized NADPH oxidase.

#### **Nitric Oxide Generation with Ischemia**

Nitric oxide (NO) generation was demonstrated as a component of the initial response to experimental ischemia using the fluorophore DAF-2 DA. This dye is de-esterified intracellularly to DAF-2, which reacts with NO and its higher oxides to form the fluorescent DAF-2T. ECs of in situ subpleural microvessels in rat lungs showed an initial increase in DAF-2T fluorescence at about 45 seconds of ischemia, with a progressive increase

over the subsequent 5 to 10 minutes (see Figure 131.1). Specific cellular localization of DAF-2T was confirmed by colocalization with the endothelial marker DiI-AcLDL (33). Abrogation of the fluorescent signal upon ischemia by pretreatment with a NO synthase (NOS) inhibitor indicated specificity of the signal for NO (33).

ECs possess at least two isoforms of NOS: endothelial NOS (eNOS) and inducible NOS (iNOS) (34). eNOS requires increased levels of calcium ( $\text{Ca}^{2+}$ ) and calmodulin binding for its dissociation from caveolin and activation, whereas iNOS is  $\text{Ca}^{2+}$  independent. That eNOS is responsible for NO generation with ischemia was clear when the use of  $\text{Ca}^{2+}$ -free medium or the presence of a calmodulin inhibitor suppressed the increase in DAF-2T fluorescence with ischemia (33). Disruption of caveolae by pretreatment of cells with cyclodextrin or filipin to alter cholesterol-rich domains also inhibited endothelial NO generation, indicating that eNOS activation with ischemia requires a signal from caveolae as well as the increase in  $\text{Ca}^{2+}$ /calmodulin (22).

### Intracellular $\text{Ca}^{2+}$ Elevation with Ischemia

The effect of  $\text{Ca}^{2+}$  depletion on NO generation suggests that intracellular  $\text{Ca}^{2+}$  is increased with ischemia. Lungs were imaged in situ using fluorophores to monitor changes of intracellular  $\text{Ca}^{2+}$  in pulmonary endothelium during the ischemic episode (20,33,35). Ischemia led to increased  $\text{Ca}^{2+}$  in ECs in situ that was observed at approximately 10 to 15 seconds after the stoppage of flow, and reached a plateau at approximately 5 minutes (see Figure 131.1). Simultaneous monitoring of the  $\text{Ca}^{2+}$ - and NO-sensitive fluorophores confirmed that the  $\text{Ca}^{2+}$  increase with ischemia preceded NO generation. Temporally, the increase of intracellular  $\text{Ca}^{2+}$  followed the change in cell membrane potential, and an agent (cromakalim) that blocked membrane depolarization with ischemia also blocked  $\text{Ca}^{2+}$  increase.

### Source of Intracellular $\text{Ca}^{2+}$

Increased intracellular  $\text{Ca}^{2+}$  with ischemia was partially prevented by perfusion with  $\text{Ca}^{2+}$ -free medium or, to a lesser extent, by pretreatment with thapsigargin, an agent that leads to the depletion of  $\text{Ca}^{2+}$  from intracellular stores through inhibition of  $\text{Ca}^{2+}$ -ATPase of endoplasmic reticulum (19,20,33). These results indicate that the ischemia-mediated increase of intracellular  $\text{Ca}^{2+}$  is due primarily to  $\text{Ca}^{2+}$  influx from both its intracellular release and  $\text{Ca}^{2+}$  influx from the extracellular medium (20,33,35).

### Voltage-Gated $\text{Ca}^{2+}$ Channels

Voltage-gated  $\text{Ca}^{2+}$  channels (VGCC) can mediate calcium influx in response to membrane depolarization (36). The presence of VGCCs has been shown in freshly isolated microvascular ECs from bovine adrenal medulla (37–39), rat brain (40), and rat lung (41), although it has been difficult to demonstrate functional channels in passaged ECs in culture. RPMVECs express both the  $\alpha$ -1G and  $\beta$ 3 subunits of T-type

VGCC, and the expression of these proteins was significantly increased upon flow-adaptation (42). T-type  $\text{Ca}^{2+}$  channels open after a relatively small depolarization (10–20 mV), unlike L-type and other high-voltage  $\text{Ca}^{2+}$  channels, which require a larger change in membrane potential (43,44). Thus, the change in membrane potential of approximately 15 to 20 mV with ischemia in the intact lung (35) and flow-adapted ECs (42) is compatible with the involvement of T-type  $\text{Ca}^{2+}$  channels in the ischemic response. This role is supported by inhibition of  $\text{Ca}^{2+}$  influx in the presence of a T-type VGCC inhibitor (42).

### Flow Adaptation and the Response to Altered Shear

Pulmonary vascular ECs in situ are constantly exposed to shear forces, and presumably are adapted to these conditions. It seems intuitive that cells cultured under static conditions, as is the usual procedure, would lose this state of adaptation. Thus, cells in culture respond to imposition of shear but would not be expected to respond to cessation of flow. We evaluated this presumption by measuring the response of ECs to ischemia as a function of duration of shear exposure in culture. Exposure of routinely (i.e., statically) cultured ECs to flow for a brief ( $\sim$ 1/2 hour) period failed to elicit membrane depolarization or ROS generation when flow was discontinued. If cells were kept under flow for a more prolonged period (i.e., sufficiently long for flow-adaptation), both membrane depolarization and ROS generation were observed with ischemia, as described for the intact lung (21,23). A partial response to simulated ischemia was observed after 16 to 24 hours of exposure to shear, whereas a maximal response required flow-adaptation for 48 to 72 hours. Similar results for flow-adapted cells were obtained for bovine pulmonary artery ECs BPAECs, RPMVECs, and MPMVECs (21,23).  $\text{K}_{\text{ATP}}$  channel expression with flow-adaptation increased at the mRNA and protein levels (Figure 131.2; for color reproduction, see Color Plate 131.2) as did the inwardly rectified  $\text{K}^{+}$ -current. This induction supports the notion that  $\text{K}_{\text{ATP}}$  channels are important for the response to simulated ischemia. The failure of statically cultured cells to show membrane depolarization and ROS generation with simulated ischemia can be explained in part by their low level of  $\text{K}_{\text{ATP}}$  channel expression.

### ENDOTHELIAL CELL SIGNALING IN RESPONSE TO ISCHEMIA

Recent studies have provided convincing evidence that ROS generated in low amounts during physiological perturbation act as second messengers to initiate a signaling cascade. Thus, the generation of ROS by the endothelium in response to altered shear stress suggests a signaling function. To examine the expression of signaling molecules, events subsequent to the initial response to ischemia were studied. These studies utilized primarily the in vitro artificial capillary system, which allows for a prolonged period of simulated ischemia without affecting the  $\text{O}_2$  and nutrient supply.

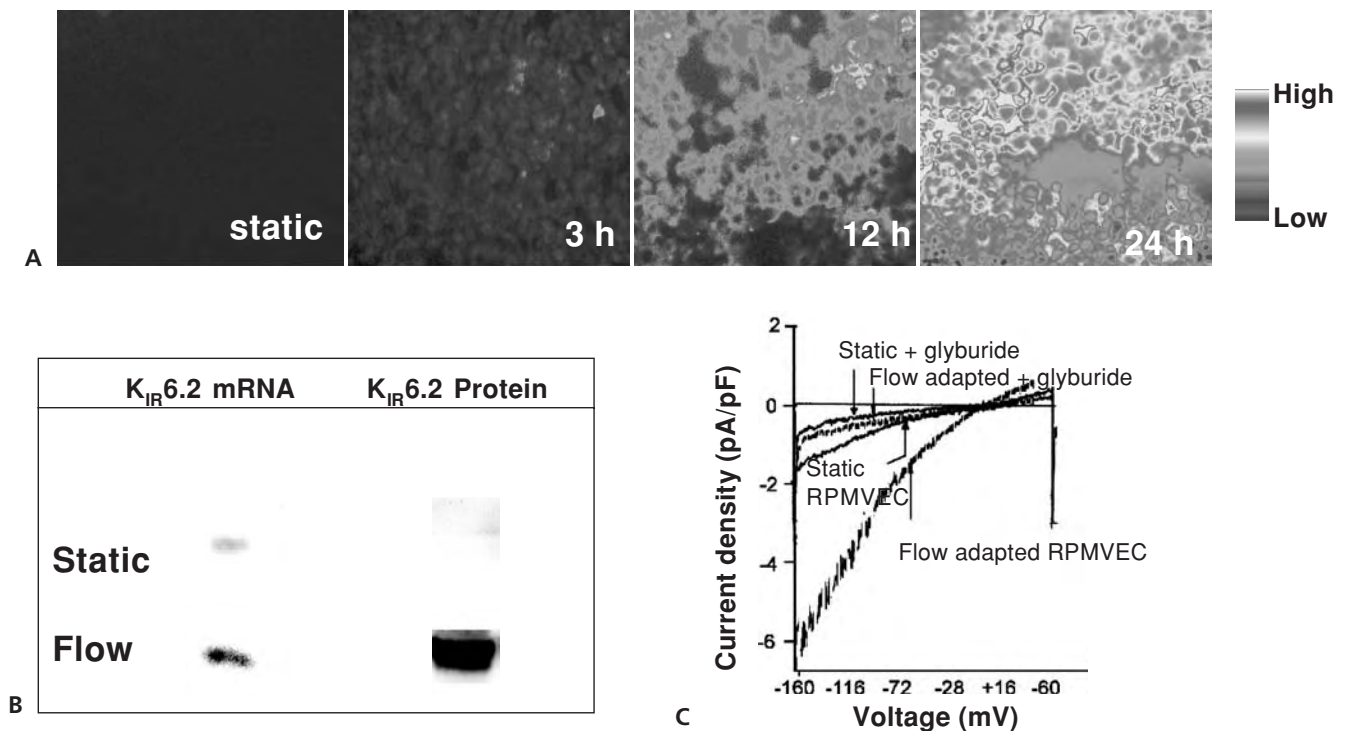

Figure 131.2. Induction of  $K_{ATP}$  channels during flow-adaptation. (A) Increase in fluorescence in cells flow-adapted at  $10 \text{ dyn/cm}^2$  for varying periods. Cells were labeled with fluorescently labeled glyburide (BODIPY-glyburide,  $50 \text{ nM}$ ). The resulting fluorescence indicating binding of glyburide to the sulfonylurea receptor (SUR) was observed with a microscope. (B) Representative blots of  $K_{IR}6.2$  mRNA and protein content of RPMVECs cultured under static conditions or adapted to flow ( $10 \text{ dyn/cm}^2$  for 24 h). Total RNA was extracted, absorbed as a dot on a nitrocellulose membrane, and hybridized with  $^{32}\text{P}$ -labeled  $K_{IR}6.2$  cDNA. Protein was analyzed by Western blot using polyclonal antibodies to the COOH terminus of  $K_{IR}6.2$ . (C) Inwardly rectifying whole cell  $K^+$  currents ( $K_{IR}$ ) in RPMVECs. Representative recordings obtained from static (no flow) cells and cells adapted to flow at a shear stress of  $10 \text{ dyn/cm}^2$  for 24 hours. Increased current is seen for flow-adapted compared with static cells. Glyburide ( $K_{ATP}$  blocker) completely abolished the increased current. For color reproduction, see Color Plate 131.2.

### Sensing of Altered Shear

As defined earlier, ischemia entails a loss of blood flow and, with respect to mechanotransduction, equates to a loss of shear force. Because the cell membrane forms a boundary with the flowing blood, it seems reasonable to predict that sensing of altered shear might be elicited through membrane-anchored structures. Indeed, structures such as the specialized invaginated microdomains on EC membranes (i.e., caveolae) have been reported to be shear sensitive (45). Caveolae are enriched with cholesterol and glycosphingolipids and contain caveolin as a principal component (46).

The function of these organelles is altered by depleting membrane cholesterol through treatment with filipin or cyclodextrin (membrane-permeable and impermeable compounds, respectively). The role of membrane cholesterol in mechanotransduction may be related to the regulation of membrane fluidity, which may affect the function of membrane proteins (47,48). As described earlier, flow-adapted BPAECs depleted of cholesterol and subjected to ischemia showed decreased NO production with ischemia, indicating that NOS activation is coupled to caveolar microdomains. Our recent studies with *caveolin-1*-null mouse microvascular ECs

have shown loss of the characteristic response to loss of shear. Thus, caveolae appear to serve either as a primary flow sensor or as a mechanism to integrate signals from other cellular components such as the cytoskeleton.

### Activation of Signaling Cascades

Signaling by low levels of ROS is mediated through activation of mitogen-activated protein kinase (MAPK) pathways. The terminal kinases in these pathways are p38, extracellular-regulated-kinase (ERK), and c-jun N-terminal kinase (JNK). In flow-adapted ECs, ischemia resulted in phosphorylation of ERK1 and -2, indicating activation of this kinase (22). Phosphorylation was observed during the first 10 minutes of ischemia and reached a plateau at 20 to 30 minutes. Inhibitors of ROS generation suppressed ERK phosphorylation, confirming that it was a response to the oxidant signal. ERK phosphorylation in this model also was suppressed by disruption of caveolae. Thus, ERK1/2 activation in ischemia requires both ROS production and a signal from caveolae. Subsequent activation of NOS requires both ERK1/2 activation and increased  $\text{Ca}^{2+}$ /calmodulin (22). Activation of the transcription factor activator protein (AP)-1 with ischemia

(see below) suggests activation of JNK, but this was not evaluated directly.

### Activation of Transcription Factors and Cell Proliferation

Having established that ischemia in flow-adapted ECs activates signaling pathways, the subsequent downstream events were evaluated. Activation of eNOS has been described. Analysis of nuclear extracts from flow-adapted ECs by electrophoretic mobility shift assay indicated a nuclear translocation of nuclear factor (NF)- $\kappa$ B components (p65 and p50) when studied at 1 hour of ischemia. Nuclear translocation also was demonstrated for the c-Jun/c-fos subunits of AP-1 (49). Activation of both NF- $\kappa$ B and AP-1 was abolished by pretreatment of cells with inhibitors of ROS generation, indicating that their activation is linked to ROS-mediated signaling pathways (49).

ROS can mediate Ras-induced cell cycle progression and mammalian cell proliferation (50), an effect that may be mediated in part through activation of AP-1. After 24 hours of ischemia, flow-adapted BPAECs demonstrated an increase in  $^3$ H-thymidine incorporation and an increase in the percent of cells in the proliferative phases of the cell cycle (49). In flow-adapted RPMVECs, ischemia caused a 2.5-fold increase in the cellular proliferation index and a threefold increase in the percentage of cells in the S plus G2/M phases (51). These results indicate increased DNA synthesis, cell division, and cell proliferation in response to ischemia. Proliferation after ischemia was abolished by inhibitors of cell membrane depolarization and ROS generation, indicating that proliferation results from signaling associated with ROS. Control studies eliminated the possibilities that proliferation with the ischemic model was due to loss of contact inhibition or a response to cell death (51). We postulate that ROS stimulates proliferation through a signaling cascade, as a response to cessation of flow and in an effort at neovascularization.

### ISCHEMIA-INDUCED OXIDATIVE STRESS

Although ROS generation in low amounts is considered a physiological signaling mechanism, excess generation can promote cell injury due to oxidation of cellular biomolecules.

#### Lung Injury with Oxygenated Lung Ischemia

As described earlier, ROS are generated by pulmonary endothelium during ischemia in the presence of adequate cellular oxygenation. The primary source of ROS is the EC membrane NADPH oxidase that generates  $O_2^{\cdot-}$ . Dismutation produces  $H_2O_2$ , which can react with  $O_2^{\cdot-}$  (especially in the presence of  $Fe^{2+}$ ) to generate the hydroxyl radical ( $\cdot OH$ ). This potent oxidant can interact rapidly with cellular biomolecules and result in the oxidation of lipids, protein, and DNA.

We have used several techniques to evaluate ischemia-induced tissue oxidative injury at the biochemical level. A recently developed imaging technique permitted the detection of lipid peroxidation with ischemia in the endothelium of the continuously ventilated isolated rat lung. The fluorophore diphenyl-2-pyrenylphosphine (DPPPP) localizes in the plasma membrane and responds specifically to lipid hydroperoxides (52). Lipid peroxidation was detected at 3 minutes of ischemia using this highly sensitive method (53). Analysis of lipid peroxidation in lung homogenates by measurement of thiobarbituric acid reactive substances (TBARS) and conjugated dienes is less specific and less sensitive, in part because the background includes all cells and not just the endothelium. Using these methods, lipid peroxidation was detected at 15 to 30 minutes of ischemia, with progression at 60 minutes (21). A parallel increase in lung protein carbonyls with time of ischemia indicated protein oxidation (54). These oxidative changes were blocked by scavengers of ROS.

The presence of free  $Fe^{2+}$  greatly accelerates the rate of oxidative injury through the facilitation of  $\cdot OH$  generation via Fenton chemistry. Using chemical assay, free  $Fe^{2+}$  in lung homogenates subjected to ischemia increased 45% in 15 minutes and 3.5-fold (to 0.3 mmol/mg protein) in 30 minutes (55,56). Under fluorescence imaging, pulmonary ECs were the predominant site of the increase in free iron ( $Fe^{2+}$ ) (56). The increase in  $Fe^{2+}$  depended on EC membrane depolarization and increased intracellular  $Ca^{2+}$ , but was independent of ROS generation. The increase in  $Fe^{2+}$  with ischemia presumably reflects its release from labile intracellular stores. The presence of  $Fe^{2+}$  chelators markedly inhibited ischemia-induced lipid peroxidation (56). Thus, oxidative injury to the pulmonary endothelium results from toxic radicals generated by the interaction of  $Fe^{2+}$  with ROS produced by NADPH oxidase. In vivo, the antioxidant capacity of the blood presumably delays (compared to isolated lungs perfused with synthetic medium) the oxidative injury associated with ischemia-mediated ROS generation.

### Reperfusion-Mediated Lung Injury

Reperfusion injury has been described as the tissue damage that occurs with reperfusion following a period of ischemia. The commonly accepted mechanism is the generation of ROS associated with tissue reoxygenation (obviously, ROS cannot be produced during tissue anoxia, because some  $O_2$  is required, by definition). This paradigm generally is called ischemia-reperfusion injury, although it would be more appropriately designated as injury due to anoxia-reoxygenation. The most widely studied biochemical pathway for ROS generation with reoxygenation is through xanthine oxidase, which arises during anoxia through proteolytic cleavage of xanthine dehydrogenase. The purine substrates for xanthine oxidase are generated during anoxia by breakdown of ATP and its metabolic products;  $O_2$  is provided during the reperfusion phase. Anoxia-reoxygenation with continued perfusion can be

studied by ventilating isolated lungs with O<sub>2</sub>-free gas. (This experiment would be difficult to interpret in an intact animal because of the systemic effects of the resultant hypoxia.) Anoxia–reoxygenation in isolated rat lungs resulted in ROS generation, with resultant oxidation of lipid and protein components. These effects were blocked by a xanthine oxidase inhibitor (17).

The possibility of reperfusion injury associated with restoration of shear stress, as contrasted with reoxygenation, has been investigated using perfused rat lung, although studies are few and interpretation is unclear (57–60). Reperfusion of rat lung following normoxic ischemia for 30 to 60 minutes had no significant effect on lung lipid or protein oxidation beyond that observed during the ischemia period, but did result in release of lactate dehydrogenase, shedding of angiotensin-converting enzyme (ACE) from pulmonary endothelium, and lung fluid accumulation (57). These effects could have been a consequence of injury sustained during the ischemic phase of the experiments.

Ischemia–reperfusion in lungs of intact animals has been studied using various models including clamping of the lung hilus (61,62), ligation of a pulmonary artery (63,64), or lung transplantation (65). Lung injury has been observed, although the contribution of the pulmonary endothelium and the respective roles of anoxia–reoxygenation versus ischemia–reperfusion are unclear.

### NORMOXIC ISCHEMIA IN SYSTEMIC VASCULAR ENDOTHELIUM

The response of pulmonary endothelium to ischemia raised the question whether similar effects occurred in other vascular beds. K<sup>+</sup>-induced depolarization in human umbilical vein ECs (HUVECs) resulted in tyrosine kinase activation, rac translocation to the cell membrane, and O<sub>2</sub><sup>•-</sup> generation, indicating an analogous response to that observed in pulmonary endothelium (66). ROS production has been demonstrated during ischemia in the heart and intestine, although this was a sidelight to the major focus (reperfusion) of the studies (67,68). ROS production in these organs occurred during the early phase of ischemia but subsequently was inhibited by lack of O<sub>2</sub>. We have evaluated the role of ischemia in aortic endothelium using techniques similar to those described for the lung (24). Obviously, zero flow in the aorta is not compatible with life, but this preparation was used for extrapolation to other systemic vascular beds. An isolated aorta preparation consisting of a longitudinal section of freshly dissected rat aorta fixed into a flow chamber with the endothelial layer facing up was subjected to a 1-hour period of flow (to give a shear stress of 10 dynes/cm<sup>2</sup> for 1 hour) to reestablish flow-adaptation. Both this isolated aorta preparation and flow-adapted aortic ECs in culture showed cell membrane depolarization and ROS generation with ischemia, a response similar to that observed in pulmonary endothelium (24). As with pulmonary endothelium, membrane depolarization was associated with altered K<sub>ATP</sub>

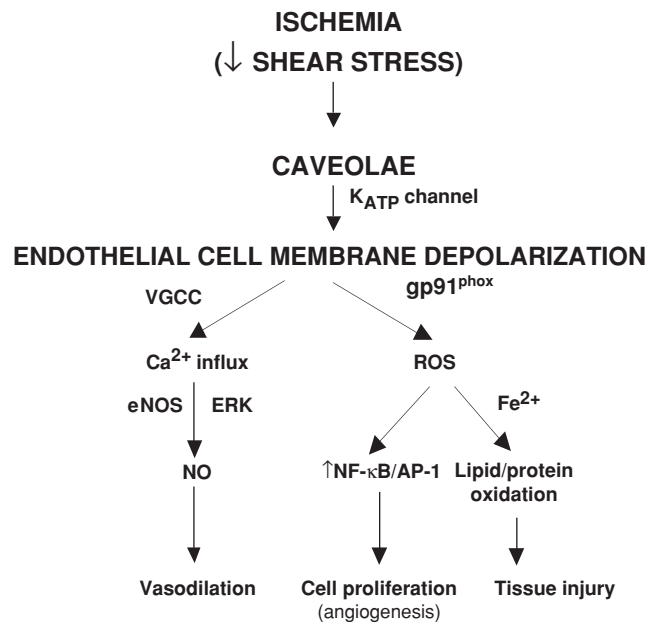

Figure 131.3. Proposed pathways for NO generation, cell proliferation, and tissue injury with ischemia. Loss of shear stress due to flow cessation is sensed by the EC, resulting in activation of NADPH oxidase, ROS generation, and elevated intracellular Ca<sup>2+</sup>. ROS-dependent activation (phosphorylation) of ERK1/2 leads to Ca<sup>2+</sup>-dependent activation of endothelial NO synthase and NO generation. The cell signaling cascade results in EC proliferation. NO generation, and cell proliferation might represent mechanisms to restore blood flow. Release of free Fe<sup>2+</sup> in the presence of ROS results in oxidative stress with oxidation of cellular lipid and protein components.

channel activity, and ROS generation required the activation of NADPH oxidase. Gradual lowering of shear in the reflow-adapted aortas showed no significant change in ROS generation until shear was reduced by approximately 95% from the level used for reflow-adaptation (24). This indicates that the ischemic response is not proportional to the change in shear but rather is threshold-dependent, as observed also for the perfused rat lung (14).

Thus, these results indicate that the endothelial response to cessation of flow is not unique or limited to the pulmonary endothelium, and ROS generation could occur in other vascular beds as long as tissue Po<sub>2</sub> levels are adequate for NADPH oxidase activity. Although ischemia-mediated generation of ROS, and probably NO, requires the presence of O<sub>2</sub>, membrane depolarization and elevated intracellular Ca<sup>2+</sup> do not. Both of the latter have been observed in many tissues with ischemia, although careful study is required to dissect the respective roles of altered shear stress versus decreased tissue ATP in their genesis.

#### KEY POINTS

- Overall, the studies described in this chapter provide a new paradigm for ischemia, in which the loss of

shear or the mechanical component of flow initiates an endothelial response (Figure 131.3).

- Our results show that cessation of flow triggers rapid depolarization (within 1–2 seconds) of the EC plasma membrane, caused by deactivation of K<sub>ATP</sub> channels.
- This is followed closely by activation of membrane-localized NADPH oxidase and ROS generation. Subsequent events include release of Ca<sup>2+</sup> from intracellular stores and opening of T-type voltage dependent Ca<sup>2+</sup> channels, resulting in increased intracellular Ca<sup>2+</sup>, caveolar-dependent phosphorylation of ERK1/2, activation of endothelial NO synthase, and NO production.
- The increased production of ROS activates several EC transcription factors (among them NF-κB and AP-1) and leads to increased EC division and proliferation.
- These responses to altered shear stress are not unique to the pulmonary circulation. They occur in aortic endothelium and possibly other vascular beds during the early phase of ischemia before O<sub>2</sub> is depleted. This response to ischemia may serve the physiologic purpose of promoting vasodilatation by the generation of NO and stimulating neovascularization to re-establish the impeded blood flow.

ACKNOWLEDGMENTS

We thank our many colleagues and collaborators who participated in these studies, especially A.B. Al-Mehdi, Y. Manevich, Z. Wei, and I. Matsuzaki. We especially thank T. Milovanova and J. Rossi for assistance with the manuscript.

# Endothelium and the Initiation of Atherosclerosis

---

Myron I. Cybulsky

*Toronto General Research Institute, University Health Network,  
University of Toronto, Ontario, Canada*

The identification of pathogenic risk factors for atherosclerosis, such as hyperlipidemia, hypertension, and diabetes, has led to modifications in lifestyle and novel therapies that have had a significant impact on the morbidity and mortality associated with atherosclerosis-related diseases. However, despite such advances, these diseases remain highly prevalent in industrialized nations, and the recent increase in obesity and diabetes, especially in children, forecasts a resurgence in the incidence of atherosclerosis-associated morbidity. Over the last three decades, the field has rediscovered the critical role that inflammation plays in the pathogenesis of atherosclerosis. An important component of inflammation is the emigration of leukocytes from the blood into tissues. The vascular endothelium, being situated at the interface between the blood and tissues, has important regulatory functions in atherosclerosis. In normal arteries, the endothelium has homeostatic functions, including nonadhesive and antithrombotic properties, and it provides a barrier to plasma protein and lipoprotein extravasation (1). Endothelial cells (ECs) are not a passive impermeable “Teflon-like” lining, but are active cells, which respond to diverse blood- and tissue-derived stimuli. For example, in response to the repertoire of local cytokines and modified lipoprotein components, ECs synthesize and present molecules that regulate the recruitment of distinct leukocyte subpopulations to atherosclerotic lesions. Profound and diverse changes in EC phenotype in response to different cytokines have been referred to as *EC activation* (2). ECs also can respond to external mechanical forces, including hemodynamic forces of blood (3). This is probably why atherosclerotic lesions initially form at sites of arterial branches and curvatures. These regions have unique hemodynamics and EC gene expression patterns that influence signaling, the cellular composition of intimal cells, and responses to systemic risk factors for atherosclerosis.

This chapter focuses predominantly on the role of the endothelium in atherogenesis, particularly in early stages of the disease, because most mechanistic data are derived from animal models of early atherosclerosis. Insights from this field may lead to the development of novel therapeutic approaches

directed at EC biology and inflammation. These therapies, in conjunction with modification of lifestyle and therapies that target lipoprotein metabolism, hypertension, and hyperglycemia, may provide synergistic benefits to populations at risk, may alleviate or delay the progression of atherosclerotic lesions, and may reduce the incidence of morbidity and mortality associated with complications of advanced lesions.

## CLINICAL AND PATHOLOGICAL FEATURES OF ATHEROSCLEROSIS

Atherosclerosis is a disease of elastic and muscular arteries. It is the principal antecedent to myocardial infarction, stroke (cerebral infarction), claudication, and aneurysm formation (4). These complications generally occur in the setting of advanced atherosclerosis. Atherosclerosis develops indolently for decades prior to onset of those complications that lead to clinical manifestations. Progressive, chronic, and severe narrowing of the arterial lumen usually causes ischemia of tissues. The chronic nature of this process enables the formation of a collateral blood supply, which is promoted by tissue hypoxia. We now appreciate that infarctions usually result from sudden and complete occlusion of the vascular lumen by a thrombus associated with complications in an atherosclerotic plaque. Angiographic studies of coronary arteries have revealed that, prior to thrombosis, culprit plaques do not produce severe luminal narrowing, but may occasionally impinge into the vascular lumen (5). This is because atherosclerotic lesions are characteristically eccentric, in that they involve only part of the artery wall, which enables the uninvolved portion to undergo compensatory enlargement or outward remodeling and maintain a vascular lumen of a normal or near-normal diameter. Compensatory enlargement of atherosclerotic arteries was first described by Glagov (6), and is regulated by ECs. ECs sense changes in hemodynamic forces (shear stress) that result from alterations in the vascular lumen and institute complex biological programs that lead to normalization of the lumen size and shear stress (3). Outward arterial remodeling

masks the extent of atherosclerosis that is detected by angiography, and furthermore, this technique cannot identify lesions that are predisposed to thrombosis. Therefore, investigations are under way to determine if other vascular imaging modalities, such as intravascular ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET) scanning, can detect the structural or metabolic features of atherosclerotic lesions that predict their clinical outcome.

Atherosclerotic lesions, also referred to as *atheromas* and *plaques*, have a range of morphological features (7,8). Initially, the intima is involved, but as lesions grow with time, the underlying media becomes atrophic, with reduced vascular smooth muscle cells (VSMCs) and extracellular matrix (ECM). In some cases, mononuclear inflammatory cells infiltrate the arterial adventitia. Atherosclerotic lesions consist of vascular and inflammatory cells, ECM, lipids, cellular debris, calcification, or even ossification. The cellular component includes ECs lining the arterial lumen and neovasculature within lesions, VSMCs derived from the media or potentially from circulating progenitors, fibroblasts or myofibroblasts, monocyte/macrophages, lymphocytes (mostly T cells), and mast cells. Monocytes and lymphocytes are recruited to the arterial intima from the blood in early as well as advanced atherosclerotic lesions. In the intima, monocytes transform into macrophages, express scavenger receptors, and engulf modified lipids to become foam cells. Macrophages can proliferate in lesions. Smooth muscle cells and fibroblasts likely synthesize the bulk of ECM and form a band of dense collagen below the arterial endothelium, termed the *fibrous cap*, which likely provides structural support to plaques. The central core contains extracellular lipid droplets, is rich in macrophages, and may contain necrotic cell debris and large cholesterol clefts. The edges or shoulder regions often contain inflammatory cells and neovasculature, indicative of angiogenesis. Lesion morphology varies from those composed predominantly of collagen with or without calcification to those with a large necrotic core and thin fibrous cap. The pathogenesis of these distinct features in lesions is poorly understood.

Atherosclerotic lesion formation can be subdivided into initiation (development of small fatty streaks), expansion (vertical and lateral growth, as well as coalescence of small fatty streaks), development of a fibro-fatty plaque (intimal VSMC recruitment, collagen deposition and formation of a fibrous cap), and growth through organization of mural thrombi. Thrombosis is associated frequently with advanced atherosclerotic lesions and, in fact, may be an important mechanism for growth of plaques (5,9). The two major causes of thrombosis are plaque rupture and plaque erosion. Plaque rupture, also referred to as plaque fissuring and fibrous cap disruption, results in the formation of a defect or gap in the fibrous cap that separates the lipid-rich core from flowing blood. Plaque erosion refers to plaque thrombosis with EC loss, but absence of rupture in the fibrous cap. Human pathological studies determined that plaque rupture occurs in most cases, especially

in men. Ruptures and hemorrhages tend to occur in shoulder regions of lesions and are associated with inflammation, angiogenesis, a large necrotic core, and thin fibrous cap. The production of proteases (e.g., matrix metalloproteinases and cysteine proteases), oxygen radicals, vasoactive substances, and coagulation factors by activated immune cells, or tissue disruption resulting from hemorrhage originating from the neovasculature are potential mechanisms. Focal calcification within lesions also may provide a mechanical stimulus that predisposes to plaque rupture. Coronary artery thrombosis due to plaque erosion is less frequent than plaque rupture, tends to occur in women, and its pathogenesis is poorly understood. One possibility is that luminal ECs contribute to the initiation of thrombosis, but then migrate into the thrombus, resulting in the appearance of an erosion. Clinical data suggest that patients with unstable angina harbor multiple vulnerable plaques in more than one coronary artery (10) and that systemic factors in the setting of atherosclerosis predispose to thrombosis of multiple plaques and induce a condition termed *acute coronary syndrome* (5,9).

#### MURINE MODELS OF ATHEROSCLEROSIS

Significant insights into the pathogenesis of atherosclerosis have been gained from animal models, and most utilize hypercholesterolemia as the main stimulus for atherosclerotic lesion formation. Because hypercholesterolemia is only one of several major risk factors that have been identified in humans, animal models may not reflect the entire pathogenic spectrum of human atherosclerosis. Nevertheless, many important insights have been gained, especially from recently available murine models, in which embryonic stem cell and transgenic technologies have been used to alter the expression levels of various genes. The development of murine models defective in genes controlling lipid metabolism and lipoprotein expression offers valuable tools to dissect complex interactions between diet and genetics in atherosclerosis. Two models have been used predominantly – the apolipoprotein E knockout (*ApoE<sup>-/-</sup>*) (11,12), and the low-density lipoprotein (LDL) receptor knockout (*LDLR<sup>-/-</sup>*) (Table 132-1) (13). These hypercholesterolemic models develop atherosclerotic lesions throughout the arterial tree, and their distribution pattern and morphologic features share many similarities with human atherosclerosis, suggesting that similar pathogenic mechanisms may be involved (14–16). A significant difference in the *ApoE<sup>-/-</sup>* and *LDLR<sup>-/-</sup>* models is the degree of hypercholesterolemia and extent of atherosclerosis found when mice are fed regular chow-based diets without lipid additives. *ApoE<sup>-/-</sup>* mice fed a normal chow mouse diet develop hypercholesterolemia (predominantly elevated very low-density lipoprotein [VLDL]) and atherosclerotic lesions; however, if fed a “Western-type” diet (0.15% cholesterol, 21% fat), the hypercholesterolemia is enhanced, and lesions develop more rapidly (11,14). In contrast, *LDLR<sup>-/-</sup>* mice fed a normal chow diet have only a twofold elevation in plasma cholesterol (primarily

KO, knockout; SC, standard chow; WD, Western-type diet; mono, monocyte; m $\phi$ , macrophage; mLDL, oxidatively-modified LDL, MMTV, mouse mammary tumor virus; Tg, transgenic; BM Tx, bone marrow transplantation; WBC, white blood cell.

intermediate-density lipoprotein [IDL]/LDL fraction) (13) and do not develop lesions in the short term (16). When fed a cholesterol-rich diet, these mice develop marked hypercholesterolemia (elevated VLDL, IDL, and LDL associated with decreased high-density lipoprotein [HDL]) and lesions throughout the aorta. Because hypercholesterolemia and aortic lesion formation in *LDLR*<sup>-/-</sup> mice is dependent on initiating a hypercholesterolemic diet, the onset of lesion development can be precisely controlled, and these mice provide a unique opportunity for studying early events in atherogenesis.

## ENDOTHELIAL CELL ACTIVATION DURING ATHEROGENESIS

ECs form the interface between the blood and tissues and have important homeostatic functions, including maintenance of a nonadhesive and antithrombotic surface. Inflammatory cytokines, including interleukin (IL)-1 and tumor necrosis factor (TNF)- $\alpha$ , activate ECs and modulate their phenotype by inducing the expression of newly synthesized cell surface molecules. Inducible expression of EC adhesion molecules, such as E-selectin, P-selectin, vascular cell adhesion

molecule (VCAM)-1, and intercellular adhesion molecule (ICAM)-1, and chemokines that are secreted and presented on glycosaminoglycans, actively promotes leukocyte adhesive interactions. IL-1 and TNF- $\alpha$  also upregulate the expression of major histocompatibility (MHC) class I and tissue factor. In contrast, interferon (IFN)- $\gamma$  induces the expression of ICAM-1 and MHC class II, but not other adhesion molecules or MHC class I, and IL-4 selectively upregulates the expression of VCAM-1. These examples illustrate that different stimuli can induce unique activation of ECs, and can have profound influence on various endothelial properties, including cell adhesion, thromboresistance, cell shape, permselectivity, and immunological functions (2).

Studies of human atherosclerosis and experimental animal models have provided abundant evidence that hypercholesterolemia and associated infiltration and retention of LDL in the artery wall is an important pathogenic stimulus for the initiation and progression of atherosclerosis. LDL is retained in the intima through specific interaction with proteoglycans (17) and undergoes aggregation, oxidation, and/or enzymatic modification, which leads to the release of bioactive phospholipids that can activate ECs and incite an inflammatory response. This aspect of atherogenesis will not be reviewed here, and the reader is referred to several excellent reviews (18,19).

EC activation during atherogenesis was first observed during the early 1990s in hypercholesterolemic rabbit models (20). This study found that expression of a novel EC-leukocyte adhesion molecule, identified as VCAM-1, was upregulated selectively on ECs overlying early atherosclerotic lesions in the rabbit aorta. Expression of VCAM-1 by ECs was not observed in regions that were not involved by atherosclerotic lesions. These data suggested that the endothelium lining the arterial luminal surface actively regulates the adherence and recruitment of blood mononuclear leukocytes to the intima, which is one of the earliest events observed in atherogenesis and a necessary step for macrophage accumulation in the intima and transformation into foam cells.

Our laboratory and others compared the expression of VCAM-1, ICAM-1, and E-selectin in aortas in hypercholesterolemic rabbits, *LDLR*<sup>-/-</sup> and *ApoE*<sup>-/-</sup> mice (21,22). Northern blot analysis demonstrated increased *VCAM-1* and *ICAM-1*, but not *E-selectin*, steady-state mRNA levels in hypercholesterolemic mouse and rabbit aortas, which correlated with the extent of atherosclerotic lesion formation, as determined by staining intimal lipid deposits with oil red O (21). In small lesions, VCAM-1 and ICAM-1 were expressed predominantly by ECs, whereas in large foam cell-rich lesions, many intimal cells expressed these molecules. It is likely that expression by intimal cells accounted for increased *VCAM-1* and *ICAM-1* steady-state mRNA levels in Northern blots. VCAM-1 also was expressed by medial VSMCs adjacent to lesions. This phenotypic change may occur in activated VSMCs or cells in the process of migration to the intima.

Expression patterns of EC VCAM-1 and ICAM-1 were highly reproducible and similar in distribution among rab-

bits and *LDLR*<sup>-/-</sup> mice fed cholesterol-containing diets. EC expression was most pronounced at the periphery of both large and small lesions and extended several cells beyond the edge. VCAM-1 expression was essentially restricted to lesions, whereas ICAM-1 expression extended into the uninvolved aorta. These data suggest that adhesion molecule expression in atherosclerotic lesions of mice and rabbits may be under similar mechanistic control; however, the regulation of VCAM-1 expression is more tightly controlled than ICAM-1 by lesion-derived factors. We observed virtually identical VCAM-1 and ICAM-1 immunohistochemical staining patterns in *ApoE*<sup>-/-</sup> mice and Watanabe heritable hyperlipidemic rabbits fed standard laboratory chow, which indicates that hypercholesterolemia, and not other dietary factors, was responsible for upregulated VCAM-1 and ICAM-1 expression in lesions. The endothelium over central portions of rabbit, but not mouse, lesions frequently expressed VCAM-1. These observations on adhesion molecule expression patterns in atherosclerotic lesions are consistent with and extend previous observations in animal models (20,22–25).

In humans, several groups detected VCAM-1, ICAM-1, and E-selectin expression by immunohistochemical staining in advanced atherosclerotic plaques obtained at autopsy or from hearts of transplant recipients (26–31). ICAM-1 expression was found consistently in ECs over plaques and in intimal VSMCs and macrophages. As expected, the expression of E-selectin was restricted to vascular endothelium, but was variable among individuals. Caution should be exercised in interpreting these data, since the anti-E-selectin antibody used in these studies (BBA1 from British Biotechnology) has subsequently been shown to cross-react with P-selectin. Advanced human coronary artery plaques displayed focal VCAM-1 expression in luminal ECs, usually in association with inflammatory infiltrates. Focal endothelial VCAM-1 expression also was found in uninvolved vessels with diffuse intimal thickening. VCAM-1 was expressed by some smooth muscle cells and macrophages and by ECs of neovasculature at the base of plaques.

## THE CONTRIBUTION OF LEUKOCYTES TO THE FORMATION TO ATHEROSCLEROTIC LESIONS

The recruitment of both blood monocytes and lymphocytes to the arterial intima is critical to the formation of an atherosclerotic lesion. This process persists even in advanced lesions (18,19,32–35). Recruited monocytes transform into macrophages, express scavenger receptors, and engulf modified lipids to become intimal foam cells. Knockout of scavenger receptor-A and CD36, a class B scavenger receptor, reduced atherosclerosis in mice (36,37), although a recent study has not supported these data (38). Monocyte recruitment, particularly at the periphery of lesions, may contribute to their lateral growth. Monocytes and macrophage foam cells also may contribute to the progression of atherosclerotic lesions by producing cytokines and growth factors. In this process, cell

activation via Toll-like receptor signaling is likely an important step (39,40). Cytokines and growth factors, in turn, may amplify mononuclear leukocyte recruitment, induce migration of VSMCs into the intima, and stimulate cell replication. Because early fatty streaks are composed almost entirely of macrophage foam cells, the recruitment of monocytes to the intima may be a critical event in the initiation and expansion of these early atherosclerotic lesions.

The critical role of monocytes/macrophages in atherogenesis is highlighted by experiments using osteopetrotic (*op/op*) mice, which are deficient in macrophage colony stimulating factor (M-CSF or CSF-1) due to a point mutation in this gene. Binding of M-CSF to its receptor, *c-fms*, initiates many biological responses, including monocyte/macrophage chemotaxis, growth, survival, and expression of genes, including the class A scavenger receptor. *Op/op* mice have impaired production of blood monocytes and deficiency of peritoneal and tissue macrophages. A lack of osteoclasts accounts for osteopetrosis, and an inability for teeth to erupt impairs the consumption of solid food and requires feeding of a special liquid diet. Atherosclerosis studies were carried out in *op/op* mice bred into an atherosclerosis-susceptible background, and these mice had markedly reduced atherosclerotic lesions formation (41–43). One possibility for the marked reduction in lesions may have been because *op/op* mice have reduced numbers of circulating blood monocytes. However, a subsequent study demonstrated that even heterozygous (*op/+*) mice had dramatically reduced lesion size despite only a 20% reduction in circulating monocytes and absence of osteopetrosis (44). M-CSF influences many aspects of monocyte/macrophage biology, and we do not know what aspects of atherosclerotic lesion formation were impaired in *op/+* mice.

Lymphocytes also participate in atherogenesis. Recent studies provide convincing evidence for the role of the immune system in atherogenesis (9). Lymphocytes constitute only a small fraction of cells in atherosclerotic lesions, but perhaps their most important function is to regulate the local cytokine milieu and thus either promote or suppress lesion formation. CD4<sup>+</sup> Th1 cells are the predominant T-cell subtype in atherosclerotic lesions, and they respond to antigens presented in association with MHC class II by releasing proinflammatory cytokines that activate macrophages and ECs, including IFN- $\gamma$ , TNF- $\alpha$ , and lymphotoxin (45). CD4<sup>+</sup> T cells reactive to antigens that are present in lesions, such as oxidized LDL (oxLDL), heat shock protein 60, and *Chlamydia*, have been cloned from human atherosclerotic lesions (46–48). *ApoE*<sup>-/-</sup> mice deficient in the recombinase-activating gene 1 (*Rag-1*<sup>-/-</sup>) lack adaptive immunity and develop twofold less atherosclerosis when fed standard chow, but had lesions comparable to immunocompetent *ApoE*<sup>-/-</sup> mice when fed a Western-type diet (49). In the *LDLR*<sup>-/-</sup> background, lesion development in *Rag-1*<sup>-/-</sup> mice was reduced by 54% after 8 weeks of feeding a Western-type diet; however, significant differences in lesion area gradually subsided as the diet was continued for 12 and 16 weeks (50). *ApoE*<sup>-/-</sup> mice with severe combined immunodeficiency (SCID) developed 75%

less atherosclerosis, and reconstitution of these mice with CD4<sup>+</sup> T cells increased atherosclerosis (51). This proatherogenic activity may be exerted at least partly through secretion of the cytokine IFN- $\gamma$ , because mice deficient in IFN- $\gamma$  receptor, IFN- $\gamma$ , or the transcription factor T-bet, which that is required for Th1 differentiation, develop smaller atherosclerotic lesions (52–56). In contrast to proinflammatory cytokines, transforming growth factor (TGF)- $\beta$  and IL-10 are protective factors in atherogenesis (57–60) as are antibodies to oxLDL epitopes produced by B-1 B lymphocytes (61,62).

## FUNCTIONS OF ADHESION MOLECULES AND CHEMOKINES IN ATHEROSCLEROSIS

The activation of ECs during atherogenesis results in the expression of adhesion molecules and chemokines in atherosclerotic lesions. Although these molecules can influence many aspects of vascular biology, one of their key functions is the recruitment of leukocytes from blood into tissues. The process of leukocyte emigration from blood into tissues has been subdivided by many investigators into tethering, rolling, arrest, stable or firm adhesion, and transendothelial migration (TEM) (63,64). Tethering is the first adhesive interaction, which captures and slows the velocity of a leukocyte as it makes contact with the endothelial monolayer. Tethering and rolling are mediated by binding of E-, P-, or L-selectin to a ligand (e.g., sialyl-Lewis<sup>x</sup> [sLe<sup>x</sup>] on P-selectin glycoprotein ligand [PSGL]-1, a P-selectin ligand) or by low affinity  $\alpha 4\beta 1$  integrin (VLA-4, CD49d/CD29) binding to VCAM-1. Adhesive interactions that mediate rolling have rapid binding and release rates (high  $k_{on}$  and  $k_{off}$ ) (65,66). Arrest, firm adhesion, and TEM (also known as diapedesis) are mediated by leukocyte integrins, which bind to members of the immunoglobulin gene superfamily (e.g., VCAM-1 and ICAM-1). Rolling leukocytes are in close proximity to endothelium and are exposed to chemokines presented on the EC surface (67,68). Chemokine binding to receptors on leukocytes initiates signals that upregulates  $\beta 1$  and  $\beta 2$  integrin ligand-binding capability and allows them to interact with VCAM-1 and ICAM-1 (69–71). The recruitment of specific leukocyte types to a site of inflammation is determined by the repertoire of integrins and chemokine receptors expressed by different leukocytes and by the cytokines produced by the inflammatory response. Cytokines determine what adhesion molecules and chemokines are expressed by endothelium and produced in the inflammatory site. The details of how different adhesion molecules and chemokines mediate specific steps of leukocyte–EC adhesive interactions will not be reviewed, because a number of excellent reviews on this subject are available (63,64,72,73).

During the last two decades, many lines of transgenic mice bearing a deficiency of an adhesion molecule or chemokine have been developed, and the contribution of these adhesion molecules in atherogenesis has been investigated. These mice were backcrossed into the *ApoE*<sup>-/-</sup> or *LDLR*<sup>-/-</sup> background,

and the extent of atherosclerotic lesion formation was assessed by estimating the volume of lesions in the aortic root or determining the surface area of the aorta occupied by lesions. The histological features of lesions and their cellular composition also were determined.

P-selectin deficiency in the *LDLR*<sup>-/-</sup> background had a modest effect in male but not female mice (74), and the effect was greater in the *ApoE*<sup>-/-</sup> background (75–77). For example, at 4 months of age, in the *ApoE*<sup>-/-</sup> background, the P-selectin-deficient group had 3.5-fold smaller aortic sinus lesions than did the P-selectin wild-type group. In the P-selectin deficient group, lesions were limited to fatty streaks and contained fewer macrophages (76). By 15 months, progression to fibrous plaques was observed throughout the aorta in both groups, although lesions in the aortic sinus were smaller and less calcified in the P-selectin-deficient group. E-selectin deficiency had a relatively small effect on lesion formation in both males and females (75). Mice with combined P- and E-selectin deficiency had less lesion formation than *P-selectin*<sup>-/-</sup> mice alone (78). Platelets may also contribute to atherogenesis (77,79–81). P-selectin is involved in mediating the adhesion of activated platelets to ECs and leukocytes (81). The deposition of platelet chemokines onto endothelium (82) and soluble P-selectin, derived primarily from ECs, induces the formation of procoagulant microparticles (77).

Deficiency of VCAM-1 or  $\alpha 4$  integrin results in embryonic lethality (83–85). During embryogenesis, these molecules mediate the fusion of the allantois to the chorion. This is because VCAM-1 is normally expressed on the tip of the allantois, which subsequently forms the umbilical cord and the fetal vasculature of the placenta, whereas  $\alpha 4$  integrin is expressed on the chorion. The embryonic lethality of *VCAM-1*-null mice was circumvented by generating mice that express a mutant form of VCAM-1 at markedly reduced levels. Approximately 25% of these VCAM-1 domain 4-deficient (*VCAM-1 D4D*) mice were viable, which was sufficient for breeding them into the *LDLR*<sup>-/-</sup> background. Mice were fed a 1.25% cholesterol-enriched diet for 8 weeks. En face analysis of oil red O-stained aortas revealed reduced lesion area compared with *VCAM-1*<sup>+/+</sup> mice (86). *VCAM-1 D4D* mice were also bred into the *ApoE*<sup>-/-</sup> background, and lesion formation in the aortic root was quantified. These studies revealed a *VCAM-1* gene dosage effect on aortic root atherosclerotic lesions at 16 weeks of age. The aortic root lesion area was reduced by 84% and 56% in *VCAM-1*<sup>D4D/D4D</sup> and *VCAM-1*<sup>+/D4D</sup> mice, respectively, and lesions in *VCAM-1*<sup>D4D/D4D</sup> mice were limited to very small nascent fatty streaks (87). Together, these studies suggest that VCAM-1 has a critical role in atherogenesis. Similarly, its ligand, the  $\alpha 4$  integrin, should have an important function in atherosclerosis. This has been difficult to test, because mice deficient in  $\alpha 4$  integrin are not viable. However, data supporting this have been generated using infusion of  $\alpha 4$  integrin blocking peptide, which reduced lesion formation in mice (88). VCAM-1 and  $\alpha 4$  integrin were also key mediators of U937 cell rolling and adhesion in an ex vivo perfusion model of the carotid artery bifurcation harvested from *ApoE*<sup>-/-</sup> mice (89).

In contrast to VCAM-1, ICAM-1 appears to play a minor role in the formation of early atherosclerotic lesions. In experiments carried out in parallel with *VCAM-1 D4D* mice, ICAM-1-deficient mice in the *LDLR*<sup>-/-</sup> background had comparable lesion formation in the aorta to wild-type littermate controls (86). In the *ApoE*<sup>-/-</sup> background, deficiency of ICAM-1 reduced the extent of aortic lesions, but to a lesser degree than did P-selectin deficiency (75). Leukocyte CD11b expression was not essential for the development of atherosclerosis (90).

Members of the chemokine family play important roles in atherogenesis. Although many chemokines are likely involved, the discussion here focuses on primarily monocyte chemoattractant protein (MCP)-1 (or CCL2), fractalkine (CX3CL1), and their receptors, because they illustrate most of the key concepts. Many chemokines, including MCP-1 and fractalkine, are expressed in atherosclerotic lesions, both by ECs on the lesion surface and by cells deep within the lesion (91–93). Oxidized lipids have long been implicated as important mediators of atherosclerosis and foam cell formation (94), and minimally oxidized LDL, but not native LDL, induces MCP-1 production in vascular wall cells such as ECs and VSMCs (95). Chemokines thus emerged as a possible molecular link between oxidized lipoproteins and foam cell recruitment to the vessel wall. In addition to being produced in lesions, certain chemokines, such as regulated on activation, normal T-cell expressed and secreted (RANTES), can be deposited on ECs by circulating blood cells, including platelets (82).

Studies in transgenic mice overexpressing MCP-1 and mice in which either MCP-1 or CCR2 (its receptor) have been genetically deleted have provided strong evidence in support of this hypothesis. In bone marrow transplantation studies in mice, overexpression of MCP-1 in the blood vessel wall macrophages leads to increased foam cell formation and increased atherosclerosis (96). Similarly, deletion of MCP-1 in mice blocked the progression of dietary-induced atherosclerosis (97,98). CCR2 is the only known receptor for MCP-1, and deletion of CCR2 in mice afforded significant protection from both macrophage accumulation and atherosclerotic lesion formation in response to a high-fat diet (99,100). Finally, studies have shown that treatment of mice with an MCP-1 antagonist resulted in a reduction in dietary-induced atherosclerosis (101). A recent study suggests that CCR2 and MCP-1 regulate the release of a key monocyte subset from the bone marrow, and mice lacking these molecules have reduced numbers of circulating monocytes (102). Collectively, these studies provide evidence that activation of CCR2 by MCP-1 plays an important role in monocyte recruitment into early atherosclerotic lesions, and suggest that interruption of the MCP-1/CCR2 axis can reduce lesion formation.

The degree to which monocytes respond to MCP-1 is influenced by a number of factors, including the number of CCR2 cell surface receptors. Studies indicate that lipoproteins contribute to the regulation of CCR2 expression. Individuals with hypercholesterolemia have higher levels of CCR2 on their monocytes; CCR2 expression correlates positively with plasma LDL cholesterol levels and negatively with plasma HDL levels

(103,104). These findings suggest that high cholesterol levels may lead to increased sensitivity of monocytes/macrophages to MCP-1, thereby increasing the movement of blood monocytes into early atherosclerotic lesions.

The subsequent downregulation of CCR2, as monocytes differentiate into macrophages, might then serve to maintain macrophages in lesions. Oxidized lipids, which accumulate in early atherosclerotic lesions not only induce MCP-1 production, but also influence the level of CCR2 expression on monocytes. Unlike native LDL, which upregulates CCR2, oxidized lipids downregulate CCR2 (103). The mechanism for this downregulation may involve the binding and internalization of oxidized lipids by CD36, a scavenger receptor, and subsequent activation of the peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ), a member of the nuclear hormone receptor family. Indeed, purified components of oxidized lipids activate PPAR $\gamma$ . Rosiglitazone, a synthetic ligand that activates PPAR $\gamma$ , decreases CCR2 expression on monocytes (105). The systemic administration of rosiglitazone inhibits the development of atherosclerosis in mice, consistent with its effects on CCR2 expression (106). Further evidence for the importance of MCP-1/CCR2 in atherosclerosis comes from the observation that individuals who are homozygous for the -2518 G/G allele in the *MCP-1* regulator region – a change that leads to increased levels of *MCP-1* mRNA – have a higher incidence of coronary artery disease (107). Although provocative, this study included relatively small groups of patients, and the clinical relevance of this polymorphism must be verified in larger studies.

Fractalkine and its receptor also have been directly linked to the development of early atherosclerotic lesions. Fractalkine is the sole member of the CX3C family, and has unique structural and functional attributes (108,109). Most chemokines are secreted peptides, but fractalkine is a type-1 transmembrane protein with an N-terminal chemokine domain anchored to the cell membrane through a contiguous extended mucin-like stalk, transmembrane, and cytoplasmic domains. TNF- $\alpha$ -converting enzyme (also known as a disintegrin and metalloproteinase domain 17 [ADAM17]), can cleave the mucin stalk of fractalkine near the plasma membrane and release soluble chemokine (110,111). Fractalkine binding to its seven-transmembrane domain G-protein-coupled receptor triggers signaling, but also directly mediates cell adhesion (112). Full-length transmembrane fractalkine is an efficient cell adhesion molecule, and can capture cells expressing its cognate receptor (CX3CR1) under physiologically relevant flow conditions (113,114). CX3CR1 has two common coding polymorphisms, namely V249I and T280M, which are in strong linkage disequilibrium (almost always occurring on the same allele). These have been associated with interindividual differences in susceptibility to both human immunodeficiency virus (HIV) infection and atherosclerosis (115–117). The M280 polymorphism has been linked to a decrease in the incidence of coronary artery disease in humans, and exhibits lower fractalkine binding (117,118). Mice with genetic deficiency of CX3CR1 have been crossed into the *ApoE*<sup>-/-</sup> back-

ground and showed substantially smaller lesions throughout the aorta in dietary-induced atherosclerosis (119,120). *Fractalkine*-null mice crossed into the *ApoE*<sup>-/-</sup> and *LDLR*<sup>-/-</sup> backgrounds had more dramatic reduction in lesion area at the brachiocephalic artery than in the aortic root (121).

#### REGIONAL DIFFERENCES IN ENDOTHELIAL CELL GENE EXPRESSION, SIGNALING, AND COMPOSITION OF THE ARTERIAL INTIMA IN THE NORMAL AORTA

Atherosclerosis is precipitated and accelerated by systemic risk factors such as elevated cholesterol, acute phase proteins, high blood pressure, oxidation products from smoking, and high blood sugar and advanced glycation endproducts in diabetes. Although the entire arterial tree is exposed to these stimuli, atherosclerotic lesions form predictably at arterial curvatures, bifurcations, and branch points, which suggests that local factors contribute to disease susceptibility, and implicates the unique and complex patterns of blood flow (“disturbed” hemodynamics) that are found in these locations (3). The prevailing hypothesis is that disturbed hemodynamic forces predispose ECs to atherosclerosis, whereas uniform laminar shear stress, found in straight segments of arteries, is atheroprotective. Hemodynamic forces may influence EC shape, proliferation, gene expression, signal transduction and permeability, transport, and retention of lipoproteins in the intima.

Abundant data from in vitro studies suggest that hemodynamic forces have profound effects on EC biology. Different shear stress profiles can induce unique repertoires of gene expression (122–124). Shear stress alters the expression of adhesion molecules in cultured ECs (125,126), and uniform laminar shear reduces cytokine-induced expression of certain adhesion molecule (127). Elucidating the molecular mechanisms of how ECs sense shear stress and of how shear modulates EC gene expression remains an area of active investigation.

In vivo studies have also provided important insights into unique biological properties of endothelium prior to the formation of atherosclerotic lesions. Unlike regions with uniform laminar flow, in which ECs are elongated and uniformly oriented in the direction of flow, ECs in regions with disturbed flow have a polygonal shape or are elongated with the cell axis oriented in random directions. In animals with normal levels of plasma lipoproteins, ECs have unique gene expression profiles in regions of arteries predisposed and protected from atherosclerosis. Low levels of VCAM-1 and ICAM-1 are expressed in regions predisposed to atherosclerosis in normal rabbits and mice, although ICAM-1 expression in normal aortas is more extensive (21). Similarly, elevated expression of VCAM-1 and ICAM-1 was found in *ApoE*<sup>-/-</sup> mice at sites predisposed to atherosclerosis prior to the formation of lesions (22). Recently, gene profiling studies of porcine aortic endothelium revealed distinct gene expression patterns in a region of the arch that is predisposed to atherosclerosis (128).

Alterations in EC gene expression may affect signaling pathways. Previously, we demonstrated striking topographic variations in EC nuclear factor (NF)- $\kappa$ B signal transduction. NF- $\kappa$ B is a dimeric transcription factor that is retained in the cell cytoplasm by an inhibitor protein (I $\kappa$ B). Upon stimulation, I $\kappa$ B kinases (IKKs) phosphorylate I $\kappa$ Bs and target them for ubiquitination and degradation by proteasomes. NF- $\kappa$ B then translocates to the nucleus, where it transactivates gene expression. NF- $\kappa$ B induces the expression of numerous genes that are found in atherosclerotic lesions. We found that NF- $\kappa$ B was primed for activation in a region of the mouse ascending aorta with a high probability (HP) for developing atherosclerosis, compared to a low probability (LP) region (129). In mice with normal plasma lipoprotein levels, expression of NF- $\kappa$ B (p65) and I $\kappa$ Bs was significantly higher in the cytoplasm of HP region endothelium, but NF- $\kappa$ B activation (determined by nuclear translocation of p65) was present in only a minority of cells. When mice were exposed to systemic endotoxin or hypercholesterolemia, NF- $\kappa$ B activation and upregulated expression of NF- $\kappa$ B-responsive genes was found preferentially in the HP region. These data illustrate how a topographic difference in endothelial signaling mediates accentuated regional gene expression in response to systemic risk factors for atherosclerosis. These findings are supported by recent gene profiling studies of porcine aortic ECs, which found upregulated expression of NF- $\kappa$ B elements, without significant activation (predominantly cytoplasmic localization or p65), and several broad-acting inflammatory cytokines and receptors in a region with disturbed flow (128). This study also identified enhanced antioxidant gene expression, suggesting that increased oxidative stress may occur in regions of disturbed flow. This is intriguing in light of observations from the Lusis laboratory that EC responses to oxidized lipoproteins determine the genetic susceptibility of mice to atherosclerosis (130). It is likely that regional alterations in EC gene expression will influence signaling pathways other than just NF- $\kappa$ B. Furthermore, hemodynamic factors also may modulate endothelial signaling molecule functions by influencing post-translational modifications, such as phosphorylation.

Low-level expression of adhesion molecules and proinflammatory genes by arterial endothelium in normal animals may induce a low-grade inflammatory response and induce the recruitment of mononuclear leukocytes. In fact, intimal macrophages have been detected predominantly at lesion-predisposed sites in normal rabbit aortae (131) as well as in humans (132). Recently, we obtained data from wild-type mice with normal levels of plasma cholesterol indicating that monocytes/macrophages are prevalent in the intima of atherosclerosis-predisposed regions in the aorta. These monocytes are recruited from the blood, and some of them express dendritic cell markers. Furthermore, the abundance of aortic intimal macrophages directly correlates with the predisposition of various mouse strains for developing atherosclerosis when placed on an appropriate genetic background (133–135). In the setting of hypercholesterolemia, lipoproteins accumulate and are modified in the arterial intima, and

we propose that intimal macrophages, which are strategically located in these regions, become activated and secrete proinflammatory factors that initiate and amplify an inflammatory response. A better understanding of the milieu in which atherosclerotic lesion form and the factors that predispose certain regions to atherosclerosis may lead to novel therapeutic approaches directed at ECs and at mediators of inflammation that may alleviate or delay the progression of atherosclerosis.

#### KEY POINTS

- ECs regulate key aspects of atherogenesis ranging from the earliest stages to advanced lesions.
- ECs display a distinct phenotype in arterial regions predisposed to atherosclerosis.
- ECs regulate inflammation that occurs during atherogenesis by expressing adhesion molecules and presenting chemokines.
- Leukocytes play a critical role in the formation of atherosclerotic lesions and adhesion molecules, and chemokines are important mediators of leukocyte biology during atherogenesis.

#### Future Goals

- To elucidate the molecular mechanisms of how unique hemodynamic forces at arterial regions predisposed to atherosclerosis alter EC biology
- To develop new approaches to evaluate atherosclerotic lesion formation in murine models, such as surrogate markers and direct measurement of leukocyte recruitment into lesions, and use these to gain novel insights into the functions of adhesion molecules and chemokines

## The Hepatic Sinusoidal Endothelial Cell

Laurie D. DeLeve

*University of Southern California, Keck School of Medicine, Los Angeles*

The hepatic sinusoidal endothelial cell (EC) was not recognized as a highly differentiated cell type until the sinusoid was examined by perfusion fixation combined with electron microscopy, as described in Wisse's seminal papers in 1970 and 1972 (1,2). Our understanding of hepatic sinusoidal EC characteristics took an additional step forward with the first description of a method to isolate a highly pure population of these cells (3,4).

### MORPHOLOGY OF HEPATIC SINUSOIDAL ENDOTHELIAL CELL AND THE SINUSOID

The hepatic sinusoids (Figure 133.1) form the equivalent of a capillary system. The hepatic sinusoid lacks an organized basement membrane on the abluminal side of the hepatic sinusoidal ECs (SECs). The virtual space between the hepatic SECs and the hepatocytes is called the space of Disse. The space of Disse contains loosely organized extracellular matrix and resident pericytes that surround the hepatic SECs, the so-called *stellate cells*. Stellate cells are vitamin A-storing cells. In addition, they are contractile and thus capable of regulating sinusoidal diameter. On the luminal side of the hepatic sinusoidal endothelium are the resident macrophages, the Kupffer cells. When measured *in vivo* by light microscopy, the diameter of the hepatic sinusoid ranges from 6 to 7  $\mu\text{m}$ , increasing slightly from the periportal to the centrilobular area. Sinusoids are smaller than neutrophils, which measure approximately 8.5  $\mu\text{m}$ . It has been hypothesized that, because leukocytes are larger than the sinusoids, the entry of leukocytes into the sinusoid compresses the space of Disse and forces fluid out through fenestrations within hepatic SECs (discussed later), whereas with passage of the leukocyte back out of the sinusoid the space of Disse will restore the original shape and cause suction of fresh fluid back into the space (*forced sieving*). In addition, the compression of the sinusoidal cells by the leukocytes is postulated to promote mixing of the fluid within the space of Disse (*endothelial massage*) (5).

Microvascular endothelium may be classified according to whether the cell layer is continuous, discontinuous, or fen-

estrated; and whether it possesses an organized basement membrane on the abluminal surface. In continuous endothelium (e.g., capillaries in skin, lung, central nervous system [CNS], and muscle), the cytoplasm is continuous and the cells are connected by tight junctions (6). With the exception of the blood-brain barrier, continuous endothelium contains abundant caveolae. Discontinuous ECs have gaps between or within cells. Fenestrated ECs (e.g., capillaries of exocrine and endocrine glands, intestinal mucosa, choroid plexus, and glomeruli) form a subset of discontinuous endothelium in which ECs possess round openings or pores that transverse the body of the cell, connecting the luminal and abluminal surfaces. Hepatic SECs have fenestrations. The fenestrae are supported by a cytoskeletal ring made up of actin and myosin; they are therefore dynamic structures that can contract or dilate (7).

Endothelial fenestrae are further classified according to whether they possess a diaphragm or are open. Examples of ECs with fenestrae subtended by diaphragms are those cells in the renal peritubular capillaries and ascending vasa recta; capillaries of intestinal villi, pancreas, adrenal cortex, and endocrine glands; choriocapillaries of the brain and eye (8); and the bone marrow sinusoid (9). In mammals, only the hepatic SECs and glomerular ECs have nondiaphragmed (open) fenestrae. However, glomerular ECs have an organized basement membrane, whereas SECs do not. Thus, the phenotype of hepatic SECs is unique among all endothelium in that it is characterized by open fenestrae in the absence of an organized basement membrane. Hepatic SEC fenestrae are between 150 to 175 nm, as visualized by transmission electron microscopy or 105 to 110 nm, as ascertained by scanning electron microscopy, with somewhat larger fenestrae in the periportal region than in the centrilobular region of the liver lobule (5). As with other fenestrated ECs, the fenestrae are organized in clusters called *sieve plates*.

The term *sinusoidal* refers to capillaries that are tortuous and in intimate contact with underlying parenchymal cells. In mammals, three types of sinusoidal ECs exist: those in the bone marrow, liver, and spleen. In each case, the endothelium is discontinuous. Splenic SECs are rod-shaped cells running parallel to the longitudinal axis of the sinus and having

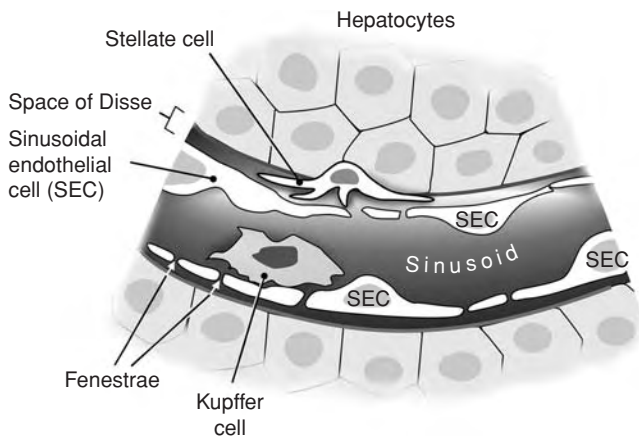

Figure 133.1. Schematic of the hepatic sinusoid.

continuous cytoplasm. The basement membrane of splenic SECs is ring-like and runs transverse to the ECs (10–12). Bone marrow SECs possess fenestrae with a diaphragm and an underlying basement membrane. The passage of red cells through the walls of the splenic and bone marrow sinus occurs through interendothelial slits that appear when cells migrate through the wall. In the remainder of the chapter, the abbreviation SEC will be used to refer to hepatic SEC.

#### CELL–CELL CROSS-TALK BETWEEN SINUSOIDAL ENDOTHELIAL CELLS AND OTHER CELL TYPES IN THE LIVER

The unique SEC phenotype depends on their proximity to other liver cells (13). Vascular endothelial growth factor (VEGF) is one of the major growth factors responsible for fenestration of ECs (14), a key feature of SECs. Paracrine secretion of VEGF by adjacent hepatocytes and stellate cells is essential to maintain the normal SEC phenotype (15). VEGF stimulates nitric oxide (NO) production by endothelial NO synthase (eNOS) in ECs (16–19), and autocrine production of NO is an essential regulator of SEC properties (15). However, high constitutive expression of VEGF by neighboring epithelial cells is also characteristic of other types of fenestrated endothelium, including the glomerulus and choroid plexus, which are morphologically and functionally distinct (20). Thus, in the liver, additional microenvironmentally derived paracrine factors are likely to contribute to the maintenance of this unique SEC phenotype.

Hepatocytes and stellate cells are necessary to maintain a normal SEC phenotype. Conversely, SECs play a critical role in postinjury liver regeneration and hepatic morphogenesis during development. For example, during liver regeneration, SECs are indispensable for promoting hepatocyte growth in a complex, interdependent process driven by paracrine mediators secreted by SECs, hepatocytes, and perhaps other types of liver cells (21–25). The mediators best characterized in the regulation of liver regeneration are hepatocyte growth factor

(HGF) secreted by SECs (21), and VEGF secreted by hepatocytes (22,25,26), but other growth factors are also involved (23,24). Analogous to the critical role played by SECs in liver regeneration, hepatic ECs are also essential for liver organogenesis (27,28). Both vasculogenic ECs and nascent vessels are needed for the earliest stages of hepatic morphogenesis, prior to the development of functional blood vessels (27).

#### FUNCTIONAL CONSEQUENCES OF SINUSOIDAL ENDOTHELIAL CELL PHENOTYPE

##### Oxygen Delivery

The liver (like the lung) receives a dual blood supply. The hepatic artery – which branches off the abdominal aorta – delivers oxygen ( $O_2$ ) to the various cells of the liver, whereas the portal vein delivers poorly oxygenated, nutrient-rich blood from the intestines. Both the hepatic artery and portal vein drain into the hepatic sinusoids. The admixture of arterial and venous blood results in a lower-than-normal capillary  $PO_2$ . According to Fick's law of diffusion,  $O_2$  delivery is proportional to the  $O_2$  gradient from blood to tissue and surface area, and inversely correlated with the distance. Although the  $PO_2$  (hence  $O_2$ ) gradient is reduced, the unique properties of the sinusoid serve to optimize the other variables of the equation. For example, the presence of thin cytoplasm, open fenestrae, and the lack of an organized basement membrane reduce the distance that  $O_2$  must diffuse. Moreover, the flattened SECs cover an extremely large surface area. The importance of these adaptations is apparent in liver disease, in which the loss of SEC fenestration and the formation of an organized basement membrane (a process termed *capillarization*) lead to reduced oxygenation of hepatocytes (see the section on Capillarization and Pseudocapillarization).

##### Sieve Function

Because the fenestrae of SECs do not have diaphragms, and because no organized basement membrane exists, SECs are able to filter fluids, solutes and particles, chylomicron remnants and other lipoproteins, and protein-bound drugs. As a result, plasma constituents gain ready access to the space of Disse, where they may be taken up by the hepatocytes. Two examples of sieve function are discussed here: chylomicron trafficking and filtering of protein-bound drugs.

Dietary lipids are assembled with specific apolipoproteins to form chylomicrons, the largest circulating lipoproteins (>100 nm diameter). Chylomicrons are metabolized by endothelial lipoprotein lipase in the systemic circulation to form chylomicron remnants. In the liver circulation, chylomicron remnants less than 100 nm pass through the open fenestrae into the space of Disse (29–31). The role of the liver in clearance of chylomicron remnants is confirmed by the accumulation of chylomicron remnants in the blood after functional hepatectomy (32). The sieve function of SECs was demonstrated by studies using transmission electron

microscopy, which showed the size differential of chylomicron remnants in sinusoidal blood versus those in the space of Disse (29–31).

Freer access of hepatocytes to plasma is also important for drug metabolism. For high-clearance drugs, unbound drug is taken up by hepatocytes, the bound and unbound fractions re-equilibrate, and additional unbound drug is taken up during a single pass through the liver. Thus, fenestration allows the amount of drug taken up by the liver to exceed the unbound fraction present in the afferent circulation.

### Scavenger Function and Immunity

SECs and Kupffer cells are the two hepatic members of the reticuloendothelial system. SECs play an important role in innate immunity. SECs act as scavenger cells, clearing circulating waste macromolecules and antigens. Several properties of the sinusoid suggest that they are uniquely suited to this task (33). First, SECs and Kupffer cells are in intimate contact with one another on the luminal side of the endothelium, and act as “sentinels” for gut- and portal vein–derived macromolecules and antigens. Second, SECs present a broad surface area to circulating blood. Third, sinusoidal flow is slow and intermittent, particularly in the periportal region (where the portal vein branches enter the lobule), prolonging contact time between macromolecules and SECs (34). Fourth, SECs have an active endocytotic apparatus with numerous coated pits and vesicles. The coated pits have exposed cationic residues that facilitate the specific endocytosis of negatively charged molecules taken up by receptor-mediated endocytosis. The specific activity of several lysosomal enzymes is as high or higher in SECs compared with Kupffer cells, and much higher than in hepatocytes, which permits active degradation of the endocytosed macromolecules. Finally, several receptors are present that allow SECs to eliminate an array of ligands by receptor-mediated endocytosis.

At least five types of specific receptors for endocytosis are present on mammalian SECs, and these are responsible for eliminating soluble waste macromolecules from the circulation. These include the: (a) hyaluronan receptor, (b) mannose receptor, (c) collagen  $\alpha$ -chain receptor, (d) Fc- $\gamma$  receptor, and (e) scavenger receptor (Table 133-1) (35). The macromolecules cleared by receptor-mediated endocytosis include physiological waste, such as major matrix molecules and cellular constituents, such as lysosomal enzymes; pathophysiological ligands, such as advanced glycation end products (AGEs) and oxidized low-density lipoprotein (LDL); and exogenous soluble ligands. Although SECs endocytose this colloidal and macromolecular waste, Kupffer cells phagocytose insoluble, or particulate, waste products (35). Clearance of soluble and particulate waste products by the hepatic cells of the reticuloendothelial system contributes significantly to the innate immune system.

SECs do not constitutively express E- or P-selectin; the literature is contradictory as to whether E- or P-selectin is expressed in response to activation. Intercellular adhe-

**Table 133-1: Receptor-Mediated Endocytosis of SECs**

<i>Specific Receptors</i>	<i>Ligands</i>
Hyaluronan receptor	Matrix polysaccharides and proteoglycans (e.g., hyaluronan, dermatan sulfate and chondroitin sulfates)
Collagen $\alpha$ -chain receptor	Collagen $\alpha$ -chains of several types of collagen
Scavenger receptor	Amino-terminal propeptides of types I and III procollagen AGEs Oxidized LDL Oligodeoxynucleotides Modified blood proteins
Mannose receptor	Carboxy-terminal propeptide of type I procollagen Tissue-type plasminogen activator
Fc- $\gamma$ receptor	IgG-antigen immune complexes

sion molecule (ICAM)-1 (CD54) and lymphocyte function-associated (LFA)-3 (CD58) are constitutively expressed on SECs, and ICAM-1 is further upregulated upon exposure to inflammatory cytokines. Vascular cell adhesion molecule (VCAM)-1 (CD106) is not constitutively expressed (36–41), but is induced by inflammatory mediators. Although normal SECs express platelet-endothelial cell adhesion molecule (PECAM)-1 (CD31), an adhesion molecule on the cell-cell borders of ECs needed for transendothelial migration, PECAM-1 is expressed intracellularly and not on the SEC surface (15,39).

SECs may present antigen to CD4<sup>+</sup> and CD8<sup>+</sup> T cells. In keeping with its antigen-presenting role, SECs have been shown to express major histocompatibility (MHC) class I and class II molecules, and the costimulatory molecules CD80, CD86 (42), and CD40 (43,44). Based on the anatomical and infrastructural properties outlined earlier, the sinusoids are ideally situated for eliminating gut-derived pathogenic organisms. In addition to removing pathogens from the circulation, SECs contribute to the induction of tolerance by presenting MHC class II restricted antigens to naïve CD4<sup>+</sup> T cells. This process inhibits the expansion of interferon (IFN)- $\gamma$ -producing Th1 type CD4<sup>+</sup> effector cells (proinflammatory) and promotes the outgrowth of interleukin (IL)-4/IL-10-expressing Th2 type CD4<sup>+</sup> effector cells (antiinflammatory) (45). SECs also cross-present soluble antigens on MHC class I molecules, such as food antigens or self-proteins to CD8<sup>+</sup> T cells, resulting in the induction of hepatic immune tolerance (46). The ability of SECs to induce tolerance contrasts

with myeloid antigen-presenting cells, which typically induce protective immunity when cross-presenting antigens to CD8<sup>+</sup> T cells. The propensity for induction of tolerance occurs under the influence of immunosuppressive mediators normally present in the hepatic microenvironment, including IL-10, prostaglandin E<sub>2</sub>, and transforming growth factor (TGF)- $\beta$  (43). The induction of peripheral immune tolerance by the liver permits allogeneic liver transplantation despite MHC incompatibility, leads to immune tolerance of antigens present in the portal circulation, and results in increased acceptance of grafts when the venous drainage is routed into the portal vein (44). Hepatocytes metabolize numerous xenobiotics and are at high risk of immune attack against neoantigens formed on the cell surface by protein adducts of highly reactive metabolites formed by the hepatocyte. It has been speculated that the SEC barrier protects hepatocytes from immune attack by inducing tolerance to such neoantigens (44).

### CAPILLARIZATION AND PSEUDOCAPILLARIZATION

Liver disease and aging are associated with altered SEC phenotype. In experimental animals and in humans, liver fibrosis (a consequence of many disease states) is preceded by the loss of fenestration and the formation of a fully organized basement membrane, a process termed *capillarization* (47–51). In aged experimental animals and in humans over age 40, a similar albeit less severe process occurs (termed *pseudocapillarization*), in which there is decrease or loss of fenestration and partial formation of a basement membrane (52,53).

As noted earlier, the porosity of SECs is critical for O<sub>2</sub> transfer to hepatocytes and clearance of fluids and solutes, including protein-bound drugs and waste products. Thus, capillarization and pseudocapillarization would be predicted to diminish hepatocyte function. Indeed, capillarization in the cirrhotic liver leads to reduced O<sub>2</sub> delivery to underlying hepatocytes (52), resulting in impaired O<sub>2</sub>-dependent hepatocellular functions such as oxidative drug metabolism (54–56). Similarly, pseudocapillarization in the aged rat is associated with a decline in high-energy phosphate and other metabolites, consistent with hepatocyte hypoxia (52). It has been suggested that pseudocapillarization impairs the clearance of chylomicron remnants by the liver, and that this effect may contribute to age-related atherosclerosis (5,57,58). Pseudocapillarization also may help to explain the well-established association between aging and reduced drug metabolism, both by limiting clearance of high-clearance protein-bound drugs and by decreasing O<sub>2</sub> delivery required for oxidative drug metabolism (e.g., P450 metabolism).

With capillarization, a change also occurs in receptors and adhesion molecules on the surface of SECs. SECs are the major cell type responsible for removing glycosaminoglycans from the blood. One measure of cirrhosis is increased serum hyaluronan, which reflects increased production by stellate cells and decreased clearance by SECs (59,60–62). The major

receptor for hyaluronan clearance is the hyaluronan receptor for endocytosis (HARE) (63,64). Given that hyaluronan clearance is decreased in cirrhosis, one might predict capillarization to be associated with reduced SEC expression of HARE. However, this has not yet been documented. Lymphatic vessel endothelial receptor (LYVE)-1, a hyaluronan receptor typically associated with lymphatic ECs, is also present on normal SECs (65). Although LYVE-1 is decreased on SECs in cirrhosis (65), LYVE-1 seems to play a minor role in hyaluronan clearance by SECs (64).

As discussed earlier, PECAM-1 is normally present in the cytoplasm of SECs, but not on the cell–cell border. Interestingly, capillarization is associated with localization of PECAM-1 at the intercellular junction (15,39,66). It remains to be established what impact this redistribution of PECAM-1 has on SEC function.

As a final example of capillarization-mediated effects on SEC receptors, the laminin receptors,  $\alpha 6\beta 1$  and  $\alpha 2\beta 1$ , are induced with capillarization and colocalize with increased laminin deposits along the sinusoids (66).

### DRUG-INDUCED TOXICITY TO SINUSOIDAL ENDOTHELIAL CELLS

Several factors render SECs particularly vulnerable to drug-induced injury. First, because orally ingested drugs gain entry to the systemic circulation via the portal vein, SECs are exposed to higher blood levels of the drug compared with other parts of the circulation. Second, SECs display significant P450 activity and can therefore readily metabolize blood-borne drugs (in some cases to more toxic intermediates) (67–69). Finally, in the process of metabolizing drugs, hepatocytes release toxic metabolites into the space of Disse, creating a concentration gradient between the hepatocyte and the lumen of the sinusoid. Given the close proximity between SECs and hepatocytes, and the lack of an intervening organized basement membrane, SECs are exposed to high levels of hepatocyte-derived toxins. This fact may explain why mild drug toxicity preferentially targets SECs, whereas more marked toxic insults are required for damage to hepatic venular ECs and other vascular beds.

Forms of toxic liver injury that may be initiated by damage to SECs include sinusoidal obstruction syndrome (SOS; also known as veno-occlusive disease), nodular regenerative hyperplasia (NRH), sinusoidal dilatation, and peliosis hepatis. All four of these diseases are characterized by damage to SECs and/or hepatic venular ECs. A number of drugs have been linked to the development of at least two of these lesions. Indeed, in some cases, a single drug has been implicated in the development of all four lesions in the same liver. Among the most common drugs that lead to SEC toxicity are azathioprine (all four lesions), 6-thioguanine (peliosis hepatis, NRH, SOS), urethane (peliosis hepatis, SOS), thorotrast (peliosis hepatis, NRH), oral contraceptives (sinusoidal dilatation, peliosis hepatis, and NRH), and anabolic steroids (peliosis hepatis, NRH) (70–73).

## SINUSOIDAL OBSTRUCTION SYNDROME

### Overview

This syndrome was originally called *hepatic veno-occlusive disease*, because the most obvious lesions, as detected by light microscopy, are located in the central veins (74). The first description of SOS in humans came from South Africa, in individuals who had ingested bread made from inadequately winnowed wheat contaminated by plants containing pyrrolizidine alkaloids (75). In non-Western nations, SOS is still seen in individuals who ingest pyrrolizidine alkaloids, either in the form of “bush teas” or as contaminants of the food supply. The major plant species implicated are the pyrrolizidine alkaloids *Crotalaria*, *Heliotropium*, and *Senecio*. In North America and Western Europe, SOS occurs sporadically as a complication of chemotherapy for malignancy or of long-term immunosuppression by azathioprine for kidney and liver transplantation (71,76–80). The chemotherapeutic drugs most clearly associated with SOS at conventional doses are gemtuzumab, ozogamicin, actinomycin D, dacarbazine, cytosine arabinoside, mitramycin, 6-thioguanine, and urethane (73,81,82). Treatment of Wilms tumors, and in particular right-sided Wilms tumors, with actinomycin D plus abdominal irradiation is a greater risk factor for SOS than actinomycin D alone (83,84). The most common cause of SOS in Western nations is the myeloablative conditioning therapy used prior to bone marrow transplantation for malignancy. The incidence of SOS in patients undergoing myeloablative conditioning regimens varies from 0% to 50% (85–90). The wide range in incidence in different transplant centers is due to differences in patient selection criteria and differences in conditioning regimens. Chemotherapy regimens that include cyclophosphamide and radiation regimens using higher doses of total body irradiation carry a greater risk for developing SOS. Case fatality rates also varies widely, ranging from 0% to 67%, likely due to differences in diagnostic criteria. In regimens containing cyclophosphamide, the case fatality rate is approximately 30%, and this may be higher than for regimens without cyclophosphamide (85,89,91). The diagnosis usually is made based on the clinical features of painful hepatomegaly, weight gain, and hyperbilirubinemia (86,88). The clinical features of SOS have recently been reviewed in detail (92).

### Mechanisms of Sinusoidal Obstruction Syndrome

The clinical presentation of SOS is consistent with a vascular origin of disease. In other intrinsic liver diseases, portal hypertension due to circulatory disruption is a consequence of liver function abnormalities. In contrast, in SOS, ascites due to portal hypertension precedes abnormalities in liver function. Based on the light microscopy findings of venous occlusion, it was assumed for many years that the central vein was the primary culprit in this syndrome. However, clinico-pathological correlative studies have demonstrated that involvement of the central veins is not essential for the development of SOS (93).

Indeed, studies in an experimental model of SOS suggest that the disease is initiated by changes within the sinusoid (discussed later). Based on the clinical and experimental studies that support the sinusoidal origin of the disease, it was proposed to change the name from hepatic veno-occlusive disease to SOS (92). This name change also serves to distinguish SOS from other forms of liver disease, characterized by occlusions of the hepatic vein, that are referred to as hepatic veno-occlusive disease. These include radiation-induced liver disease and post-liver transplantation occlusion of hepatic veins. Although changes in the sinusoid may be critical for initiating SOS and for mediating the clinical phenotype, the central veins are frequently involved in more severe disease (93). This suggests that the more marked the insult, the more extensive the involvement of distant endothelium.

### In Vitro Studies

When SECs are isolated by centrifugal elutriation, yields are approximately  $80 \times 10^6$  cells per rat liver and approximately 10 to  $12 \times 10^6$  per mouse liver, with 98% purity or better and 99% viability or better (15). SECs isolated by this method have the characteristic features of fenestrae grouped in sieve plates at the time of isolation. A number of methods are currently in use to isolate SECs, and it remains to be determined whether these disparate methods are isolating the same populations of cells (94).

A variety of drugs and toxins implicated in SOS have been studied in SEC cultures. A common feature of these compounds is that they are more toxic to SECs compared with hepatocytes, and they are detoxified by glutathione (GSH). The following is a brief review of the factors that determine selective toxicity to SECs, as demonstrated by in vitro studies.

Monocrotaline, a pyrrolizidine alkaloid found in so-called “bush teas,” is one of the best-characterized toxins that cause SOS in humans. Monocrotaline is converted by P450 to the electrophilic metabolite, monocrotaline pyrrole, and this activation occurs only in the liver. Monocrotaline pyrrole formed in SECs is detoxified by SEC GSH. Thus, when formed in excess, it may lead to profound GSH depletion. Depletion of GSH stores precedes SEC cell death in vitro. Moreover, GSH precursors that prevent monocrotaline-pyrrole-mediated depletion of GSH in SECs prevent cell death (95). Monocrotaline is more toxic to SECs than to hepatocytes, and depletion of hepatocyte GSH does not exacerbate hepatocyte toxicity (95). Taken together, these data suggest that selective toxicity to SECs is related to the formation of monocrotaline pyrrole. Monocrotaline pyrrole formed by SECs and secreted into the sinusoidal lumen is transported by red blood cells to the lung and leads to lung toxicity.

Similar to monocrotaline, dacarbazine also is activated by P450 in a liver-dependent manner. Dacarbazine is toxic to SECs, but not to hepatocytes. Dacarbazine is detoxified by GSH, but GSH depletion does not render hepatocytes susceptible to toxicity (69). Thus, as with monocrotaline, these findings suggest that the selective toxicity to SECs is related to metabolic activation of the drug.

Cyclophosphamide is employed in certain myeloablative regimens in bone marrow transplantation, and is the chemotherapeutic drug most frequently associated with SOS in this setting. Cyclophosphamide is converted by P450 to 4-hydroxycyclophosphamide, which then spontaneously tautomerizes to acrolein and phosphoramidate mustard. P450-mediated activation of cyclophosphamide takes place in hepatocytes, but not SECs. Thus, cyclophosphamide is not directly toxic to primary cultures of SECs. However, in coculture studies of SECs with hepatocytes, cyclophosphamide is metabolized by hepatocytes, and the resulting metabolite (namely acrolein) exerts paracrine-mediated toxicity to SECs. Importantly, the toxicity to SECs occurs with cyclophosphamide levels in the therapeutic range, whereas much higher doses are required to damage hepatocytes (96). The differential sensitivity of SECs and hepatocytes to acrolein may be explained by differences in the GSH detoxification capacity of these two cell types (GSH is preferentially depleted in SECs). The selective susceptibility of SECs *in vivo* – as distinct from other ECs – is likely due to high concentrations of the metabolite in the space of Disse.

Azathioprine is a prodrug. Conjugation to glutathione, catalyzed by glutathione S-transferase, yields 6-mercaptipurine, and consumes cellular glutathione. Cells rapidly take up azathioprine, so that concentrations of orally ingested azathioprine are highest in the gut and in the liver. *In vitro* studies have demonstrated that profound GSH depletion precedes azathioprine-induced cell death in SECs, which suggests that GSH depletion plays a role in toxicity to SECs (95). Toxicity to SECs is greater than to hepatocytes *in vitro*. However, depletion of hepatocyte GSH increases toxicity and abolishes the difference in susceptibility, demonstrating that the relative resistance of hepatocytes is due to greater GSH detoxification capacity by hepatocytes. 6-Thioguanine, a metabolite downstream of 6-mercaptipurine, also causes SOS, so that the mechanism of injury might involve more than the GSH depletion that occurs when azathioprine is metabolized to 6-mercaptipurine; however it has never been examined whether 6-thioguanine might also deplete GSH through another mechanism.

In summary, *in vitro* studies have demonstrated common features among toxins implicated in SOS. The drugs and toxins studied in the *in vitro* model are selectively more toxic to SECs than to hepatocytes, they are GSH detoxified, and toxicity to SECs *in vitro* does not occur until SEC GSH is depleted.

### *In Vivo Studies*

The development of a reproducible animal model of SOS has facilitated uncovering the morphological changes and the biochemical underpinnings of this syndrome (Figure 133.3). The monocrotaline rat model follows a highly reproducible course when the toxin is given by gavage in Sprague-Dawley rats, but shows tremendous variability when administered by another route or to another strain of rats. The time-course of events can be divided into pre-SOS (0–48 hours after monocrotaline), early SOS (days 3–5), and late SOS (days 6 and 7) (97).

In pre-SOS, light microscopic changes are minimal, and clinical features are absent. However, morphological changes can be detected within the first 12 hours by scanning electron microscopy, transmission electron microscopy, and *in vivo* microscopy. At 12 hours, there occurs a loss of SEC fenestration, formation of gaps within and between SECs, and swelling or rounding up of SECs. By 48 hours, red blood cells penetrate beneath the swollen cells into the space of Disse (98). The swollen SECs block the sinusoids, the space of Disse becomes the path of least resistance, and blood begins to flow in the space of Disse, with dissection of the sinusoidal lining. Kupffer cells, SECs, and stellate cells embolize into the lumen of the sinusoid and further block sinusoidal flow.

In early SOS, between days 3 and 5, the predominant histological features are centrilobular necrosis and hemorrhage, with loss of SECs and venular ECs (see Figure 133.2). The clinical manifestations are similar to those described in the human syndrome, namely hepatomegaly with a 24% to 80% increase in liver weight, ascites formation, and hyperbilirubinemia with bilirubin levels as high as 10 mg/dL.

In late SOS (days 6 and 7), the centrilobular necrosis resolves completely, but there is venular fibrosis and persistent damage to SECs and venular ECs with hemorrhage.

The number of perfused sinusoids reaches a nadir by day 4 and remains decreased through day 10. Kupffer cells decrease in number by day 1, but there is a progressive influx of blood-derived mononuclear cells adherent to areas denuded of SECs and venular ECs, and these aggregates of mononuclear cells contribute to the sinusoidal obstruction by day 4.

The pathophysiology of pre-SOS involves two important (and related) biochemical events: (a) altered SEC expression of matrix metalloproteinases (MMPs), and (b) changes in SEC actin cytoskeleton. Each of these mechanisms represents a potential target for preventative therapy.

MMPs are enzymes that break down extracellular matrix and allow cells to separate from the underlying matrix. Hepatic MMP-9 expression and activity is increased 12 hours after monocrotaline administration, increases markedly by 48 hours, and then continues to rise through day 4 (99). The increase in MMP-2 in the liver is delayed, and the magnitude of the elevation is much less than MMP-9. *In vitro* studies of SECs, hepatocytes, stellate cells, and Kupffer cells reveal that SECs are the major source of both basal and monocrotaline-induced MMP-9 and -2 activity (99). The increase in MMPs coincides with the progressive denudation of the sinusoidal lining, suggesting that increased MMP activity may cause the dehiscence of the SECs from the space of Disse. Prophylactic administration of inhibitors of MMP-9 and -2 prevents the histological changes and the clinical features of SOS, which confirms the causal role of MMPs in the disease (99).

The reactive metabolite of monocrotaline, monocrotaline pyrrole, binds covalently to F-actin in ECs, leading to its depolymerization (99,100). This process may contribute to the rounding up of SECs, which is the earliest morphological change observed by *in vivo* microscopy (98). Blockade of monocrotaline-induced F-actin depolymerization in SECs

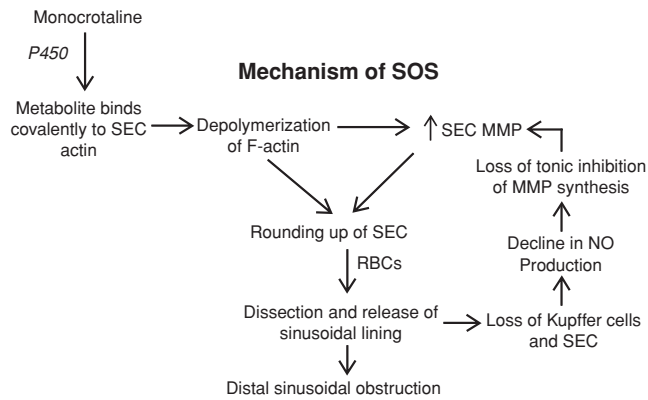

Figure 133.2. Proposed mechanisms in SOS. This scheme depicts the morphological and biochemical changes observed in the monocrotaline model of SOS. MMP, matrix metalloproteinase; NO, nitric oxide; RBC, red blood cell; SEC, sinusoidal ECs.

prevents the increase in MMP activity (99). The link between F-actin disassembly and increased MMP activity also has been observed in other models (101–103). Thus, the combined effects of F-actin depolymerization on cell shape and MMP expression, which allows SECs to be released from the underlying matrix, may lead to penetration of red blood cells beneath the endothelial barrier and dissection of endothelium off the matrix in the space of Disse.

After monocrotaline administration, hepatic vein NO levels decrease on day 1, drop by 70% on day 3, and remain low through day 8. The decline in the first 24 hours parallels the loss of Kupffer cells, whereas the subsequent reduction in NO corresponds with the loss of SECs (104). Inhibition of NO synthase (NOS) exacerbates monocrotaline toxicity. Conversely, infusion of V-PYRRO/NO, a liver-selective NO prodrug, results in dose-dependent attenuation of SOS (104). V-PYRRO/NO prevents the rounding up of SECs, thereby preserving an intact SEC lining and maintaining sinusoidal perfusion. V-PYRRO/NO prevents synthesis of MMP-9 in the monocrotaline model. Inhibition of MMP synthesis by NO is consistent with studies in other models, in which

Figure 133.3. Sinusoidal obstruction syndrome. The left panel shows a normal liver. The *arrows* indicate ECs lining the central vein, and *arrowheads* indicate normal sinusoidal ECs. The right panel shows the centrilobular region of the liver in early SOS, with loss of ECs within the central vein, loss of SECs, severe centrilobular necrosis, hemorrhage, and congestion ( $\times 20$  magnification).

inhibition of endogenous NO production enhances IL-1 $\beta$ -induced increases in synthesis of MMP 9, whereas administration of NO donors inhibits synthesis of MMPs (105–111).

This process seems to create a positive feedback loop, whereby decreased NO production leads to further reductions in NO (see Figure 133.3). Monocrotaline-mediated loss of Kupffer cells and SECs results in decreased NO production. Because NO is necessary for the tonic suppression of MMP-9, levels of this metalloproteinase increase. The change in MMP activity, in conjunction with F-actin depolymerization, leads to dissection of the space of Disse, as described earlier. The dissection causes additional SECs to slough, thus perpetuating the cycle.

The centrilobular necrosis in SOS is completely prevented by interventions that preserve the integrity of the sinusoidal lining, such as MMP inhibition and preservation of NO levels. These data strongly support the notion that hepatocyte ischemia is secondary to the sinusoidal lesion.

### NODULAR REGENERATIVE HYPERPLASIA

Nodular regenerative hyperplasia (NRH) is most commonly asymptomatic, being detected incidentally at autopsy. The prevalence is around 2.5% of the population, as determined in large autopsy series (70,112). Symptomatic disease presents with signs of portal hypertension (e.g., variceal hemorrhage, ascites, and splenomegaly). However, NRH rarely leads to end-stage liver disease.

Although the etiology of NRH remains unclear, the disease appears to be associated with areas of impaired perfusion alternating with areas of reactive hyperplasia in which perfusion is maintained (113). It is believed that reduced O<sub>2</sub> delivery in the hypoperfused areas leads to hepatocyte apoptosis or atrophy (114). The common feature of the various risk factors for NRH is that they predispose to impaired portal venous or sinusoidal blood flow. Examples of microcirculatory toxicity that lead to NRH are long-term azathioprine immunosuppression for kidney or liver transplantation, and myeloablative chemotherapy for bone marrow transplantation. Both azathioprine (95) and myeloablative chemotherapy (96) are toxic to SECs, and have been implicated in other diseases in which the SECs are the putative target, such as peliosis hepatis and SOS (71,93,115). Thus, NRH in renal, liver, or bone marrow transplantation seems to be due to SEC toxicity, with regional impairment of the sinusoidal circulation.

### PELIOSIS HEPATIS

Peliosis is a rare disease characterized by blood-filled cavities within the liver parenchyma. The peliotic lesions vary from less than 1 mm to several centimeters. Peliosis is most common in the liver, but also may involve the spleen, bone marrow, or abdominal lymph nodes. Peliosis hepatis has been linked to

drugs such as azathioprine and anabolic steroids. In addition, peliosis may occur in patients with acquired immunodeficiency syndrome (AIDS), tuberculosis, leukemia, lymphoma, multiple myeloma, and myeloproliferative diseases.

Studies in patients with AIDS provide the most clear-cut evidence for the SEC origin of peliosis hepatis. In these patients, peliosis is caused by infection with *Bartonella* sp. bacilli. *Bartonella* sp. have been detected in SECs by electron microscopy (116). This leads to disruption of the SEC lining, sinusoidal dilatation, and ultimately to the formation of cavities that lack SEC lining (117,118). Later in the disease, the endothelial lining of the cavities may be partially restored. When *Bartonella* involves the organs of the reticuloendothelial system, which have a discontinuous endothelium, peliotic cavities develop, whereas *Bartonella* infection in the skin, which has a continuous endothelial lining, causes bacillary angiomatosis (118).

### ACETAMINOPHEN TOXICITY

In the early stages after acetaminophen toxicity, extreme hepatic congestion occurs in both humans (119–123) and experimental animals (124–129). In the mouse, the congestion is so extreme that up to half of the red blood cell volume can accumulate in the liver (128). Ultrastructural studies have demonstrated the appearance of large pores in the SECs, accumulation of red blood cells in the space of Disse, and partial separation of SECs from the underlying hepatocytes, but without complete dehiscence (130). These circulatory changes precede hepatocyte necrosis and likely contribute to the liver toxicity (131). In vitro studies in murine liver cells have shown that acetaminophen is more toxic to SECs than to hepatocytes (132), and this may account for the microcirculatory impairment.

The early morphological changes in acetaminophen toxicity are very similar to the early features in SOS. Analogous to SOS, NO and MMPs appear to play a role in the development of the microvascular injury in acetaminophen intoxication (133–135). NO derived from eNOS protects against acetaminophen toxicity, whereas NO derived from iNOS contributes to acetaminophen injury (134). Preservation of NO levels with V-PYRRO/NO (133) or inhibition of MMP-2 and -9 attenuates acetaminophen-induced microvascular injury and parenchymal necrosis (135).

### INJURY DURING LIVER TRANSPLANTATION

In liver transplantation, the donor liver is preserved and transported in a cold University of Wisconsin solution. A variable degree of injury may manifest itself when the liver is reperfused in the transplant recipient, and this ischemia-reperfusion injury can lead to graft failure. The major target for reperfusion injury is the SEC (136–139), with accompanying cell death, partial denudation of the sinusoidal lining, and

deterioration of the liver microcirculation. Cold preservation leads to increased calpain protease activity in SECs (140–142), which leads to depolymerization of F-actin in SECs (143), and consequent upregulation of MMP-9 and -2 activity (144). eNOS is downregulated and iNOS is upregulated by ischemia–reperfusion, whereas preservation of NO levels and inhibition of iNOS are protective of the injury (145–147). Tonic NO production by eNOS is known to suppress new synthesis of MMPs, so that the decrease in eNOS may be a permissive factor in the increase in MMPs. Inhibition of MMPs reportedly reduces hepatocyte necrosis and aminotransferase elevations after ischemia–reperfusion (148). Upregulation of MMPs likely accounts for the dehiscence of SECs from the space of Disse in ischemia–reperfusion injury. One of the other consequences of F-actin depolymerization and increased MMP activity is increased platelet adherence to SECs (149). This accumulation of platelets and leukocytes contributes to SEC injury after cold preservation (149–151).

In addition to injury due to ischemia–reperfusion, the sinusoidal lining may be injured in live donor transplantation. When a portion of a liver is transplanted into a recipient, a mismatch occurs between the afferent circulation that was appropriate for the original liver of the recipient and the small-for-size graft. The increased blood flow is associated with transient portal hypertension and gaps in the sinusoidal lining and hepatocyte injury (152,153). The portal hypertension may damage an endothelial lining already compromised by ischemia–reperfusion.

#### KEY POINTS

- SECs are a highly specialized type of EC. The de-differentiation that occurs in capillarization and pseudocapillarization has significant local and systemic consequences.
- SECs are the initial target in a number of liver diseases. Given the limited amount of research in this area, it is likely that other diseases also are initiated by injury to SECs.
- Great similarity is apparent in the early events leading to SEC damage in ischemia–reperfusion injury, SOS, and acetaminophen toxicity. It will be intriguing to determine why the damage resolves quickly in ischemia–reperfusion injury and acetaminophen intoxication, but persists in SOS.

#### Future Goals

- To elucidate the active endocytotic apparatus in SECs, which should lend itself to strategies to protect SEC from injury
- To examine strategies to reverse capillarization

# Hepatic Macrocirculation

## Portal Hypertension as a Disease Paradigm of Endothelial Cell Significance and Heterogeneity

---

Winston Dunn and Vijay Shah

*Mayo Clinic College of Medicine, Rochester, Minnesota*

The hepatic circulation is a low-pressure vascular bed that accommodates large volumes of blood (1). Total hepatic blood flow in humans is approximately 1,500 mL/min and accounts for 15% to 20% of cardiac output. The liver, like the lung, receives a dual blood supply; 70% of total hepatic blood flow is from the portal vein, and 30% from the hepatic artery. Blood from the hepatic artery and portal vein supplies the liver sinusoids and ultimately drains into the hepatic vein. Any one of these segments of the hepatic circulation – the hepatic artery, portal vein, sinusoids, hepatic vein – may be inflicted by disease, with sometimes devastating consequences. This chapter examines the structure and function of the hepatic macrocirculation, with an emphasis on cirrhotic portal hypertension as a paradigm of hepatic vascular disease and endothelial cell (EC) heterogeneity.

### HISTORY

The hepatic vasculature has been the subject of interest for millennia. Indeed, seminal observations of patients with portal hypertension, and its major complications of ascites and esophageal variceal hemorrhage, provided a strong foundation for our present-day knowledge of the hepatic circulation (Table 134-1). Several important themes emerge from a consideration of the history of the field. First, there is noticeable change in methodology over time from physical examination to gross anatomy, followed by studies in physiology and pathology, and culminating in methods at the interface of organ and cell physiology and molecular biology. Second, studies of the diseased liver have provided profound insights into the physiology of the normal hepatic vasculature. Last, it is instructive to reflect on the controversies and errors that arose over the centuries, including the original misconceptions of Galen regarding the vascular anatomy of the liver, and Banti's

mistaken notions of the role of the spleen in the pathogenesis of cirrhosis. Often, hundreds of years were required before these errors in thought were rectified, thus highlighting the importance of challenging dogma.

### STRUCTURE AND FUNCTION OF THE HEPATIC MACROCIRCULATION

#### Portal Venous Blood Flow

Portal venous blood is derived from the mesenteric venous circulation, which drains blood from the capillary beds of the stomach, intestines, spleen, and pancreas (Figure 134.1A). Blood flows from the portal vein into the liver sinusoids, and ultimately into the hepatic vein. This arrangement is unusual for a venous system, in that it consists of two capillary beds – the mesenteric capillaries and liver sinusoids – linked in series.

Under normal physiological conditions, the liver circulation functions as a passive reservoir accommodating venous and arterial inflow. Owing to the disproportionately large contribution of the portal vein (70%), total hepatic blood flow is largely determined by mesenteric hemodynamics. Mesenteric blood flow, in turn, is mediated primarily by mesenteric arterioles and, to a lesser extent the gut mucosa, which increases blood flow in response to nutrient absorption. Thus, portal venous inflow ultimately is controlled at the level of the mesenteric arterioles. Blood flow to the mesenteric circulation not only provides oxygen (O<sub>2</sub>) and nutrients to the gut tissue but also plays an important role in supporting the secretion and transport of macromolecules taken up by the gut mucosa for further metabolism and processing in the liver. In keeping with these functions, total mesenteric (hence, portal venous) blood flow is markedly stimulated during the postprandial period.

**Table 134-1: Timeline of Historical Landmarks Relating to Hepatic Circulation and Portal Hypertension**

<i>Time</i>	<i>Investigator</i>	<i>Major Observation (Refs.)</i>
Paleolithic Era	Prehistoric writers in Southern France Egyptian physicians	Cave art depicts the liver as a bloody, highly vascular organ (24) First recorded descriptions of the hepatic vasculature, including recognition that intestinal blood flows into the liver and that the liver is comprised of venous vascular channels (these anatomic concepts were further evaluated and debated by Hippocrates and Aristotle in the 4th to 5th century B.C., by Galen in the 2nd century A.D., by Erasistrates of Chios, Alexandria in the 3rd century, and by Herophilus of Chalcedon in the 3rd century) (25–31)
1500 B.C.	Ancient Egypt Ancient Hindus Ancient Mayans	Recognition of ascites (25,32)
Third century	Erasistrates Hippocrates Galen	Pathogenesis of ascites is actively debated (33–36)
Dark Ages, Middle Ages, 5th–10th century		Lack of substantive advances in the study of the hepatic circulation
14th century	English literature	Ascites based on Greek term for “leather water bag” appears in English language
15th century	DaVinci	Revival of the study of hepatic vascular anatomy (37)
16th century	Andrews Vesalius	(38)
16th century	Stahl of Germany	Incorrectly surmises that portal vein congestion or “abnormal plethora” is responsible for most chronic diseases (39)
1628	William Harvey	With discovery of the circulation of blood, able to correct a number of misconceptions relating to hepatic circulation that were perpetuated from the errors of Galen and Aristotle (40)
1600s	Glisson Cambridge	Validated the observations of Erasistrates and Harvey that blood flows from the intestine through hepatic channels, back to the heart, lungs, and arterial circulation, sequentially (41)
1700s – 1800s	Malpighi Wepfer Kiernan	Recognition of the hepatic acinus and portal triad (hepatic artery, portal vein, bile duct) (42–44)
1800s	Banti-Florence	Incorrectly surmises that portal hypertension is a result of splenomegaly (45,46)
1800s	Eck-Rossin	Recognition that portal hypertension could be corrected by portal caval shunting (47)
20th century	Gilbert and Villaret-France	First used the term <i>portal hypertension</i>
1950	Myers and Taylor	First demonstration of portal pressure measurement using hepatic venous pressure gradient analysis (48)
1950s	McIndoe – Mayo Clinic	Recognizes that portal hypertension is a result of hepatic vascular obstruction rather than splenomegaly (49)

Compiled from the textual recounts of the history of the hepatic circulation recently delineated by the renowned hepatologist and liver historian, Adrian Rubin. See Ref. 50. Reuben A, Groszmann R. Portal hypertension: a history. In: Sanyal A, Shah V, eds. *Portal Hypertension*. Totowa, NJ: Humana Press, 2005.

### Hepatic Arterial Blood Flow

The hepatic artery, derived from the celiac plexus, provides only one-third of the total hepatic blood flow yet supplies the liver with a significant portion of its O<sub>2</sub> requirements. Blood from the high-pressure hepatic artery drains into hepatic sinusoids, either directly or after perfusing critical structures in the liver, including the peribiliary plexus, the vasa vasorum of hepatic veins, the portal tract interstitium, and Gleason's capsule

(2). In the sinusoids, hepatic artery blood mixes with poorly oxygenated blood from the low-pressure portal vein, providing a boost in O<sub>2</sub> delivery to hepatocytes. From the hepatic sinusoids, blood drains into the hepatic vein, followed by the inferior vena cava, and ultimately the right atrium. A remarkable feature of the liver circulation is the capacity of the sinusoids to “decompress” the highly pressured arterial inflow and thus maintain extremely low pressures. In the absence of such a mechanism, sinusoidal hemodynamics would be altered in

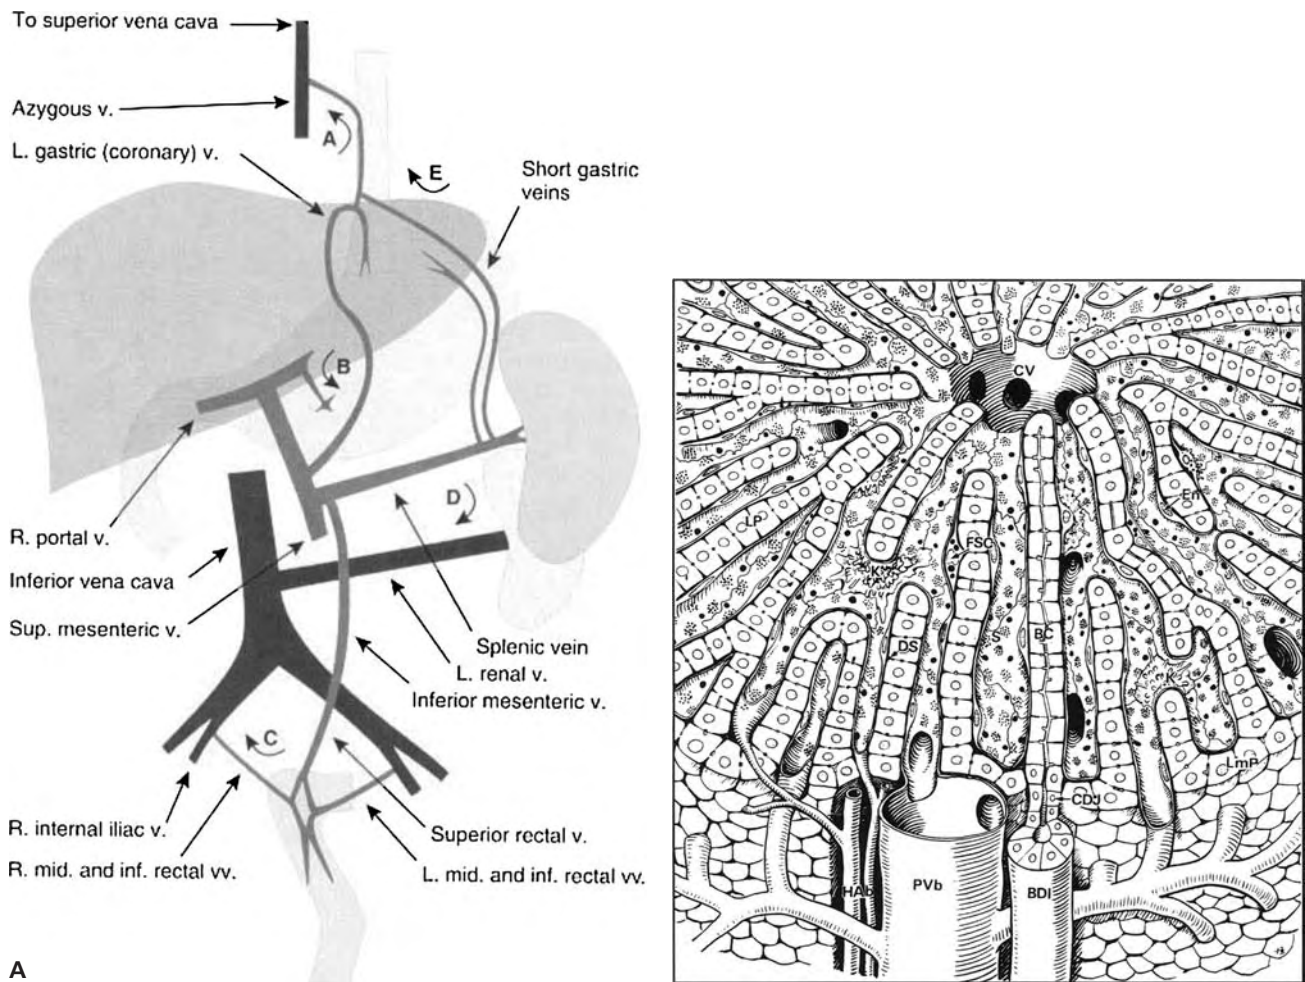

Figure 134.1. (A) Portal and collateral circulations. (A) Left gastric vein and (E) short gastric vein drains via the esophageal varices into the azygous vein. (B) Umbilical vein often is recanalized and, with the paraumbilical plexus in the abdominal wall, leads to the classical sign of caput medusae. (C) Superior rectal vein drains through hemorrhoid into middle rectal vein and internal iliac vein. (D) Abdominal viscera can drain via the retroperitoneal collaterals and drain into left renal vein. (Reprinted with permission from Feldmar A. *Sleisenger and Fordtrar's Gastro-intestinal and Liver Disease*, 7th ed. Philadelphia: Elsevier, 2002). (B) Vasculature architecture of the liver. Blood flow enters the liver via the portal vein (PVb) as well as the hepatic artery (HAb). Whereas portal blood enters directly into the sinusoids (S), hepatic arterial blood perfuses into distinct anatomic locations prior to reentering the sinusoids. Sinusoidal blood leaves the liver via the central veins (CV). Sinusoidal ECs (En) form the fenestrated sinusoidal wall. Kupffer cells (K) are located within the sinusoids, whereas hepatic stellate cells, also termed *fat storing cells* (FSC), lie within the space of Disse (DS), adjacent to the single layer of hepatocytes (liver plate, LP). Bile canaliculi (BC) drain bile into the interlobular bile ducts (BDL) via the canaliculoductal junction (CD) in the opposite direction to flow in the vascular channels. (Reproduced with permission from Motta P, Muto M, Fujita T. *The Liver. An Atlas of Scanning Electron Microscopy*. Tokyo: Igaku-Shoin Medical Publishers, 1978:129.)

a catastrophic way. The exact mechanism of decompression of high-pressure arterial blood within the sinusoids remains unclear.

Impairment of hepatic arterial flow normally has minimal detrimental effect on liver function since alternative portal vein-based perfusion pathways develop quickly, in part through autoregulation mechanisms described later in this chapter. However, under pathophysiological conditions such as following liver transplantation or in conditions associated with diminished portal vein flow (e.g., portal vein thrombosis and liver cirrhosis), hepatic arterial flow is of paramount importance in maintaining adequate hepatic perfusion. Sig-

nificant reduction or cessation of hepatic blood flow in these settings can result in dramatic ischemic insults, not only within the biliary system, but also at the level of sinusoidally perfused hepatocytes.

Another interesting characteristic of hepatic arterial flow is its propensity to supply tumors with perfusion analogous to the role of the bronchial circulation in lung tumors. In the hepatic circulation, the unique anatomical basis of primary tumors has been exploited through the procedure of hepatic artery chemoembolization, which allows for targeted delivery of therapeutics and occlusion of the tumor vasculature with limited effects on the hepatic parenchyma and other organs.

## AUTOREGULATION OF LIVER BLOOD FLOW

The total blood flow through the liver remains relatively constant over time. Such constancy, which helps to maintain normal portal pressure as well as liver clearance of xenobiotics and endogenous peptides, is mediated by autoregulation of hepatic arterial flow in response to changes in portal blood flow. This is thought to occur through a mechanism termed *the hepatic arterial buffer response* (3), a concept based on adenosine washout from the space of Mall, a thin fluid space surrounding the portal triad. Adenosine is constantly secreted around the terminal branches of the hepatic arteriole and portal venule (space of Mall) (see Figure 134.1B). When the portal blood flow increases, adenosine is washed away at a faster rate, resulting in hepatic arteriole vasoconstriction (3). Conversely, reductions in the clearance of adenosine result in adenosine accumulation and ensuing compensatory dilation of the hepatic artery. The increase in hepatic artery flow removes the excess adenosine, thereby maintaining adenosine concentration and total hepatic blood flow at a constant level. These regulatory mechanisms are vital in pathophysiological conditions associated with low portal vein flow, such as occurs with cirrhosis and portosystemic collateral shunting, hemorrhage, and surgical portocaval shunts. One would anticipate that the hepatic arterial and portal venous ECs must be playing a delicate balancing act in adenosine production and sensing; however, the endothelium-specific mechanisms responsible for this equilibrium remain largely unexplored.

## ENDOTHELIUM IN DISEASE: PORTAL HYPERTENSION AS A PARADIGM FOR ENDOTHELIAL CELL HETEROGENEITY

### Portal Hypertension at the Interface between Cell Biology and Plumbing

Arguably, the most important and interesting disease condition that afflicts the hepatic macrocirculation is portal hypertension. Portal hypertension results in EC-based hemodynamic derangements in nearly every vascular bed and is a prototypical disease that highlights the disparate and opposing responses of ECs in different vascular beds. The term *portal hypertension* or, more strictly, *portal venous hypertension*, refers explicitly to a pathological elevation of pressure in the veins that carry blood from the mesenteric organs (including the spleen) to the liver. Implicit in the working definition of portal hypertension is the necessary condition that the rise in portal pressure is not simply a consequence of an increase in systemic venous pressure – as might occur with congestive heart failure, for example – but rather reflects an elevated pressure gradient between the portal venous inflow to the liver and its hepatic venous outflow.

Significant advances have been made in our understanding of the cellular and molecular mechanisms of portal hypertension, including the central role of the dynamic interplay of the liver EC and the hepatic stellate cell (HSC). However,

Figure 134.2. EC phenotypic changes in different vascular beds in portal hypertension. NO generation is diminished in the hepatic circulation in cirrhotic portal hypertension, thereby contributing to increased resistance, and NO generation is increased in the peripheral and mesenteric circulation, thereby contributing to increased flow into the portal circulation. The ensuing collateral circulation aims to decompress the portal circulation and is driven by NO-mediated angiogenesis as well as dilation of pre-existing collaterals. (Reprinted with permission from Shah V. Cellular and molecular basis of portal hypertension. *Clin Liver Dis.* 2001;5:629–644.)

from a pathophysiological and clinical standpoint, the problem continues to lend itself to a “plumber’s approach.” Blood flow through the liver is driven by the pressure gradient ( $\Delta P$ ) between the portal vein and hepatic vein. According to Ohm’s Law, the pressure gradient  $\Delta P$  is the product of hepatic resistance ( $R$ ) and mesentery blood flow ( $Q$ ) (Equation 1):

$$\Delta P = Q \times R \quad (\text{Equation 1})$$

Portal hypertension, which is defined as an elevation in the pressure gradient, may result from increased resistance to flow and/or increased inflow through the mesentery artery; both of these usually go hand-in-hand (Figure 134.2). In most cases, the initiating factor is an increase in resistance (e.g., cirrhosis, caval web, etc.). Increased resistance leads to increased inflow through a process that is not completely understood but

involves porto-systemic shunting, systemic arterial vasodilation, fluid/sodium retention, and eventually increased blood flow into the portal circulation.

### Increased Intrahepatic Resistance as a Form of Endothelial Dysfunction

Cirrhosis is associated with a reduction in the number and luminal diameter of sinusoids, which results in diminished cross-sectional area. According to Poiseuille's Law, the resistance ( $R$ ) to flow is inversely proportional to the radius ( $r$ ) of a tube to the fourth power (Equation 2):

$$R = 8 \eta L / r^4 \quad (\text{Equation 2})$$

Thus, insofar as the sinusoidal surface area determines the "radius" of the hepatic vasculature, its overall reduction leads to markedly increased sinusoidal resistance. Two mechanisms contribute to the reduced surface area (hence increased resistance) in cirrhosis. First, there is mechanical obstruction of sinusoids secondary to fibrosis, anatomical derangement, and capillarization. Second, the sinusoids display elevated vascular tone. This latter process occurs through a dynamic interplay between liver ECs and HSCs. In liver injury and cirrhosis, liver ECs evidence endothelial dysfunction while the HSCs in hyperdynamic circulation syndrome become activated, expressing actin and myosin, and developing contractile properties similar to vascular smooth muscle cells (VSMCs) or pericytes. The constrictive tone of HSCs, like that of VSMCs, is modulated by a yin-and-yang balance of endothelium-derived factors, with nitric oxide (NO) and endothelin (ET)-1 seemingly most important in the hepatic circulation (4,5). The importance, in this dynamic component, of increased intrahepatic resistance lies in its susceptibility to therapeutic interventions when compared to the relatively static component of mechanical fibrosis and fixed scar. Although a sinusoidal basis for tonus changes in liver is appealing, the anatomic location of pressure drops across the liver (i.e., portal venules, sinusoids, or hepatic venules) is not fully established and is probably variable depending on the physiologic and pathobiologic circumstances.

### Too Little Nitric Oxide

In cirrhosis and portal hypertension, the liver sinusoids probably experience a higher shear stress than normal, owing to the hyperdynamic circulation (6). Although shear stress is a normally a strong stimulus for release of NO in endothelium, portal hypertension is associated with an impairment in endothelium-dependent vasodilatation, a marker for NO bioactivity (7). Acetylcholine challenge into the ex vivo perfused cirrhotic liver via the portal vein results in minimal vasodilatation and even paradoxical vasoconstriction, which is akin to the endothelial dysfunction observed in other diseased vascular beds such as the atherosclerotic coronary artery (7).

Reduced intrahepatic NO production is the result of diminished endothelial NO synthase (eNOS) activity at the

post-translational level. In cirrhosis, the amount of intrahepatic eNOS protein is unchanged, and overexpression of eNOS fails to improve endothelial function. Caveolin-1 protein abundance is increased in the ECs of injured and cirrhotic liver (8), and binding of caveolin to eNOS diminishes eNOS activity (6). In addition to caveolin-mediated inhibition of eNOS, cirrhosis also may be associated with diminished eNOS phosphorylation and activity. Phosphorylation at Serine 1177 by the phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt) pathway increases enzyme activity. In animal models of cirrhosis, eNOS phosphorylation is diminished, and adenovirus transfection with constitutively active Akt restores intrahepatic eNOS activity and normalizes portal pressure, suggesting a defect in eNOS phosphorylation in cirrhosis (9). In support of the relevance of these post-translational changes in eNOS in human portal hypertension, statins have been shown to decrease hepatic sinusoidal resistance by increasing hepatic NO generation (although statins may have other beneficial mechanisms of action as well) (10).

NO donors can improve intrahepatic resistance but, unfortunately, these agents also may fuel a hyperdynamic circulation, characterized by NO excess in extrahepatic vascular beds. For example, low-dose isosorbide has been shown to attenuate postprandial portal pressure increases but it does so at a cost of a drop in systemic blood pressure, which can be problematic in cirrhotic patients (11). A new agent, NCX-100, is a NO donor coupled to ursodeoxycholic acid (UDCA), which has been shown in animal models to allow NO delivery specifically to the sinusoidal microcirculation without significant systemic effects (12). Clinical trials in humans are anticipated.

### Too Much Endothelin-1

Another important vasoactive agent in portal hypertension and liver injury is ET-1 (5). Normally an endothelium-derived vasoconstrictor, ET-1 is mainly produced by activated HSCs in liver cirrhosis, and is probably upregulated by transforming growth factor (TGF)- $\beta$ , which is increased in this disease (13). ET-1 acts in an autocrine and paracrine fashion through two distinct G-protein-coupled receptors, endothelin-A (ETA) receptor and endothelin-B (ETB) receptor. There is some controversy regarding the role of these receptors in hepatic vascular function and portal hypertension. However, it is generally believed that in ECs, ET-1 interacts with ETB to activate eNOS and mediate vasodilation (13), whereas in HSCs and VSMCs, ET binds to ETA to induce vasoconstriction in the hepatic circulation. In addition to modulating vascular tone, ET-1 also may be involved in wound healing response, which is a key mechanism of fibrosis and cirrhosis development.

### Hyperdynamic Circulation

The pressure gradient across the portal bed is determined not only by resistance, but also by blood flow (see Equation 1).

**Table 134-2: Systemic Vascular Changes Associated with a Rat Model of Prehepatic Portal Hypertension**

	1 Hour	1 Day	2 Days	3 Days	4 Days
Total peripheral resistance	↑	↓	↓	↓	↓
Plasma volume	—	—	↑	↑	↑
Cardiac index	↓	—	—	—	↑
Mesentery artery resistance	↑	↑	—	—	↓
Mesentery inflow	↓	↓	↓	—	↑

In portal hypertension, the high pressures are often compounded by an increase in both parameters. The increase in portal venous inflow is part of a hyperdynamic circulatory state (HCS), characterized by widespread vasodilatation and increased blood flow in the mesenteric and most peripheral beds. The mechanisms underlying HCS are controversial. Although NO activity has been implicated in its pathogenesis, it is possible that NO levels are elevated as a secondary response to high flow-mediated shear stress, and that they play a role in perpetuating rather than initiating the syndrome (14). Using a prehepatic surgical model of the hyperdynamic circulation, namely portal vein ligation (PVL), Groszmann and colleagues demonstrated that NO production and NOS activation are a very early step in the development of the HCS, suggesting that NO overproduction may be a cause, rather than consequence, of HCS (15,16) (Table 134-2). However, arguing against a pathogenic role for NO in this syndrome is the demonstration – by some, but not all groups – that *eNOS*-knockout mice are susceptible to a hyperdynamic circulation in a model of prehepatic portal hypertension (17,18).

It has been hypothesized that HCS arises from bacterial translocation, endotoxemia, and tumor necrosis factor (TNF)- $\alpha$ , with secondary activation of endothelium and NO release. Cirrhotic patients often have bacterial translocation from the gut to mesenteric lymph nodes due to increased intestinal permeability and impaired immune clearance (19). Bacterial endotoxin triggers TNF- $\alpha$  production by mononuclear cells and Kupffer cells, and TNF- $\alpha$  then upregulates EC *eNOS* activity at the post-translational level via both the PI3K and Akt pathways (19). Bacterial translocation and endotoxemia are therefore targets for therapeutic intervention. Indeed, antibiotics such as norfloxacin have been shown to decrease bacterial translocation across intestinal mucosa in animal studies, and to dampen hyperdynamic circulation in human studies (20,21).

An interesting question is why portal hypertension is associated with increased *eNOS*/NO activity in the peripheral circulation, yet diminished activity in the liver sinusoids. Although the answer is not yet known, the observation provides a striking example of vascular bed-specific phenotypes in liver disease.

### Portosystemic Collateral Circulation

Abnormally high pressures in the portal circulation may lead to portosystemic collaterals that bypass the sinusoids and thus decompress the portal bed. The collaterals – which form direct connections between the engorged portal circulation and the lower-pressure venous system – create a parallel circuit that lowers the overall resistance (R) to portal blood flow (Equation 3):

$$1/R_{\text{portal}} = 1/R_{\text{hepatic}} + 1/R_{\text{collaterals}} \quad (\text{Equation 3})$$

Unfortunately, these collaterals cannot fully decompress the portal circulation. Moreover, they may result in life-threatening complications, such as the development of bleeding esophageal varices. In addition to varices, collaterals may take the form of capillary ectasias, such as portal hypertensive gastropathy, a mosaic pattern of vascular-based epithelial cell injury that occurs in patients with portal hypertension and that may present as gastrointestinal bleeding. Although physiological studies have focused on the anatomy and hemodynamics of portosystemic collaterals, more recent detailed molecular studies have begun to elucidate the growth factors and mediators responsible for vasculogenesis, neoangiogenesis, and collateralization.

### Special Circulations Affected by Hyperdynamic Circulation

As alluded to earlier, portal hypertension results in EC-based hemodynamic derangements in nearly every vascular bed. Two peripheral beds that undergo clinically relevant hemodynamic changes are the kidney and lung. In the kidney, the reduced blood pressure and perceived “underfilling” of renal blood flow results in activation of endogenous vasoconstrictors and volume repletion pathways such as the renin-angiotensin, aldosterone, and antidiuretic hormone (ADH) systems (Table 134-3). These compensatory responses are not only inadequate, but they render the kidneys exquisitely sensitive to subsequent insults (e.g., small doses of nonsteroidal anti-inflammatory drugs or contrast dye), leading in some cases to renal *decompensation* (the hepatorenal syndrome). Interestingly, this form of renal dysfunction is entirely dependent on hepatic and systemic factors, and is reversed upon successful treatment of the liver disease.

The pulmonary vascular endothelium also responds in unique and interesting ways to cirrhosis and portal hypertension. In normal conditions, ET-1 mediates pulmonary artery vasoconstriction via the ETA receptor. In the so-called *hepatopulmonary syndrome*, excess ET-1 levels in the blood appear to stimulate ETB receptors in the pulmonary vasculature to promote *eNOS* activation, pulmonary shunting, and hypoxemia (22). Conversely in some patients, ET-1 elevation seems to act on ETA receptors to promote vascular remodeling and portopulmonary hypertension (22). It has been difficult to

**Table 134-3: Systemic Vascular Changes That Occur in Human Portal Hypertension and Associated Renal Failure**

determine which patients will develop these heterogeneous and opposite responses of portal hypertension on the pulmonary vascular endothelium (23).

## DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

### Hepatic Venous Pressure Gradient Measurement

A variety of techniques are available for assessing volume, pressure, and flow within the mesenteric circulation. Some of these techniques are utilized predominantly for research purposes, whereas others have clear clinical utility. The identification of a technique that provides reliable, accurate, and reproducible hemodynamic information in a noninvasive manner continues to be the Holy Grail of portal circulatory investigation. One of the most mechanistically interesting methodologies is the ability to indirectly estimate portal pressure by using a wedge balloon catheter technique – hepatic venous pressure gradient (HVPG) monitoring – which is akin to the Swan Ganz measurements used to estimate systemic hemodynamics. Although the most accurate determination of portal pressure in experimental model systems can be determined by direct puncture of the portal venous vasculature, the potential complications outweigh the utility of this approach in most clinical circumstances. To perform HVPG monitoring, a balloon catheter is passed through the vena cava to the hepatic vein, where pressures are obtained with the balloon deflated within the hepatic vein and subsequently with inflation of the balloon and occlusion of the hepatic vein branch. The occluded pressure reading reflects the pressure within the hepatic sinusoids, because a column of blood is contiguous between the inflated balloon and the sinusoids. The free hepatic vein pressure is subtracted from the occluded hepatic venous pressure to provide the HVPG, an indirect assessment of pressure within the hepatic sinusoid. This technique can be useful to make a definitive diagnosis of portal hypertension, establish the site of increased portal resistance, and monitor the portal pressure response to treatments.

### Diagnosing Sites of Altered Resistance According to Location

Increased resistance may be caused by structural and/or functional lesions in prehepatic, intrahepatic, and/or posthepatic locations. Within the liver, the site of increased resistance can be further identified as presinusoidal, sinusoidal, or postsinusoidal. These distinctions can often be ascertained using HVPG monitoring.

#### Prehepatic Resistance

Prehepatic resistance can be caused by portal vein thrombosis. In adults, it is usually related to cirrhosis, splenectomy, hypercoagulable state, and cancer. Due to the portal vein thrombus, the increased pressure in the portal vein remnant cannot be transmitted to the hepatic sinusoid, and thus HVPG-based methodology tends to underestimate hepatic venous wedge pressure (HVWP). Portal hypertension results in massive splenomegaly and varices formation. Varices may even occur along the common bile duct and occasionally cause obstructive jaundice and hemobilia. Otherwise, liver function is usually unaffected because hepatic blood flow is augmented through hepatic arterial buffer response (as discussed earlier and evidenced clinically in Figure 134.3). Over 5 to 12 weeks, the portal vein thrombus transform into a collagenous plug with tortuous venous channels; this is called *cavernous transformation*. Both cavernous transformation and the development of portal systemic collaterals are examples of venous angiogenesis or *venogenesis*, which are in contradistinction to the angiogenesis that frequently occurs in the arterial vasculature in other conditions such as coronary and peripheral arterial occlusion.

#### Intrahepatic Resistance

Intrahepatic presinusoidal resistance is exemplified by schistosomiasis and granulomatous disease such as sarcoidosis. In cirrhosis caused by alcoholic liver disease or viral hepatitis, the increased resistance occurs at the sinusoid. HVWP

Figure 134.3. Example of hepatic blood flow autoregulation. A case of a patient with portal vein thrombosis (*left*) with compensatory marked dilatation of the hepatic artery (*right*). (Reprinted with permission from Gulberg V, Schoenberg S. Hepatic arterial buffer response: visualization by multiphasic high-resolution 3D magnetic resonance angiography. *J Hepatol*. 2004;40:181.)

accurately reflects portal venous pressure (PVP) and is elevated. Postsinusoidal intrahepatic resistance can be caused by veno-occlusive disease. Venocclusive disease is the occlusion of terminal hepatic venules and sinusoids as a result of endothelial damage. It is commonly seen in pyrrolizine alkaloid ingestion and aggressive chemotherapy associated with bone marrow transplant. The patient presents with weight gain, hepatomegaly, ascites, and hyperbilirubinemia.

### Posthepatic Resistance

The most notable cause of posthepatic resistance in the hepatic macrocirculation is Budd-Chiari syndrome. Budd-Chiari syndrome is venous thrombosis located anywhere between the right atrium and small radicals of the hepatic vein. It is commonly seen in patients with hypercoagulable states, pregnancy, myeloproliferative disorder, and cancer. The caudate lobe of the liver drains directly into the inferior vena cava and is typically spared. Clinical presentation depends on the time course, and may include acute liver failure or insidious onset of cirrhosis. Ischemic injury and congestion are seen histologically in the liver vasculature. HVPV usually is elevated owing to the high sinusoidal pressure resulting from the occlusion.

### GOALS FOR BRIDGING BENCH-TO-BEDSIDE GAP

The hepatic circulation and its involvement in portal hypertension is one example of the intense efforts being made in an attempt to bridge the bench-to-bedside gap. Endothelial research has traditionally been a physiologically oriented field. Indeed, major advances have been made using methodologies that allow researchers to translate research data into new treatment therapies for patients, including the use of  $\beta$ -blockers, mesenteric vasoconstrictors, nitrates, and other agents that act directly through modulating vascular phenotype, in many cases directly at the level of the EC. Today, many investigations are focused on more molecular approaches, although the emphasis on translating study data from relevant animal models to humans remains a priority for investigators in this field.

### KEY POINTS

- The hepatic circulation has many unique features that distinguish it from other vascular beds; diseases of the hepatic circulation, such as portal hypertension, stimulate heterogeneous responses in ECs throughout other vascular beds.
- The hepatic circulation maintains a dual blood supply that is reciprocally and carefully regulated.

- Portal hypertension is a complex disease of the hepatic circulation that occurs from multiple different causes and affects vascular ECs in almost every organ as well as the liver.

### Future Goals

- To identify noninvasive methods to estimate changes in the hepatic circulation
- To develop therapies for hepatic-circulatory diseases that can be targeted to specific vascular beds, thereby avoiding untoward complications
- To continue to translate basic advances in vascular biology to the disease models of the hepatic circulation and, in turn, translate these advances to patients with portal hypertension

## Inflammatory Bowel Disease

---

Ossama A. Hatoum and David G. Binion

*Froedtert Memorial Lutheran Hospital, Medical College of Wisconsin, Milwaukee*

Human idiopathic inflammatory bowel disease (IBD), Crohn disease (CD) and ulcerative colitis (UC) are lifelong illnesses characterized by chronic inflammatory destruction of the gastrointestinal tract. IBD is estimated to affect between one to two million Americans, and is most commonly diagnosed during adolescence or early adulthood, thus representing a significant burden of disease throughout the patient's lifetime (1). The description of terminal ileitis in 1932, later commonly referred to as CD, distinguished chronic intestinal inflammation and stricture formation from intestinal tuberculosis (2), in which the resected gut tissues failed to demonstrate acid-fast bacilli on histological examination. The anatomic distribution of CD was later revised to include the large bowel (3,4). Samuel Wilks initially described UC, distinguishing it from hemorrhagic bacterial dysentery by 1859. The first description of the natural history of UC was reported in 1909. Despite decades of intense research efforts, the etiology of IBD remains obscure and, as a result, treatment options are not specific and focus on blunting the chronic inflammatory process in the gut. A majority of CD patients ultimately require surgical intervention for complications, most commonly the emergence of symptomatic strictures in the intestinal lumen. Approximately one fourth of UC patients require colectomy for the treatment of medically refractory disease or the detection of neoplastic transformation, a well-recognized complication of long-standing chronic gut inflammation. Recent evidence from genetic and immunologic investigation has identified alterations in the innate immune response and inappropriate immune activation of the mucosal immune system in response to enteric microbiologic antigens as a potential inciting influence in the development of IBD. Investigation of the molecular events in IBD also has identified a central role of the intestinal microvascular endothelium in the regulation of mucosal immunity and leukocyte trafficking into the gut, as well as its role in the regulation of intestinal perfusion, which is profoundly altered in these conditions.

### THE INTESTINAL MICROCIRCULATION AND GUT-SPECIFIC ENDOTHELIUM

Perfusion of the human gut in the peritoneal cavity is supplied by the celiac axis, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA), which branch from the anterior abdominal aorta, with marked variability between individuals. The celiac artery arising from the anterior aorta branches into the left gastric, common hepatic, and gastroduodenal arteries supplying the stomach, duodenum, pancreas, and liver. The SMA originates from the anterior aorta posterior to the pancreas, giving rise to four major branches – including the pancreaticoduodenal, ileocolic, right colic, and middle colic arteries – and a series of smaller jejunal and ileal branches, all of which are encased in the mesentery. These arteries provide the primary supply to the small intestine and two-thirds of the proximal large intestine. The IMA arises from the aorta just proximal to the bifurcation, branches into the left colic and multiple sigmoid arteries, and terminates in the superior rectal artery. The IMA provides the major arterial supply to the descending and sigmoid colon as well as the proximal rectum. These mesenteric intestinal arteries form a series of arcades, ultimately branching into terminal arcades, which then generate numerous straight vessels (i.e., the vasa recta) that enter the intestinal wall along the mesenteric attachment. These penetrating arterioles in the gut form a plexus in the submucosal space, which then leads to both mucosal and serosal side-branches.

The human gastrointestinal tract, particularly the small intestine, is highly vascularized, with a rich microcirculation that branches from resistance arterioles located beneath the muscularis mucosa into arcades of capillaries and venules that reach into the villous tip. The individual villi may possess a fountain-like subepithelial capillary network, which will play an essential role in physiologic function in the gut. Vascular perfusion of the gut is distinct from other organ systems, and is frequently characterized by high rates of blood flow, oxygen

utilization, and transcapillary exchange of fluid and solutes. At rest, intestinal perfusion via the SMA will range from 29 to 70 mL/min/100 g intestinal tissue (5–8), whereas in the fed state, splanchnic hyperemia increases perfusion by 28% to 132% (8). Vascular perfusion of the gut is dynamic and, as expected, is determined largely on the basis of physiologic need. Work from Granger and colleagues demonstrated up to a fourfold increase in perfusion during nutritive function in the small intestine (8). Vascular perfusion of the gut is stimulated differentially in various areas of the gastrointestinal tract by partially digested food, bile, bile salts, and fats. The microcirculation in the gut, from stomach through large intestine, is involved in essentially all aspects of intestinal physiology and homeostasis. Both secretory and absorptive functions of the gut epithelium occur in a close relationship with the microcirculation. Indeed, the majority of the fluids secreted daily in the gastrointestinal tract originate from the gut's vascular supply.

In addition to the high levels of perfusion associated with the metabolic demands of digestion and absorption of nutrients, the microcirculation in the gut plays an integral role in mucosal immunity. Indeed, the gut is the largest immune organ in the body, acting at the interface between the body and the external environment of the gut lumen. Recruitment of specific circulating leukocyte populations into the gut is regulated in part by the expression of specific vascular addressins on the endothelial lining of the intestinal microcirculation, including both the lamina propria microvessels as well as the Peyer patches. These patterns of leukocyte recruitment play a key role in gut immune homeostasis, simultaneously protecting the body from exposure to deleterious pathogens, and allowing for nutrition and the absorption of digestive material without mounting an immune response to food (i.e., oral tolerance), which is integral to health. Thus, endothelial cells (ECs) lining the gut microcirculation, specifically the postcapillary venules, play a "gatekeeper" role in the selective recruitment of circulating immune cells to the antigenically rich environment of the intestine through the highly regulated expression of leukocyte addressins and chemokines (9).

### THE ROLE OF THE ENDOTHELIUM IN CHRONIC INTESTINAL INFLAMMATION

The histologic pattern of tissue injury in IBD involves a spectrum of pathology. Focal intestinal inflammation is the hallmark feature of CD, which may range from crypt abscess formation to increased mononuclear inflammatory cell infiltrate accompanied by architectural distortion of intestinal crypts. Perhaps the earliest macroscopically identifiable lesion in CD is the aphthous ulcer, which occurs in the vicinity of postcapillary venules overlying lymphoid aggregates (10). The presence of noncaseating epithelioid granulomas is another hallmark feature of CD, which may be detected in from 15% to 70% of intestinal specimens (10,11). This wide variability may reflect the methods of tissue sampling (i.e., endoscopic vs. surgical

acquisition of tissues). The cellular components of granuloma formation in CD have been linked to specific cytokine and adhesion molecule expression patterns, with tumor necrosis factor (TNF)- $\alpha$  emerging as the key cytokine in the formation of this lesion. Late histologic features of CD are characterized morphologically by large ulcers that denude the mucosa, sinus tracts, and bowel strictures caused by transmural fibrosis.

Histologically, UC is characterized by acute and chronic inflammation and microvascular hemorrhage limited to the mucosa. The lamina propria is typically edematous, with dilation and congestion of capillaries and extravasation of red cells. In severe UC, the epithelial surface is damaged, with ulceration that may lead to more extensive bowel wall injury, including ischemic necrosis.

Early investigation into the role of ECs in IBD pathogenesis focused on histologic evaluation, characterizing the morphology of the microvasculature in chronically inflamed bowel. Using transmission electron microscopy, Dvorak and colleagues evaluated intestinal specimens from CD-resected material (12). These ultrastructural studies revealed abnormalities in the ECs lining the microcirculation in areas of the intestine affected by CD, including loss of monolayer integrity with tissue edema, extravasation of red blood cells, focal venular endothelial necrosis adjacent to areas of undamaged ECs, and EC hypertrophy.

Increased appreciation for the active role of the endothelium in the regulation of leukocyte recruitment during inflammation prompted the investigation of endothelial-leukocyte interactions in IBD. Initial investigation used histologic approaches, with various groups demonstrating increased expression of cell adhesion molecules (CAMs) in the intestinal microvasculature in both CD and UC (13). Immunolocalization studies demonstrated marked increase in E-selectin and intercellular adhesion molecule (ICAM)-1 expression in IBD intestine, whereas vascular cell adhesion molecule (VCAM)-1 expression was less clearly demonstrated (14). Subsequent investigation by Briskin and colleagues demonstrated an increase in the gut-specific homing molecule mucosal addressin cell adhesion molecule (MAdCAM)-1, which plays a major role in the recruitment of leukocytes expressing the  $\alpha$ 4 integrin into the mucosal immune compartment (15). In normal tissues, MAdCAM-1 was shown to be constitutively expressed in the endothelium of venules of intestinal lamina propria. However, the proportion of venular endothelium within lamina propria that expresses MAdCAM-1 was increased, compared with normal tissues, at inflammatory foci associated with UC and CD (15).

In addition to these studies demonstrating increased expression of EC adhesion molecules and enhanced leukocyte recruitment (14), further investigations examined alterations in the populations of leukocytes that were recruited into the IBD gut. Alterations in leukocyte homing patterns in IBD gut were characterized by Salmi and colleagues, who demonstrated that naïve lymphocytes are preferentially recruited to the chronically inflamed intestinal microvascular endothelium, whereas normal and uninvolved intestinal microvessels

preferentially bound memory lymphocytes and monocytes (16). These findings were confirmed by Burgio and colleagues, who also demonstrated an altered pattern of leukocyte binding in CD, in which monocytes and naïve T cells were again preferentially recruited to the chronically inflamed intestine through lamina propria microvessels (17). These authors also demonstrated increased expression of ICAM-1, E-selectin, and CD34 (a glycoprotein component of the peripheral node addressin) in the IBD gut microvessels. These data suggest that patterns of naïve leukocyte recruitment into the chronically inflamed IBD intestine are linked to altered expression of homing addressins on the IBD intestinal endothelium. Given the antigenically rich environment in the gut, the recruitment of naïve lymphocytes into the mucosal immune compartment may play an important role in the aberrant immune activity and perpetuation of chronic inflammation (18).

To more fully define the contribution of microvascular ECs in chronic intestinal inflammation, studies have been carried out using cultures of intestinal microvascular ECs from patients with and without IBD. Human intestinal microvascular ECs (HIMECs) have been isolated and characterized, demonstrating classic endothelial markers including Weibel-Palade bodies, expression of von Willebrand factor (vWF), platelet-endothelial cell adhesion molecule (PECAM)-1/CD31, E-selectin, ICAM-1, and VCAM-1, as well as unique patterns of leukocyte adhesion and growth, compared with human umbilical vein ECs (HUVECs) (19,20). More importantly, HIMECs also have been isolated from involved and uninvolved CD and UC intestine. HIMECs isolated from both chronically inflamed CD and UC gut demonstrated a significantly enhanced capacity to adhere leukocytes (e.g., neutrophils, as well as T-cell and monocyte-like cell lines), compared to control HIMECs (i.e., EC lines generated from “normal” margins from bowel resection for reasons other than IBD, including diverticulosis, cancer, and trauma), a phenomenon that was elicited only following activation with proinflammatory cytokines (interleukin [IL]-1 $\beta$ , TNF- $\alpha$ , and bacterial lipopolysaccharide [LPS]). Leukocyte “hyperadhesion” appears to be an acquired phenomenon, because HIMEC cultures derived from uninvolved IBD intestinal segments failed to demonstrate increased leukocyte binding (21). Interestingly, the phenotype of “hyperadhesion” following inflammatory activation was maintained in those IBD HIMECs that were passaged *in vitro* during the lifetime of the culture (19). The mechanisms underlying leukocyte hyperadhesion in the chronically inflamed IBD HIMECs did not appear to involve increased levels of CAM expression compared to control cultures, which prompted an investigation of possible alterations in the intracellular mechanisms that govern the downregulation of inflammatory activation in ECs. Nitric oxide (NO) plays a central role in the regulation of endothelial activation and the maintenance of vascular homeostasis, exerting a potent antiinflammatory effect and downregulating the activation of vascular ECs as well as their capacity to bind circulating leukocytes, normally an early and rate-limiting step in the inflammatory process. Control HIMECs displayed distinct

patterns of NO generation through both constitutive endothelial NO synthase (eNOS; NOS3) as well as inducible NOS (iNOS; NOS2), which was expressed following inflammatory activation (22). In marked contrast, IBD HIMECs (both CD and UC) failed to express iNOS and increased levels of NO following inflammatory activation (23). Preliminary investigation of eNOS demonstrated unchanged levels of mRNA between control and IBD HIMEC lines (22). However, this investigation did not consider eNOS function, which may be altered due to activation status and cofactor association (e.g., “uncoupling” of the enzyme) (24). This loss in NO generation in IBD HIMECs was linked to enhanced leukocyte binding, because the administration of NO donors restored a normal binding pattern in the activated IBD HIMECs. Further investigation demonstrated that iNOS-derived NO in the IBD HIMECs appears to function as an endogenous antioxidant, quenching the superoxide anion, which is a central mediator of inflammatory activation in gut microvascular ECs. These data again suggest epigenetic mechanisms that lead to preservation of an altered activation status characterized by loss of NO generation in the IBD HIMECs exposed to chronic inflammatory stress *in vivo*. The mechanisms that lead to altered iNOS expression in the chronically inflamed IBD HIMECs have not been fully defined.

#### VASOREGULATION AND MICROVASCULAR DYSFUNCTION IN CHRONIC INTESTINAL INFLAMMATION

The endothelium not only provides a structural barrier between the circulation and surrounding tissue, but ECs also secrete mediators that influence vascular hemodynamics in the physiologic state. ECs contribute to the regulation of blood pressure and blood flow by releasing vasodilators such as NO and prostacyclin (PGI<sub>2</sub>), as well as vasoconstrictors, including endothelin (ET)-1 and platelet-activating factor (PAF). The major biologic effects of these chemically diverse compounds are regulated by localization of specific receptors on vascular cells, through their rapid metabolism, or at the level of gene transcription. NO is constitutively secreted by ECs, but its production is modulated by a number of exogenous chemical and physical stimuli, whereas the other known mediators (PGI<sub>2</sub>, ET, and PAF) are synthesized primarily in response to changes in the external environment.

An investigation of intestinal perfusion in the setting of chronic inflammation in IBD has been carried out using a variety of *in vivo* and *in vitro* techniques. Angiographic studies of the IBD intestine have demonstrated preserved anatomy in the SMA and IMA, with significant abnormalities in the vasa recta, characterized by tortuous, dilated vessels together with the loss of normal tapering and terminal coiling as they penetrate the bowel wall (25,26). In early stages of IBD, angiographic studies have demonstrated arterioles that abruptly taper as the vessels reach the bowel wall with right-angle bifurcation, bizarre distribution, and small luminal irregularities in the peripheral

branches (25,26). Furthermore, advanced IBD lesions demonstrate reduced vessel diameter, decreased vascular density, and diminished blood flow in the involved segments, which may contribute to an impaired capacity to heal and resolve the chronic inflammatory “wound.”

Alterations in the IBD microvascular architecture were characterized by Wakefield and colleagues (27) using scanning electron micrographs of corrosion microcasts from control and CD patients. These studies identified occlusive fibrinoid lesions in the arterioles supplying affected intestine, which were not demonstrated in uninvolved areas of bowel. Morphologically, the chronically inflamed microvessels were tapered and stenosed, compared with vessels from uninvolved and control bowel. Vascular damage was demonstrated as an early pathologic finding, which preceded the development of mucosal ulceration. Vascular damage appeared to be highest where vessels penetrated through the muscularis propria, and bursts of angiogenic vessels were seen in distal areas of the mucosal circulation. These authors concluded that multifocal gastrointestinal infarction plays a pathogenic role in the chronic inflammatory lesion in CD, with the extent of vascular damage correlating with the severity of intestinal injury.

The concept of microvascular dysfunction and relative tissue ischemia was further investigated by Funayama and colleagues, who used tissue histometry to describe remodeling in the CD intestinal microcirculation (28). Assuming that medial atrophy is an indirect measure of decreased vascular perfusion and pressure, these investigators characterized atrophy of arterial media in the submucosal CD vessels, which indirectly suggests ischemia and increased vascular resistance in deeper submucosal arteries. Taken together, these studies suggest that the microvascular anatomy in the chronically inflamed CD intestine has undergone extensive remodeling. However, these studies did not directly assay microvascular function or any potential factors that may appear to lead to these alterations in vascular architecture.

Assessment of intestinal microvascular physiology in human IBD has been characterized using direct and indirect methods to assess microvascular blood flow. Hulten and colleagues used an intraoperative isotope washout technique, as well as *in vivo* abdominal angiography to characterize IBD-specific alterations of intestinal blood flow, demonstrating perfusion patterns associated with distinct phases of disease (5). Early fulminant IBD with severe inflammation was characterized by increased vascular perfusion, which is typical of an acute inflammatory response. In contrast, reduced regional blood flow was seen in chronically inflamed and remodeled tissues, particularly in areas of CD stricture. These observations have been confirmed in subsequent studies that demonstrate diminished vascular perfusion associated with fibrosis and longstanding inflammation. Using endoscopic laser Doppler flowmetry (29), decreased mucosal blood flow was seen in the neoterminal ileum after ileocollectomy and in rectal mucosal perfusion in patients with longstanding UC (30).

The poorly healing, refractory inflammatory ulcerations and damage in the IBD intestine suggest that these diseases are

associated with microvascular dysfunction resulting in diminished vasodilatory capacity and tissue hypoperfusion. ET-1, a potent vasoconstrictor, is known to be elevated in CD and UC patients' tissue, again suggesting an ischemic vascular supply to the chronically inflamed bowel (31). The molecular physiology underlying microvascular dysfunction in IBD was assessed directly by Hatoum and colleagues, who characterized vasodilator responses in human intestinal microvessels by measuring *in vitro* vasodilatory capacity in response to acetylcholine (ACh) from perfused arterioles (50–150 micron diameter) isolated from intestinal resections (32). Normal intestinal microvessels vasodilate in response to ACh via NO- and cyclooxygenase (COX)-1 and -2-dependent mechanisms, whereas chronically inflamed IBD arterioles (in both CD and UC) demonstrate a significantly diminished vasodilatory response (32,33). This decreased vasodilatory capacity in the chronically inflamed IBD microvessels was directly related to a loss of NO-dependent function. These same vessels were found to be heavily dependent on COX to maintain their vascular tone. A significantly increased expression of COX-1 and -2 occurred in the IBD arterioles compared with control (32). Microvascular endothelial dysfunction in chronically inflamed IBD tissues was associated with excess levels of oxidative stress, as measured by intravital dyes and confocal fluorescence microscopy; this was not present in vessels isolated from normal intestine or uninvolved areas of IBD bowel (32). The microvascular dysfunction identified in arterioles from chronically inflamed IBD gut was not a generalized response to inflammation, because it was not demonstrated in vessels isolated from acute inflammation (*i.e.*, diverticulitis) and uninvolved areas of IBD. This demonstrates that medications used to treat IBD patients at the time of surgery did not contribute directly to the microvascular dysfunction, and further substantiates that intrinsic, acquired alterations in the chronically inflamed and remodeled microcirculation underlie this pathophysiology.

#### THE MICROVASCULAR ENDOTHELIUM AS A THERAPEUTIC TARGET IN INFLAMMATORY BOWEL DISEASE

The process of microvascular endothelial activation and CAM expression has emerged as a potential therapeutic target in the treatment of inflammatory diseases (34). Targeting endothelial–leukocyte interactions for therapeutic benefit in patients with IBD has emerged as an early area for human trials and has received intense research interest. Over the past decade, three experimental agents (antisense ICAM-1, anti- $\alpha 4$  antibody, and anti- $\alpha 4\beta$  antibody) have been extensively evaluated in placebo-controlled trials for both CD and UC. These agents have demonstrated important results regarding efficacy and safety (35).

The initial trials of antiadhesion-molecule therapy in IBD targeted ICAM-1, using an antisense oligonucleotide strategy with the compound alicaforsen (ISIS 2302, ISIS

Pharmaceuticals, Carlsbad, CA) (36). ICAM-1, a member of the immunoglobulin superfamily, is an inducible transmembrane glycoprotein that is constitutively expressed at low levels on vascular ECs, including gut microvessels, and plays a central role in the recruitment and retention of leukocytes in inflammatory foci (37–40). Following experimental success in the use of humanized antibodies targeting ICAM-1 in refractory rheumatoid arthritis patients (41), trials were carried out targeting increased ICAM-1 expression in CD patients. Alicaforfen, a 20-base phosphorothioate antisense oligodeoxynucleotide molecule designed to specifically hybridize to a sequence in the 3' untranslated region of human *ICAM-1* messenger RNA, forms an oligodeoxynucleotide-RNA heterodimer susceptible to degradation by the ubiquitous nuclease RNase-H, and ultimately reducing cell-specific message content and ICAM-1 protein expression (42–46). In the initial trial by Yacyszyn and colleagues, a steroid-sparing effect and clinical remission was demonstrated in 40% of treated CD patients who received intravenous infusions of the agent (36). However, subsequent clinical trials of alicaforfen in CD have failed to replicate this level of success. More recent trials have focused on UC patients using topical therapy with an enema preparation of alicaforfen; this approach has demonstrated prolonged responses in the treated subjects (47,48), and further studies of the compound in the UC patient population are ongoing.

Pioneering investigation by Koizumi and colleagues defined a pivotal role for integrin–integrin ligand interaction in the pathogenesis of a spontaneous animal model of colitis that occurs in the cotton-top tamarin, a New World primate from South America (49). Using this animal model, these authors demonstrated a central role for the leukocyte  $\alpha 4$  integrin interacting with specific endothelial integrin-ligands (i.e., MAdCAM-1, VCAM-1) in the pathogenesis of chronic colitis. Animals treated with an anti- $\alpha 4$  antibody demonstrated significant clinical improvement (50), and the success of these early observations led to the development of novel therapeutic strategies targeting the interaction of  $\alpha 4$  integrin-positive leukocytes with their cognate endothelial ligands, including MAdCAM-1. Subsequent studies using rodent models of IBD also have demonstrated critical roles for CAMs in the initiation and perpetuation of chronic gut inflammation (51,52).

The first successful anti- $\alpha 4$  integrin trials used the humanized antibody, natalizumab, in patients with relapsing and remitting multiple sclerosis (MS) and CD. Ghosh and colleagues demonstrated remission rates of 44% and a response rate of 71% in a multicenter European CD trial. In early 2005, natalizumab was given approval by the U.S. Food and Drug Administration for inducing and maintaining remission in MS. During this time, large multicenter CD and MS trials were ongoing throughout the world, and an estimated 4,000 patients had received this compound through protocols and open-label use, when evidence linking natalizumab with severe CNS viral infection led to immediate suspension of the drug. Three cases of progressive multifocal leuko-

encephalopathy (PML) were identified (two MS patients and one CD patient), with two patients dying as a result of the JC viral reactivation and resultant brain damage. Retrospective analysis of stored serum samples demonstrated reactivation of JC virus with the emergence of detectable viral load in a preclinical time period in a CD patient who ultimately died from PML (53). The unexpected emergence of viral reactivation with catastrophic CNS infection suggests that the future use of widespread anti- $\alpha 4$  integrin blockade (blocking both  $\alpha 4\beta 7$ - and  $\alpha 4\beta 1$ -expressing leukocytes) would require extensive safety monitoring for any realistic potential future use.

Despite the tragic complications encountered during the early use of natalizumab, trials of selective leukocyte inhibition in the treatment of chronic inflammation and IBD have continued. A recent successful trial targeting a subset of  $\alpha 4$  integrin-expressing leukocytes was carried out by Feagan and colleagues (54). Using a humanized antibody targeting  $\alpha 4\beta 7$  integrin (MLN02, Millenium Pharmaceuticals, Cambridge, MA), these investigators demonstrated significant response and remission in patients with active UC (response 66%, remission 33% at 6 weeks). Among the 118 patients who received the active compound, no severe infections occurred, including viral reactivation. This positive trial suggests that efforts to more selectively target leukocyte–endothelial interaction may provide a strategy to achieve both efficacy and safety in therapeutic adhesion molecule blockade for IBD.

## CONCLUSION

Data from multiple lines of investigation have demonstrated that the endothelium plays an important role in the pathogenesis and clinical course of IBD. In response to the stress of chronic inflammation, endothelium in the IBD intestine demonstrates an altered physiology, with impaired vascular perfusion. This microvascular dysfunction is the result of impaired endothelial generation of NO as well as other mediators of vasorelaxation. Likewise, local endothelial populations in chronically inflamed IBD intestine demonstrate altered patterns of leukocyte recruitment, with preferential adhesion of naïve leukocytes. Finally, novel strategies targeting endothelial–leukocyte interaction are emerging as potent biologic therapies for patients with refractory IBD.

## KEY POINTS

- The endothelium lining the gut microvasculature plays a critical role in mucosal immune homeostasis through expression of CAMs and vascular addressins that govern leukocyte traffic into the bowel.
- The endothelial lining of the submucosal arterioles in the human intestine regulates vascular perfusion

through NO-, COX-, and endothelium-derived hyperpolarizing factor (EDHF)-dependent mechanisms.

- The human inflammatory bowel diseases (CD, and UC) are characterized by alterations in microvascular anatomy, as well as endothelial physiology. These include impaired endothelial-dependent dilation as well as altered patterns of endothelial-leukocyte interaction. Loss of NO generation has been identified in both of these manifestations of IBD-associated endothelial dysfunction.
- Therapeutic trials of anti-CAM therapy have been initiated in patients with IBD. Molecules targeting the  $\alpha 4$  integrin as well as ICAM-1 are presently undergoing investigation for both CD and UC.

## The Vascular Bed of Spleen in Health and Disease

---

Péter Balogh

*Faculty of Medicine, University of Pécs, Hungary*

The spleen is the largest filter of blood in the body. The major functions of the spleen are to remove aging red blood cells, to participate in innate immunity, and to promote adaptive immune response. The branching arterial system in the spleen is sheathed by lymphoid tissue (white pulp) and ends in a venous sinus system (red pulp). The red pulp, which serves to filter blood and remove senescent erythrocytes, consists of afferent arterial cords (an open blood system lacking an endothelial lining) leading to venous sinuses that are lined by discontinuous endothelium. The white pulp represents the lymphoid region of the spleen and consists of B and T lymphocyte-rich lymphoid sheaths surrounding the arterial system. Despite these common properties, important anatomical differences exist between the spleen of humans and rodents. Thus, caution is required when extrapolating results from one species to another. The goal of this chapter is to discuss the properties of endothelial cells (ECs) that line the various vascular beds of the spleen, and where necessary to point out the differences between the human and rodent architecture.

### **HISTORICAL BACKGROUND, OR, THE MYSTERII PLENUM ORGANON**

For the better part of history, the spleen was attributed with the function of removing agents that would prove harmful to the individual, thus reducing contamination of the healthy blood. In contradistinction to Aristotle, Galen argued that the liver, and not the heart, was the principal organ providing the body with strength and spirit. Galen held that the spleen contained black bile and was responsible for controlling emotions by eliminating sadness and melancholy. Remarkably, this interpretation of splenic function would prevail until the mid-18th century. Even William Harvey, a physician renowned for his discovery of the circulation, believed that the sign of a properly functioning spleen was the person's ability to laugh and that its impairment would manifest in the patient's loss of cheerful spirit, replaced by sullenness (1,2).

The notion that the spleen carries out functions beyond filtering of black bile or spiritual cleansing can be traced back to the Renaissance period in Bologna and elsewhere in Italy, when it was suggested that the spleen removes harmful substances from the feces via its vascular supply. Soon thereafter, Marcello Malpighi using light microscopy was able to describe the splenic corpuscles, which were named after him and are now referred to collectively as the splenic white pulp, followed about two centuries later by Theodor Billroth, who first adequately described the microscopic structure of the red pulp (hence the term *cords of Billroth*). Based on subsequent microscopic observations, the spleen was recognized to possess three distinct regions – namely, white pulp and red pulp, separated by a marginal zone. The white pulp is further divided into follicles and periarteriolar lymphoid sheaths. Each of these regions is associated with a unique vascular bed, lined by phenotypically distinct subsets of ECs (Figure 136.1; for color reproduction, see Color Plate 136.1).

The spleen's connection with the lymphohemopoietic system was first established in the early 1770s by William Hewson, who identified lymphocytes in the spleen and thymus. Subsequent work by Rudolf Virchow revealed the similar morphology of white blood cells and splenic white pulp lymphocytes. The spleen's ability to remove blood-borne particles (including fragmented erythrocytes) was later recognized by Emil Ponfick, one of Virchow's numerous apprentices of pathology fame, and during the early decades of the 20th century the spleen's role in immunologic defense gradually came to light (2).

Morphological studies performed during the 1920s revealed considerable erythropoietic activity in the mammalian spleen during embryogenesis, a process that was subsequently localized to areas outside the sinuses. This arrangement is in contrast to what takes place in the yolk sac, where vasculogenesis and intravascular red blood cell formation occur simultaneously as a result of the parallel differentiation of hemangioblasts (3,4).

Subsequent studies during the late 1960s and early 1970s demonstrated that both the embryonic and adult spleen contain cells capable of reconstituting multilineage (lymphoid

Figure 136.1. Endothelial labyrinth around the lymphohemopoietic compartments of the spleen. Various segments of the splenic vasculature can be identified by their different endothelial surface phenotype in separate regions of the spleen. (A) The main vessel types are identified as CD31-positive central artery, CD31/IBL-7/1 double-positive arterioles in the white pulp; MAdCAM-1-positive marginal sinus coexpressing IBL-7/1 marker at some locations in the marginal zone; and a few scattered IBL-7/1 positive sinuses in the red pulp. (B) The T cells (Thy-1) are arranged around the central arteriole (arrow), to which follicles containing B cells (B220) are attached. The red pulp is outlined as the major macrophage-containing domain (F4/80). (C) The arrow points at a transitional area between the IBL-7/1-positive white pulp arteriole and the MAdCAM-1-positive segment of the marginal sinus is shown, coexpressing both markers. (D) Sinusal heterogeneity of the red pulp area. A fraction of sinuses label only with mAb IBL-7/1 or express IBL-7/1 and IBL-9/2 markers at approximately equal intensity (arrow), whereas the majority of red pulp sinuses and possibly venules dominantly display the IBL-9/2 antigen (62). For color reproduction, see Color Plate 136.1.

and myeloid) long-term hematopoiesis in irradiated animals, as well as committed precursor cells (particularly in the erythromyeloid line)(5,6).

## STRUCTURE AND FUNCTION OF SPLENIC VASCULATURE

### Overview of the Splenic Circulation: Structural Differences Between Human and Rodents

For its size, the spleen in both human and rodents receives a disproportionately large amount of blood flow, corresponding to approximately 5% to 10% of total cardiac output (7). This volume is pumped into the spleen through the splenic artery (a. lienalis) whose subsequent branching forms the basic scaffolding elements of the tissue. The number of arterial branches in humans is considerably higher than in rodents. In either case, small-sized arterioles (termed *central arterioles*) are surrounded by lymphatic tissue (white pulp), including a T cell-

rich periarteriolar lymphoid sheath and B cell-rich follicles. These arterioles in humans are often arranged in bundles, where arterioles and two to three parallel capillaries are held together in a reticular sheath (8,9). In some individuals several vessels may originate from one larger arteriole, thus forming the penicillar arterioles, primarily in the red pulp.

The smallest branches of the central arterioles (termed *terminal arterioles*) traverse the white pulp and, depending on the species, may connect either to the marginal sinus surrounding the white pulp (in rodents) or to the red pulp sinuses in the perifollicular zone outside the marginal zone (in humans). In rats and mice, a few larger white pulp arterioles may reach the red pulp by traversing the marginal zone. Using intravital microscopy, a distinct set of white pulp terminal arterioles was described recently in mice, which continue into smaller capillaries whose bud-like terminal segment within the white pulp is arborized into loosely organized honeycomb-like structures. At these locations the blood may seep into the surrounding tissue. The spatial relationship of these complexes to the marginal sinus is currently unclear; moreover, it is also probable that the cells lining these vascular regions are of nonendothelial origin, as indicated by the lack of expression of a panendothelial *Tie2* promoter-driven reporter gene in this formation. Kinetic analysis of labeled cells has raised the possibility that these honeycomb-like regions may act as a splenic entry port for recirculating T cells into the spleen by allowing their firm adhesion to the vessel wall. Using large-molecular-weight soluble fluorophores, it appears that most of the blood flow is directed toward the veins at a relatively high velocity, with a smaller fraction of the blood extravasating into the red pulp at a slower speed. Thus, the honeycomb-like structures in the white pulp (or at the white pulp-red pulp juncture) may represent a novel "open" segment of the splenic vasculature, in addition to the red pulp sinuses (10,11).

The reticular cells and fibers constituting the circumferential reticulum enclosing the white pulp also serve as a stromal support for the marginal sinus or perifollicular space. The ambiguity as to which type of cell – endothelial or reticular/fibroblastic – forms the inner lining of lumens within this space explains the judicious use of the term *sinus-lining cells*. As an example of the above uncertainty, mucosal addressin cell adhesion molecule (MAdCAM)-1 is expressed in this segment of the vasculature in mice, whereas expression of MAdCAM-1 in the marginal zone of human spleen is limited to fibroblasts (12,13).

In contrast to that of rodents, the human spleen does not contain a marginal sinus. Instead, some arterioles terminate in a perifollicular zone (which is absent in rodents), and others reach the red pulp, in a fashion similar to that in mice and rats (12). Prior to their termination within the red pulp, these arteriolar capillaries are surrounded by a complex multi-layer structure that forms the basic scaffolding of splenic cords (of Billroth), primarily composed of macrophages, dendritic cells, and a fibroblastic reticular meshwork. It is also commonly referred to as the *periarteriolar macrophage sheath* (14). In humans the dominant cell type is the sialoadhesin-positive

**Table 136-1: Vascular Features of Splenic versus Lymph Node Homing of Lymphocytes**

<i>Feature</i>	<i>Spleen</i>	<i>Lymph Node<sup>a</sup></i>
Type of vascular bed functioning as exit port	Terminal arteriole/marginal sinus	Postcapillary venule
Location of the exit port	B-cell area (marginal zone or perifollicular zone)	T-cell area (paracortex)
Type of the endothelium lining the vessel	Flat (sinus endothelium) <sup>b</sup>	High endothelium (cuboidal dimensions)
Molecular constraints	Independent from L-selectin and its various ligands <sup>c</sup>	L-selectin dependent

<sup>a</sup>General features are listed, without detailing the differences between peripheral and MALT-associated lymph nodes.

<sup>b</sup>The auxiliary role of other sinus-lining cells (marginal zone macrophages) cannot be ruled out.

<sup>c</sup>The adhesion and migration of hemopoietic progenitors by VCAM-1/VLA-4 and of B cells by CD22 also appear to be regulated differently between the spleen and bone marrow, where the engagement of these surface molecules are involved in the BM (but not the splenic) homing (19,20).

macrophage (15). This “open” segment of the red pulp vasculature inserted between the terminal arterioles and the small venules is unique to the splenic circulation, and although it has received considerable attention in the field of splenic circulation, its mechanisms of action remain unclear.

Although the spleen is considered a peripheral lymphoid organ, it differs in fundamental ways from peripheral lymph nodes. A unique feature of the spleen is the presence of the marginal zone, a compartment composed of specialized macrophage subsets and a distinct set of B cells – the marginal zone B cells. These lymphocytes differ from their follicular counterparts in many aspects, including their phenotype, functional properties, and developmental requirements. As a result of their dominance in the marginal zone, the extravasation of circulating lymphocytes in the human and rodent spleen takes place in this B-cell rich (non-follicular) compartment, in contrast to lymph nodes and tonsils, where lymphocytes home via high endothelial venules to T-cell rich domains. The principal differences between the vascular aspects of splenic versus lymph node homing processes are summarized in Table 136-1.

In the human (sinusal) spleen the venous sinuses are lined with tightly fitting ECs, which may be pushed apart to create interendothelial slits (IES), indicating the presence of a process subject to regulation. In rodents (traditionally considered to be nonsinusal – i.e., having an absence of sinuses between arterioles and venous capillaries in their spleens), the large gaps between ECs exert a considerably lesser obstacle to blood cell passage. As a result of the open circulation, a substantial amount of blood is filtered through red pulp reticular cells and fibers before reentering the red pulp sinuses through their endothelial pores and slits. These reticular (or barrier) cells surround the arterial endings in usual pericyte-like fashion, whereas their extensions are connected to each other, thus creating an extravascular meshwork for the corpuscular filtering of extravascular blood before it reaches the venous phase of circulation (14). It is this reentry phase that

serves as a checkpoint for removing those red blood cells whose physical deformability is impaired due to internal abnormalities (e.g., plasmodia in malaria infection) or are fragile (e.g., complement-damaged erythrocytes in antibody-induced anemia). The connection of blood flow between the arterial ending and the initiation of venous sinuses may be facilitated by the active movement/repositioning of reticular fibroblasts, thus bringing together two closely situated vascular segments. Moreover, these cells may even form lumens, thus complementing the endothelial gap between two vascular segments (9). The ordered arrangement of these or related cells in the splenic white pulp in mouse has been demonstrated to be involved in the transport of soluble macromolecules, acting as a molecular sieve (16).

The “open circulation” described earlier appears to be the typical form of vasculature in both human and rodents. Due to the relatively large amount of blood flow for its size, it is probable that the majority of blood volume within the spleen is likely to drain into venous sinuses without percolating through extravascular spaces for any length of time. Thus the spleen simultaneously possesses both open and closed circulatory pathways.

After their origin in the perifollicular zone and red pulp (or the equivalent marginal zone/sinus in rodents), the sinusoids converge into larger venules and finally merge into trabecular veins. The effluent blood (that has been filtered through the meshwork of red pulp chords) leaves the spleen through the v. lienalis, which is joined by the vena mesenterica superior to form the portal vein. Because the cellular content of a hematopoietic tissue is maintained by controlling simultaneously the access and egress of leukocytes, it is surprising that, in addition to the uncertainties surrounding the precise mechanism underlying the access of leukocytes and their precursors to the spleen, the control of their reverse movement from the spleen into the circulation has almost entirely been ignored.

It is generally accepted that the spleen contains lymphatic vessels, as evidenced by the presence of thin-walled vessels

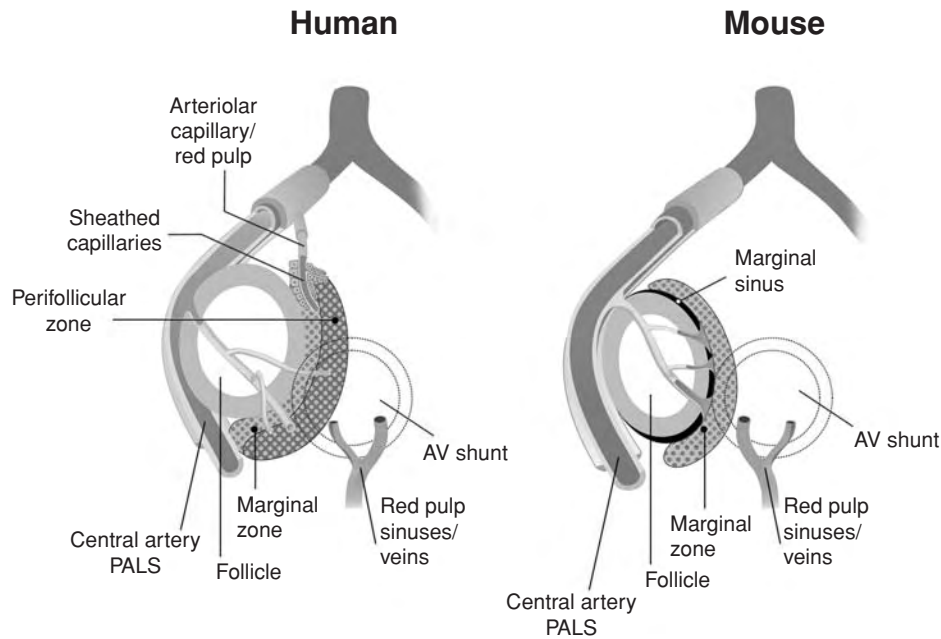

Figure 136.2. A hypothetical scheme of splenic circulation in man compared to rodents (“HuMouse”). After the branching of main artery, smaller arteriolar segments penetrate the white pulp. On the left side, the human structure is shown, with features characteristic for the human conditions on the left side of the drawing (SC: sheathed capillaries, PFZ: perifollicular zone). On the right side, the mouse arrangement is shown. The parts in the middle of the graph indicate the common elements in both species (MZ, marginal zone; PALS, periarteriolar lymphoid sheath). For color reproduction, see Color Plate 136.2.

lacking basement membrane deeply embedded in the white pulp. However, little is known about the physiological importance of these vessels (17,18).

A “minimalist” scheme of vasculature in human versus rodent spleen is shown in Figure 136.2 (for color reproduction, see Color Plate 136.2). Table 136-2 summarizes the essential differences between various splenic vascular segments in man and rodents.

### Ultrastructural Characteristics of Splenic Endothelium

Although most ultrastructural studies of the splenic vasculature have focused on the unique marginal sinus (or perifollicular space) and red pulp, a small number of transmission electron microscopic studies of the white pulp have demonstrated a continuous endothelium lining the central arteriole and downstream arteriolar capillaries. The endothelium rests on a basal lamina that, like other vessels in the spleen, contains heparan sulfate, chondroitin sulfate A and/or C, chondroitin sulfate B, and sialic acid residues, substances that are also present on the luminal aspect of splenic endothelia (with the exception of red pulp sinuses) (21). The endothelial lining of the central artery is surrounded proximally by two or three layers of smooth muscle cells and distally (because the vessel terminates in the marginal sinus or red pulp sinus) by cytoplasmic processes of reticular cells (9). The transition between smooth

muscle cell and reticular cell covering is marked by a progressive reduction in endothelial continuity and the appearance of fenestrated basement membrane. This structure is created by the ring fibers (or annular fibers) on the abluminal side of the endothelium, intertwined by longitudinal fibers.

The terminal segment(s) of arteriolar capillaries may form (a) simple funnel-like structures with splits and pores or cut-across, (b) small ampulla with pores, or (c) one larger ampulla covering multiple arterioles (9).

The red pulp sinuses are lined with ECs (also named *rod cells*) that run parallel to each other and to the course of blood flow. In contrast to the continuous-type vessels (central arteriole, terminal arterioles, and veins), the luminal surface of rat sinuses lacks heparan sulfate, chondroitin sulfate A and/or C, chondroitin sulfate B, and sialic acid residues, which are restricted to the fenestrated basal lamina within this compartment (21). The nuclei of sinus ECs characteristically protrude into the vessel lumen. In addition to these ovoid nuclear protrusions, the luminal aspect of the endothelium may also contain short drop-like or filiform micro-extensions. In various diseases (such as hepatic cirrhosis with portal hypertension, hereditary spherocytosis, and idiopathic thrombocytopenic purpura) the number of these extensions may increase (9). The lateral aspects of ECs are connected by two main types of intercellular connections: adherens junctions and, to a lesser extent, tight junctions. As with other vascular beds, desmosomes are absent in splenic endothelium. The actin filaments

**Table 136-2: Comparison of Main Features of Some Splenic Vascular Bed Homologues in Human and Rodents**

<i>Vascular Bed Segment</i>	<i>Humans</i>	<i>Rodents</i>
Central arteriole	Often present in non-T-area; smaller diameter indicating more numerous branching (8).	Usually runs in the central part of T-cell zone; thinner muscular layer.
Terminal arterioles	Surrounded by sialoadhesin-positive macrophages (primarily in the perifollicular zone, outside the MZ).	Sialoadhesin-positive macrophages are restricted to the marginal zone, the arterioles end in marginal sinus.
Marginal sinus	Absent	Present

(running parallel to the length of cell) are typically associated with the junctional membranes and are continuous with the actin filaments in contractible stress fibers at both forms of contact, presumably rendering the sinus wall able to adjust to volume/pressure alterations of the splenic circulation (22–24).

In addition to the outward protrusion of nuclei and micro-extensions, sinus endothelium in the rat spleen also displays an extensive canalicular membrane system composed of inwardly projecting channels of approximately 20-nm width. These tubular structures penetrate the entire cell, and their continuity with the plasma membrane on both sides of the EC indicates that they may be open on both ends. In addition to these tubular formations, spherical forms of membrane invaginations restricted to the membrane-proximal regions of cytoplasm (i.e., not traversing the entire cell), such as caveolae and coated pits, have also been described. The function of these compartments is currently unknown; they have been speculated to be involved in the release and storage of various substances, including calcium or endothelin, thrombomodulin or fibroblast growth factor (FGF) (25–27).

On the abluminal aspect of the sinus endothelium, the cells are connected to each other by ring fibers that overlap the above interendothelial bridges. These bands are formed by the extensions of reticular cells located nearby and are inserted into small grooves on the abluminal surface of rod cells, without causing any protrusion on their luminal aspect (9).

### Developmental and Functional Characteristics of Splenic Endothelium

The heterogeneous nature of the splenic vasculature combined with its diverse functions during ontogeny has considerably hampered our understanding of EC function in this organ. In general, site-specific EC phenotypes are epigenetically predetermined and/or mediated by the local tissue microenvironment (28). In rodents, immediately after birth the tissue architecture of the spleen lacks any discernible compartmentalization, including a lack of follicle formation, separation of T-cell and B-cell zones, and the absence of marginal zone. Figure 136.1 illustrates the lymphoid/myeloid “parenchymal”

and “endothelial” compartmentalization of the adult spleen. Although a substantial amount of evidence in humans indicates the heterogeneous composition of endothelium in the spleen, most of the developmental data have been compiled from animal studies. Therefore, the results obtained must be interpreted with caution.

The developing spleen represents a complex organization of hematopoietic tissue–stem cell niches, which gradually shifts in function from an overwhelmingly myelopoietic tissue (forming mainly erythroid cells and, to a lesser degree, granulocytes and megakaryocytes) to a peripheral lymphoid organ that retains its potential to support hematopoiesis. Splenic organogenesis is under the combined control of several regulators, including homeodomain transcription factors. The available evidence indicates that the spleen (already present in sharks, the most ancient group of vertebrates to have adaptive immunity) in mammals develops from the dorsal pancreatic mesenchyme, independently of pancreatic epithelium. Transgenic mice overexpressing Sonic Hedgehog factor (Shh) driven by the *Pdx-1* promoter (an essential regulator of early pancreatic development) lack pancreatic mesoderm, due to its conversion into intestinal mesenchyma, and also fail to develop a spleen (29). Increased hedgehog (Hh) signaling induced by the absence of Hh-inhibitor Hhip also blocks the formation of the spleen, for which the deficiency of FGF10 is believed to be responsible (30). The spontaneous mutation observed in dominant hemimelia (Dh) is associated with abnormal limb and visceral development affecting the splenic mesodermal plate (SMP), and it also causes asplenia (31).

Subsequent to its symmetric appearance, SMP is induced to undergo a leftward growth, a process that involves FGF9 and FGF10 under the control of *Bapx1/Nkx3.2*. Asplenia is also observed in mice that are null for either *Bapx1/Nkx3.2* or *Wt1* or *POD-1/capsulin* (32). Attempts to determine genetic interaction of *Hox11* with *Wt1*, *Bapx1/Nkx3.2*, and *capsulin* led to the conclusion that *Wt1* functions downstream of *Hox11* (33–40). More recently another form of abortive splenic development has been described as a result of aberrant iron metabolism and toxicity mediated by iron overload in polycythemia (*Pcm*) mutation. This condition probably affects mesenchymal stromal precursors in the red pulp

area (41). Although present, the spleen in these animals is aberrantly small, its red pulp stromal architecture is atrophic, and the various vascular elements (central artery and distinct red pulp sinuses, respectively) are abnormally arranged. In mice deficient in the *Nkx2.3* homeodomain transcription factor, atrophic splenic differentiation with variable severity was observed. In these animals the marginal sinus lining cells in the rudimentary spleen lacked the MAdCAM-1 glycoprotein (42,43).

The differentiation of endothelial precursors at splenic locations is paired with the induction of various transcription factors. Of these, the *SCL/TAL1* encoding a basic helix-loop-helix-type transcription factor appears to be upregulated early during the hematopoietic differentiation simultaneously in both the hematopoietic cells and endothelium, including the developing spleen (44). Both in human and adult mice the expression of *SCL/TAL1* protein is detected in the red pulp endothelium as well as macrophages, whereas in humans its mRNA is also expressed in the white pulp vessels, primarily at the peripheral regions of follicles (45). The deletion of the *Scl/Tal1* gene resulted in embryonic lethality preceding the formation of spleen, indicating that its function is not restricted to splenic organogenesis, but is more fundamental in vasculogenesis and endothelial differentiation (46). In addition, chromosomal rearrangement of the *SCL/TAL1* gene is frequently observed in acute T-cell leukemia. During sequential *in vitro* endothelial and/or hemopoietic differentiation from embryonic stem cells, BMP4 induces the differentiation of FLK-1-positive cells into FLK-1/*SCL* double-positive intermediates. Vascular endothelial growth factor (VEGF) interacts with FLK-1 to promote endothelial (and also hematopoietic) differentiation and expansion of these FLK-1/*SCL* double-positive cells (47). It is not yet known whether similar events take place in the emerging spleen. Because the VEGF receptor 3 (VEGFR3) (FLT-4) is mainly expressed on lymphatic endothelium precursors, its role in splenic vasculogenesis is likely to be only secondary, if any (48).

In addition to the VEGF family members, another important group of factors involved in the vascular modeling and angiogenesis is the angiopoietins (Ang1, Ang2, and Ang3), recognized by the receptor tyrosine kinase Tie2 (49). Ang1 elicits endothelial survival and stabilization, whereas Ang2 induces vascular destabilization and subsequent neovascularization or neoangiogenesis. Tie1 and Tie2 are also expressed by hematopoietic stem cells and are required for hematopoiesis in the bone marrow (50). The *Tie2* promoter has been used to drive EC-specific expression of several genes *in vivo*. In *Tie2-GFP* transgenic mice, reporter gene expression was detected in most vascular beds but was notably absent in the honeycomb-like structures at the termination of arterial capillaries in mouse (11). Similar lack of expression at the marginal sinus was observed in mice carrying other EC-specific promoters, including receptor protein tyrosine phosphatase  $\mu$ , (RPTP $\mu$ ), endothelial nitric oxide synthase (NOS), and von Willebrand factor (vWF) (51–53). Together, these data point to a complex ontogeny of ECs lining of splenic vessels.

In the postnatal period, the tumor necrosis factor/lymphotoxin (TNF/LT) family members are involved in directing the proper segregation of lymphoid and stromal compartments of the white pulp and marginal zone, thus rendering the spleen capable of mounting effective immune responses. These do not appear to influence the prenatal hematopoietic function (54). A striking consequence of lack of lymphotoxin-beta receptor (LT $\beta$ R) signaling is the absence of MAdCAM-1 antigen from the sinus-lining cells of the marginal sinus (55). It appears to be a temporally fixed trait, as the availability of LIGHT (alternative soluble ligand for LT $\beta$ R) cannot reestablish the display of MAdCAM-1 by these cells in LT-deficient animals, in contrast to the induction of follicular dendritic cell differentiation and T/B segregation (56). Interestingly, the perturbation of TNF/LT receptor signaling does not seem to affect the architecture of splenic red pulp, including its vascular elements (57).

In contrast to these conditions in which the expression of MAdCAM-1 antigen on marginal sinus-lining cells is reduced or missing, sphingosine 1-phosphate receptor (S1P)<sub>3</sub>-null mice demonstrate an abnormally expanded population of MAdCAM-1-positive cells in a disorganized marginal zone region. This effect was apparently due to the nonlymphoid cells within the spleen, as established by reciprocal bone marrow transplantation and hemopoietic reconstitution (58).

Immunohistochemical studies have revealed intriguing spatial and temporal differences in EC phenotype within the spleen of humans and rodents. For example, several EC-specific cell membrane or intracellular markers are restricted to one splenic compartment, such as white pulp, marginal zone, or red pulp in both human and mice (Table 136-3). Although largely descriptive, these findings provide compelling evidence for the existence of multiple EC phenotypes within the spleen, presumably reflecting marked functional heterogeneity (59–67).

## SPLENIC ENDOTHELIUM IN DISEASE

Vascular pathology of the spleen can be divided into vessel-derived and other diseases, originating from nonvascular tissue components. Although primary vascular splenic diseases are rare (and often asymptomatic), the spleen is a frequent site of secondary manifestations in a wide range of hematological, immunologic, oncologic, infectious, vascular, and systemic disorders. This last section will focus on vascular pathology due to aberrant development of vessels.

The most frequent of these disorders are splenic vascular tumors. Depending on their growth characteristics, these tumors can be divided into (a) benign (including hemangioma, hamartoma, and lymphangioma) (b) variable (littoral cell angioma, hemangioendothelioma, and hemangiopericytoma), and (c) malignant (angiosarcoma) types. On ultrasound, the primary tumors often manifest as solitary or multiple echogenic nodules, intramural dilatations, or cysts. They

**Table 136-3: Phenotypic Features of Distinct Vascular Segments of the Spleen**

<i>Antigen/Marker (Refs.)</i>	<i>Region</i>			<i>Function</i>
	<i>Central Arteriole and White Pulp</i>	<i>Marginal Sinus<sup>a</sup></i>	<i>Red Pulp</i>	
CD31 (8)	++	+	+/-	Modulates cell activation responses, endothelium apoptosis and cell adhesion
CD34	++	+/-	+/-	L-selectin ligand in a glycosylation-dependent manner
vWF	+	-	-	Platelet adhesion to damaged endothelium
<i>Ulex europaeus</i> agglutinin (UEA-I)	++	-	+	Specific for Fuc $\alpha$ 1-2gal sugar moieties
CD8 (59)	-	-	+	Coreceptor for major histocompatibility class I-associated antigen recognition on T cells
CD36 (60)	-	-	+	Class B scavenger receptor expressed by macrophages
<i>Bandeiraea simplicifolia</i> lectin (BS-1)	++	+	+	Specific for $\alpha$ -gal and $\alpha$ -galNAc sugar moieties
MAdCAM-1 (13)	-	++	-	Receptor for $\alpha$ 4 $\beta$ 7 integrin
IBL-7/1 (61,62)	+/- <sup>b</sup>	++	+ <sup>c</sup>	Unknown
IBL-9/2 (62)	-	-	++	Unknown
Stabilin-2 (63) (man and mouse)	-	-	++	Hyaluronate binding.
Bonzo/CXCR6 (64)	-	-	+	Receptor for CXCL16 involved in CD8 T cell movements in the splenic red pulp
CD104 (65) (integrin $\beta$ 4)	+	-	-	Noncovalently associates with integrin $\alpha$ 6/CD49f
OX2/CD200 (66) (rat and mouse)	+	+	+	Inhibitory receptor on myeloid cells (macrophages and granulocytes)
HIS 52/RECA-1 (rat) (67)	+	+	+	Unknown

<sup>a</sup>Features characteristic for mice and/or rats are indicated *in italic*.

<sup>b</sup>The central arteriole does not express the IBL-7/1 epitope.

<sup>c</sup>IBL-7/1 reacts with red pulp sinus endothelium in a heterogeneous manner: IBL-7/1<sup>hi</sup> vessels are IBL-9/2 negative, and the IBL-7/1<sup>lo</sup> endothelia coexpress the IBL-9/2 antigen (62).

are typically located in the subcapsular region or splenic parenchymal and are often observed spreading into the surrounding tissue (68,69). Their exact origin is sometimes difficult to establish, as the proliferating lumen-forming cells may display considerable lineage infidelity (e.g., coexpression of endothelial and macrophage-related surface markers) (70). Routine histopathologic observation often reveals sinus erythrophagocytosis and cytoplasmic hemosiderin deposition, which can be correlated with the clinical symptoms of hypersplenism (anemia and thrombocytopenia).

In experimental models, several viral oncogenes have proved capable of inducing EC proliferation in the spleen. For example, middle T antigen of murine polyoma virus induces malignant proliferation of ECs in newborn mice. Interestingly, the same oncogene recruits potential tube-forming cells in the spleen of adult mice (71,72). SV7, a clone of the Moloney murine sarcoma virus 349 encoding mos protein involved in components of the mitogen-activated protein kinase transduction pathway, also induces splenic vascular tumors (73,74). Furthermore, heterozygosity of the von Hippel-Lindau (*vHL*) tumor suppressor gene appears to predispose to the develop-

ment of spontaneous or carcinogen-inducible splenic vascular tumors of diverse biological behavior (75). It remains to be seen whether any of these or similar viral elements or loss of VHL tumor suppressor function leading to increased production of VEGF and angiopoietins can be responsible for the occurrence of splenic vascular tumors in humans.

In addition to the primary tumors of endothelium, vascular proliferation in the spleen may also occur as a secondary event in myelofibrosis with myeloid metaplasia (MMM). A recent study reported that in the spleen of MMM patients a characteristic microvascular shift occurred, in which the CD34-positive capillary expansion led to the substantial reduction of CD8-positive sinuses. An underlying reason for the pronounced neoangiogenesis may be the increased frequency of CD34/CD133-positive hematopoietic cell subset that would have the potential to mature into ECs. An attractive hypothesis seems to be that, in addition to the angiogenic potential of circulating hemangioblasts, the vessel formation from these local progenitors may also account for the neoangiogenesis observed in the spleen of MMM patients (76).

## KEY POINTS

- The labyrinth of the spleen's vasculature is unique in possessing both open and closed circulatory pathways – still surrounded by a number of important features to solve, including its exact vascular pathways and the regulation of perfusion volume directed into the open and closed channeling systems – and precise mechanism of leukocyte homing to the spleen and their reentry into the systemic circulation.
- The splenic endothelium displays an extensive complexity in its ontogenic, developmental, and phenotypic traits related to their topographic distribution, including the possibility of heterogeneous tissue derivation from distinct ancestry. This complexity indicates that the endothelium of the spleen at different tissue compartments probably performs considerably diverse activities related to the spleen's functions in hemopoiesis and immune responses in both normal and pathological conditions.

## Adipose Tissue Endothelium

---

Gary Hausman

*USDA-Agricultural Research Service, University of Georgia, Athens*

Adipose tissue can be found throughout the body but is primarily distributed in several subcutaneous and visceral locations or “depots” (1). The general distribution pattern and location of adipose tissue depots and the proportion of total body fat that each depot represents varies widely between species. In humans and swine the subcutaneous depot represents a much larger proportion of total adipose tissue than in rodents. In fact, several distinct layers of subcutaneous adipose tissue are present in humans and swine. Excessive adipose tissue accumulation in humans is often associated with the adverse health consequences of the metabolic syndrome (2). An adipose tissue distribution pattern favoring visceral adipose tissue often is implicated in this syndrome.

Adipose tissue can be considered a metabolic buffer by sequestering fatty acids after a meal and releasing them when needed at a later time (3). Adipose tissue blood flow (ATBF) and its regulation is an essential component of the metabolic function of adipose tissue (3). The fact that increased ATBF leads to increased clearance of triglycerides by the tissue illustrates the physiological impact of ATBF (3).

Our understanding of the role of adipose tissue as an endocrine organ has evolved rapidly since the discovery of leptin (2). Adipose tissue is an active organ that produces and secretes a variety of factors into the circulation, including leptin and several interleukins (2), which also illustrates the physiological impact of ATBF. In contrast to ATBF, very little is known or published on adipose tissue endothelium per se. Furthermore, the widespread distribution of adipose tissue and the many location- or depot-dependent characteristics (including blood flow) (4) precludes extrapolation of results from one depot to the next.

The history of ATBF and adipose tissue endothelial biology is reviewed by Crandall and colleagues (5). Adipose tissue blood vessels were first studied in the late 1800s when investigators noted a close spatial and temporal relationship between developing adipocytes and developing blood vessels (5). In 1945, adipose tissue was shown to be significantly more vascular than expected (until that time, adipose tissue had been

traditionally considered an inert tissue) (6). The first functional studies of ATBF, carried out in the 1950s, demonstrated the movement of lipid to and from adipose tissue by means of the circulation (5). Approximately 35 years ago, capillary filtration coefficient for adipose tissue was shown to be two- to threefold higher compared with resting skeletal muscle (5). Recent years have witnessed the development of sophisticated technologies to assess ATBF, including the <sup>133</sup>Xenon washout method, which permits measurement of ATBF in conscious subjects (7,8). The advent of microsphere techniques for measuring blood flow coupled with techniques to directly quantify adipocyte cell number and size allowed a unique quantitation of ATBF per cell, which became standard for ATBF studies (4). This milestone, in turn, led to firmly establishing the remarkable influence of anatomical location or depot and metabolic state on ATBF (5) (Table 137-1).

### STRUCTURE AND FUNCTION

#### Overview of Adipose Tissue Blood Flow

The use of new technologies to measure ATBF as well as fat cell size and number has yielded important insights into mechanisms of ATBF (3–5). ATBF is influenced by many factors including diet, hormones, innervation, exercise, and locally produced factors (3,5). ATBF fluctuation in the fed and fasted state in the rat is dependent on the depot or location, as is adipocyte hypertrophy (Table 137-1). Recent studies in humans demonstrated that basal and glucose-stimulated ATBF within the subcutaneous depot is dependent on the particular subcutaneous layer (9). It is now established that basal adipocyte blood flow per cell remains relatively constant as adipocytes undergo hypertrophy (5). Furthermore, a consistent decrease in basal blood flow per unit weight of tissue with adipose tissue growth is observed, since adipocyte number per unit weight is decreasing. Therefore, ATBF regulation is complex, involving the interactions of many physiological and anatomical influences.

**Table 137-1: The Influence of Anatomical Location or Depot on Adipose Tissue Blood Flow, Growth Modality, and Innervation Density in Growing and Adult Rats**

	Blood Flow		Hypertrophy > Hyperplasia	Innervation Density
	Fed	Fasted		
Mesenteric	+++	+++++	+++++	+++++
Epididymal	++	+++++	+++	+++
Retroperitoneal	++	+++	++	++

### Overview of Structural Properties of Adipose Tissue Endothelium

Very little is known about the structural properties of adipose tissue endothelium in growing or aged animals and humans. Some but not all capillaries were found to be fenestrated in mouse adipose tissue (10). However, only a single depot was studied. Most information comes from studies of fetuses and young animals. Fetal adipose development is characterized by an exceptionally close spatial and temporal relationship between vascular and adipocyte development (11–16) (Table 137-2). Structural development of fetal adipose tissue arterioles and capillaries varies according to location, depot, or layer of subcutaneous tissue (5,11). In the fetus, the degree of capillary growth and elaboration relative to adipocyte lipid accretion or differentiation is predictive of the ultimate degree of vascularity and adipocyte cellularity (5,11). It is not known what regulates depot-dependent structural development of vascular beds in fetal adipose tissue. Interestingly, many functional and structural characteristics are shared by adipose tissue endothelial cells (ECs) and preadipocytes (12–16) (Table 137-2).

Lectin binding and expression of extracellular matrix components by fetal porcine adipose tissue capillary endothelium is not influenced by either depot or age (17) (Table 137-3). However, lectin binding and other qualitative cytochemical traits of adipose tissue endothelium are hormonally regulated during fetal porcine development (18). In this regard, hydrocortisone, but not thyroxine or growth hormone, influences the development of lectin binding and other cytochemical traits of adipose tissue capillary endothelium with no influence on the relative number of blood vessels (18). Lectin binding by adipose tissue endothelium during fetal development indicates that adipose tissue endothelium remains immature relative to endothelium in associated tissues like the dermis (Table 137-3).

Adipose tissue vasculature is supplied by a relatively sparse sympathetic innervation, with adrenergic nerve varicosities

distributed down to the capillary level (19,20). Adrenergic innervation of adipose tissue vasculature is evident during late fetal development (19), and adrenergic innervation density and blood flow are highly correlated across several rat adipose tissue depots (Table 137-1).

Adipose tissue capillary endothelium changes markedly at the ultrastructural and structural level with adipocyte hypertrophy in the young rat (Figure 137.1). In a very short time, capillary lumen diameters are reduced by one half and numerous ultrastructural features indicate a very dynamic endothelium associated with adipocyte hypertrophy (Figure 137.1A). In contrast, adipose tissue capillary endothelium appears relatively quiescent after this period of rapid hypertrophy (Figure 137.1B). These changes in capillary endothelium are extremely rapid in the young rat and are associated with a transient and rapid rate of adipocyte hypertrophy (the subsequent rate of adipocyte hypertrophy is much slower).

### Overview of Functional Properties of Adipose Tissue Endothelium and Blood Flow

Clearly the dominant function of adipose tissue endothelium and ATBF is involvement in the regulation of energy homeostasis by either sequestering or releasing energy substrates as dictated by the physiological state (3,5). In particular, adipose tissue capillary beds help to regulate blood lipid levels in two ways (20). First, very-low-density lipoproteins (VLDLs) and chylomicrons are sequestered from the blood by binding to capillary endothelial-bound lipoprotein lipase (LPL) (21). Second, the subsequent breakdown or lipolysis of VLDL and chylomicron lipid to fatty acids is catalyzed by capillary endothelial-bound LPL. Conversely, when dictated by fasting or other physiological states, another major function of ATBF is to remove the fatty acids liberated by adipocyte-derived hormone-sensitive lipase (HSL) for distribution throughout the body (3). This is demonstrated by adrenaline infusion, during which parallel increases occur in free fatty acid release from adipose tissue and ATBF (3). These functions are extremely significant to the whole animal, considering the extent of adipose tissue accumulation and distribution throughout the body. Specific influences on ATBF include glucose ingestion, mixed meal ingestion, short-term fasting, overnight fasting, and exercise, whereas fat feeding alone does not elicit an ATBF response (3–5,22). Regulation of ATBF in humans is primarily under adrenergic control (3). For example, a major proportion of postprandial enhancement of ATBF in humans is under  $\beta$ -adrenergic regulation (22).

The recently discovered function of adipose tissue as an endocrine organ highlights the potential significance and function of adipose tissue endothelium and ATBF in health and disease (23,24). Studies of the most chronicled of the adipose tissue “hormones” – i.e., leptin – indicate that it may be secreted in a pulsatile nature (3). Glycerol and free fatty acids are also secreted into the blood or plasma in a pulsatile manner. The pulsatility of free fatty acids and glycerol concentrations

may involve adipose tissue vasculature if the pulse generator is a neural-based mechanism (3).

### Comparison of Adipose and Nonadipose Vascular Beds

Immunocytochemistry for laminin and type IV collagen- and lectin-binding studies demonstrate some features of adipose tissue vascular beds common to other vascular beds. For example, the distinction between arterioles and venules based on phosphatase activity develops similarly in adipose tissue and skeletal muscle but develops earlier in several other tissues (25). Furthermore, similar glycoconjugates are present on capillary endothelium in adipose tissue, muscle, and several other tissues (Table 137-2) (17). In particular, galactose residues are detected on capillary endothelium in adipose and other tissues (Table 137-3) (17).

Blood flow and hemodynamic characteristics that are similar for adipose tissue and skeletal muscle include transcappillary glucose exchange (26) and changes in blood flow/unit weight with age (27). Characteristics that distinguish adipose tissue from skeletal muscle include a greater resting blood flow/unit weight and capillary filtration coefficient for adipose tissue (3,5). The relative number and size of arteri-

oles is greater in adipose tissue than in muscle during fetal development, which potentially provides a structural basis for greater resting ATBF (11). Finally, moderate exercise doubles ATBF while increasing skeletal muscle blood flow tenfold (28).

A number of studies demonstrate that the adipose tissue endothelium is distinct from endothelium in most other tissues in several remarkable ways. For example, the influence of antiangiogenic agents on adipose tissue accretion indicates that adipose tissue endothelium is maintained in an immature state because mature endothelium typically is not influenced by antiangiogenic agents (29,30). However, experimentally induced vascular endothelial growth factor (VEGF) inhibition in mice resulted in significant capillary regression in six other glands or organs in addition to adipose tissue (10). Nevertheless, adipose tissue is clearly distinguished by the many lineage, functional, and structural links between angiogenesis and adipogenesis (Table 137-2). In particular, a remarkable and unprecedented reciprocal regulation of angiogenesis and adipogenesis was demonstrated during adipogenesis induced in vivo (Table 137-2) (14). The quality and extent of this evidence validates the distinction of adipose tissue endothelium from other endothelium based on developmental relationships with parenchymal cells.

Scoring was as follows: 0, no stain; +, intermediate staining; and ++, maximum staining.

\*Included dense connective tissue around blood vessels and nerves and bands of connective tissue that separate adipose tissue layers from one another and from muscle.

### Distinction between What Is Known in Vitro and in Vivo

ECs from human (31,32), rat (33), and bovine adipose tissue (34) have been isolated and characterized in vitro. However, the limited information on adipose tissue endothelium in vivo

precludes a meaningful comparison of in vitro and in vivo studies on adipose tissue endothelium.

### ADIPOSE TISSUE ENDOTHELIUM IN DISEASE

Obesity and type 2 diabetes are associated with general endothelial dysfunction, but very little is known about adipose tissue endothelium per se in disease (2,3). A limited number of studies include a report that obesity in humans is associated with decreased blood flow and glucose uptake in several depots (35).

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Various therapeutic implications and applications of understanding adipose tissue angiogenesis and ATBF have been extensively reviewed (5). Recent studies point to several novel endothelium-based means to treat or curb obesity, such as inducing overexpression of angiopoietin 1 (Ang1) in adipose tissue (Table 137-2) and targeting a proapoptotic peptide to an adipose tissue vasculature membrane protein (36). Furthermore, treatment with antiangiogenic agents can be used to selectively regress adipose tissue (29,30). Finally, evidence of endothelial progenitor cells in adipose tissue provides further support for the hypothesis that adipose tissue may serve as a source of microvascular ECs for therapeutic purposes (Table 137-2).

Figure 137.1. Capillaries in adipose tissue from a 10-day-old (A) and 28-day-old (B) rat. At 10 days, capillary lumens (*lu*) are very narrow and vessel walls are thin and contain many large vesicles and EC processes (*p*) extending into the lumen and the extravascular space. The highly dynamic ultrastructure of capillaries at 10 days compared to capillaries at 28 days is associated with the very rapid rate of adipocyte hypertrophy in the 10-day-old and younger rat. Capillaries in the older rats have narrow lumens and very thin walls with numerous smaller vesicles. Note the capillary external lamina (A and B, *arrows*), which is considerably thinner and more distinct at 28 days (B, *arrows*). Inset bar is equal to 1  $\mu\text{m}$  and is also applicable to B. Also indicated are adipocytes (*stars*) and a perivascular cell (*pc*).

## KEY POINTS

- Several lines of evidence indicate that adipose tissue endothelium is relatively immature, which would accommodate the very dynamic morphological changes in adipocytes and adipose tissue that occur during lipid accretion.
- Adipose tissue capillary endothelium plays a critical role in sequestering and catabolizing blood lipids for assimilation in adipocytes.
- The extent and regulation of ATBF is dependent on anatomical location and is highly correlated with adipocyte hypertrophy and innervation density.
- The nature and extent of developmental and functional relationships between adipose tissue endothelium and parenchymal cells distinguish adipose tissue from other tissues.
- Further study is necessary to elucidate the lineage, developmental, and functional relationships between adipose tissue endothelium and parenchymal cells during the development and maintenance of obesity and type 2 diabetes.
- Continued research is necessary to examine the significance and full impact of an immature adipose tissue endothelium in normal and disease states.

## Renal Endothelium

---

Bruce Molitoris

*Indiana Center for Biological Microscopy, Indiana University School of Medicine*

The kidney, which receives approximately 20% of the cardiac output, has one of the richest and most diversified endothelial populations found within any organ. Such diversity may be explained on at least two counts. First, phenotypic diversity reflects the capacity of the endothelium to contribute to differential transport capabilities across the various segments of the nephron. Second, the endothelium must withstand unparallelled environmental extremes in oxygenation and osmolality (Figure 138.1; for color reproduction, see Color Plate 138.1). For example, endothelial cells (ECs) in the outer cortex are exposed to a normal osmolality and oxygen ( $O_2$ ) tension, whereas those in the inner medullary region are exposed to an osmolality of up to 1,200 mOSM and  $O_2$  content as low as 20 mm Hg.

From a mechanistic standpoint, phenotypic diversity of the renal endothelium must arise from site-specific epigenetic modification of ECs and/or reversible effects of the tissue/blood microenvironment. To date very little is known about the different endothelial populations within the kidney, let alone the molecular basis for their heterogeneity. Thus, the goals of this chapter are to delineate current knowledge concerning ECs in the kidney, stimulate research related to understanding the differing functions of renal ECs under physiological conditions, and explore the role of phenotypic diversity in disease processes.

### STRUCTURE AND FUNCTION

The unique structure of the vascular tree within the kidney is shown in Figure 138.1. Anatomically, the kidney is divided into four zones. The cortex occupies the outermost aspect of the kidney. As one moves toward the renal pelvis from the cortex, one encounters the outer medullary region, consisting of outer and inner stripes, and finally the inner medullary region. Although the renal arteries enter the kidney via the inner renal pelvis, a series of large branching arteries deliver primary arteriolar blood into the outer cortex via the interlobular arteries terminating in a network of afferent arte-

rioles. Although overall blood flow to the kidney averages 4 mL/g tissue/min, there is great heterogeneity within the kidney. The outer cortex receives 5–6 mL/g/min with ever deeper areas receiving less. The inner cortex, outer medulla, and inner medulla receive 2–3, 1, and 0.5 mL/g/min, respectively. Thus, over 90% of the blood flow is directed to the cortical area. Afferent arterioles have a continuous smooth muscle layer and are the major resistance vessels controlling the glomerular filtration rate (GFR). They terminate to form the glomerular capillary network where formation of the primary urine takes place via filtration. Each glomerular capillary network gives rise to a single efferent arteriole. In contrast to their afferent counterpart, efferent arterioles have a limited discontinuous layer of smooth muscle cells.

Efferent arterioles follow one of two paths. Those that arise from glomeruli within the mid and outer cortex give rise to an  $O_2$ -rich, dense network of capillaries (the so-called *peritubular plexus*), which run alongside the proximal and distal convoluted tubules of the kidney. The latter arrangement is unique in that it consists of two capillary beds (glomerulus and peritubular capillaries) separated by an arteriole. The rich cortical capillary network arises from nonanastomosing glomerular efferent arteries and joins the venous drainage system within the outer cortex as the superficial cortical veins and the interlobular veins for the mid and inner cortex. Those efferent arterioles that arise from the innermost or juxtamedullary glomeruli (at the border between the cortex and medulla) give rise to the vasa recta, which run parallel to loops of Henle and collecting tubules in the medulla (1). Descending arteriolar vasa recta branch into several vessels that penetrate the inner depths of the medulla, give rise to a dense capillary network within the outer medulla, and return to the cortex via venous ascending vasa recta (AVR). Descending vasa recta (DVR) and AVR are packed together in vascular bundles in the outer medulla like highways going up and down. The vasa recta provide the sole blood supply to the medulla.

In the inner medulla the bundles become interspersed with the nephron segments. In the inner stripe of the outer medulla vasa recta emerge from the periphery of the vascular bundles

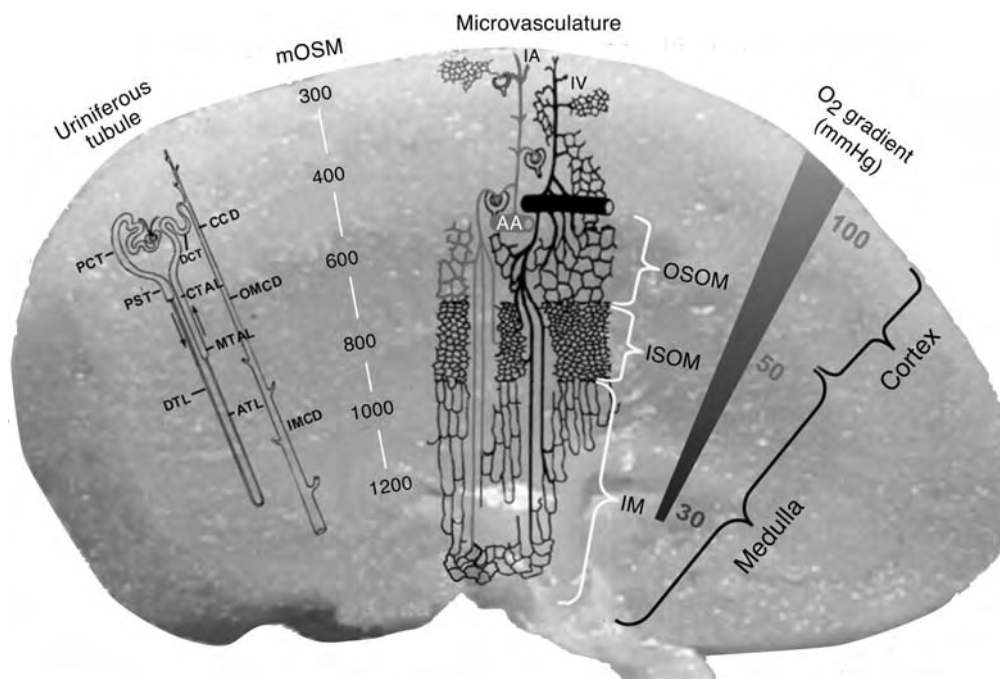

Figure 138.1. Schematic representation of the vascular differences in the microvasculature within the kidney. The arcuate artery (AA) gives rise to the interlobular artery (IA), from which all afferent arterioles arise to perfuse the glomerular capillaries. Also shown are the osmotic and  $O_2$  gradients from the outer cortex to the inner medulla. The medulla vascular supply arises from the juxtaglomerular efferent arterioles that branch and then descend into the medulla. As a result, the outer stripe of the outer medulla (OSOM) has minimal arteriole capillary density. OSOM, outer stripe of the outer medulla; ISOM, inner stripe of the outer medulla; IM, inner medulla; PCT, proximal convoluted tubule; PST, proximal straight tubule; DTL, descending thin limb; ATL, ascending thin limb; MTAL, medullary thick ascending limb; CTAL, cortical thick ascending limb; DCT, distal convoluted tubule; CCD, cortical collecting duct; OMCD, outer medullary collecting duct; IMCD, inner medullary collecting duct; AA, arcuate artery; IA, interlobular artery. For color reproduction, see Color Plate 138.1.

to supply blood to a dense capillary network, the so-called *interbundle plexus*, providing arterial capillary blood. In contrast, there is little in the way of an arteriole supply to the outer stripe of the outer medulla. Rather, the vessels providing primary nutrient supply and  $O_2$  delivery to the outer stripe derive from the ascending venous vasa recta and thus this region is perfused primarily by venous capillary blood.

The unique vascular architecture of the kidney results in a gradient of decreasing oxygenation (and  $O_2$  delivery) from the cortex to the medulla. This arrangement is essential for development of the countercurrent mechanism necessary for the recycling of osmotic compounds to maintain the marked osmotic gradient that increases as one goes from the outer cortex to the inner medullary region (Figure 138.1) (1). Importantly, the cortical medullary junction (outer stripe of the outer medulla) is a watershed zone having primarily venous capillary networks and a very low preponderance of arteriolar capillaries.

The density of the vascular space within the kidney also varies between the cortex and medullary regions. Pathologists often include the microvascular space as part of the “renal interstitium” because standard H&E stains do not identify ECs and thus one cannot differentiate the microvascular area

from the true interstitial space. However, under physiological conditions the “cortical interstitial/vascular space” constitutes approximately 10% of the kidney by volume, with this percentage increasing as one ages. Within the medulla there is a gradual increase in interstitial volume from 10% to 20% in the outer medullary region to 30% to 40% in the papillary region.

ECs within this heterogeneous vascular system also vary tremendously structurally and functionally depending upon location (Table 138-1). Afferent arterioles give rise to glomerular capillaries that are lined by fine fenestrated endothelium with fenestrae ranging in size from 70 to 100 nm in diameter. Diaphragms do not extend across these fenestrae and the fenestrae are surrounded by microfilaments (2). These fenestrae are not the result of caveolae fusing, as human glomerular endothelial fenestrae are devoid of caveolin-1, and caveolin-1-deficient mice have normal glomerular endothelial fenestrae (3). Glomerular ECs are known to synthesize both nitric oxide (NO) and endothelin-1 and express vascular endothelial growth factor (VEGF) receptors that have been shown to enhance EC permeability and induce endothelial fenestrations (4). Additional evidence indicates that VEGF is important for EC survival and repair in glomerular diseases characterized by EC damage (5–7). Thus, VEGF produced by epithelial cells

**Table 138-1: Properties and Functions of Renal Endothelium**

<i>Blood Vessel</i>	<i>Smooth Muscle Cells</i>	<i>Endothelium</i>	<i>Unique Properties</i>	<i>Major Function</i>
Afferent arteriole	Continuous		Juxtaopposed to macula densa, vasoresponsive to angiotensin II, etc.	Regulate single nephron blood flow
Glomerular capillary		Continuous, fenestrated, no diaphragm	Express VEGFR, synthesize NO and endothelin-1	Selective filtration of macromolecules based on size and charge
Efferent arteriole	Discontinuous		Nonbranching in cortex, branching in juxtamedullary glomeruli (JMG)	Regulate filtration fraction
Peritubular plexus		Fenestrated facing epithelial cells	OKM5	Handle bulk of reabsorbed H <sub>2</sub> O and ions
DVR	Discontinuous pericytes	Continuous, nonfenestrated	AQP1, urea transporter, Arise from JMG efferent arterioles	Countercurrent exchanger serving to prevent washout of osmotic gradient created by loops of Henle: enters increasingly hyperosmolar medulla, thus gains solutes and loses water
AVR	Discontinuous pericytes	Continuous, highly fenestrated, diaphragm	Extremely thin ECs	Countercurrent exchanger serving to prevent washout of osmotic gradient created by loops of Henle: leaves high osmolar environment as it moves towards cortex, thus loses in DVR and gains back water; net effect is the osmolality of blood at end of AVR approaches that of blood at beginning of DVR (slightly higher NaCl)

appears to be an important regulator of glomerular EC function and permeability. The production of VEGF is primarily by podocytes (glomerular epithelial cells), distal tubule epithelium, and collecting duct epithelium, especially in the outer medulla (see Chapter 68).

Within the cortex, microvascular ECs are fenestrated on those portions of the cell that border tubule epithelial cells. Erythropoietin-producing cells are localized in the renal cortical interstitial space adjacent to capillary endothelial and tubular epithelial cells. As efferent arterioles from juxtamedullary glomeruli penetrate into the outer stripe of the outer medulla, the outer smooth muscle layer is replaced by a discontinuous layer of pericytes (Figure 138.2). This marks the beginning of the DVR and upon further penetration into the inner medulla pericytes become less numerous. In both the inner and outer medullary regions the ascending venous vasa recta outnumber the descending arterial vasa recta. The DVR have a continuous nonfenestrated endothelium with a zona occludens limiting their permeability. They express both water channels (e.g., AQP1) and a facilitated urea transporter. In the inner medullary region, the DVR terminate and form a sparse capil-

lary plexus that coalesces to form the AVR. Within the AVR fenestrations in ECs again occur with approximately 50% of the endothelial wall covered by fenestrae in the inner medullary region and 15% to 30% in the outer medullary region (Figure 138.2). These fenestrations have diameters of 50 to 100 nm and are bridged by a thick diaphragm. ECs within the AVR are extremely thin (Figure 138.2) and have a remarkably high hydraulic conductivity.

Little information exists regarding the nonstructural differences between renal ECs in vivo and even less is known about their characteristics or behavior in vitro. Because of the tremendous heterogeneity of ECs within the kidney, initial studies were undertaken to determine differences in expression of specific EC markers. In the human kidney, peritubular capillary ECs exhibited immunohistochemical characteristics similar to those of peripheral macrophages, including OKM5 (medullary only), von Willebrand factor (vWF), and interleukin (IL)-1 positivity. Glomerular capillary ECs expressed vWF, but not OKM5. Additional studies have identified RECA-1 and JG-12 as pan-EC-specific monoclonal antibodies for all vascular beds in the rat. Human, but not murine, tissue

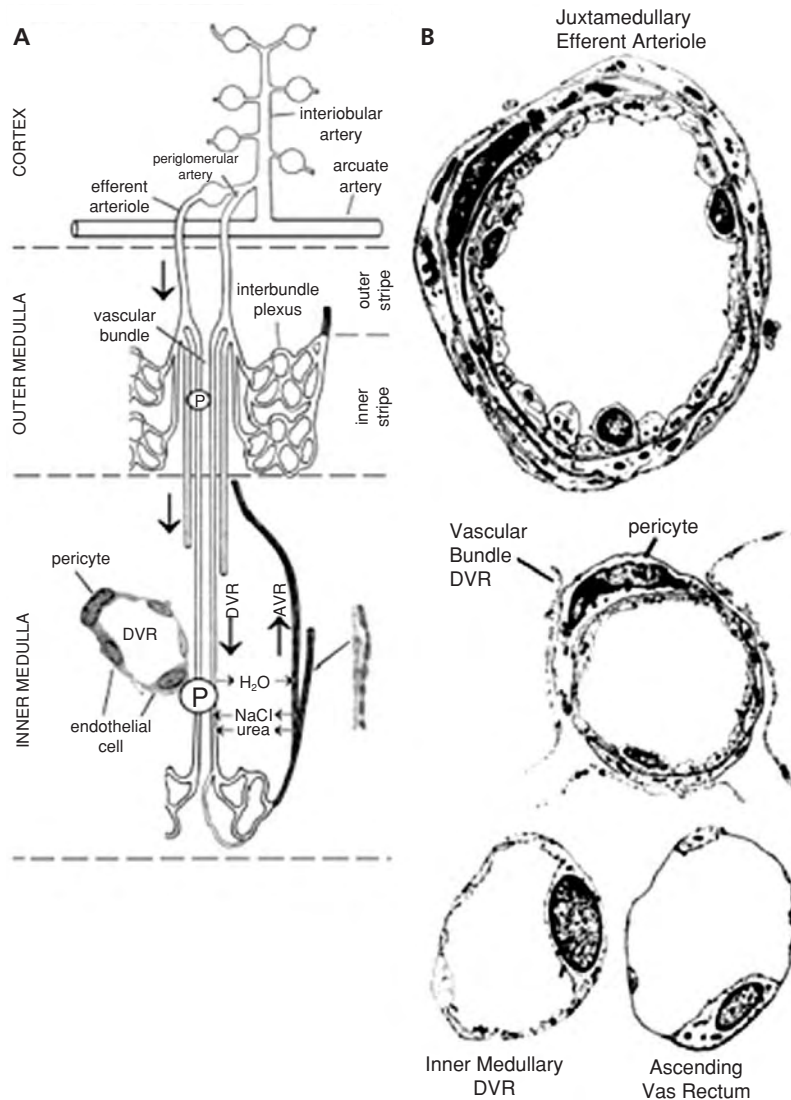

Figure 138.2. Schematic representation of the different forms of ECs found within the peritubular microvasculature of the kidney in the different zones of the kidney. (Adapted with permission from Pallone TL, Turner MR, Edwards A, Jamison RL. Countercurrent exchange is the venal medulla. *Am J Physiol Regul Integr Comp Physiol.* 2003;284:R1153–R1175.)

peritubular and glomerular ECs express HLA-DR. The presence of MHC class II proteins raises the possibility that these cells present antigen (8). The OKM5 antibody may be a specific marker for medullary ECs (9) and also reacts to macrophages.

Recently, both conditionally immortalized mouse glomerular ECs (2) and a “microvascular” EC line from mouse kidney (10) have been isolated and grown in cell culture. The glomerular ECs were isolated from H-2K-ts A58 transgenic mice carrying a gene encoding a temperature-sensitive variant of the SV 40 large tumor antigen, directing growth at 33°C and differentiation at 37°C. This immortalized mouse glomerular EC line (termed mGenC-1) expressed vWF, podocalyxin, CD31, CD101, vascular endothelial (VE)-cadherin, GSL I-B4, and ULEX, and these cells internalized acetylated low-density lipoprotein (acLDL). Additional

studies to characterize these glomerular cells have not been reported. The mouse renal microvascular EC line (REC-A4) was developed using a bead technique with anti-CD31mAb attached. Different clonal lines were propagated and one was selected for further study. These cells lacked Weibel-Palade bodies and fenestrae, but did have other characteristics highly suggestive of ECs. Moreover, the cells also showed a sensitivity towards Shiga toxin-1, demonstrated LDL uptake, formed tube-like structures on Matrigel, and demonstrated constitutive surface expression of CD31, intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 (10). There is no reported evidence regarding differential lectin binding characteristics of different renal EC populations or differential binding of potentially selective antibodies to these same populations.

## RENAL ENDOTHELIUM IN DISEASE: DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

The renal vascular endothelium is known to be a primary target in several disease processes including glomerular nephritis, vasculitis, lupus nephritis, preeclampsia, hemolytic uremic syndrome, ischemic acute renal failure, renal transplantation rejection, and chronic progressive kidney disease. For example, hemolytic uremic syndrome (HUS) and related thrombotic microangiopathies result from an infection with a certain verotoxin-expressing strain of *Escherichia coli* (0157:H7). The hallmark of this disease process is glomerular and renal microvascular EC injury with associated apoptosis, detachment, and intracapillary thrombus formation. The preferential involvement of glomerular and renal ECs may relate to the approximately 50-fold increase in the differential expression of the Gb3 receptor for verotoxins within these ECs. Recently a model of thrombotic microangiopathic hemolytic anemia in the rat has been developed utilizing selective renal arterial perfusion with an anti-EC antibody (6). This pathologic process, as in HUS, results in progressive glomerular and tubular interstitial damage. Notably, subcutaneously administered VEGF accelerated renal recovery in this animal model. Associated findings with VEGF therapy included an increased number of glomeruli with intact endothelium, a denser peritubular capillary network, and less interstitial fibrosis and cortical atrophy (6).

Glomerular endothelial fenestrae can also be lost within hours following VEGF removal. This results in glomerular endotheliosis, reduction/loss in GFR, and proteinuria (3). Such a mechanism may be operative in preeclampsia, where increased levels of placental-derived soluble VEGF receptor 1 inhibitor (soluble fms-like tyrosine kinase 1, sFLT-1) result in VEGF neutralization (9,11). Overexpression of VEGF leads to collapsing glomerulopathy, further demonstrating that tight regulation of VEGF is critical to glomerular development and function (11).

Microvascular endothelial damage is the salient feature associated with acute vascular rejection and, in chronic allograft nephropathy, the single most common cause of long-term graft loss (12). Peritubular capillary EC deposition of C4d was an independent predictor of graft loss. Furthermore, the number of circulating ECs in renal transplant recipients may be a marker of renal endothelial damage (13). Studying renal transplant biopsies (12) has revealed that angioregression and progressive loss of the peritubular capillary network strongly contributed to the development of interstitial fibrosis and graft dysfunction in chronic allograft nephropathy.

Ischemic acute renal failure has recently been shown to be associated with renal microvascular endothelial injury and dysfunction (14,15). During ischemic injury and/or sepsis there is an upregulation of a variety of chemokines and cytokines including IL-1, IL-6, IL-8, monocyte chemoattractant protein (MCP)-1, and tumor necrosis factor (TNF)- $\alpha$ ,

all of which are instrumental in initiating an inflammatory cascade. At the endothelial level ischemic acute renal failure was associated with an increase in vWF in the systemic circulation (16). Furthermore, utilizing the *Tie2-GFP* transgenic mouse (Jackson Laboratory), Sutton and colleagues identified and characterized EC F-actin aggregation in conjunction with alterations in the integrity of the adherens junctions within the renal microvasculature (15). Specifically, there was loss of localization of VE-cadherin immunostaining, and this was associated with a permeability defect identified using fluorescent dextrans and intravital multiphoton microscopy. Alterations have also been described in endothelial-leukocyte interactions including enhanced expression of both P- and E-selectin as well as ICAM-1 (13). The potential importance of this enhanced expression is shown by several studies utilizing knockout mice null for *P-selectin*, *E-selectin*, or *ICAM-1*, all of which exhibit reduced cellular injury and improved functional state of the kidney (13).

Additional studies have delineated differential inflammatory cell infiltration over time during the phases of injury and recovery following ischemia (17). The relative importance of these leukocyte populations is presently being explored. In vivo depletion of CD4<sup>+</sup> cells, but not CD8<sup>+</sup> cells, protected against ischemia-reperfusion injury (16). Furthermore, blockade of the B7-1/CD28 costimulatory pathway reduced mononuclear cell infiltration and renal functional deterioration. In the kidney, this emphasizes the importance of the AVR as B7 expression is limited to ECs of the AVR. The expression of EC adhesion molecules is not a universal phenomenon in acute renal failure (ARF), as it does not occur during toxin-induced ARF, and no leukocyte accumulation is seen in the kidney (18). Further work has demonstrated that injecting human umbilical vein ECs (HUVECs) into the systemic circulation prior to the ischemic injury results in lessening of the injury. The positive effect was greater when HUVECs were injected intra-arterially, but still present following intravenous injection. The reduction in cell epithelial injury, and renal functional deterioration, necessitated that the injected ECs express endothelial NO synthase (eNOS) expression as EC not expressing eNOS did not provide protection (19).

One particular region of the kidney seems to have progressive ischemic injury during the reperfusion period: the outer stripe, also known as the *cortical medullary junctional region*. As is shown in Figure 138.1, this is essentially a watershed zone receiving its primary and limited vascular supply from the O<sub>2</sub>-poor ascending venous vasa recta. Following ischemic injury, this area of the kidney receives the lowest level of reperfusion, although the mechanisms underlying this lack of reperfusion have not been elucidated (14). It is generally believed that the lack of adequate reperfusion to this area leads to worsening epithelial cell injury and acute renal failure, recently described as the extension phase of ischemic cell injury within the kidney (14). This may well relate to the high expression of specific cell adhesion molecules by the venous ECs within this region resulting in white blood cell adherence (18). Multiple other factors are also involved in this lack of reperfusion, including

Figure 138.3. Loss of microvascular endothelium in progressive renal disease. In the contrast to normal glomerular (A) and peritubular (B) endothelium, there is a progressive loss of glomerular capillary loops (C) and peritubular capillaries (D) in the remnant kidney model of progressive renal disease. Not shown is the ability of VEGF to prevent this loss and deterioration in renal function that is associated with capillary loss. For color reproduction, see Color Plate 138.3.

coagulation abnormalities, but this lack can not be explained by reduced total RBF.

The importance of continuing microvascular inflammation and progressive microvascular dropout leading to progression of renal failure has recently been emphasized by a series of studies by Basile and associates (20). Utilizing a model of moderate to severe acute ischemic injury in rats, these investigators have demonstrated a permanent reduction in vascular density leading to reduced renal  $O_2$  tension. Furthermore, anti-transforming growth factor (TGF)- $\beta$  treatment attenuated microvascular dropout, and this was associated with a reduction in interstitial cellularity positive for the specific fibroblast marker S100A4 (20). Following severe renal ischemia, there also occurs a prolonged (6 weeks) enhanced production of IL-1 $\beta$  and persistent CD4<sup>+</sup>-T cell infiltration (21).

The role for progressive endothelial dysfunction in chronic kidney disease has also been advanced in other models of progressive renal failure (Figure 138.3; for color reproduction, see Color Plate 138.3). An underlying theme to this work has been the essential nature of VEGF in kidney development and angiogenesis following renal injury. VEGF was first shown to play a major role in renal development by blocking VEGF activity utilizing an antibody in newborn mice. This resulted in disrupted and reduced renal cortical capillary formation, abnormal glomeruli lacking capillary tufts, and an overall reduction in number of nephrons (7). Subsequent work utilized a remnant kidney model in which one kidney is removed and the upper and lower poles of the remaining kidney are also removed. Therefore, the rat is left with one-sixth of the original kidney mass, and this remaining renal tissue undergoes a well-characterized hypertrophy followed by progressive

loss of renal function associated with glomerular sclerosis, interstitial fibrosis, and proteinuria. In this model, there was an early angiogenic response with proliferation of peritubular and glomerular ECs. However, this was short-lived, and EC proliferation then decreased to below levels seen in sham operated control animals. Reduction in EC proliferation was associated with enhanced interstitial expression of the antiangiogenic factor thrombospondin (TSP)-1 and also a decrease in VEGF production (5). These changes were also correlated with progressive macrophage infiltration. Additional evidence indicated that inflammatory cytokines, including IL-1 $\beta$ , IL-6 and TNF- $\alpha$ , inhibited VEGF mRNA expression and protein secretion in cultured renal tubular epithelial cells. Furthermore, treatment of animals with this progressive renal disease with intravenous VEGF resulted in minimized functional deterioration and lowered mortality rates. This was associated with a marked increase in glomerular EC proliferation, peritubular capillary EC proliferation, and a twofold increase in eNOS expression. The VEGF-treated rats also exhibited less type III collagen interstitial deposition and a reduction in epithelial cell injury (22).

#### GOALS FOR BRIDGING BENCH-TO-BEDSIDE GAP

Clearly, understanding renal EC biology is in its infancy. Over the past 5 years the renal endothelium has been shown to be important in both acute and chronic renal disease processes involving both glomerular and peritubular capillary networks. This study will lead to enhanced investigation and adaptation of techniques and approaches developed for other vascular beds. Understanding baseline phenotypic and genotypic differences in the diverse endothelial populations within the kidney will provide insight into their role in physiological processes. This same approach following acute and chronic stimuli will pave the way for therapeutic advances. Preventing endothelial injury, enhancing its recovery, and maintaining homeostasis of the endothelium will all be important. However, there is a long way to go to improve our basic understanding before therapeutic advances will be possible.

#### KEY POINTS

- The renal endothelium plays a heretofore underappreciated primary role in both acute and chronic kidney diseases.
- Microvascular dropout is a primary event in chronic kidney disease progression resulting from a number of different disease processes.
- Glomerular capillary injury, GFR, and proteinuria are all related to glomerular EC alterations.

- In acute renal failure secondary to ischemia and sepsis, the microvascular endothelium plays a central role in injury and the ability of the kidney to recover.

#### Future Goals

- To enhance understanding of the phenotypic and genotypic differences and responses of renal ECs
- To develop techniques to visualize and manipulate renal ECs in vivo with greater sensitivity and specificity

## Uremia

Jan T. Kielstein<sup>\*,†</sup> and Danilo Fliser<sup>\*</sup>

<sup>\*</sup>Medical School of Hannover, Germany;

<sup>†</sup>Stanford University School of Medicine, California

The uremic syndrome can be defined as the deterioration of multiple biochemical and physiological functions in parallel with progressive renal failure. A myriad of compounds, termed *uremic toxins*, lead to a complex and variable symptomatology—the uremic syndrome. One hallmark of this syndrome is the rapid development of cardiovascular disease. A cornerstone in the complex pathogenesis of this cardio-renal interaction is the endothelium, because it controls many aspects of vascular function. The endothelium produces a wide range of regulatory molecules that, in health, provide a carefully balanced antiatherogenic environment. In contrast, endothelial dysfunction has been demonstrated repeatedly in renal failure, is present in the absence of anatomically obvious disease, and appears to be useful in the prediction of morbidity and mortality in other cardiovascular risk groups. One of the most important and intensively studied mediators of endothelial function is nitric oxide (NO). Numerous preclinical and clinical studies have shown that NO bioavailability is reduced in chronic kidney disease (CKD). NO deficiency contributes to the progressive nature of CKD, endothelial dysfunction, and associated risk for cardiovascular events. Mechanisms of NO deficiency are likely multifactorial. They include substrate limitation, competitive inhibition of NO synthase (NOS) by endogenous NOS inhibitors, and premature quenching of NO by free radicals. Recent evidence points to an important role for the NOS inhibitor, asymmetric dimethylarginine (ADMA). This compound has a wide range of actions that are consistent not only with its role in uremia pathophysiology but also as a common pathway through which cardiovascular risk factors exert their deleterious effects. Unlike other uremic toxins, it also predicts for progression of renal disease. The goal of this chapter is to review the role of uremic toxins in mediating endothelial cell (EC) dysfunction, with a particular emphasis on ADMA. Understanding the pathways involved in the accumulation of ADMA may provide a foundation for therapeutic intervention in the cardio-renal syndrome.

### HISTORY

One of the first descriptions of uremia comes from Hippocrates, who wrote that “If a dropsical patient be seized with hiccup the case is hopeless” (1). Aretaeus, the Cappadocian, who worked in Alexandria in approximately the 1st century B.C. wrote, “Certain persons pass blood periodically; they are very pale, without appetite. They are languid and relaxed in their limbs, but light and agile in their head. Their eyes become dull, dim and rolling; hence may become epileptic; others are swollen, misty, dropsical; and others again are affected with melancholy and paralyses” (2). Despite this detailed description of what later turned out to be uremia, these authors did not even speculate on the underlying pathogenetic mechanisms. In his book *De Sedibus et Causis Morborum per Anatomen Indagitis*, Giovanni Battista Morgagni (1682–1771) was the first to propose that specific signs and symptoms are linked to particular anatomical changes at autopsy. In *De Sedibus*, letter XXX, Morgagni describes a patient who, in the last few months of his life, presented with symptoms of nausea, vomiting, and headache associated with episodes of loss of consciousness. The most interesting autopsy finding in this case was the description of two greatly shrunken, hard, irregularly shaped, grayish kidneys. Morgagni commented on his observations by stating that he had treated other patients with the same symptoms and that, on autopsy, they showed the same morphological picture. He therefore concluded that this renal pathology was the cause of the symptoms described (3). In 1827, Richard Bright (1789–1858) published his outstanding book *Reports of Medical Cases*, in which he addressed the same topic in considerable detail and presented 24 case reports of patients who had proteinuria and edema during life. Seventeen of them subsequently died, and at autopsy 8 of them had small “granulated” kidneys (reviewed in 4). Bright, by deriving logical scientific conclusions based on simple but well-structured clinical observations, was also the first to describe “dangerous secondary consequences which may destroy the patient

at any period of the disease” in several of his patients. He classified these secondary consequences into two categories: (a) inflammation of serous or mucous membranes (such as the pericardium or pleura), and (b) cerebral hemorrhage – problems that plague patients with chronic renal disease to this day. In collaboration with William Prout (1785–1850), Bright was able to identify that the level of urea in the blood and tissues of one of his patients was particularly high, while the level in the urine was “very small.” Together, Bright and Prout raised the possibility of gross chemical abnormalities occurring concurrently with the development of granulated kidneys (reviewed in 4). This suggested a chemical dimension to the clinicopathological syndrome that had so quickly gained acceptance. Jean Prévost (1790–1850) and Jean Dumas (1800–1884) in Geneva noted in 1821 that in animals the blood urea level rose markedly following bilateral nephrectomy (reviewed in 5). This marked the development of the renal function assay as it is still used today. In 1827, Friedrich Wöhler (1800–1882)

in Berlin succeeded in synthesizing urea. His achievement attracted considerable attention and fortuitously occurred the same year that Richard Bright published his clinicopathological observations related to renal disease. Together, these early, seminal findings paved the way for investigating the complex syndrome of uremia.

**MODERN DEFINITION OF UREMIA**

The word *uremia* means “urine in the blood” and was first coined by Piorry and Lheritier in 1840 (6) to indicate the intoxication resulting from insufficient purification of the blood by the kidneys. The short and descriptive nature of the word belies the complexity of the underlying clinical syndrome (Figure 139.1). Uremia is associated with a multitude of metabolic abnormalities including fluid, electrolyte, and hormone imbalances that develop in parallel with deterioration

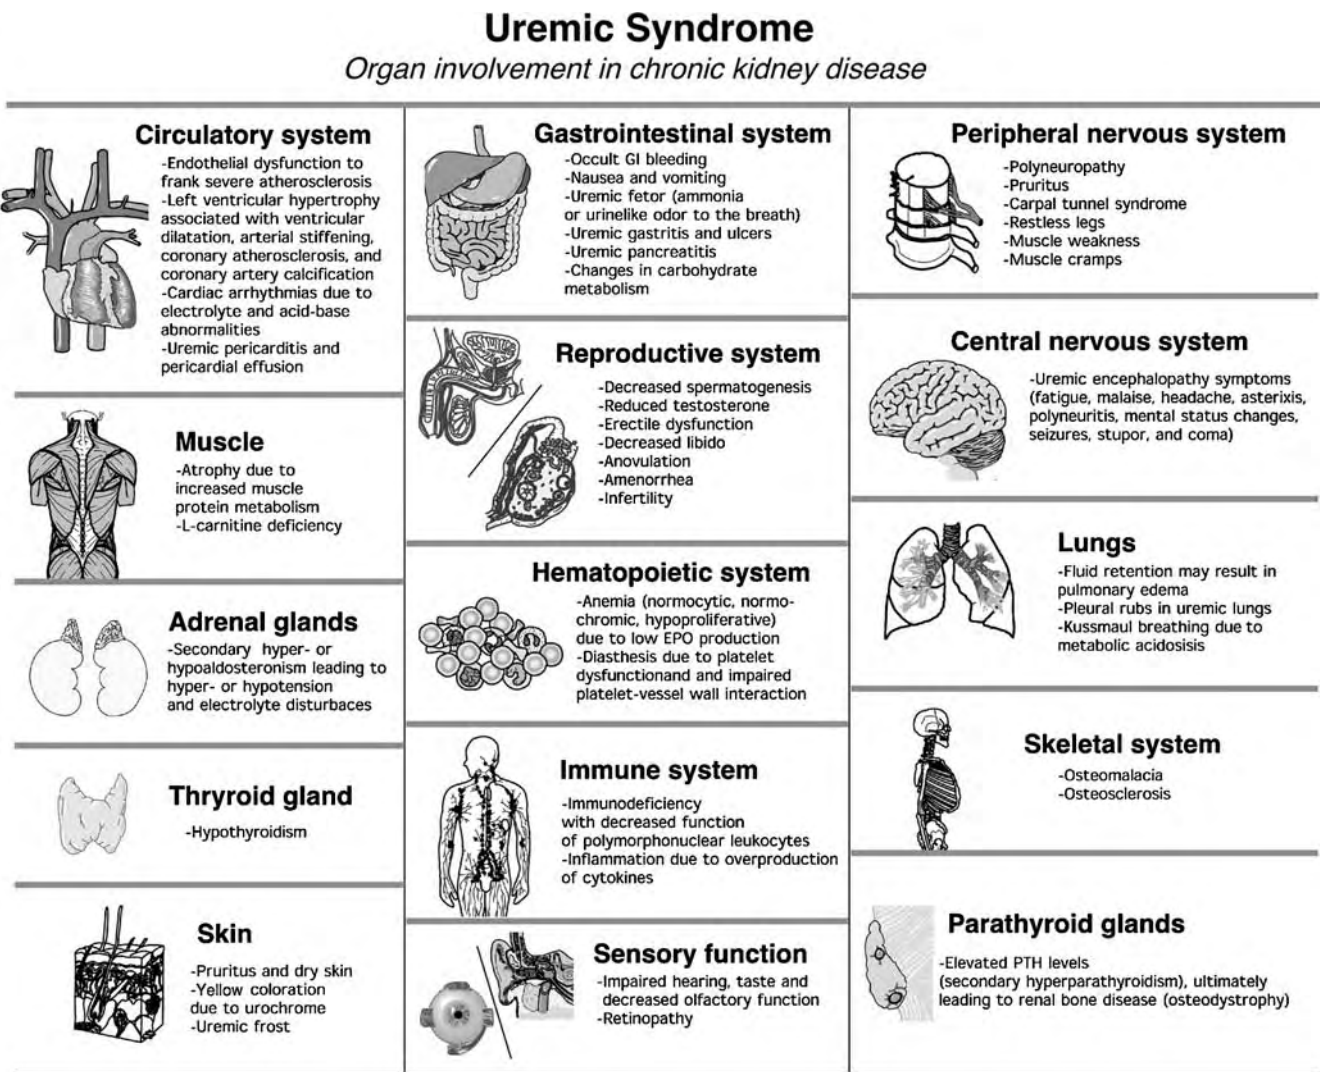

Figure 139.1. Overview of the organ involvement in chronic kidney disease/uremic syndrome. (Adapted with permission from *Dialysefibel 2.2*, 2nd edition. Günther Schönweiss, Bad Kissingen, abakiss, 1996.)

**Table 139-1: Stages of Chronic Kidney Disease**

Stage of Chronic Kidney Disease	Description	Glomerular Filtration Rate (GFR) in mL/min/1.73 m <sup>2</sup>
1	Kidney damage with normal or ↑ GFR	≥90
2	Kidney damage with mild ↓ GFR	60–89
3	Kidney damage with moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	<15 (or dialysis)

of renal function. Some of these abnormalities are reflected in the choice of synonyms that have been used for uremia (e.g., urinary poisoning, chronic Bright disease, azotemia, chronic renal insufficiency, and chronic renal disease). Uremia usually becomes clinically apparent once creatinine clearance is less than 20 mL/min, although some patients may be symptomatic at higher clearance levels. The syndrome may be heralded by the clinical onset of nausea, vomiting, fatigue, anorexia, weight loss, muscle cramps, pruritus, and change in mental status. Uremia as a clinical condition of untreated severe kidney failure is rarely seen in developed countries since the advent of dialysis treatment and renal transplantation. However, a significant segment of the world population lacks ready access to renal replacement therapy, and for individuals living in these areas uremia is a dreaded prelude to death. However, even those patients who receive optimal therapy (including renal transplantation and effective dialysis treatment) continue to demonstrate abnormal levels of so-called uremic toxins, because these therapies are aimed toward reduction and not normalization of uremic toxin levels. Thus, the terms *uremia* and *CKD* are often used interchangeably. In general, the uremic syndrome is associated with CKD, but it also may occur with acute renal failure (ARF) if loss of renal function is rapid and profound. In an attempt to define the different degrees of CKD, the National Kidney Foundation released a five-stage classification (Table 139-1) (7).

## UREMIC TOXINS

Of the uremic toxins, urea is often considered the prototype. However, extensive studies addressing the possible pathophysiological role of urea in the uremic state found little evidence that urea is toxic per se. In support of this conclusion, the addition of urea to the dialysate failed to produce the typical symptoms of the uremic syndrome (8). Moreover, survival of patients on dialysis is independent of urea removal (9).

In fact, no single uremic toxin has been identified that accounts for all of the clinical manifestations of uremia. Rather an ever-expanding myriad of uremic retention solutes accumulate in the uremic patient with end-stage renal disease

(ESRD), an effect that is directly or indirectly attributable to deficient renal clearance. Collectively, these retained solutes result in complex and variable symptomatology. They are referred to as uremic toxins insofar as they interact negatively with biological functions. Apart from inorganic compounds, urea, oxalic acid, parathyroid hormone (PTH), and  $\beta_2$ -microglobulin ( $\beta_2$ -M), more than 2,000 putative “uremic toxins” have been identified in uremic blood (10). In 1978 Bergstrom and Furst (11) first proposed minimal criteria for the characterization of uremic toxins: (a) they should be chemically identifiable and quantifiable (i.e., measurable) in biological fluids, (b) the concentration in uremic subjects should exceed that in nonuremic subjects, (c) the concentration should correlate with specific uremic symptoms that disappear at the normal concentration, and (d) toxic effects in a test system should be demonstrable at the concentration found in uremic subjects. All of these criteria are rarely met, however, often for technical reasons.

Recently, the concept of uremic toxins has changed, such that any substance that interferes with normal physiological functions in renal failure is recognized as a “uremic toxin.” This broader definition acknowledges that concentrations in the plasma may not reflect intracellular let alone subcellular concentrations of the putative toxin. Furthermore, “normal” concentrations of various compounds may in fact be harmful to patients with CKD and lead to pathophysiology. Some compounds may play a role in the progression of renal disease and/or contribute to dialysis-related complications. Thus, the complex mosaic of clinical symptoms seen in the uremic syndrome is probably attributable to one or more of these solutes. Knowledge about the nature and kinetic behavior of the responsible compounds may provide a foundation for novel therapies.

## THE PROBLEM OF RENAL FUNCTION MEASUREMENT

As we discuss later, subclinical renal disease is a risk factor for atherosclerosis, an endothelial-based disease. Thus, early diagnosis is important. Unfortunately, the reliable assessment of kidney function remains an area of uncertainty among health-care professionals – even nephrologists. Kidney function is routinely assayed by measuring serum urea and creatinine. The relationship between the glomerular filtration rate and serum creatinine is curve-linear. Thus, serum creatinine is an insensitive marker for mild to moderate reductions in GFR. As an assay for renal function, creatinine levels are further limited by their inter-individual variability due to age, muscle mass, protein intake, and sex. Glomerular filtration rate may be estimated using formulas (e.g., Cockcroft-Gault and Modification of Diet in Renal Disease [MDRD]) of easily obtained values (plasma creatinine, serum urea nitrogen, serum albumin, age, gender, race). At present, inulin clearance is considered the gold standard for GFR measurement. Because this method is not suitable for routine use, creatinine clearance

measurements are widely used. However, obtaining accurate 24-hour timed urine collections is not only labor intensive and expensive but also fraught with difficulties for patients, especially elderly ones with neurological or urological comorbidities. Thus, an important goal in the nephrology field is to identify a stable, convenient, and clinically reliable marker of GFR (1). Two markers that show promise are serum cystatin C and symmetrical dimethylarginine (SDMA). Serum cystatin C concentration is a better marker of renal dysfunction (i.e., reduced GFR) than plasma creatinine concentration, at least in elderly subjects with plasma creatinine concentrations within the normal range (12). SDMA has been found to be a reliable marker of renal function (13,14), but rather cumbersome and expensive equipment is required for its measurement.

### THE EPIDEMIC OF CHRONIC KIDNEY DISEASE

Approximately 11% of the United States population suffers from some degree of CKD (7). The number of individuals with kidney failure treated by dialysis and transplantation exceeded 320,000 in 1998 and is expected to surpass 650,000 by 2010. By then, renal replacement therapy will cost up to \$28 billion per year (the equivalent of the entire NIH budget for 2006). Stated another way, 0.1% of the population will encumber 2% of the national health budget.

CKD stage 5 is associated with a dramatic increase in cardiovascular morbidity and mortality (15). The cardiac mortality among dialysis patients younger than 45 years is approximately 100 times greater than in the general population (16). Even patients with incipient renal disease (CKD stage 1) have been shown to have endothelial dysfunction and an increased cardiovascular risk (17), which clearly increases with the degree of renal impairment (18). In a study of over 1,000,000 individuals enrolled in the Medicare program in the United States (19), outcomes were reported for patients with CKD alone (2.2%) and in combination with diabetes (1.6%). After two years of follow-up, the rates for requiring renal replacement therapy were 1.6 and 3.4 per 100 patient-years for patients with CKD alone and those with both disorders, respectively. More devastating, by comparison, the death rates were 17.7 and 19.9 per 100 patient-years. In addition, rates for atherosclerotic vascular disease for these two groups (per 100 patient-years) were 35.7 and 49.1, whereas heart failure rates were 30.7 and 52.3, respectively, even in the absence of fluid retention. Hence, patients with CKD are more likely to die of cardiovascular disease than to reach ESRD. Therefore, current guidelines recommend that patients with CKD be considered in the "highest risk group" for subsequent cardiovascular events and that treatment recommendations based on CVD risk stratification should take into account the highest-risk status of patients with CKD.

Despite this worrisome development, the mechanisms underlying the increased risk for cardiovascular morbidity and mortality remain obscure. Results of several cross-sectional studies have suggested that the Framingham risk factors such

as older age, diabetes mellitus, systolic hypertension, left ventricular hypertrophy (LVH), and low levels of high-density lipoprotein (HDL) cholesterol are insufficient to capture the extent of CVD risk in subjects with CKD. New, nontraditional risk factors, such as the endogenous NOS inhibitor ADMA, may prove to be more specific and reliable in predicting progression of CKD (stages 1–4) to dialysis dependency as well as cardiovascular events in patients with CKD (13,20,21).

### ENDOTHELIAL DYSFUNCTION IN UREMIA AND ASYMMETRIC DIMETHYLARGININE – A UREMIC TOXIN PAR EXCELLENCE

A number of conditions found in patients with uremia may lead to endothelial dysfunction, including anemia, metabolic acidosis, hyperkalemia, parathyroid and vitamin D abnormalities, endocrine abnormalities, and malnutrition. Endothelial dysfunction is characterized by reduced vasodilation capacity, a proinflammatory and/or prothrombotic activity. It is characteristic of most forms of cardiovascular disease – e.g., hypertension, coronary artery disease, chronic heart failure, peripheral artery disease, diabetes, and CKD. Mechanisms that participate in the reduced vasodilatory responses in endothelial dysfunction in general include reduced NO generation, oxidative stress, and reduced production of the hyperpolarizing factor. For purposes of this discussion, we will focus on the role of ADMA as a cause of endothelial dysfunction in renal disease.

ADMA had been known to biochemists for decades as a naturally occurring analogue of L-arginine (22). In 1992, Vallance and coworkers demonstrated elevated levels of dimethylarginines in patients with ESRD (23). In this seminal report, the authors speculated that the accumulation of ADMA, which competitively inhibits NOS, might contribute to the hypertension and predisposition to infections associated with CKD.

Thus far, over 600 reports on ADMA have been published. Collectively, these studies support a role for ADMA as a uremic toxin, a powerful marker of endothelial dysfunction and atherosclerosis, and a solid predictor of mortality in selected patient populations (20,24–26). Indeed, there is increasing evidence that ADMA represents a common pathway in mediating endothelial dysfunction associated with both traditional and nontraditional cardiovascular risk factors in uremic as well as nonuremic patients (27).

NO is the most potent biological vasodilator. It plays a critical role in inhibiting key processes associated with atherosclerosis, including monocyte adhesion, platelet aggregation, and vascular smooth muscle cell proliferation. Hence, endothelial dysfunction as a result of reduced NO activity is an early step in the course of atherosclerotic vascular disease, and evidence has accumulated that inhibition of NO synthesis by endogenous substances may be causally involved in this process (27). A family of NOS with endothelial, neuronal, and macrophage isoforms converts L-arginine to NO and citrulline by stereospecific oxidation of the terminal guanidino nitrogen

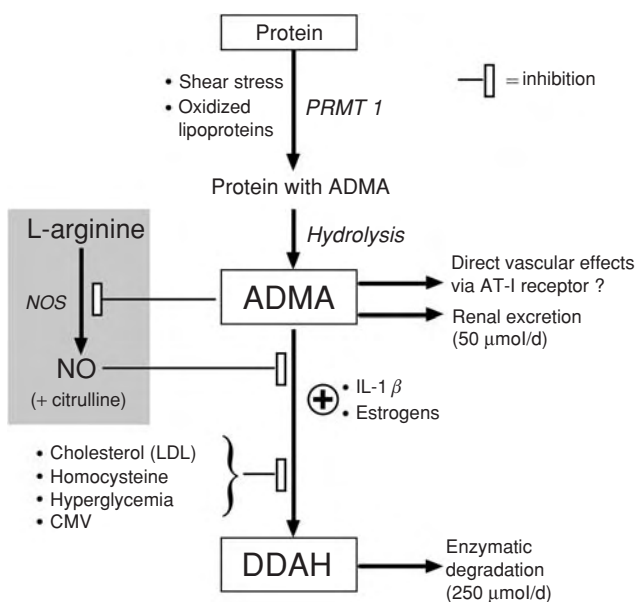

Figure 139.2. Overview of biochemical pathways for generation, elimination, and degradation of ADMA. ADMA stems from methylation of arginine residues in proteins. The reaction is catalyzed by PRMTs that transfer a methyl group to each guanidino nitrogen of an arginine residue. This reaction results in a methylated arginine derivative (protein-containing ADMA). Hydrolysis of the methylated proteins releases ADMA. All methylarginines (ADMA and SDMA) are excreted into the urine and are in part metabolized to  $\alpha$ -keto acids by the enzyme activity of dimethylarginine pyruvate aminotransferase (DPT). The major route of ADMA elimination ( $250 \mu\text{mol/d}$ ) occurs via degradation through the enzyme dimethylarginine dimethylaminohydrolase (DDAH). DDAH hydrolyzes ADMA to form dimethylamine and L-citrulline. Only a minor portion of ADMA ( $50 \mu\text{mol/d}$ ) is eliminated (unchanged) in the urine. The text boxes depict factors that influence the activity of PRMT and DDAH. CMV, cytomegalovirus; IL, interleukin.

of the amino acid L-arginine (28). This process can be selectively inhibited by competitive blockade of the NOS active site with naturally occurring guanidino-substituted analogues of L-arginine such as ADMA (Figure 139.2) (29).

Humans generate approximately  $300 \mu\text{mol}$  ( $\sim 60 \text{ mg}$ ) ADMA per day (30). Although an analogue of L-arginine, ADMA does not appear to be directly generated from the free amino acid. Rather, ADMA is released from proteins that have been post-translationally methylated and subsequently hydrolyzed. These proteins are largely found in the nucleolus and appear to be involved in RNA processing and transcriptional control (31). Protein-arginine methyltransferases (PRMTs) catalyze the formation of methylarginine residues. A number of cell types, including human ECs, elaborate ADMA (32). To date, it is unclear whether ADMA generation is constant or whether increased PRMT activity and/or increased protein turnover might contribute to elevated ADMA levels. The latter mechanism is supported by the observation that in patients with ESRD, increased protein catabolic rate is correlated with elevated circulating levels of ADMA.

Because ADMA was found to be elevated in dialysis patients, it was believed that the compound was normally eliminated by the kidney (23). However, an early study in rabbits revealed renal excretion not to be the major route of elimination, suggesting the presence of a catabolic pathway (33). Subsequent investigations led to the identification of one such pathway, which involves dimethylarginine dimethylaminohydrolase (DDAH)-mediated hydrolysis of ADMA to dimethylamine and L-citrulline (Figure 139.2) (34). Thus far, two isoforms of DDAH have been characterized and cloned; DDAH I is predominately found in tissues that express neuronal NOS (nNOS), whereas DDAH II is localized in tissues expressing endothelial NOS (eNOS) (35).

DDAH I and II have emerged as key enzymes regulating the cellular and tissue levels of ADMA;  $50 \mu\text{mol}$  ADMA per day is excreted in the urine, whereas approximately  $250 \mu\text{mol}$  ADMA per day is eliminated via degradation of DDAH (30). This is in line with clinical data showing that patients with incipient renal disease and normal renal excretory function, as documented by measurement of true glomerular filtration rate using inulin clearance, have markedly elevated plasma ADMA levels (36). This could possibly be a result of decreased activity of DDAH I, which is highly expressed in brain, kidney, pancreas, and liver, or due to increased PRMT activity/protein turnover (35). In fact, a study in humans showed higher renal extraction of ADMA compared to SDMA extraction (37). Thus the kidney plays a predominant role in the elimination of ADMA, combining two mechanisms: urinary excretion as well as enzymatic degradation of ADMA.

Compelling evidence for the critical role of DDAH activity in regulating NO synthesis in vivo was demonstrated in transgenic mice overexpressing DDAH. The increased DDAH activity in these animals led to a 50% decrease of ADMA levels, which in turn increased NOS activity and thereby lowered blood pressure (38). Systemic ADMA infusion in humans resulted in a decrease in plasma cGMP and significant hemodynamic alterations, including reduced effective renal plasma flow (ERPF), sustained decrease in cardiac output, increase in systemic vascular resistance, and decrease in heart rate (39). These results are in accordance with data obtained using non-invasive techniques (30). Collectively, these preclinical and clinical findings indicate that ADMA has well-defined effects on cardiovascular and renal function in healthy subjects. It is therefore conceivable that ADMA causes sustained changes in vascular function through an intracellular action in ECs at blood concentrations found in patients with cardiovascular pathology.

#### ASYMMETRIC DIMETHYLARGININE AND CARDIOVASCULAR MORBIDITY AND MORTALITY IN PATIENTS WITH RENAL DISEASE

Since Lindner and coworkers first reported the association between ESRD and premature atherosclerosis/cardiovascular

mortality, there has been little progress in understanding the underlying molecular mechanisms (15). Depending on age, patients on renal replacement therapy encounter a five- to 500-fold risk of dying from cardiac causes. Many studies have documented endothelial dysfunction in patients with patients undergoing dialysis (40). Given the correlation between ESRD and elevated levels of ADMA, and considering the role of this uremic toxin in inhibiting NO, it is tempting to speculate that ADMA contributes to the premature atherosclerosis/cardiovascular mortality.

Consistent with this hypothesis, a cross-sectional study revealed that ADMA is higher in dialysis patients with cardiovascular complications than in those without such complications (41). Moreover, a cohort study has demonstrated a strong and independent link between ADMA, mortality, and cardiovascular events in ESRD patients (20). In further studies, ADMA was shown (a) to be an independent risk factor for increased intima media thickness of the carotid artery (IMT) in ESRD patients (42), (b) to be an independent predictor for progression of intimal lesions (42), (c) to be strongly associated with IMT in mild to moderate chronic renal insufficiency (43), and (d) to demonstrate a strong independent link with IMT in apparently healthy individuals in the general population (44).

### The Cardio–Renal Interaction

The heart and the arterial system form an integrated unit that coherently responds to hemodynamic stimuli as well as to risk factors for atherosclerosis. For example oxygen requirement is related to left ventricular geometry; coronary hypertension, with endothelial dysfunction and reduced coronary reserve; diastolic dysfunction; and structural remodeling of myocardium and vascular bed. Accordingly, in physiological and in disease states – e.g., uremia – cardiac and arterial remodeling proceed in parallel (45,46). There are several lines of evidence, which when considered collectively suggest that ADMA-induced EC dysfunction is causally related to development of LVH in dialysis patients. First, in patients with hypertension, there is a strong association between endothelial dysfunction and concentric LVH (47). Second, in patients on dialysis, the reactive hyperemic response of forearm blood flow (an outcome measure strongly influenced by endothelial function) is inversely correlated with common carotid IMT and left ventricular mass (48). Third, there is a strong independent association between ADMA levels and left ventricular mass in patients on maintenance hemodialysis (49). Fourth, ADMA is much higher in dialysis patients with concentric LVH than in those with eccentric LVH or normal left ventricular mass (Figure 139.2). Fifth, concentric LVH occurs in experimental models of chronic NO inhibition (50). Finally, severe concentric hypertrophy and vascular damage is a hallmark in the knockout mouse lacking the *eNOS* and the *ApoE* genes (51). Thus, ADMA may play a pathophysiological role in diverse cardiovascular conditions, including coronary artery disease, carotid artery disease, and heart failure.

### ASYMMETRIC DIMETHYLARGININE AND MINOR RENAL DYSFUNCTION

Even minor renal dysfunction has recently been recognized as a cardiovascular risk factor (7). Interestingly, several studies found markedly elevated plasma ADMA levels not only in patients on dialysis but also in patients with progressive CKD and even in patients with incipient renal disease and normal renal function (52). Accumulation of ADMA may cause impaired acetylcholine-induced endothelium-dependent vasorelaxation in patients with incipient renal disease and normal renal function (17). In humans, as in many species, the process of aging results in deterioration of renal function even without primary renal disease. Previous studies have documented that aging affects renal hemodynamics, as manifested by increased renovascular tone and reduced dilatation of postglomerular vessels in response to stimuli such as acetylcholine or amino acids (53–56). Furthermore, in senescent individuals, reduced availability of NO is thought to be linked to the increase in blood pressure and renovascular resistance, possibly a reflection of arteriosclerosis (57,58). In comparison to concentrations in young healthy adults, ADMA concentrations have been markedly increased in the normotensive elderly and particularly in the hypertensive elderly (59). The significant relationship between high ADMA blood levels, reduced renal perfusion, and high blood pressure values is compatible with the notion that accumulation of this NOS inhibitor in senescent individuals is involved in the decrease of renal perfusion and increase of blood pressure. Recent studies indicate that ADMA may have far-reaching effects on the senescence process because *in vitro* it shortens telomere length by activating telomerase (60).

### ASYMMETRIC DIMETHYLARGININE INHIBITS VASCULAR REPAIR

Besides leading to renal damage, ADMA might also be involved in inhibiting repair of renal lesions by endothelial progenitor cells (EPCs). EPCs have recently come into focus in cardiovascular research because they are thought to be responsible for endothelial repair (61). EPCs circulate in the cardiovascular system, where they home and incorporate into sites of active neovascularization. In fact, EPCs orchestrate re-endothelialization of damaged vessel walls, also by secreting a large number of important cytokines, which attract and govern cells that are indispensable in the process of endothelial repair. A recent study suggests that increased endothelial NO availability is required for improvement of endothelial progenitor cell mobilization, myocardial repair, and neovascularization after myocardial infarction (62). An increased ADMA level and thereby a decreased NO production may lead to a deficiency of EPCs. Indeed, a study by Thum et al. showed an inverse correlation between ADMA plasma concentration and circulating EPC levels in patients with coronary artery disease (63).

The pathophysiological relevance of ADMA may go even beyond its interference with cardiovascular function. For example, there is experimental evidence that ADMA may be implicated in dementia, endocrine alterations, osteoporosis, and fertility as well – i.e. in alterations that are also typically found in patients with advanced renal insufficiency.

#### KEY POINTS

- The uremic condition – i.e., CKD – is a major cardiovascular risk factor.
- Accelerated atherosclerosis due to impaired renal function is the result of the complex interaction of many compound, uremic toxins, most of which lead to reduced bioavailability of NO.
- Identifying patients at risk using reliable markers of renal function as well as better predictors of cardiovascular mortality is still an unmet need.
- Endogenous inhibition of NO synthase – e.g., via ADMA – seems to be a marker and mediator of endothelial dysfunction in uremia as well as in non-renal patients.

#### Future Goals

- To foster public awareness, reliable and feasible markers of renal function, and advances in understanding the pathophysiology of injury and the repair mechanisms – e.g., by using bone marrow-derived cells – as a prerequisite to successfully meet the unique challenge of cardiovascular disease in CKD

## The Influence of Dietary Salt Intake on Endothelial Cell Function

---

Paul W. Sanders

*University of Alabama at Birmingham,  
Department of Veterans Affairs Medical Center, Birmingham*

The past two decades of endothelium-related research have altered our concepts of the function of this organ significantly. Endothelial cells (ECs) are metabolically active input–output sensors that detect and respond to mechanical and biochemical changes in the extracellular environment. Recent work has further promoted the concept that the endothelium can react to changes in dietary NaCl (also referred to as salt in this chapter) intake independently of blood pressure through changes in the extracellular milieu, particularly shear force. EC function appears to be a critical factor involved in the vascular response to changes in salt intake.

### DIETARY SALT ALTERS ENDOTHELIAL CELL PRODUCTION OF TRANSFORMING GROWTH FACTOR- $\beta$ AND NITRIC OXIDE

Initial studies examined the effect of salt intake on production of transforming growth factor (TGF)- $\beta$  in the kidney. Expression of all three mammalian TGF- $\beta$  family members – TGF- $\beta$ 1,  $\beta$ 2, and  $\beta$ 3 – increased in renal cortical tissue from rats fed a diet containing 8.0% NaCl (high salt), compared to tissue from rats maintained on a 0.3% NaCl (low salt) diet (1). Subsequent experiments focused on production of TGF- $\beta$ 1. Steady-state mRNA levels and production of total and active TGF- $\beta$ 1 were increased in glomerular preparations (1) and aortic rings (2) from rats on the high-salt diet, compared to preparations from rats on the low-salt diet. Increased TGF- $\beta$ 1 levels were no longer detected when aortic ring preparations were denuded of their endothelium, demonstrating that the endothelium was the source of the TGF- $\beta$ 1. Immunohistochemical analyses of aorta from rats on the high-salt, but not low-salt, diet revealed increased nuclear accumulation of phosphorylated Smad2/3 in the EC lining (Figure 140.1A), suggesting that TGF- $\beta$ 1 is signaling in ECs. Taken together, these data imply

that in addition to potential paracrine effects on adjacent cells, including vascular smooth muscle, mesangial, and glomerular epithelial cells, TGF- $\beta$ 1 acts in an autocrine manner in ECs of the glomerulus. Although the effect of salt intake on TGF- $\beta$  production was not specific to glomerular ECs – it was also observed in aortic ECs – the magnitude of the effect was greater in the glomerular preparations.

Previous studies in rats (3–6) and healthy humans (7) have demonstrated an association between increased salt intake and elevated nitric oxide (NO) production. Increased NO production permits renovascular vasorelaxation (particularly of the afferent arteriole), augments glomerular filtration rate, and improves the pressure–natriuresis curve, facilitating salt excretion (8,9). Gene transfer of the endothelial isoform of NO synthase (NOS3; also termed eNOS) into the thick ascending limb of the loop of Henle of mice with genetic deletion of NOS3 restored L-arginine-mediated NO production and inhibition of NaCl transport (10). In rats, an increase in dietary salt intake was shown to increase steady-state mRNA and protein levels of NOS3 in preparations of glomeruli and aortic rings. The increase in NOS3 protein was associated with increased baseline and calcium-ionophore-stimulated NO production (2,11). Inhibition of NO with G-(N)-nitro-L-arginine-methyl ester (L-NAME) in rats produced salt retention and salt-sensitive hypertension (12) and, if protracted, resulted in renal injury, particularly if the animals were maintained on a high-salt diet (13). In cultured nonglomerular ECs, TGF- $\beta$ 1 has been reported to stimulate NO production, an effect that is dependent on Smad-mediated induction of NOS3 transcription (14,15). These latter findings raised the possibility that the autocrine effect of TGF- $\beta$ 1 observed in animals on high-salt diets may serve as a compensatory mechanism to induce production of NO. Indeed, studies using a neutralizing antibody to TGF- $\beta$ 1 confirmed a modulatory role for TGF- $\beta$ 1 in the EC production of NO by inhibiting the increase in NOS3

Figure 140.1. (A) The representative immunohistochemical analysis of phospho-Smad2/3 of aortic tissue from SD rats on low-salt (0.3% NaCl) and high-salt (8.0% NaCl) diets for four days. A polyclonal antibody that specifically recognized phosphorylated Smad2/3 (Santa Cruz) was used to show the significant activation of this pathway and nuclear localization of phospho-Smad2/3 in aortic ECs (arrows) of rats on the high-salt diet. EC staining of rats on the low-salt diet was faint. The vascular smooth muscle layers of both sections stained with the antibody. (B) Nuclear localization (arrows) of phospho-p38 MAPK (left) and phospho-p42/44 MAPK (right) in SD rats maintained on the 8.0% NaCl diet. (B is modified with permission from Ying W-Z, Sanders PW. Increased dietary salt activates rat aortic endothelium. *Hypertension*. 2002;39:239–244.)

protein levels in preparations from rats on the high-salt diet (2,11).

Although TGF- $\beta$ 1 appears to induce NOS3 expression in critical target organs that react to changes in blood pressure and blood volume, NO provides an essential inhibitory feedback mechanism. Glomerular and vascular ring preparations incubated with the NOS inhibitor, L-NAME, produced increased amounts of TGF- $\beta$ 1, whereas incubation with a NO donor, ( $\pm$ )-(E)-4-ethyl-2-[(E)-hydroxyimino]-5-nitro-3-hexenamide (NOR3), decreased production of total and active TGF- $\beta$ 1 (16). Thus, NO limits the production of active TGF- $\beta$ 1; the mechanism was independent of blood pressure and flow, because the experiments were performed in vitro under static conditions. NO has been shown to inhibit production of thrombospondin-1 in cultured mesangial cells directly in a guanylyl cyclase-dependent fashion (17). This inhibition of thrombospondin-1-mediated activation of TGF- $\beta$ 1 (18,19) may explain the potential benefit of NO by a mechanism of decreasing the positive feedback loop that drives expression of TGF- $\beta$  in this model. The key is the development of a balance between TGF- $\beta$ 1 and NO. A relative excess of TGF- $\beta$ 1 would be detrimental if NO production does not increase, which occurs in the Dahl-Rapp salt-sensitive rat (16).

## ENDOTHELIAL CELL SIGNALING MECHANISMS AND DIETARY SALT

ECs in culture respond to shear stress, the frictional force ordinarily generated by blood flow, initially through opening an inwardly rectifying potassium channel that hyperpolarizes the cell (20,21), promoting increases in intracellular calcium concentration (22). Shear stress promotes both rapid (nongenomic) and delayed (genomic) events in ECs (23). By virtue of their location and response to shear stress, ECs serve as biomechanical sensors that detect and respond to changes in blood flow. Dietary salt increases blood volume and renal blood flow in normal rats (24,25); increased flow promotes shear stress. Hemodynamic forces are strong activators of the endothelium and modulate expression of numerous genes (26). Relevant to this discussion, shear stress has been shown to induce expression of TGF- $\beta$ 1 in cultured ECs, and this process is inhibited by tetraethylammonium (TEA), an inhibitor of the shear-activated potassium channel (27). Similar to these studies, the initial event that stimulates TGF- $\beta$ 1 production by aortic ring and glomerular preparations from rats fed a high-salt diet appears to be the opening of a TEA-sensitive potassium channel, because incubation in TEA in vitro inhibited production of total and active TGF- $\beta$ 1 (1,2). As expected from experiments that demonstrated a direct effect of TGF- $\beta$  on NOS3 expression, incubation in TEA also reduced NOS3 expression and NO production (2,11). Downstream of these cell surface events, activation of the mitogen-activated protein kinase (MAPK) pathways occurs. Dietary salt activates in a dose-dependent fashion both p38 MAPK and p42/44 MAPK pathways in aortic ring and glomerular preparations (Figures 140.2 and 140.3) (28,29). Nuclear accumulation of p38 MAPK

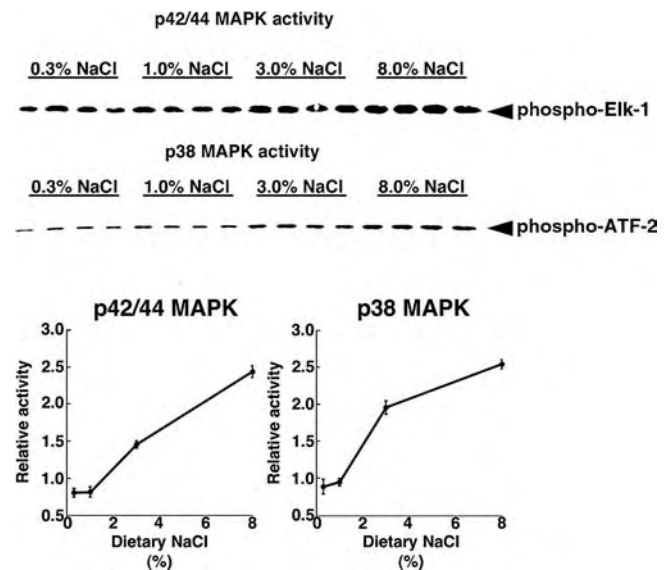

Figure 140.2. Aortic ring preparations from SD rats demonstrated a dose-dependent increase in the activities of p38 MAPK and p42/44 MAPK as the dietary intake of salt increased. (Modified with permission from Ying W-Z, Sanders PW. Increased dietary salt activates rat aortic endothelium. *Hypertension*. 2002;39:239–244.)

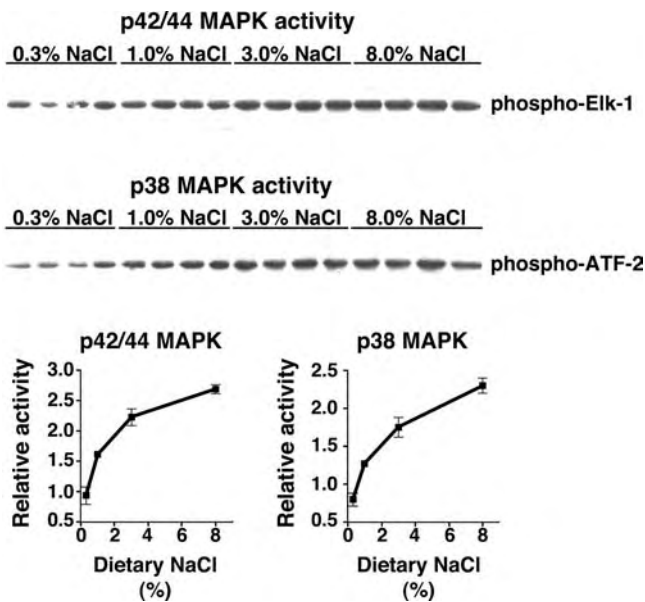

Figure 140.3. Glomerular preparations from SD rats demonstrated a dose-dependent increase in the activities of p38 MAPK and p42/44 MAPK as the dietary intake of salt increased. (Modified and reproduced with permission from Ying W-Z, Sanders PW. Dietary salt intake activates MAP kinases in the rat kidney. *FASEB J*. 2002;16:1683–1684.)

and MEK1/2 was demonstrated using immunohistochemistry (Figure 140.1B) and was associated with increased phosphorylation of the downstream transcription factors, activating transcription factor 2 (ATF2) and Elk2 (28). Using specific pharmacologic inhibitors, activation of both MAPK pathways was shown to be essential in stimulating TGF- $\beta$ 1 production in aorta and glomeruli of rats fed the high-salt diet (28,29). Importantly, intravenous administration of TEA just prior to harvesting the aorta inhibited the increase in glomerular MAPK activity in vivo (29). The combined data suggest that production of TGF- $\beta$ 1 in response to changes in salt intake is a function of multiple interdependent signaling cascades that include Smad2/3, p38 MAPK, and p42/44 MAPK. In turn, TGF- $\beta$ 1 has a direct impact on NOS3 expression and function. The mechanism is compatible with a shear force-mediated process, although this has not yet been demonstrated as the sole mechanism in vivo.

TGF- $\beta$ 1 was previously shown to induce NOS3 mRNA expression in cultured bovine aortic and human umbilical vein ECs via the Smad2/3-signaling pathway in addition to other pathways (14,15). Simply adding excess active TGF- $\beta$ 1 to glomerular preparations from animals maintained on a low-salt diet did not increase NOS3 expression in the 24-hour timeframe of the study, whereas adding TGF- $\beta$ 1 produced a dose-dependent increase in NOS3 in glomerular preparations from rats on the high-salt diet (11). The implications are that Smad2/3-mediated signaling alone was insufficient, although activation of the Smad pathways was not examined in the latter studies and other explanations, such as sensitization of the endothelium with increased receptor numbers, are

also a possibility. Increased NOS3 levels required dietary salt-induced activation of additional signaling pathways. These findings are not unique to this process of gene transcription induced by TGF- $\beta$ . Activation of the Smad2/3-signaling pathway has been previously reviewed (30–35) (see Chapter 35). To summarize, binding of TGF- $\beta$ 1 to the type I TGF- $\beta$  receptor (T $\beta$ RI or activin receptor-like kinase 5[ALK5]) complex permits recruitment of the type II receptor and activation of the complex through autophosphorylation. Smad2/3 is then phosphorylated, permitting binding to Smad4 and migration of the heteromeric complex into the nucleus and binding to specific *cis*-regulatory elements in gene promoter segments. Activation of the Smad2/3 pathway is needed for transcriptional regulation of many TGF- $\beta$ 1-regulated genes, including the TGF- $\beta$ 1 gene itself (36). The Smad complex binds DNA with low affinity and requires other binding proteins, such as ATF-2 (37,38) and activator protein (AP)-1 (39,40), to induce specific and efficient gene transcription (35,41). Thus, the combined data support activation of multiple signaling pathways that increase TGF- $\beta$ 1 gene expression by ECs in response to changes in salt intake (Figure 140.4). Interestingly, these same pathways appear to be involved in the regulation of thrombospondin-1, which activates TGF- $\beta$ 1 (18,19) in rat proximal tubular cells and mouse fibroblasts (42).

As reviewed by Lebrin and colleagues (43), there are other effects of the Smad2/3 pathway, including inhibition of EC proliferation and migration. However, in ECs, TGF- $\beta$ 1 can also bind and activate ALK1, which signals through the Smad1/5 pathway. Activation of this pathway requires endoglin, which is expressed on ECs (44,45) and antagonizes the effects of ALK5-mediated cell proliferation and migration (43,46). Endoglin also appears to play an important role in determining the protein half-life of NOS3 through interactions with Hsp90 (47). Mutations in ALK1 account for one form of hereditary hemorrhagic telangiectasia, or Osler-Weber-Rendu syndrome, an autosomal dominant disease characterized by development of arteriovenous malformations and other vascular dysplasias (48,49). The potential role of ALK1 and the balance between ALK5 and ALK1 activation during increases in dietary salt intake have not been explored.

## OBSERVATIONS IN PATHOPHYSIOLOGICAL STATES

Initial insight into the pathological significance of salt intake independent of blood pressure came from studies by Yu and associates (50), who showed that feeding an 8.0% NaCl diet to normotensive Wistar-Kyoto (WKY) rats and spontaneously hypertensive rats (SHR) increased TGF- $\beta$ 1 production and produced fibrosis in the kidney and left ventricle. The authors concluded that excessive salt intake might play a direct role in cardiovascular and renal disease. In a recent study, administration of an 8.0% NaCl diet to the Fisher-Lewis rat model of orthotopic renal transplantation accelerated the development of chronic allograft nephropathy (CAN) (51). In this model,

Figure 140.4. Cartoon depicting the postulated events responsible for augmented production of TGF- $\beta$  by ECs in response to increases in salt intake. As shear stress increases, a TEA-sensitive potassium channel opens, permitting increases in intracellular calcium concentration. Through a process not yet clarified, both p38 MAPK and p42/44 MAPK are activated, permitting phosphorylation and activation of transcription factors that participate with the Smad2/3 signaling pathway to coordinate gene transcription. The process is amplified by increasing the production of TGF- $\beta$ , which, when activated, can bind to the T $\beta$ RI (ALK5) receptor. NO, perhaps by interfering with the activation of TGF- $\beta$ 1 or through other as yet undefined mechanisms, inhibits the positive feedback loop that drives expression of TGF- $\beta$ .

the contralateral kidney was surgically excised two weeks prior to the change in salt intake. The rats did not develop hypertension over the 12 weeks of observation but demonstrated an increase in tubulointerstitial fibrosis and glomerular sclerosis in the transplanted kidneys (51), along with an increase in urinary excretion and renal cortical levels of TGF- $\beta$ 1 (Sanders and colleagues, unpublished observations). Control and sham rats in that study also demonstrated modest increases in albuminuria without overt renal pathology when fed the high-salt diet over the same time period (51). The association between dietary salt intake and albuminuria has been confirmed in a large cohort of human subjects in a recent study that demonstrated a significant relationship between urinary salt excretion and both left ventricular mass index and urinary albumin excretion (52). The combined studies suggest that dietary salt intake can alter cardiorenal risk factors, and further that there may be a vulnerable population that has a heightened sensi-

tivity to the adverse cardiorenal effects of salt, such as subjects following renal transplantation.

A direct correlation between steady-state mRNA of TGF- $\beta$ 1 and NOS3 was demonstrated in normotensive Sprague-Dawley (SD) rats fed diets containing various amounts of NaCl (11,16). The relationship was also examined in the Dahl-Rapp salt-sensitive (S) rat, which is an inbred strain that develops hypertension and subsequent progressive renal failure when fed a high-salt diet. Although the relationship existed between active TGF- $\beta$ 1 and NO in S rats, the slope was increased such that at any level of NO, TGF- $\beta$ 1 levels were greater in S rats compared to SD rats. Glomerular and vascular production of TGF- $\beta$ 1 was increased in prehypertensive S rats and was further exaggerated with the onset of salt-sensitive hypertension (16). The mechanism accounting for the increased sensitivity of S rats is under investigation but does not appear to be related to alterations in activation of the p38 MAPK and

p42/44 MAPK pathways (16). These findings again emphasize the concept of a population at risk to the adverse effects of excess salt intake. The root cause might be diminished plasticity of ECs in critical vascular beds such as the glomerulus; the application of this environmental stress in the setting of EC dysfunction ultimately creates a milieu that facilitates end-organ damage.

Reducing dietary intake of salt can slow the progression of chronic kidney disease in rats. Using the uninephrectomized SHR as a model of progressive renal failure, Benstein and associates showed that a low-sodium (0.09%) diet alone resulted in less proteinuria and glomerular sclerosis than did administration of a diuretic while continuing a standard (0.45%) sodium diet (53). In this study, systolic blood pressures determined by tail-cuff methodology did not differ among the groups over a 36-week period. These data fit well with another study that showed that administration of a diuretic to animals that continued the high salt intake did not reduce intrarenal production of TGF- $\beta$  (1). Also, although the mainstays of therapy of chronic kidney disease include angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor antagonists (ARB), both of which appear to slow the progression of kidney failure in part by inhibiting the stimulation of TGF- $\beta$ 1 production by angiotensin II (54–57), an excess salt intake could promote TGF- $\beta$ 1 independently of angiotensin II. Thus, efforts to monitor and reduce salt intake through dietary restriction may slow renal disease progression through reduction in production of TGF- $\beta$ 1.

In a retrospective analysis of progression of chronic kidney disease, subjects with baseline creatinine clearances between 10 and 40 mL/min were grouped according to consistent urine sodium excretion rates of either less than 100 meq/d (2.3 g Na<sup>+</sup>) or greater than 200 meq/d (4.6 g Na<sup>+</sup>). Mean blood pressures of the groups did not differ, and both glomerular and tubulointerstitial diseases were represented in both groups. Creatinine clearance declined more rapidly in the high-salt group compared with the low-salt group ( $-0.51 \pm 0.09$  vs.  $-0.25 \pm 0.07$  mL/min/month;  $p < 0.05$ ). Also, proteinuria increased in the high-salt group and fell in the low-salt group (58). Although this report was not a randomized, controlled trial, it presents intriguing findings that support salt restriction in patients with advanced chronic kidney disease.

Although serum TGF- $\beta$ 1 levels were not affected by salt intake, intrarenal production and urinary excretion of TGF- $\beta$ 1 increased as salt intake increased in rats (1). Ellis and colleagues (59) demonstrated an increase in urinary excretion of TGF- $\beta$ 1 in diabetic subjects who had either microalbuminuria or macroalbuminuria, compared to healthy controls and diabetic patients without microalbuminuria or macroalbuminuria. Although it seems unlikely that urinary TGF- $\beta$ 1 will have diagnostic utility, because TGF- $\beta$ 1 plays such an important role in progression of chronic kidney disease in a variety of disease states (60–68), serial assessment of this parameter might prove useful in determining the activity of this growth factor in the kidney and the potential benefit of an intervention. For example, decreases in urinary TGF- $\beta$ 1 excretion

with treatment of patients with type II diabetes mellitus with an ARB has been documented (69,70). Houlihan and associates (70) also demonstrated an excellent direct correlation between urinary TGF- $\beta$ 1 excretion and sodium excretion in their population of patients who had type II diabetes mellitus and microalbuminuria. Although this study showed a direct correlation between salt intake and urinary TGF- $\beta$ 1 excretion, it did not show a decrease in urinary excretion of TGF- $\beta$ 1 with reduction in salt intake because the study was designed to show an effect of the ARB. As a secondary analysis, there did not appear to be sufficient numbers of patients to provide the power needed to detect an effect of reduced salt intake.

## CONCLUSION

This review emphasizes the concept that the plasticity of the endothelium plays an integral role in altering vascular tone and renal function, especially in response to changes in dietary salt intake. Furthermore, with the caveat that there are limitations to these studies, the data suggest that there are populations at greater risk of developing end-organ damage from high salt intake and these individuals have lost the requisite EC flexibility to adapt to this environmental stress. Intermittent excessive salt intake probably poses no substantial risk to individuals lacking this risk factor. In contrast, those individuals with EC dysfunction from a genetic or acquired source might develop an imbalance between NOS3 and TGF- $\beta$ 1, permitting excess biological activity of this important fibrogenic growth factor and subsequent development or acceleration of vascular and kidney damage.

## KEY POINTS

- ECs modulate production of TGF- $\beta$ 1 and NO in response to changes in dietary salt intake.
- Dietary salt intake promotes alterations in EC function through a process that appears to be shear mediated.
- Increased salt intake activates multiple pathways that include Smad2/3, p38 MAPK, and p42/44 MAPK pathways.
- Increased salt intake increases TGF- $\beta$ 1 production, which in turn increases NOS3 protein and NO production.
- NO levels adjust TGF- $\beta$ 1 production by ECs, supporting an important negative feedback role for NO.

## Future Goals

- To define the signal transduction events involved in the upregulation of TGF- $\beta$ 1 by dietary salt and the mechanism by which NO inhibits EC production of TGF- $\beta$ 1

- To determine the functional adaptation and consequences of salt intake on EC function in the vasculature of the kidney

## ACKNOWLEDGMENTS

## The Role of the Endothelium in Systemic Inflammatory Response Syndrome and Sepsis

Laszlo M. Hoesel and Peter A. Ward

University of Michigan Medical School, Ann Arbor

The terms *systemic inflammatory response syndrome (SIRS)*, *sepsis*, *severe sepsis*, *septic shock* and *multiorgan failure (MOF)* are currently used to characterize the progressive stages of a very complex and therapeutically challenging disorder of the immune and inflammatory systems. Although SIRS is a result of a systemic activation of the innate immune system regardless of cause, sepsis, severe sepsis, and septic shock are accompanied by proven or suspected infection with or without impaired organ function. Despite tremendous research efforts for over 20 years, sepsis remains the leading cause of death in intensive care units (ICUs). SIRS and sepsis occur in approximately 750,000 patients per year in the United States, with a rising incidence of approximately 1.5% per year (1). With a mortality rate of currently 30% to 70%, sepsis and related disorders represent a major burden to the U.S. health care system, with costs estimated to be approximately \$16.7 billion per year (2).

The endothelium represents the natural barrier between the intravascular and extravascular spaces. However, endothelial cells (ECs) are not inactive "border controls"; in fact, among other functions, they are involved in maintaining vasomotor tone, blood flow, local balance of various mediators, programmed cell death (apoptosis), and hemostatic balance. During infectious conditions, activated leukocytes must transmigrate to infectious sites to engulf, phagocytose, and destroy invading microbes. This is an active process not only for the migrating leukocytes but also for the ECs. During this process, numerous pro- and anti-inflammatory mediators lead to activation of the endothelium and result in the expression of various adhesion molecules, which in turn facilitate or inhibit the transmigration of activated leukocytes into tissues. In addition, ECs can generate their own inflammatory mediators and express adhesion molecules. At the same time, the body's inflammatory response leads to the activation of the coagulation (intrinsic and extrinsic pathways) as well as the fibrinolytic system. Although ECs represent an anticoagulant surface under physiologic conditions, their stimulation by a variety of proinflammatory mediators, as seen in SIRS and sep-

sis, results in a procoagulant phenotype. These changes clearly contribute to the development of increased microvascular permeability, edema formation, and hypotension (3). Therefore, much effort has been made to assess the interaction of ECs, leukocytes, and the coagulation system during inflammatory diseases, especially sepsis.

### SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND SEPSIS

#### Definitions

Sepsis is not a disease but a syndrome, and the complexity and variability of symptoms observed in septic patients have resulted in difficulties in establishing an accurate, well-accepted, and reliable definition of the condition. Until only 15 years ago, sepsis was defined as the systemic host response to an infection, equated with the presence of bacteria in blood. In 1989, a simple definition of sepsis was established on the basis of clinical symptoms and a known source of infection (4). However, although many patients showed septic symptoms, detectable levels of bacteria in the blood often were not found. Therefore, the term *systemic inflammatory response syndrome* was introduced in 1992, and sepsis was redefined as SIRS associated with suspected or proven infection (5). During the following years, however, these criteria proved too non-specific to facilitate a precise and unambiguous diagnosis or to allow staging of the disease and prognosis, although the original definition has remained. Thus, the criteria for the diagnosis of SIRS or sepsis were extended by using more clinical parameters (e.g., altered mental state, edema, hyperglycemia, hypotension, and organ dysfunction parameters) (6).

In response to a variety of infectious and noninfectious conditions, the host can react with the development of SIRS. Among the triggers of SIRS are infection, trauma, burns, ischemia and/or reperfusion injury, sterile inflammatory processes (e.g., pancreatitis), and extensive surgical procedures. The physiological changes that occur in patients with SIRS

**Table 141-1: Clinical Definitions of Sepsis**

<i>Syndrome</i>	<i>Clinical Findings</i>
SIRS	Temperature >38.5°C or <36°C Heart rate >90 beats per minute Respiratory rate >20 breaths per minute or PaCO <sub>2</sub> <32 mm Hg White blood count >12 × 10 <sup>9</sup> /L or <4 × 10 <sup>9</sup> /L or presence of >10% immature neutrophils
Sepsis	Two or more criteria of SIRS Documented (or suspected) infection
Severe sepsis	Sepsis associated with organ dysfunction (hypoperfusion, hypotension, lactic acidosis, oliguria, or alteration of mental state)
Septic shock	Sepsis-induced hypotension (systolic blood pressure <90 mm Hg or 40 mm Hg below baseline) despite adequate fluid resuscitation
MODS/MOF	Altered organ function such that homeostasis must be maintained with intervention

Paco<sub>2</sub>, arterial pressure of carbon dioxide.

are summarized in Table 141-1. In addition, possible biochemical indices of SIRS (increased levels of interleukin [IL]-6, adrenomedullin, soluble CD14, E-selectin, macrophage inflammatory protein [MIP]-1 $\alpha$ , macrophage migration inhibitory factor [MIF], C-reactive protein [CRP] and procalcitonin) have been investigated.

SIRS triggered by infection is termed *sepsis*. Severe sepsis is defined as sepsis complicated by organ dysfunction. The most frequent cause of sepsis is bacterial (gram-positive and gram-negative) infection followed by fungal, viral, or protozoal infections. The most common sites of infections are the lungs, abdomen, and urinary tract. Interestingly, although gram-positive bacteria were previously thought to be the primary organisms causing sepsis, evidence now suggests that sepsis caused by gram-negative bacteria occurs with equal frequency (7). It should also be noted that the most common condition leading to sepsis is bacterial pneumonia.

### Pathophysiological Mechanisms

Tight regulation of the immune and inflammatory systems is crucial for maintaining the balance between protective and tissue-damaging responses. SIRS and sepsis are characterized by a loss in this balance, leading to hyperactive (and often followed by hypoactive) immune and inflammatory responses. The reasons for these perturbations, however, are unknown. During the onset of sepsis, the inflammatory sys-

tem becomes hyperactive, involving both cellular and humoral defense mechanisms. Endothelial and epithelial cells, as well as neutrophils, macrophages, and lymphocytes, produce proinflammatory mediators (e.g., tumor necrosis factor [TNF]- $\alpha$ , IL-6, IL-1, and IL-8). Although these mediators appear in the bloodstream at an early time point, another proinflammatory agent, high mobility group B1 protein (HMGB1), has been identified as a late mediator during various models of inflammation and sepsis (8). The presence of these mediators in plasma is often a harbinger of the developing SIRS and sepsis syndromes. Simultaneously, soluble elements of the immune system become activated and can be detected in the plasma/serum. The concentration of serum acute-phase proteins (such as CRP) increases, and the activated cascade of the complement system leads to the production of powerful complement split products, the anaphylatoxins C3a and C5a. Together, these processes enhance the production of proinflammatory and anti-inflammatory cytokines and chemokines. Phagocytic cells (neutrophils and macrophages) respond to these chemoattractants by releasing granular enzymes and producing reactive oxygen species (ROS), such as hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), and reactive nitrogen species, such as nitric oxide (NO), which are involved in the killing of ingested bacteria. ROS and NO are capable of causing tissue damage and increased vascular permeability, ultimately leading to organ injury and failure. Furthermore, the coagulation and fibrinolytic systems become activated, which can lead to disseminated intravascular coagulopathy (DIC).

At later stages of sepsis, anti-inflammatory mediators are produced, including IL-10 and IL-13, which counteract the proinflammatory effects during the early phase. The production of anti-inflammatory mediators in the setting of sepsis has been referred to as the compensatory anti-inflammatory response syndrome (CARS) (9). As sepsis progresses, neutrophils and macrophages show reduced phagocytic activity, bacterial killing, oxygen radical production, chemotaxis, and cytokine production. The mechanisms leading to this type of immunosuppression are not yet completely understood. So far, the shift from a proinflammatory to an anti-inflammatory cell response, the development of a state of immune anergy, the apoptosis-induced loss of immune cells, and the immunosuppressive effects of lymphocytes undergoing apoptosis have been described and are considered to contribute to immune suppression in patients with sepsis (10). Taken together, various functions of the immune system are compromised during the late stage of sepsis, leading to a hyporeactive host defense system and immunoparalysis.

### THE ENDOTHELIUM DURING INFLAMMATION

Under physiologic conditions, ECs perform several functions to maintain homeostasis. ECs normally inhibit blood coagulation and do not stimulate the adherence of peripheral cells. Further, by producing prostacyclin, NO, and other vasoactive substances, ECs inhibit platelet aggregation and regulate the

tone of arterioles and venules, thereby regulating microcirculation (11). During inflammatory states, ECs come in contact with a variety of proinflammatory mediators that change their physiologic functions profoundly. This is considered "activation of ECs." As a result, an interaction with and adhesion of leukocytes with ECs is facilitated, ECs switch from an anticoagulatory to a procoagulatory state, and an altered barrier function of ECs leads to increased permeability and impaired vasomotor tone. These changes are discussed in detail in upcoming sections.

For more than 100 years, the extravasation of leukocytes from the bloodstream into tissue has been studied and was first documented in vivo in frog mesentery and tongue during the 1800s (12) and, in 1935, in the skin of experimental animals (13). Since then, specific adhesion molecules, which are expressed on leukocytes, ECs, and platelets, have been shown to participate in this process (14). Three families of cell adhesion molecules (CAM) play a central role in leukocyte-endothelial interactions: the selectins (E, P, L), the integrins ( $\beta 1$ ,  $\beta 2$ ), and the immunoglobulin superfamily (intercellular adhesion molecule [ICAM]-1, vascular adhesion molecule [VCAM]-1, etc.). Initial contact in the blood leukocyte adhesion cascade occurs when leukocytes marginate and roll along the surface of vessels at a far slower velocity than the flow of blood. Rolling and the subsequent loose adhesion are facilitated by two interactions: that of L-selectin (on leukocytes) and its ligands (including CD34, glycosylation-dependent cell adhesion molecule [GlyCAM]-1) on ECs, and that of E-selectin (on ECs) and its corresponding ligand – for example, sialyl Lewis X compounds (sLe<sup>x</sup>) (NeuAc $\alpha 2$ -3Gal $\beta 1$ -4[Fuc $\alpha 1$ -3]GlcNAc $\beta 1$ -) on leukocytes. L-selectins are constitutively expressed on leukocytes and are shed upon cell activation by the action of a membrane-associated serine protease. E-selectin is expressed on activated ECs and facilitates the adhesion of leukocytes to ECs. E-selectin is synthesized after EC stimulation with lipopolysaccharide (LPS) or proinflammatory mediators such as TNF- $\alpha$  and IL-1 $\beta$ , and binds to sLe<sup>x</sup> compounds as one ligand among several (14). P-selectin is a third adhesion molecule that is stored intracellularly in resting platelets and within the Weibel-Palade bodies of ECs. It can be found on cell surfaces rapidly (10–15 minutes) after EC stimulation due to the fusion of Weibel-Palade granules with the cell membrane. P-selectin also can be induced in ECs after contact with the same agents that induce E-selectin (15). By binding to its ligand present on leukocytes (e.g., P-selectin glycoprotein ligand [PSGL]-1), P-selectin facilitates the adhesion of leukocytes with activated platelets and ECs. Involvement of P-selectin in inflammation processes has been demonstrated in two different models of lung injury. Intravenous infusion of cobra venom factor, leading to an acute activation of the complement system and subsequently inducing lung injury, resulted in transiently elevated expression of P-selectin as early as 30 minutes after injury (16). A second model of lung injury, the deposition of immune complexes in the lung, led to a delayed peak expression of P-selectin after 2 to 4 hours. However, the protein expression of P-selectin

preceded its mRNA upregulation, suggesting release of constitutive P-selectin from EC granules followed by transcriptional upregulation. Furthermore, blockade of P-selectin with specific antibodies greatly attenuated lung injury in both models (17).

In the next step of the cascade, another set of adhesion molecules becomes engaged to facilitate the activation and firm adhesion of leukocytes to the endothelium. In addition to the role of L-selectin, neutrophils express  $\beta 2$  integrins, which comprise the largest group of adhesion receptors and are upregulated on the neutrophils after cell activation.  $\beta 2$  Integrins mediate their function by binding to specific ligands. Consisting of two noncovalent associated subunits ( $\alpha$  and  $\beta$ ), integrins are classified based on the  $\beta$ -chain and corresponding  $\alpha$ -subunit (18). Under inflammatory conditions, the  $\beta 2$  integrins  $\alpha L\beta 2$  (CD11a/CD18, LFA-1) as well as  $\alpha M\beta 2$  (CD11b/CD18, Mac-1) play an important role in adhesion and transmigration of neutrophils. Another type of  $\beta$  integrin adhesion molecule on leukocytes,  $\alpha 4\beta 1$ , (CD49d, VLA-4) is involved in late-stage leukocyte-EC interactions. The immunoglobulin superfamily functions as specific ligands for integrins on the surface of ECs. Important ligands for the  $\beta 2$  integrins are ICAM-1 through -4 (intercellular adhesion molecules), while CD11b/CD18 can also bind to complement iC3b, collagen, coagulation proteins, and fibrinogen. In contrast, very late antigen (VLA)-4 mainly binds to VCAM-1.

Once leukocytes firmly adhere to the endothelium, they transmigrate through the junctions of ECs along a chemotactic gradient. An adhesion molecule in the immunoglobulin superfamily, platelet-endothelial cell adhesion molecule (PECAM)-1, has been implicated in this process of transmigration. PECAM-1, which is expressed mostly by platelets and the endothelium, is localized at the junctions of ECs; its blockade by antibodies has been shown to inhibit leukocyte transmigration in vitro (19) and in vivo (20). Thereafter, leukocytes finally migrate into the surrounding interstitial tissue.

This paradigm of the "paracellular" route through the endothelium, in which leukocytes must pass junctional interendothelial structures on their way into the interstitium, has been challenged by several other studies. Hence, a second, "transcellular" mode of transmigration, in which lymphocytes in particular migrate through the cytoplasm of ECs, has been described. This "emperipolesis" theory was originally proposed in 1964, based on transmission electron micrographs of transmigrating leukocytes (21). This theory has recently resurfaced (22). Although molecular confirmation of emperipolesis is still lacking, such a pathway for transmigrating leukocytes, if it exists, may involve the engagement of very different molecules responsible for leukocyte transmigration. Furthermore, cascade-independent modes of leukocyte transmigration without activation of the endothelium (defined by upregulation of adhesion molecules) have been described during different types of inflammation (14). Apparently, the presence of certain chemoattractants/activators as well as the formation of intravascular neutrophil aggregates leads directly to

expression of  $\beta 2$  integrins and results in adhesion and transmigration through inactivated ECs (23,24).

As outlined earlier, ECs inhibit blood coagulation under physiologic conditions. This is facilitated by the expression of thrombomodulin and certain proteoglycans, activation of protein C, and the release of small amounts of tissue-type plasminogen activator (t-PA) (25–28). Under inflammatory conditions, the endothelium becomes a procoagulant surface in order to contain tissue hemorrhage. Triggered by bacterial components (e.g., LPS) and proinflammatory cytokines (e.g., TNF- $\alpha$ , IL-1), the expression of thrombomodulin and proteoglycans disappears and ECs start synthesizing tissue factor (29–31). In concert with decreased activation and expression of protein C, the extrinsic pathway of the coagulation pathway becomes activated. Further downstream, factors VIIa, Xa, and thrombin additionally activate the procoagulant state of ECs through a positive feedback mechanism (32). Combes and colleagues have proposed an additional mode for coagulation activation by ECs (33). Procoagulant phospholipid microparticles may be released from ECs that have undergone insertion of the complement membrane attack complex. However, to what extent these microparticles are released from ECs and contribute to a coagulation outcome remains to be determined.

In addition to cell adhesion and activation of the coagulation system, ECs are also involved in the regulation of vasomotor tone and vascular permeability. Under physiologic conditions, ECs produce and release vasodilating NO and prostacyclin as well as the vasoconstricting endothelins (28,34,35). Vasodilating mediators contribute to decreased vasomotor tone, which may result in marked hypotension if excessive. NO especially appears to play a significant role in inflammation-associated hypotension, whereas the role of prostacyclin and endothelins is not understood. ECs usually release NO in a calcium-dependent manner upon activation of constitutive endothelial NO synthase (eNOS). Under inflammatory conditions, a second, inducible NO synthase (iNOS) becomes activated in a calcium-independent manner, leading to vasodilation and hypotension (36,37). Increased permeability of the EC layer is closely associated with vasodilation and hypotension. Whereas normal ECs form a continuous, semipermeable barrier (38), activated ECs may lose their barrier function, show an increased permeability, and thereby contribute to hypotension and hypovolemia.

## THE ENDOTHELIUM DURING SEPSIS

As outlined earlier, SIRS and sepsis involve the whole organism, rather than just a local inflammatory reaction. It is now widely accepted that, during sepsis, the immune system first becomes hyperactivated, leading to an uncontrolled, overwhelming immune reaction, which may harm the organism rather than support the fight against invading microorganisms. In other words, in sepsis we have “too much of a good thing.” In addition to the cells of the immune system,

ECs are also part of the first-line defense. During inflammatory stages involving invading microorganisms, bacterial components are among the first pathogen-associated molecular patterns (PAMPs) to activate the immune system and the endothelium.

As a consequence, ECs are involved in this septic hyperactivated state. During sepsis, the endothelium first becomes activated as a normal response to inflammation, as described earlier. However, during the further course of sepsis, with its uncontrolled immune responses, ECs become dysfunctional, presumably systemically throughout the organism. These changes can be considered an exaggeration of a normal adaptive response to inflammation/infection. In later stages of sepsis, the immune system becomes paralyzed. Eventually, these changes are associated with MOF and death. In addition to structural changes within the EC itself, functional changes comprise increased expression of cell adhesion molecules (E-selectin, ICAM-1, VCAM-1), loss of leukocyte endothelial adherence, disturbed barrier function, hemostatic imbalance, altered vasomotor tone, and increased apoptosis (39). Therefore, ECs are both victim and perpetrator during the course of sepsis. First, they become hyperactivated by contact with an overwhelming “mediator storm” of proinflammatory cytokines. Later, ECs undergo structural and functional changes, including the increased production of cytokines, which further sustains the ongoing septic process.

## Lipopolysaccharide–Toll-Like Receptor Interactions

LPS, derived from the wall of gram-negative bacteria, has a high affinity for the LPS-binding protein (LBP), which is one of several acute-phase proteins in serum. LPS/LBP complexes exert their biological activity via CD14, a receptor membrane-bound (mCD14) on leukocytes. There is no conclusive evidence as to whether ECs express mCD14. However, a second, soluble form of CD14 (sCD14) has been reported to be increased in septic patients. Thus, LPS/LBP/sCD14 complexes may activate ECs without binding to mCD14 (40). Because CD14 lacks a transmembrane signaling domain, the involvement of an accessory receptor seems likely. Until recently, 10 subtypes of Toll-like receptors (TLRs) have been identified in mammals. TLR4 and, to a much lesser extent TLR2, mediate responses to LPS/LBP bound to CD14. Regulated by a variety of pro- and anti-inflammatory mediators, ECs express TLR4, which, when ligated to LPS, leads to activation of ECs during the course of sepsis. Studies using antibodies against CD14 did not completely inhibit EC activation by LPS (40). Subsequent studies have revealed that the leukocyte  $\beta 2$  integrins (CD11/CD18) may also bind LPS (41). This complex, consisting of CD11/CD18-LPS, can then further activate ECs. Similarly, gram-positive bacteria are capable of inducing septic symptoms in patients. TLR-2, found to be expressed on activated ECs, mainly mediates intracellular responses to wall components of gram-positive bacteria (exotoxins, lipoteichoic acids), although conclusive evidence for TLR2-mediated signaling in the endothelium is lacking.

### Activation of Complement Pathways

During sepsis and multiorgan dysfunction syndrome (MODS), plasma levels of the complement activation product C5a increase. C5a induces its inflammatory functions by interacting with specific receptors (C5aR) in the rhodopsin family of seven-transmembrane spanning, G-protein-coupled receptors (42). So far, the C5aR has been found on hemopoietic cells as well as in a variety of organs (lung, liver, kidney, brain). C5a was shown to induce rapid surface expression of P-selectin on surfaces of human umbilical vein ECs (HUVECs) (43). Recently, the ability of C5a to bind to ECs has been demonstrated (44). Furthermore, we were able to show that exposure of mouse dermal microvascular ECs (MDMECs) to LPS, IL-6, and interferon (IFN)- $\gamma$  resulted in increased C5aR, and incubation with C5a and IL-6 led to increased levels of proinflammatory mediators (44). These data indicate that C5aR can be upregulated on ECs and that C5a in the copresence of additional agonists may mediate proinflammatory effects of the endothelium.

### Activation of Inflammation

One of the main underlying mechanisms leading to a state of immune system hyperactivation involves the production and release of pro- and anti-inflammatory mediators (chemokines and cytokines). Chemokines are involved in attracting neutrophils to the site of inflammation, activating leukocytes after the initial rolling, and facilitating transendothelial migration of leukocytes. Endothelial and epithelial cells, as well as neutrophils, macrophages, and lymphocytes, produce large amounts of proinflammatory cytokines (e.g., TNF- $\alpha$ , IL-6, IL-1 $\beta$ , and IL-8).

TNF- $\alpha$ , which appears to be mainly synthesized in activated macrophages/monocytes, is a very early proinflammatory cytokine produced during SIRS/sepsis. Binding to its receptor leads to cell activation via the nuclear factor (NF)- $\kappa$ B transcription factor. TNF- $\alpha$  stimulates neutrophils and ECs to release a variety of proinflammatory mediators (45). Further, TNF- $\alpha$  has been shown to increase EC permeability and possibly to induce the apoptosis of ECs (39). The IL-1 family (IL-1 $\alpha$ , IL-1 $\beta$ ) represents another important series of cytokines produced during sepsis. IL-1 and TNF- $\alpha$  act synergistically, leading to further initiation of the inflammatory cascade and upregulation of vascular adhesion molecules. To counteract excessive inflammatory/immune responses, increased levels of IL-4, IL-10, IL-13 and, to some extent, IFN- $\gamma$  during sepsis may be potent anti-inflammatory mediators. However, their immediate effects on ECs remain to be investigated. The chemokines IL-8 and monocyte chemoattractant protein (MCP)-1, are additional proinflammatory components during sepsis (46). Released by ECs, IL-8 plays a key role in neutrophil chemotaxis and degranulation, whereas EC-derived MCP-1 is involved in attracting monocytes.

Taken together, the mechanisms detailed here, along with the release of bacterial products, production of strong proin-

flammatory mediators, and increased expression of vascular adhesion molecules, lead to a state of endothelial hyperactivation. Intracellular pathways become activated, more proinflammatory cytokines and chemokines are released, and neutrophils are attracted to the site of inflammation. Neutrophils release granular enzymes, ROS (such as H<sub>2</sub>O<sub>2</sub>), and NO, which are capable of causing increased vascular permeability, tissue damage and, ultimately, organ injury.

### Activation of Coagulation

As described earlier, the coagulation system becomes activated under septic conditions. This leads to increased levels of thrombin. As a major activator of platelets and ECs, thrombin enhances the expression by ECs of proinflammatory cytokines and chemokines as well as adhesion molecules (47). This activation of the endothelium results in intravascular thrombosis and fibrin deposition, resulting in DIC, which is associated with increasing organ dysfunction and risk of death. Recent studies in experimental sepsis (cecal ligation and puncture) in rodents indicate that in vivo blockade of C5a greatly attenuates the activation and consumptive depletion of the clotting and fibrinolytic systems (48).

Recent studies have shown that naturally occurring anticoagulants are inactivated or decreased during sepsis. In vitro experiments have shown that the addition of LPS and cytokines to ECs results in decreased levels of the anticoagulants, thrombomodulin, and t-PA, while procoagulants tissue factor, plasminogen activator inhibitor (PAI)-1, and microparticles were increased (31,33,49–51). These changes have been shown to occur in vivo as well. However, to what extent ECs are either affected by or contribute to this switch to generate an anticoagulant versus a procoagulant state remains to be seen.

Since activated protein C (APC) became the first drug approved for treatment of patients with severe sepsis, much effort has been made to investigate the APC pathway and its interaction with ECs. APC possesses profibrinolytic, anti-inflammatory, and antiapoptotic properties, and it counteracts the effects of thrombin and proinflammatory cytokines (47). Thus, the protein C pathway is currently positioned at the interface of the endothelium and the leukocyte response. Although the APC receptor on ECs and other immune cells (endothelial protein C receptor, EPCR) has been identified (52), its potential role during sepsis remains controversial. Pediatric patients with severe sepsis showed reduced levels of EPCR in skin biopsies (53). Conversely, in a murine model of sepsis, EPCR mRNA expression was upregulated in the liver, kidney, and lung (Table 141-2) (54). Similar results were reported after LPS injection accompanied by an increase of soluble EPCR in rodent serum, suggesting a possible shedding of EPCR from the endothelium (55). Further, recent data indicate that the microvascular anti-inflammatory effect of APC is partially mediated through the suppression of EC adhesion molecules, resulting in protection from the inflammatory insult of sepsis (47).

**Table 141-2: Adhesion Molecule Knockout Models and Their Impact on Inflammation**

<i>Knockout</i>	<i>Phenotype (Refs.)</i>
<b>Selectins</b>	
P-selectin	Striking leukocytosis, diminished leukocyte rolling, delayed leukocyte recruitment to inflammatory sites (61)
E-selectin	No leukocytosis, but delayed PMN recruitment to inflammatory sites (62)
L-selectin	Impaired recruitment of PMN, lymphocytes and monocytes to peritoneal cavity, impaired delayed hypersensitivity reaction, resistance to LPS-induced shock (63)
<b>Immunoglobulins</b>	
ICAM-1	Moderate granulocytosis, impaired PMN emigration, reduced contact hypersensitivity (64)
VCAM	Not viable; death in utero due to cardiac and other developmental abnormalities (62)
<b>Integrins</b>	
CD18	Impaired inflammatory response, delayed rejection of cardiac grafts (65)
CD11a	Modest delay in leukocyte recruitment to peritoneal cavity (66)
CD11b	Enhanced PMN survival (67)
$\beta 1$	Role in inflammation not yet investigated (68)
$\beta 7$	Impaired host protection in enteric helminthes infection (69)
<b>Human deficiencies</b>	
LAD I	Deficiencies in CD11/18 family due to mutations, impaired phagocyte emigration, chronic neutrophilia, recurrent infections without pus, normal rolling of leukocytes, but no adherence (70)
LAD II	Endogenous fucose metabolism defect, impaired selectin expression, normal leukocyte adherence but defective rolling (71,72)

PMN, polymorph neutrophil granulocytes; LAD, leukocytes adhesion deficiency

## THERAPEUTIC STRATEGIES IN INFLAMMATION AND SEPSIS

Despite the current aggressive management of patients with sepsis or septic shock in ICUs, mortality remains unacceptably high. It is therefore important that more effective interventions for the treatment of sepsis are found. Recent strategies include the neutralization of bacterial products, targeting undesirable proinflammatory responses, addition of immuno-stimulatory agents to restore the immune system, and correction of abnormalities in the coagulation system. However, clinical trials

using many of these promising new targets during sepsis have mostly turned out to be “dead ends,” especially for pharmaceutical companies. Although the blockade of LPS, TNF- $\alpha$ , and interleukins resulted in improved outcome in animal models of sepsis, clinical trials failed (56). Current efforts concentrate on promising new targets during sepsis (e.g., TLRs, complement factors [especially C5a], high mobility group B1 protein, macrophage migration inhibitory factor [MIF, MIP-1 $\alpha$ ], and apoptosis). The blockade of these new proinflammatory mediators and processes has resulted in improved outcome in animal models, but clinical trials remain to be conducted. Other strategies for clinical anti-inflammatory interventions of sepsis have included inhibition or antagonism of platelet-activating factor (PAF), arachidonic acid metabolites, adhesion molecules, ROS, NO, bradykinin, phosphodiesterase, and C1 esterase, but to no avail (56). Researchers have tried to counteract the state of immunosuppression that occurs during late-stage sepsis. To restore the proinflammatory functions of phagocytic cells, IFN- $\gamma$ , granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage colony-stimulating factor (GM-CSF) were tested as possible treatments in sepsis. However, despite encouraging results in animals, clinical trials in humans failed to show any beneficial effects of these molecules.

So far, only three clinical trials resulted in improved outcome of septic patients: the administration of low-dose corticosteroid in septic patients with low levels of blood cortisol (57), administration of APC in patients with severe sepsis (58), and maintenance of physiological level of blood glucose through intensive insulin therapy (59).

These strategies target soluble mediators and inflammatory cells that modulate endothelial response. Another approach is to directly block EC adhesion molecules and signaling pathways. Blockade of selectins inhibited the transmigration of neutrophils in vitro, however, in vivo experiments failed to confirm these observations, mainly due to cross-reaction of several of the antibodies (14). In contrast, the blockade of integrins (CD11/CD18) as well as ICAM-1 has been shown to inhibit neutrophil influx in almost every system tested (60). At present, antiadhesive strategies during sepsis remain at an experimental level and must be further investigated.

## KEY POINTS

- ECs are victims or perpetrators of adverse events during SIRS and sepsis.
- Inflammation activates ECs, resulting in increased leukocyte adhesion, decreased vasomotor tone and permeability, as well as assumption of a procoagulant state.
- Sepsis leads to uncontrolled, overwhelming hyperactivation of the immune system, rendering ECs dysfunctional.

### Future Goals

- To further determine the exact role of ECs in interaction with leukocytes
- To explore the apparent link between the inflammatory and coagulation systems
- To develop new therapeutic strategies targeting cells of the immune system and ECs

### ACKNOWLEDGMENT

This work is supported by National Institute of Health (NIH) grants GM-29507, HL-31963, and GM-61656.

## The Endothelium in Cerebral Malaria

### Both a Target Cell and a Major Player

Valéry Combes\*, Jin Ning Lou<sup>†</sup>, and Georges E. Grau\*

\*Bosch Institute, University of Sydney, Australia; <sup>†</sup>Institute of Clinical Medical Sciences, China-Japan Friendship Hospital, Beijing, China

On a global scale, malaria still represents a major problem of public health, principally because of its two major complications, cerebral malaria (CM) and severe malarial anemia. The disease manifestations apparent during that stage of the malaria parasite lifecycle when it is circulating within host erythrocytes are a result of complex host–parasite interactions. In man, most of the pathology is due to *Plasmodium falciparum*. In the case of CM, the microcirculation, and in particular the endothelium, appears to be pivotal in the interplay between infected erythrocytes (IEs), host immune cells, and host tissues.

We focus here on the cerebral syndrome, but the endothelium also has a central role in other aspects of malarial pathology; these have been reviewed recently elsewhere (1). For example, severe malaria may be complicated by pulmonary edema, the cause of which is still unknown. It shares many features with the adult acute respiratory distress syndrome (ARDS). Rehydration may predispose patients with severe malaria to develop pulmonary edema, although it is by no means a prerequisite. Indeed, evidence suggests that an increase in the lung capillary permeability – as distinct from simple intravascular volume overload – may be at the origin of this complication. Acute or chronic renal insufficiency is another common complication of severe malaria, and is often lethal. It occurs in adults and older children. The mechanisms leading to the acute tubular necrosis are not fully understood. A cytoadherence of IEs in glomerular capillaries sometimes can be observed, but is never as prominent as in the brain. Renal pathology in malaria often presents as a more chronic pathology, most notably with glomerulonephritis associated with deposits of immune complexes (2–5).

The histopathology of CM is dominated by *sequestration*; that is, the accumulation of mature IEs in the cerebral microvessels of patients. The description of this feature by Marchiafava and Bignami goes back at least to 1894 (6). Light and electron microscopy imaging have demonstrated electron-dense structures on the IE surface, called *knobs* (7,8),

which were later shown to mediate the binding of IEs to endothelial cell (EC) membranes (9–11). Sequestration is observed in almost all organs, but particularly in the brain. However, several questions remain unanswered as to the exact involvement of IE sequestration in CM: Is sequestration the cause or the consequence of endothelial lesions? In addition to IEs, histopathological analysis of brain samples from patients who recently died of CM revealed the presence of other cell types, such as platelets and monocytes (2).

Cerebral capillaries and venules distended with IEs are the microscopic hallmark of severe falciparum malaria (3,12,13). In contrast to the peripheral blood, all mature stages of the parasite are seen within these vessels, both in adults (14–16), and in African children (17). Distended venules are more prominent in the gray matter, where they appear evenly distributed. Edema, hemorrhages, and necrosis are features of the endothelial alteration in CM.

Hemorrhages, described as “punctiform” or “ring hemorrhages,” are a common pathological feature of CM and are distributed throughout the brain (including the retina and brainstem). They are more common in children who have had convulsions associated with CM than in other children (18). These ring hemorrhages contain a blocked central capillary, with an agglutinated mass of IEs surrounded by brain tissue that is necrotic and contains demyelinated fibers (14,19) or a glial reaction. It has been suggested that ring hemorrhages are a specific response to vessel blockage by IEs and reperfusion, resulting in a concentric pattern of hemorrhage surrounding a necrosed vessel (20); they are, therefore, different from the petechial hemorrhages seen after a variety of hypoxic insults, as in, for example, typhus fever. Small malarial granulomata, also called *Dürck nodules*, are a distinctive pathological feature of malaria (3). They are not found in patients who die shortly after the onset of symptoms, and probably represent a more advanced stage of repair following hemorrhage in which necrotic tissue has been replaced by neuroglial cells and microglial tissue (3,14,21). Among numerous pathological

features, the retinopathy appears to be the only clinical sign distinguishing malarial from nonmalarial coma (22).

All patients with *P. falciparum* infection demonstrate IE sequestration to some extent, including immune individuals with asymptomatic parasitemia and nonimmune patients. For this reason, the mere presence of parasites in the peripheral blood or tissues is not sufficient to identify malaria as a cause of organ dysfunction or pathology. Only autopsies reveal nonmalarial causes of death in parasitemic individuals and allow the identification of features specific to malaria (22). Although postmortem analyses provide a gold standard in rigorous diagnosis, they only allow the study of the pathology of severe malaria at the terminal stage, so that informative changes early in the disease process are inaccessible (1).

## REACTIVITY OF ENDOTHELIUM AS A CENTRAL DETERMINANT OF MALARIAL PATHOLOGY

### Mediators Affecting the Endothelium and Produced by It

Fatal falciparum malaria is accompanied by a systemic endothelial activation (23) and a widespread induction of endothelial activation markers. In addition to the “mechanical theory” that explains CM by the IE plugging of microvessels, the “cytokine theory” suggests that an overproduction of inflammatory cytokines by host cells, in response to the presence of IEs, is responsible for the development of the neurological syndrome. A combination of both theories is more likely to be operational (24–26). In any case, cytokines, chemokines, and other mediators acting on or released by endothelium are of major importance in the pathogenesis of CM.

### Cytokines and Chemokines

After the early insights of Maegraith (27,28), suggesting that host mediators could mediate the pathogenic events triggered by the parasite, several lines of evidence have suggested that tumor necrosis factor (TNF) is an important element in the pathogenesis of experimental CM (29–31). High circulating levels of TNF can be deleterious, because TNF may increase sequestration through the upregulation of host ligand molecules responsible for the cytoadherence of parasitized erythrocytes, especially intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and E-selectin, thus increasing mechanical obstruction of cerebral or other blood vessels, as evidenced in man (3,32) and in the experimental mouse model for CM (33,34). Following data in experimental CM (35,36), the demonstration of high plasma TNF levels in patients with severe falciparum malaria (37–40) provided a rationale for clinical trials using agents that would prevent the release of TNF or interfere with its actions. However, attempts to prevent CM by administration of anti-TNF antibody did not reduce mortality in humans, partly because the timeframe of intervention was too narrow (41).

It is clear that high plasma TNF levels cannot be the only element responsible for the symptoms unique to cerebral and

lethal *P. falciparum* malaria. Lymphotoxin (LT), a TNF-related cytokine (previously called TNF- $\beta$ ), might play an important role in the pathogenesis of CM, as suggested by the observation that mice null for the *LT- $\alpha$*  gene are protected against this complication (42). However, the possible involvement of *LT- $\alpha$ / $\beta$*  in human CM still must be confirmed, although elevated circulating levels of *LT- $\alpha$*  have been reported in malaria patients (43).

Pathology in CM likely depends on an imbalance between TNF, *LT- $\alpha$* , and other proinflammatory cytokines, on the one hand, and anti-inflammatory cytokines on the other hand (44). Among the important “anti-inflammatory” cytokines are interleukin (IL)-10 (45,46), and transforming growth factor (TGF)- $\beta$  (47,48). IL-10 plays a host protective role in murine malaria (46). Treatment of CM-resistant (CM-R) mice with anti-IL-10 monoclonal antibody (mAb), in vivo, switches their phenotype toward susceptibility to CM (46). In man, correlative studies of plasma IL-10 levels and severe malaria manifestations have shown associations generally consistent with the mouse studies. Serum levels of IL-10 are elevated in acute falciparum malaria patients in Thailand prior to antimalarial therapy and decrease after treatment (49–51). It was concluded that elevated plasma cytokine levels in severe malaria are associated with systemic pathologic changes, rather than cerebral involvement, consistent with the concept of TNF proposed in mouse studies (52). In African children with malaria, plasma IL-10 concentration is elevated, including in CM patients (53). The lowest concentrations are found in severe anemia patients, and investigators suggested that the relative deficiency in IL-10 might play a role in this complication of malaria infection. IL-10 can be released by a wide range of immune and inflammatory cells. In Gabonese patients with uncomplicated *P. falciparum* infection, an increase was noted in circulating CD4<sup>+</sup> T lymphocytes expressing IL-10 (54).

As recently reviewed (55), IL-8 and macrophage inflammatory protein (MIP)-1 $\alpha$  concentrations correlate with parasitemia and disease severity. MIP-1 $\alpha$  is a potent inhibitor of hematopoietic cell proliferation and might be one of the agents responsible for prolonged anemia in malaria (56,57). These two molecules in the brain could be involved in the recruitment of leukocytes (neutrophils and monocytes, respectively) at the inflamed site. Similarly, a role might be postulated for the CXC chemokine GRO- $\alpha$  in CM; GRO- $\alpha$  is known to target ECs, both GRO- $\alpha$  and its receptor CXCR-2 are expressed by microglia, and GRO- $\alpha$  signaling has been implicated in the pathogenesis of brain lesions in multiple sclerosis (58). Chemokines also may be involved via their complex interactions with cytokines. In particular, IL-12 could influence pathogenesis in an unexpected way, through interaction between leukocytes (CD4<sup>+</sup>, CD8<sup>+</sup>, natural killer [NK]) and ECs, via factors such as interferon-inducible protein (IP)-10 and various chemokines induced by interferon (IFN)- $\gamma$  (59). Also, IL-12 could upregulate cell adhesion molecules (CAMs) on ECs, arrest their cycle, and inhibit angiogenesis (59). This IL-12-induced upregulation of CAMs could take part in the

homing and sequestration of leukocytes within the microvasculature.

### Soluble Adhesion Molecules

During the course of CM, elevated levels of soluble ICAM-1, E-selectin and VCAM-1 were found, pointing to the existence of widespread endothelial activation (23,60–62). Moreover, elevated concentrations of soluble thrombomodulin also were found in association with the severity of the disease, indicating a substantial endothelial injury that could be of prognostic importance (61).

### Endothelial Microparticles

Microparticle release is a hallmark of cell activation and apoptosis. Microparticles can originate from almost all cell types, although those released by circulating blood cells (platelets and monocytes) and ECs have been particularly well studied. The release of elevated levels of endothelial microparticles has recently been reported to occur during CM (63). These sub-micron-sized elements were found in large amounts in the plasma of Malawian children during the acute phase of CM (63). Markedly elevated levels of microparticles were specific to the neurological complication, because they did not occur in uncomplicated malaria or severe anemia. This phenomenon is another indicator of the considerable endothelial activation occurring during CM. The high plasma TNF concentrations noted in CM patients suggest that TNF plays a role in the enhancement of the endothelial microparticle release *in vivo*, as it does *in vitro* (64). *In vitro*, endothelial microparticles produced after TNF activation express procoagulant and proinflammatory properties, in a way similar to that of the cell from which they originate. We can thus hypothesize that, if a similar phenomenon occurs *in vivo*, microparticles could have a pathogenic role in the development of the cerebral syndrome and participate in the worsening of the endothelial lesion by locally activating coagulation and potentiating leukocyte adhesion. It also could be postulated that microparticles derived from brain endothelium have distant effects on other organs.

The diverse aspects of the role of brain endothelium as an input/output device – namely as a target and a player in CM pathogenesis – are summarized in Figure 142.1.

### Evidence for an Association between Endothelial Reactivity and Susceptibility to Disease

Because CM only occurs in a small proportion of falciparum-infected patients, and because there are no clear differences between parasites isolated from patients with neurological involvement and those isolated from uncomplicated cases, the role of the host response must be a critical determinant of CM pathophysiology. Both human and experimental murine CM are the consequence of a cascade of events involving the production of toxins by the parasite (29–31) and cytokines by the host, eventually leading to the amplification of the expression of the receptors for cytoadherence, especially ICAM-1/

Figure 142.1. Diagrammatic representation of the involvement of brain ECs as an input/output device in the pathogenesis of cerebral malaria. MP, microparticles; sCAMs, soluble cell adhesion molecules; sTM, soluble thrombomodulin; CAM upreg., upregulation of the surface expression of cell adhesion molecules; BBB, blood–brain barrier.

VCAM-1 by TNF or CD36 by IFN- $\gamma$ , on brain microvascular ECs (MVECs) (1,65). This topic is discussed in detail in the section Importance of the Endothelial Compartment. Several parameters have been shown to differ in mice that are either susceptible or resistant to the neurological syndrome: Compared to their resistant counterparts, susceptible animals show higher serum levels of TNF (35), enhanced IFN- $\gamma$  production capacity in response to malaria antigens, and preferential Th1 cell subset expansion *in vivo* (44).

Because the brain microvascular endothelium is the eventual target of proinflammatory cytokines, we postulated that the variations of its responsiveness to cytokines in different individuals could modulate this sequence of events. To address this question, we purified brain MVECs from CM-susceptible (CM-S) CBA/J mice and CM-resistant (CM-R) BALB/c mice. After showing that they equally display relevant morphological and phenotypic features of microvascular endothelium, we demonstrated that brain MVECs purified from CM-S and CM-R mice exhibit a different sensitivity to TNF. CM-S brain MVECs displayed a higher capacity to produce IL-6 and to upregulate ICAM-1 and VCAM-1 in response to TNF than did CM-R brain MVECs. In contrast, no difference was found in the induction of E-selectin after TNF challenge. CM-S brain MVECs were also significantly more sensitive to TNF-induced lysis (66). This differential reactivity to TNF was further substantiated by comparing TNF receptor expression on CM-S and CM-R brain MVECs. Although the constitutive expression of TNF receptors was comparable on cells from the two origins, TNF induced an upregulation of both p55 and p75 TNF receptors in CM-S, but not in CM-R brain MVECs. A similar regulation was found at the level of TNF receptor mRNA, but not for receptor shedding. Although a protein kinase C (PKC) inhibitor blocked the response to TNF in both CM-S and CM-R brain MVECs, an inhibitor of protein kinase A (PKA) selectively abolished the response to TNF in CM-R,

but not CM-S brain MVECs, suggesting a differential protein kinase involvement in TNF-induced activation of CM-S and CM-R brain MVECs (66). These results indicate that brain MVECs purified from CM-S and CM-R mice exhibit strain-specific sensitivity to TNF, as measured by various parameters. This difference may be partly due to a differential regulation of TNF receptors and downstream signaling pathways. Moreover, a differential induction of MHC molecules on CM-S versus CM-R brain MVECs has been demonstrated (67). Altogether, these data suggest that, in addition to host T cells or monocytes, the target cell, namely the EC, also is an element accounting for the susceptibility to the neurological syndrome.

## PATHOGENIC MECHANISMS LEADING TO CEREBRAL SYNDROME

### Importance of the Endothelial Compartment

One of the reasons the endothelium is so important in CM is that it expresses cytoadherence receptors for IEs. This cytoadherence is mediated by a series of endothelial molecules including constitutive as well as inducible surface antigens, such as platelet-endothelial cell adhesion molecule (PECAM)-1, CD36, chondroitin sulfate A (CSA), ICAM-1, thrombospondin (TSP),  $\alpha v \beta 3$  or E-selectin, P-selectin, VCAM-1, respectively (68). However, the fact that the expression of some of these antigens is not restricted to ECs, nor to brain ECs (versus other ECs), makes it difficult to decide whether they play preferential role in brain circulation and to determine the specific role of the endothelial compartment.

For example, ICAM-1 is overexpressed by both endothelial and circulating cells (33); this is the reason why experiments have been conducted in the PbA model (described in details in Refs. 2,26,29,31,32) to clarify the role of this molecule in disease pathogenesis. Whereas *ICAM-1<sup>+/+</sup>* mice died 6 to 8 days after infection, *ICAM-1<sup>-/-</sup>* mice survived 15 days. A breakdown of the blood-brain barrier was evident in infected *ICAM-1<sup>+/+</sup>* mice only. Interestingly, thrombocytopenia was profound in infected *ICAM-1<sup>+/+</sup>*, but practically absent in *ICAM-1<sup>-/-</sup>* mice. Moreover, macrophage sequestration was evident in brain venules and lung capillaries of *ICAM-1<sup>+/+</sup>* mice, and was significantly less prevalent in the alveolar capillaries of infected *ICAM-1<sup>-/-</sup>* mice. These results indicate that, although the immune response is similar in both *ICAM-1<sup>+/+</sup>* and *ICAM-1<sup>-/-</sup>* mice, the absence of mortality in *ICAM-1<sup>-/-</sup>* mice correlates with a decrease of macrophage and IE trapping and a less severe thrombocytopenia. However, no information is available on the specific role of ICAM-1 of endothelial origin (69).

Nonetheless, for other molecules expressed on both endothelium and circulating cells, it has been possible to decipher the importance of the endothelial compartment using chimeric mice, generated by bone marrow transplantations, among gene knockout and wild-type mice. This has been the case for P-selectin and TNF receptor (TNFR)-2. P-selectin

is a molecule expressed on activated ECs and platelets. P-selectin-deficient mice infected with PbA had a cumulative incidence of CM that was significantly reduced compared with wild-type animals, despite identical levels of parasitemia, and reduced cerebral accumulation of platelets and leukocytes. Mice deficient only in endothelial P-selectin (i.e., *P-selectin*-null mice transplanted with wild-type bone marrow) did not show any sign of CM (vascular plugging, hemorrhages, or edema), whereas mice lacking only platelet P-selectin (i.e., wild-type mice transplanted with P-selectin-deficient bone marrow) showed signs of CM similar to that seen in wild-type mice. These results suggest that endothelial P-selectin plays an important role in the pathogenesis of CM (70).

Similarly, the respective role of endothelial versus leukocyte TNFR2 has been determined using bone-marrow chimaeras. A pathogenic role of TNFR2 in CM had been demonstrated using gene knockout mice: *TNFR2<sup>-/-</sup>*, but not *TNFR1<sup>-/-</sup>* mice are protected (71). This brings together the involvement of TNF and LT- $\alpha$ , because both cytokines bind to this receptor (31). Studies in bone marrow chimeric mice suggested that endothelial TNFR2, rather than the receptor on intravascular monocytes, is important in the pathogenesis of CM (72). Interestingly, an overexpression of TNFR2 is also evident on the cerebral microvascular endothelium in human CM in Malawian children (31).

## Interactions between Endothelium and Host Cells

### Red Blood Cells

Upon binding to endothelium, IEs are capable of inducing a variety of changes. Using pulmonary MVECs, it has been shown that IE adhesion upregulated several TNF-superfamily genes and apoptosis-related genes such as Bad, Bax, caspase-3, secreted apoptosis-related protein (SARP)-2, DFF45/ICAD, IFN- $\gamma$  receptor2, Bcl-w, Bik, and inducible nitric oxide synthase (iNOS). Also, IEs, but not normal erythrocytes, can trigger apoptosis in pulmonary MVECs (73). A direct contact between IEs and MVECs is required, because parasite-secreted molecules did not have any effect. Along the same line, IEs induce nitric oxide (NO) release via the engagement of CD23 at the surface of MVECs (74).

### Leukocytes

In murine CM, monocytes have been observed in close juxtaposition with damaged ECs (75). Although monocytes are seen in cerebral vessels in CM patients, their role remains to be established. Recently, it has been suggested that CD8<sup>+</sup> T cells may be associated with endothelial disruption in experimental CM (76), whereas the CD4<sup>+</sup> subset might be responsible for the initiation phase of the cerebral syndrome (2,77).

### Platelets

Together with classic receptor-ligand interactions, activated platelets or fibrin also may contribute to the sequestration of IEs. In larger cerebral vessels, parasites are seen that are sequestered but not attached to the vessel wall.

Autoagglutinates (clumps of mature-stage IEs formed in the presence of nonimmune serum) have been associated with severe malaria in children (78). Autoagglutination is mediated by CD36 on platelets, although not all IEs that bind CD36 form clumps with platelets (79). Clumping in vitro with platelets may be a corollary of an in vivo role for platelets promoting interactions between IEs, ECs, and leukocytes, as suggested by studies in murine (34) and, more recently, in human (80) malaria.

In recent studies using cocultures of CD36-specific IEs (IE<sup>CD36</sup>), CD36-deficient brain ECs, and platelets (81), the latter cells were shown to mediate IE binding, especially if the brain ECs had been stimulated by a proinflammatory cytokine, suggesting a novel role for platelets in IE sequestration. Although platelet bridging does not replace the direct cytoadhesion of IEs to endothelial CD36, it may represent an alternative mechanism to allow IE<sup>CD36</sup> to adhere to ECs not expressing CD36, increasing sequestration in places where CD36 expression is low, such as cerebral microvessels (82,83). CD36 adhesion may be involved in the sequestration of IEs in CM by this mechanism, and these results could explain the apparent contradiction between the scanty CD36 expression in microvessels and the predominance of the CD36-binding phenotype in field isolates.

A pathogenic role of platelets on ECs can be envisaged at several levels. Platelets can alter endothelial functions directly and/or indirectly via a modulation of leukocyte functions, or even effects on normal or parasitized erythrocytes (84). The relative importance of these functions in CM pathogenesis remains to be established, but it appears that platelets can modulate IE sequestration and have substantial effects on EC functions and viability (85).

Numerous other host cells are likely to play a role in CM pathogenesis via their interaction with brain endothelium. These include neutrophils, dendritic cells, NK, and NKT cells (2).

## CONCLUSION

Some of the simplest, yet most fundamental, questions remain to be answered. First, we still do not know how coma develops. Numerous parameters on the parasite side remain to be determined, in terms of adhesion phenotype, or of capacity to stimulate host responses. The complex cascades of events in the host response are far from being elucidated. Even if one remains narrowly focused on brain endothelium, a wide array of issues remain to be addressed: We need to know how the endothelium differs between sites of intense sequestration and other sites, whether platelets accumulate before or after IEs, how the coagulation and fibrinolysis cascades participate in vascular plugging, how mononuclear leukocytes accumulate in the lumen, and what the consequences are for the surrounding parenchyma. Only a more thorough understanding of the fine mechanisms of CM will enable us to propose new therapeutic approaches.

## KEY POINTS

- CM is one of the deadliest complications of *P. falciparum* infection.
- Endothelium is at the center of the neurological syndrome.
- EI and host cell sequestration in deep vascular beds (brain, lungs, kidneys) activates endothelium and leads to endothelial lesions.
- The endothelium is both a target cell and a major player in CM: It produces and is modified by proinflammatory molecules.
- Cytokines play a key role in the worsening of the endothelial activation.
- Endothelial microparticles could be both a circulating hallmark of endothelial activation and also act in the worsening of the lesion, together with microparticles released by other circulating cells.
- Experiments performed in the experimental CM model show that the genetic background is reflected by a differential reactivity of the endothelium to the malarial infection. This, among other parameters, may explain why only 1% of *P. falciparum*-infected patients will develop CM.
- IE sequestration is necessary but not sufficient to the development of severe malaria.

## Future Goals

- To better understand the pathogenic elements that make an uncomplicated malaria evolve into a severe malaria
- To develop antidisease molecules, rather than antiparasite molecules, which would particularly target the endothelium
- To further define the pathogenic role of microparticles in human CM
- To understand by which parameters the endothelium might differ between sites of intense sequestration and other sites

## Hemorrhagic Fevers

### Endothelial Cells and Ebola-Virus Hemorrhagic Fever

---

Viral hemorrhagic fever (VHF) is a severe multiorgan disease with strong immune involvement and diffuse vascular dysregulation, particularly of the vascular endothelium. Several families of RNA viruses are regularly associated with a VHF syndrome in humans: *Arenaviridae* (Lassa virus, Machupo virus, Junin virus, Guanarito virus, and Sabia virus), *Bunyaviridae* (Rift Valley fever virus, Crimean-Congo hemorrhagic fever virus, hantaviruses), *Flaviviridae* (Yellow fever virus, Dengue virus, Omsk hemorrhagic fever virus, and Kyasanur forest disease virus), and *Filoviridae* (Marburg virus and Ebola virus). The clinical manifestations of VHF vary and are dependent on the causative agent (see CDC homepage <http://www.cdc.gov>). However, some common clinical features include fever, various degrees of vascular dysregulation with bleeding tendency and shock development, and the vascular endothelium seems to be affected in most cases (1–3). Some of the VHF-causing pathogens target the endothelium directly, whereas others induce primarily indirect alterations through proinflammatory mediators released from infected target cells (e.g., monocytes/macrophages). Marburg (MARV) and Ebola viruses (EBOV) cause the most severe form of VHF and, thus, serve as important model pathogens for studying the pathogenesis and management of VHFs. Filoviruses, as well as some other hemorrhagic fever (HF) viruses, are biological safety level 4 (BSL4) agents, which somewhat complicates investigations. Filoviruses seem to target both the vascular system and the immune system, leading to the opinion that filovirus HF fever is a vascular disease as well as an immune syndrome (2–5). Although our understanding of the molecular mechanisms of VHF pathogenesis is still limited, some

important scientific achievements have been made in the past decade. In this chapter we specifically focus on the role of the vascular endothelium during EBOV HF, and also address some novel methodologies that allow for investigations involving endothelial cells (ECs) outside of the BSL4 containment laboratory.

#### EBOLA VIRUS CAUSES THE MOST SEVERE VIRAL HEMORRHAGIC FEVER

EBOV is a filamentous, enveloped, nonsegmented negative-stranded RNA virus that causes severe hemorrhagic fever in humans and nonhuman primates. Mortality rates up to 89% have been reported for *Zaire ebolavirus* (ZEBOV) (6). Unfortunately, currently no treatments or prophylaxis for humans are available, but promising candidates are being tested in appropriate animal models (7–10). Thus, symptomatic therapy is currently the only plausible treatment. However, even this type of treatment might not be available in the developing countries where these diseases commonly occur. The host of EBOV is unknown, but primates are frequently infected and might transmit the virus to humans. Close physical contact is required for infection, and virus uptake seems to occur via skin lesions and mucous membranes. Once it enters the lymph and blood vessels, the virus spreads preferentially to organs such as lymph nodes, liver, and spleen, where it can directly access sessile monocytes/macrophages (11). This hypothetical route for EBOV infection and spread was recently supported by experiments in *Cynomolgus* monkeys.

Intramuscular injection of EBOV resulted in local infection of monocytes/macrophages and dendritic cells and virus production. The infected cells and/or the virus travel to regional lymph nodes and to the liver and spleen. The virus was then shown to infect tissue macrophages, dendritic cells, and fibroblastic reticular cells in those organs (12,13). These data strongly indicate that the monocyte-derived macrophages and dendritic cells are primary targets in EBOV HF. Macrophages and dendritic cells seem to respond heterogeneously to EBOV infection. Although monocytes/macrophages become activated and release large quantities of cytokines and proinflammatory mediators such as tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , IL-6, and IL-8, dendritic cells respond with an insufficient release of immunomodulatory mediators (5,14).

The clinical picture of EBOV HF is characterized by abrupt onset of nonspecific flu-like symptoms such as fever, headache, muscle and abdominal pain, and nausea. At around day 6, approximately 50% of the patients infected with ZEBOV develop maculopapular rash on the trunk and shoulders. By days 7 through 10, survivors show decreasing viremia levels, whereas increasing viremia is seen in cases with disease progression. Fatal cases develop a shock syndrome associated with edema formation, hypotension, signs of pronounced disseminated intravascular coagulation (DIC), bleeding from venopuncture sites and the gastrointestinal tract, hematuria, and melena; on average, death occurs between day 10 to 17. The clinical course of severe EBOV HF and other forms of septic shock syndrome have common features (15). It is not entirely clear how the host response is mobilized in survivors, but release of immunomodulatory mediators as well as the development of specific antibodies seems to play an important role. It has been shown that there is a clear difference in the expression pattern of cytokines between fatal cases and survivors. An initial but short-lived increase of proinflammatory cytokines such as TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 in the plasma has been postulated as a marker for nonfatal infection, whereas the release of anti-inflammatory cytokines such as IL-10 and increased levels of interferon (IFN)- $\gamma$ , neopterin, and IL-1 receptor antagonist (IL-1RA) in the plasma early after the onset of symptoms seems to be indicative for fatal outcome (for summary we refer the reader to Ref. 15).

#### **ENDOTHELIAL STRUCTURES IMPORTANT FOR UNDERSTANDING OF VIRAL HEMORRHAGIC FEVER PATHOGENESIS**

The symptoms developed during EBOV HF indicate that the vascular endothelium plays an important role in the pathogenesis of the disease. The vascular endothelium has multiple functions in maintaining body homeostasis. It forms the primary selective barrier between the blood and tissue, and dysregulation of EC functions can cause changes in vascular permeability that contribute to the development of hemorrhage and shock. Furthermore, blood pressure regulation is largely modulated by ECs via release of vasoactive agents such as nitric oxide (NO) and endothelin. Additionally, the vascu-

lar endothelium mediates the host immune responses through the induction of cytokines, chemokines, and cellular receptors that recruit or activate immune cells.

The balance of macromolecule distribution and exchange of water and solutes between the vasculature and the interstitial space is controlled by vascular ECs. Whereas transport of macromolecules through the endothelium (e.g., albumin) follows a transcellular pathway, the exchange of water and small solutes takes place primarily through endothelial junctions in capillaries and postcapillary venules (paracellular pathway). Under physiological conditions, the intercellular junctions are impermeable to macromolecules, with some exceptions such as in the kidneys, liver, and spleen. In general, endothelial barrier function is decreased in inflamed tissue due to reduced intercellular adhesion, leading to enhanced extravasation of small solutes and water, and finally resulting in edema formation. In severe cases of certain forms of inflammation, intercellular gap formation occurs, allowing extravasation of larger macromolecules and water into the interstitial space and further contributing to the severity of the pathological condition (16). Although the paracellular manner of increased endothelial permeability in inflammation generally is accepted, it is currently unclear whether a transcellular transport of macromolecules contributes to edema formation as well.

The composition of endothelial junctions is heterogeneous within different organs and within the microvascular bed. The common distribution of adherens junctions throughout the vasculature makes them crucial structures for maintaining the barrier function. Particularly, postcapillary venules, displaying mainly adherens-like junctions and lacking tight junction strands (17), are the target site of increased permeability and leukocyte extravasation during inflammation. This implicates the adherens junction in vascular endothelium as a main player in regulation of endothelial barrier function. The backbone of adherens junctions is formed by the integral and calcium-dependent membrane protein, vascular endothelial (VE)-cadherin, which is connected to cortical actin filaments (18,19). This connection enhances the VE-cadherin-mediated cell adhesion and barrier function dramatically. In general, a decrease in barrier function is associated with a loss of cortical actin filaments from the VE-cadherin/catenin complex, leading to stress-fiber formation and a redistribution of the VE-cadherin/catenin complex (20). Although the actin reorganization is controlled by GTPases of the Rho-family (21), tyrosine phosphorylation of VE-cadherin and the catenins, as well as activation of both actin filament dynamics and contractile mechanisms, play a fundamental role in the regulation of endothelial barrier function during inflammation (18,19,22). In filovirus infections, those phenomena (reorganization but no tyrosine phosphorylation of VE-cadherin and the catenins) are seen in cell culture models when ECs are treated with supernatants of filovirus-infected monocytes/macrophages (23–25).

After stimulation with proinflammatory agents, ECs express adhesion molecules that mediate endothelial-leukocyte interactions. The process of leukocyte migration

includes three successive stages: rolling, mediated by the selectin class of adhesion molecules (e.g., E-selectin); tight adhesion, mediated by the leukocyte integrins and their EC counter-receptors (e.g., intercellular adhesion molecule [ICAM]-1, and vascular cell adhesion molecule [VCAM]-1); and transmigration, which involves platelet-endothelial cell adhesion molecule (PECAM)-1, CD99, and CD69 (26,27). In animal models of filovirus disease, white blood cells (particularly granulocytes) are adherent to postcapillary venules close to sites of virus-induced focal necrosis, but extravasation appears to be blocked for unknown reasons (28). It is assumed that the inflammatory response of the vascular system is an important component of EBOV HF pathogenesis. Therefore, uncovering the molecular mechanisms responsible for

the regulation of cell junctions in filovirus infection is of central importance for the understanding of EBOV pathogenesis.

**PROPOSED PATHOGENESIS**

As outlined earlier, disrupted endothelial barrier and alteration of adhesion molecule expression are thought to determine disease-decisive symptoms during severe EBOV infection. They occur through a complex mechanism that involves both direct and indirect targeting of the vascular endothelium and immune competent cells (1,2,5,23,29). Several major pathological determinants are discussed as factors in this process (Figure 143.1).

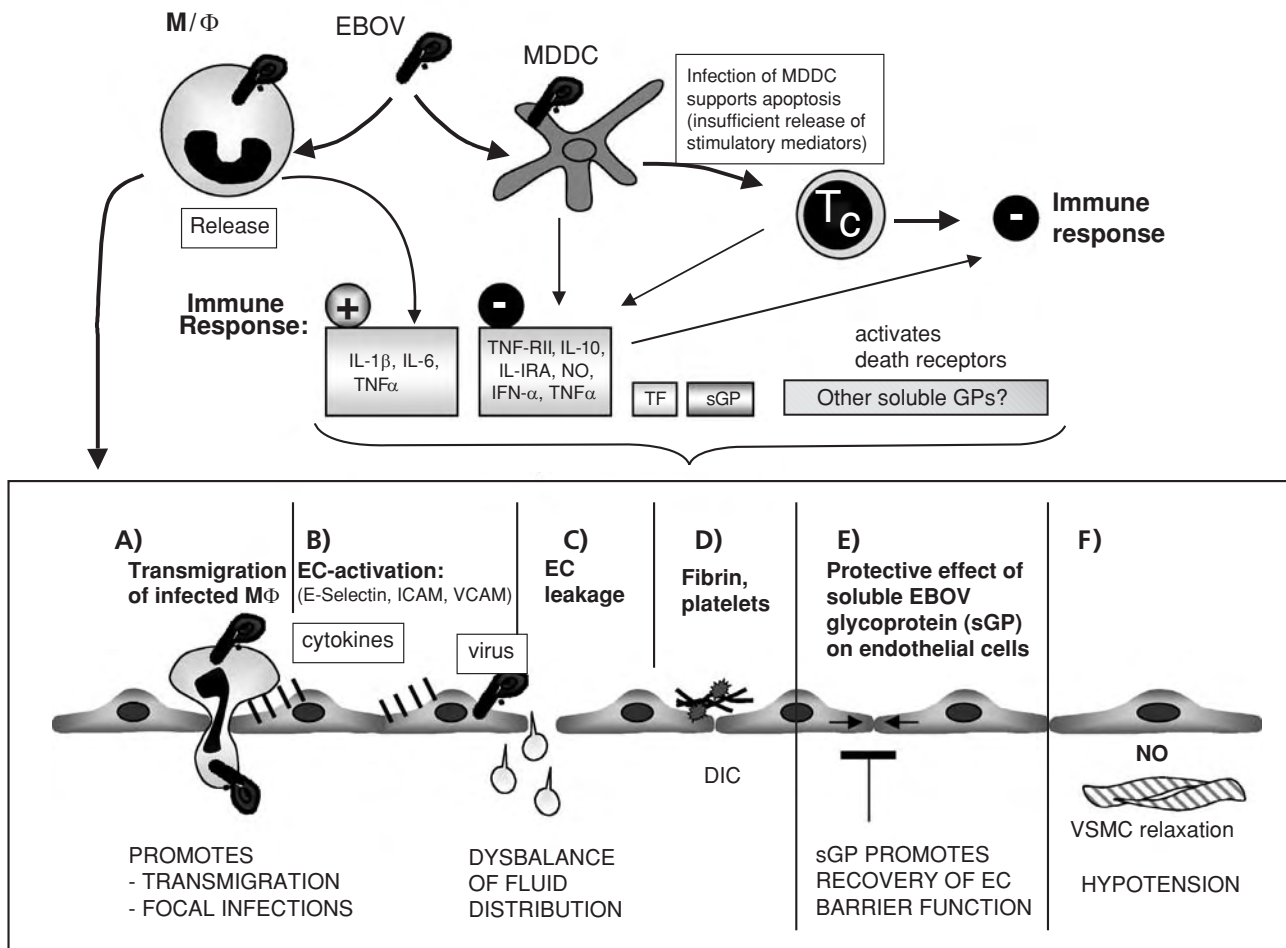

Figure 143.1. Model of Ebola virus pathogenesis. Primary target cells of EBOV include macrophages (MΦ) and monocyte-derived dendritic cells (MDDCs). Although infection of MΦ induces the release of cytokines and chemokines, the lack of this response by MDDCs may favor apoptosis of lymphocytes (Tc). In addition to release of cytokines and chemokines, infected MΦ also release tissue factor (TF) and the viral sGP. Collectively, these various mediators may exert an effect on the vascular endothelium, as shown in A through F. First, infected MΦ are activated and transmigrate through the endothelium, thereby contributing to focal infections (A). The endothelium also is activated and responds by increasing expression of cell adhesion molecules (B). This activation can occur directly via viral infection of the endothelium or indirectly as a result of mediators expressed by MΦ. Endothelial leakage (C) and fibrin deposition (D) also can be induced as an indirect effect of mediator molecules. Recent data suggest that sGP exerts an anti-inflammatory role on the endothelium by restoring the barrier function of endothelial monolayers (E). Finally, NO release from MΦ may contribute to vascular smooth muscle cell (VSMC) relaxation and consequently, hypotension.

### SOLUBLE FACTORS PRODUCED BY PRIMARY TARGET CELLS AND THEIR IMPACT ON ENDOTHELIAL DYSFUNCTION

Mononuclear phagocytic cells are primary targets for EBOV, and infection leads to lytic replication (30). In addition to virus production, the infection of mononuclear phagocytic cells leads to their activation and subsequent release of active mediators such as proinflammatory cytokines (e.g., TNF- $\alpha$ , IL-1 $\beta$ , and IL-6) and chemokines (e.g., IL-8). The activation of monocytes/macrophages is independent of virus replication (31,32). It was recently shown that interaction of macrophages with virus-like particles, consisting of only the EBOV matrix protein (VP40) and transmembrane glycoprotein (GP<sub>1,2</sub>) and nearly identical in morphology to infectious virus particles (Figure 143.2), is sufficient to induce expression of TNF- $\alpha$ , IL-6, and IL-8 similar in kinetics to activation triggered by lipopolysaccharide (LPS) (31,33). Proinflammatory cytokines and some chemokines are powerful modulators of endothelial barrier function and cause endothelial activation. Earlier studies demonstrated that the cell culture supernatants derived from filovirus-infected monocytes/macrophages were able to cause intercellular gap formation resulting from reorganization of structural components of the adherens junctions. This effect was mediated to a large extent by TNF- $\alpha$  and could be blocked by neutralizing monoclonal antibodies to TNF- $\alpha$  (24). Increased levels of cytokines were detected in vitro, in sera of infected patients, and in experimentally infected non-human primates (32,34,35). It is known that macrophage-derived cytokines act on multiple organs, but the vascular system and the endothelium seem to be the major targets in VHF, as also observed in septic forms of shock. Furthermore, infected macrophages release vasoactive mediators such as NO that cause loss of vascular smooth muscle tone (29). Data obtained from cell culture and in vivo models, as well as from postmortem material from humans, indicate that the endothelium responds to filovirus-mediated release of cytokines with

Figure 143.2. Atomic force microscopy of virus-like particles. Purified VP40-only particles (A) or VLPs expressing VP40 and GP<sub>1,2</sub> (B) were prepared on mica and scanned by atomic force microscopy in air mode. The particles are filamentous in morphology, and the surface of VP40-only particles (A) appears smooth whereas VLPs, which are studded with GP<sub>1,2</sub> display a rough surface (B).

an increase in permeability, dysregulation of vascular tone, expression of cell adhesion molecules, and a change to a procoagulant phenotype. Thus, imbalanced production of proinflammatory cytokines can be associated with negative prognosis and fatal outcome similar to septic shock.

A hallmark of filovirus infection in humans and non-human primates is coagulopathy, which is partly caused by thrombocytopenia, a common laboratory finding during infection. Thrombocytopenia might be the result of a dysregulation of megakaryocyte maturation in the bone marrow caused by high levels of interferon. The mechanisms triggering coagulation abnormalities in EBOV HF seem to be complex and are not well understood. However, recent studies on experimentally EBOV-infected nonhuman primates suggested that coagulation abnormalities are initiated early in the disease course through expression and release of tissue factor from infected monocytes/macrophages, a major activator of the clotting cascade (4,10–12,36). The level of tissue factor expression can be amplified further by proinflammatory cytokines (e.g., IL-6, IL-1, and TNF- $\alpha$ ) released from infected cells during infection. In addition, shedding of tissue factor–positive monocytes/macrophage-derived microparticles, which have strong procoagulant potential, and rapid depletion of the major anticoagulant protein C were observed. This coincided with the appearance of fibrin deposition that can result in fibrin mesh networks encapsulating infected macrophages in multiple organs (e.g., liver and spleen). The coagulation disorders in EBOV infections are consistent with the syndrome of DIC. No single test is available that is sufficient to permit a definitive diagnosis of DIC. However, D-dimer, a marker for activation of both coagulation and fibrinolytic cascades (37), is dramatically increased in EBOV-infected *Cynomolgus* macaques (13). In addition, within 3 to 4 days after infection, platelets and protein C levels were decreased, and fibrin thrombi were found in vessels of several tissues, further indicating the development of DIC (13). Consequently, therapeutic strategies aimed at controlling certain coagulation and fibrinolytic parameters may be helpful in the management of EBOV HF and other VHF syndromes. Indeed, administration of recombinant nematode anticoagulant protein c2 (rNAPc2), a potent inhibitor of tissue factor-initiated blood coagulation, proved to be beneficial in EBOV-infected macaques, resulting in survival of 33% of the animals and a significant delay in death for the rest of the animals. rNAPc2-treated animals showed less prominent fibrin deposits and intravascular thromboemboli (4,10,38).

### VIRAL CYTOPATHIC EFFECT

The vascular endothelium is considered a secondary target for virus replication. It was shown earlier that ECs are able to support a productive infection of filoviruses in vitro (24,39). In general, filovirus infection leads to a moderate cytopathic effect in susceptible cells and tissues. The mechanism

of destruction of ECs and other target cells by EBOV is not entirely understood. Most probably, several processes play a role, including viral shutdown of cellular processes, massive production and accumulation of viral proteins in infected cells, and dramatic budding of multiple Ebola viral particles from the cell membrane. It was proposed that viral full-length glycoprotein has a specific cytotoxic potential and was therefore considered to be the major viral pathogenic determinant. Particularly, the expression of EBOV glycoprotein in EC cultures caused cell destruction (40,41), and it was concluded that this effect might be relevant in EBOV pathogenesis. However, in tissue obtained from postmortem human material and from experimentally infected nonhuman primates, endothelial destruction due to infection was less prominent (4,11,12,36,42).

EBOV-infected cells that release infectious EBOV particles produce a transmembrane glycoprotein (GP) and a number of soluble glycoproteins (Figure 143.3), and it has been postulated that they may play an important role in EBOV pathogenesis (43). All viral glycoproteins are encoded by gene 4 of the EBOV genome. The primary product of this gene is a precursor of a nonstructural soluble glycoprotein (sGP) that is post-translationally cleaved into mature sGP and  $\Delta$ -peptide;

Figure 143.3. Glycoprotein expression strategy for Ebola virus. The direct transcription of viral RNA leads to the production of pre-sGP, which is post-translationally modified and cleaved into sGP and  $\Delta$ -peptide (both are secreted). RNA editing (insertion of an additional/eighth adenosine at a specific sequence) leads to production of pre-GP, which is also post-translationally modified and cleaved by furin into the disulfide-linked fragments GP<sub>1</sub> and GP<sub>2</sub>. The full-length GP<sub>1,2</sub> forms trimers on the surface of particles and mediates receptor binding and fusion to host cells.

both are secreted products, and sGP has been detected in patient serum (43,44). RNA editing is necessary to express the structural transmembrane glycoprotein GP that is also post-translationally cleaved into the disulfide-linked fragments GP<sub>1</sub> and GP<sub>2</sub> (Figure 143.3). The homotrimeric GP<sub>1,2</sub> forms the spikes on the virus particle, and is indispensable for receptor binding and fusion with the host cell membrane. In vitro studies have demonstrated that GP<sub>1,2</sub>, when expressed in ECs, is cytotoxic and thus may contribute to endothelial damage during EBOV infection (40,45). In one study, the cytotoxic effect of GP<sub>1,2</sub> in human embryonic kidney 293T and ECs was attributed to the mucin-like domain of the GP<sub>1</sub> subunit (40). EBOV GP<sub>1,2</sub> has a coiled-coil domain that forms a trimer of helical hairpin-like loops. The hairpin structure lies adjacent to the fusion-peptide region and is inserted directly into the cell membrane of target cells, providing a potential mechanism of direct toxicity. Interestingly, a recombinant virus with a mutated editing site resulting in mainly GP<sub>1,2</sub> expression showed an increased cytotoxic effect but reduced virion production, indicating that RNA editing might play a role in reducing virus cytotoxicity. The pathogenic role of the soluble glycoproteins on the endothelium was postulated; however, until recently no studies were performed allowing for the dissection of the complex mechanism of virus action on the endothelium.

The use of recombinant viral technology in combination with novel biophysical methods, such as impedance spectroscopy, allows for the investigation of EBOV pathogenesis outside the BSL4 laboratory. An interesting example is the role of EBOV glycoproteins in endothelial activation and barrier function, by which virus-like particles were used in combination with impedance spectroscopy to measure the endothelial barrier function. Virus-like particles can be produced by expression of the EBOV matrix protein (VP40) and the transmembrane glycoprotein GP<sub>1,2</sub>. Importantly, a reliable control is the expression of only VP40 that leads to virus-like particles lacking the GP. Using atomic force microscopy with a resolution of a couple of nanometers, we have compared the VLPs consisting of VP40 and GP as well as VLPs only carrying VP40 (see Figure 143.2). Particles bud from the cell membrane and display a morphology that is nearly identical to live virus but is completely free of viral genetic material and thus noninfectious.

Impedance spectroscopy is an emerging and unique biophysical method to reliably examine the endothelial barrier function using high temporal resolution and high sensitivity (45). Based on electrical impedance spectroscopy data, the transendothelial electrical resistance (TER) of a cultured EC monolayer can be determined, and it predominantly reflects the changes in paracellular permeability. EC barrier function is frequently studied in transwell filter systems by analyzing the passage of tracer substances. In contrast to impedance spectroscopy, which reliably detects changes in barrier function of about 2% (45), tracer systems are limited in temporal resolution and sensitivity and, thus, are only capable of detecting strong effects.

It was shown that infectious EBOV, as well as noninfectious virus-like particles, is able to interact with and activate ECs *in vitro*, as demonstrated by expression of ICAM-1, VCAM-1, and E-selectin adhesion molecules (31). Moreover, VLPs were able to increase the endothelial permeability measured by the highly sensitive impedance spectroscopy method and hydraulic conductivity. The permeability-increasing effect of VLPs might allow for extravasation of water, and thus contribute to the development of edema and shock observed during EBOV HF. These effects were not observed using VLPs lacking GP<sub>1,2</sub>, indicating the importance of the transmembrane glycoprotein GP<sub>1,2</sub> in the context of a virion particle for EC activation and barrier dysfunction. The effect of VLPs on endothelial permeability corresponded to the effect of approximately 200 to 300 pg/mL of TNF- $\alpha$ . These changes were associated with the formation of actin stress fibers, although VE-cadherin staining was largely intact along the cell-cell junctions (31). The moderate effect of VLPs on endothelial barrier function was further enhanced in the presence of TNF- $\alpha$ , thus

contributing to the severity of endothelial damage even in the absence of direct EC infection. Interestingly, the major soluble glycoprotein sGP failed to activate monocyte/macrophages and ECs or influence the endothelial barrier function, even when applied at high concentrations (50  $\mu$ g/mL) (31). However, when sGP was administered simultaneously with TNF- $\alpha$ , it caused a recovery of EC barrier function, implying that sGP might be able to interfere with components of the TNF- $\alpha$  signaling pathway (Figure 143.4; for color reproduction, see Color Plate 143.4). This finding suggests that sGP may have an anti-inflammatory role (31). Whether sGP interferes with EBOV virus- or VLP-mediated activation remains unclear. It is noteworthy that in animal models of filovirus disease, white blood cells adhere to the endothelial lining of postcapillary venules close to virus-induced focal necrosis, but do not extravasate into the extravascular space (28). These data suggest that leukocyte adhesion is increased while transmigration is blocked or impaired, which hypothetically could be related to the observed anti-inflammatory effect of sGP.

Figure 143.4. Effect of simultaneous application of TNF- $\alpha$  and virus-like particles or sGP on ECs. ECs were treated with TNF- $\alpha$  (1 ng/mL) and VLPs (1 particle/cell) or sGP (10  $\mu$ g/mL). Simultaneous application of TNF- $\alpha$  and VLP<sub>VP40/GP</sub> led to further decreases in TER by approximately 17%, indicating their additive effect on reducing barrier function (A). Simultaneous treatment with TNF- $\alpha$  and sGP led to a recovery of the TNF- $\alpha$ -induced changes in barrier function by 15% to 20% (B). Changes in TER were significant ( $p < 0.05$ ) from the time point marked by asterisks. (Reproduced with permission from Wahl-Jensen V, Afanasieva TA, Seebach J, et al. Effects of Ebola virus glycoproteins on endothelial cell activation and barrier function. *J Virol.* 2005;79:10442–10450.) For color reproduction, see Color Plate 143.4.

An additional indirect influence on vascular system dysregulation may result from infection and impairment of organs that are normally involved in the regulation of endothelial homeostasis. The filoviruses are able to infect a wide range of cells and tissues. In vitro data indicate that the heavily glycosylated surface protein of EBOV is able to bind to widely distributed cellular lectins (46). However, additional data are required to bolster this hypothesis. In addition to monocytes/macrophages and dendritic cells, hepatocytes and adrenal cortical cells are susceptible to EBOV infection. Infection of liver and the adrenal gland has been reported to occur in epidemic HF (47–49). EBOV infection results in direct damage of hepatocytes, with the formation of multiple foci of necrosis in the liver. Currently, it is not clear whether disseminated infection of the liver leads to a reduced synthesis of mediators with procoagulant activities, or to a reduced albumin synthesis that together may lead to a reduction of plasma osmotic pressure and contribute to edema formation. The adrenal cortex secretes many different hormones, including corticosteroids and mineralocorticoids that control blood pressure and the level of sodium and potassium in the body. Impaired function of the adrenal cortex will lead to hypotension and sodium loss, resulting in hypovolemia; this may contribute to shock development seen at late stages of EBOV HF and other VHFs.

## CONCLUSION

The investigation of pathogenic mechanisms for several VHF-viruses, such as EBOV, MARV, and Lassa virus, is complicated by the need for a high level of biocontainment of the viruses (BSL4). This has changed lately, particularly for filoviruses, with the introduction of molecular tools and models that allow for experiments under lower biocontainment conditions. The construction of viruses such as retroviruses or vesicular stomatitis virus pseudotyped with filovirus glycoproteins, and the generation of virus-like particles that resemble the particles of infectious virus but lack the viral genetic information already have provided new information, particularly in regards to virus–cell interactions. They will become even more important tools in the future, used to study virus–cell interactions as well as various aspects of pathogenesis. Changes in EC function can be subtle and difficult to detect by morphological methods such as intercellular gap formation. To demonstrate increased paracellular permeability, highly sensitive and reliable biophysical methods such as impedance spectroscopy allow the online determination of the TER. This method is able to detect discrete effects that are not obvious by morphological or tracer techniques, such as transwell filter systems. Nevertheless, even small changes in TER of 10% to 20% increase the water permeability several-fold without an obvious redistribution of junction molecules (31). Using these more sensitive methods, in combination with genetically modified viruses, will help in the future to understand VHF pathogenesis and may provide a basis for therapy (31).

## KEY POINTS

- EBOV HF pathogenesis is a complex process involving an interplay between cellular and viral factors.
- EBOV HF causes a shock syndrome that in part resembles septic shock. It is characterized by strong involvement of both the vascular ECs and immune response systems.
- Mononuclear phagocytic cells (MPCs) are primary targets for EBOV. Infection of MPC leads to the lytic replication of the virus, MPC activation, and subsequent release of active mediators such as proinflammatory cytokines, which are powerful regulators of endothelial functions and modulators of the immune system.
- Viral full-length glycoprotein has a cytotoxic potential and therefore is considered to be a major viral pathogenic determinant.
- The effect of full-length glycoprotein associated into virus-like particles on endothelial barrier function is further enhanced in the presence of proinflammatory cytokines (e.g., TNF- $\alpha$ ), thus contributing to endothelial dysfunction even in the absence of direct EC infection.

## Future Goals

- To establish reliable molecular tools and models that allow experimentation under lower biocontainment conditions
- To establish highly sensitive methods that allow the detection of minimal physiological changes in endothelial function that do not have strong morphological appearance but could have a devastating effect on organ function

## ACKNOWLEDGMENTS

Work on ECs and filoviruses in Dresden was supported by grants from the German research council (DFG), grant SCHN430/2–4 and the Priority program 1130 “Infection of the endothelium” SCHN 430/3–1 and 3–2, and the MedDrive program of the Medical Faculty of the TU-Dresden. Work on filoviruses in Winnipeg was supported by Health Canada, Public Health Agency of Canada, and a grant of the Canadian Institutes of Health Research (CIHR, MOP-43921). VWJ was supported by fellowships from the Manitoba Health Research Council (MHRC) and the Department of Medical Microbiology, University of Manitoba.

## Effect of Smoking on Endothelial Function and Cardiovascular Disease

Rajat S. Barua and John A. Ambrose

*University of California at San Francisco, Fresno*

Cigarette smoking is the single most alterable risk factor contributing to premature morbidity and mortality in the United States. About one in five deaths from cardiovascular disease is attributable to smoking. Smoking costs Americans over \$157 billion annually in health-related economic costs (1,2). Cigarette smoking predisposes to several different clinical atherosclerotic syndromes, including stable angina, acute coronary syndromes, sudden death, and stroke (1). In addition, smoking is associated with an increased incidence of aortic and peripheral atherosclerosis, which may lead to abdominal aortic aneurysms and intermittent claudication (1). Even passive smoking (environmental tobacco exposure) is reported to increase coronary artery disease (CAD) risk by 30% (1,3). Endothelial dysfunction is an important pathophysiological mechanism of atherosclerosis (4). Compelling evidence suggests that endothelial cell (EC) dysfunction is associated with (and caused by) each of the risk factors for atherosclerosis, including smoking. However, the precise mechanisms by which cigarette smoking and its components such as nicotine may cause endothelial dysfunction leading to adverse cardiovascular events remain to be fully elucidated. The present chapter summarizes the historical as well as the current perspectives on the evidence and potential mechanism(s) of cigarette smoking-related endothelial dysfunction and cardiovascular disease.

### HISTORICAL PERSPECTIVES

About 500 years ago, Columbus and his crew brought tobacco (dried leaves and seeds) from the New World to Europe. By the early part of the 19th century, tobacco was rolled in paper and smoked as cigarettes (5). It was not until the late 1930s that it was initially proposed that cigarette smoking might be associated with increased cardiac mortality (5). In the 1950s, seminal prospective cohort studies on British male physicians demonstrated that cardiovascular disease is more common in smokers

than in nonsmokers (5,6). Since then, innumerable epidemiological studies have confirmed an association between smoking and myocardial infarction (MI)/fatal CAD in men and women of all ages (1). In 1975, Asmussen and Kjeldsen provided the first direct evidence that cigarette smoking could result in endothelial injury by describing ultrastructural alterations in the endothelium obtained from the umbilical arteries of babies from mothers who smoked (7). In 1978, Aronow reported for the first time on the potential association between CAD and passive smoking (8).

It is now generally accepted that the cardiovascular consequences of smoking are due primarily to atherothrombotic modification of the vascular wall and increased thrombogenicity of the blood. In humans, to directly ascertain the relationship between cigarette smoking and atherosclerosis, various clinical imaging techniques such as angiography, vascular ultrasound, and transesophageal echocardiography, as well as pathologic analysis of the coronary arteries, have been employed. Utilizing these techniques, after controlling for various risk factors for atherosclerosis, multiple studies have reported that cigarette smoking is associated with an increase in the incidence and acceleration of atherosclerotic plaque formation (6).

### EFFECTS OF SMOKING ON ENDOTHELIAL CELL STRUCTURE

Injury to the endothelium is believed to be an initiating event in the atherosclerotic process. It also appears to be a major determinant in causing acute cardiovascular events (4). Endothelium from the umbilical arteries of babies from mothers who smoked cigarettes during pregnancy showed an irregular appearance of the cell membrane and the formation of blebs or microvillous-like projections, indicating endothelial injury (7). In vitro, exposure to cigarette smoke extract (CSE) or a high dose of nicotine was shown to be associated with an

**Table 144-1: Effect of Cigarette Smoking Exposure on the Endothelium**

	<i>Acute Exposure</i>	<i>Chronic Exposure</i>	<i>Mechanisms (Based on Combination of In Vitro and In Vivo Studies)</i>
EC structure and survival in vivo	Increased circulating ECs as well as EC microparticles	Abnormality in ultrastructural components of ECs; increased circulating ECs	Apoptosis and necrosis in vitro, with low concentration of CSE or nicotine. Primary mechanism was apoptosis; with higher concentration, necrosis was more prominent
Vasomotor function	Impaired in habitual smokers as well as in nonsmokers	Impaired in macro- as well as microvascular beds	Decreased NO availability (chronic and acute); increased ET-1 (acute); decreased PGI <sub>2</sub> availability
Proinflammatory effects	Increased soluble adhesion molecules (ICAM-1, P-selectin)	Increased adhesion molecules (ICAM-1, VCAM-1), circulating CRP, IL-6, TNF- $\alpha$	Activation of inflammatory genes due to increased oxidative stress and reduced levels of NO
Procoagulant effects	Increased circulating tissue factor activity	Decreased stimulated t-PA release; alteration of t-PA/PAI-1 molar ratio; decreased TFPI release; increased tissue factor level as well as activity in atherosclerotic plaques	Unclear; preliminary data suggest decreased NO availability and increased oxidative stress

increase in EC death or apoptosis (6,9). It had been reported that after acute as well as chronic cigarette smoke exposure, in human blood, circulating anucleated endothelial carcasses (9,10) as well as circulating ECs were increased (11). Even in nonsmokers, acute cigarette smoke exposure was associated with an increase of these circulating cells or cell particles (10). All these findings are consistent with the concept that cigarette smoke exposure is injurious to the endothelium. Table 144-1 summarizes the effects of cigarette smoke exposure on the endothelium.

#### EFFECTS OF SMOKING ON ENDOTHELIAL CELL FUNCTION

It is now evident that during the atherosclerotic process, alterations in the functional characteristics of the endothelium precede changes in morphology (4). The functional changes of the endothelium associated with cigarette smoking include vasoregulatory dysfunction, and proinflammatory and prothrombotic modification.

#### Vasoregulatory Dysfunction

Impairment of vasoregulatory function is one of the earliest functional changes in the endothelium associated with atherosclerosis. In both animal and human models, multiple studies have demonstrated that active as well as passive cigarette smoke exposure is associated with a decrease

in endothelial vasodilatory function (1,12). In humans, both acute and chronic cigarette smoke exposure impaired endothelium-dependent vasodilation (EDV) in macrovascular beds such as the coronary and brachial arteries and in microvascular beds (1,12–15). In young healthy male smokers, heavy (>1 pack/day) and light (<1 pack/week) cigarette smoking was reported to have a similar degree of impairment of brachial artery EDV (16). Recently, using high-resolution magnetic resonance imaging, it was demonstrated that chronic cigarette smoking induced global impairment of EDV in both peripheral and central conduit arteries (17). Use of nicotine (patch, spray, or gum) was also reported to be associated with partial impairment of EDV. However, the degree of impairment was less severe with nicotine use as compared to that of active cigarette smoking (18,19).

The endothelium secretes multiple vasoregulatory molecules; among them the primary vasodilator is nitric oxide (NO), and the primary vasoconstrictor is endothelin (ET)-1. As discussed later, evidence regarding the effect of smoking on these vasoregulatory molecules continues to accumulate.

#### *Effect of Cigarette Smoke on Nitric Oxide Biology*

In vitro exposure to CSE or nicotine was associated with decreased availability of EC-derived NO (6,12,20). In a more physiologically relevant in vitro experiment, Barua and colleagues demonstrated that the incubation of human umbilical vein ECs (HUVECs) and human coronary artery ECs (HCAECs) with sera from young healthy male smokers resulted in decreased NO availability (12,16,21). In these

Figure 144.1. Effects of smokers' serum NO production in vitro. Confluent (~85%) HCAECs were incubated for 12 hours with equal volumes of medium and serum from nonsmokers ( $n = 10$ ) or smokers ( $n = 15$ ) (with or without treatment as indicated) in 12-well plates. NO production in the cell culture supernatant was determined by a chemoluminescence method. Results are presented as mean  $\pm$  SEM after adjusting for the background NO and the total protein in each well. Unpaired Student's t-test: \* $p < 0.02$  versus nonsmokers' baseline; paired Student's t-test: † $p < 0.04$  versus smokers' baseline. (Reproduced with permission from Barua RS, Ambrose JA, Srivastava S, et al. Reactive oxygen species are involved in smoking-induced dysfunction of nitric oxide synthase: an in vitro demonstration in human coronary artery endothelial cells. *Circulation*. 2003;107:2342–2347.)

studies effects of sera from cigarette smokers on NO biosynthetic pathway in both cell types (HUVECs and HCAECs) were similar (12,21). Moreover, these authors found a correlation between flow-mediated brachial artery EDV and NO levels in HUVECs exposed to serum from the same individuals (12). In human subjects, it has been demonstrated indirectly in vivo by infusing N(G)-monomethyl-L-arginine (a competitive inhibitor of L-arginine, the substrate for NO biosynthesis) that the reduced EDV associated with cigarette smoking is attributable to a decreased availability of NO (1,12). However, the exact mechanisms responsible for the decrease in NO availability remain to be clearly defined.

Cigarette smoke contains a large number of free radicals and pro-oxidants. NO is also a free radical that can preferentially react with the free radicals from cigarette smoke, which would cause a decrease in NO bioavailability (1). In vitro, the addition of either free radical scavengers such as superoxide dismutase (SOD) or catalase increased NO availability in the cell culture supernatant of HCAECs exposed to smokers' serum (Figure 144.1) (21). Murohara and colleagues have shown that the CSE-induced contraction of isolated porcine coronary arteries was significantly attenuated by SOD (22). Similarly, Heitzer and colleagues reported that infusion of vitamin C, or 4 months of vitamin E oral therapy, significantly improved brachial artery EDV in human smokers (23,24). Taken together, these studies support the notion that the scavenging activity of cigarette smoke-derived free radicals leads to reduced NO bioavailability.

Cigarette smoke could also influence the availability of NO by affecting endothelial NO synthase (eNOS) expression and/or functional activity. Studies on the effect of cigarette smoking on eNOS expression have led to conflicting conclusions. In ECs isolated from the main pulmonary artery of

6- to 7-month-old pigs, CSE exposure was shown to cause a decrease in both eNOS mRNA and eNOS protein (20). Similarly, in lung tissue specimens from subjects who underwent lung resection for lung carcinoma, samples from smokers showed a decreased immunostaining for eNOS in ECs from all types of pulmonary vessels as compared with nonsmokers. These authors also reported that eNOS protein level was decreased in lung tissue homogenate from smokers (25). However, when serum from smokers was added to confluent HUVECs or HCAECs, eNOS protein expression was increased (12,21). Exposure of HCAECs to nicotine for 24 hours at concentrations similar to those in the blood of smokers resulted in increased eNOS mRNA levels (26). Recently, Beckman and colleagues, utilizing skin biopsy, demonstrated that microvessel eNOS mRNA levels were increased in cigarette smokers compared with healthy control subjects (27). In contrast to these conflicting studies related to smoking and eNOS expression, there is more consistency in the reported effects of cigarette smoking on eNOS activity. In various models, cigarette smoke exposure is associated with a decrease or an alteration (i.e., uncoupling) of eNOS activity that was responsible for the decreased NO, regardless of its effect on eNOS mRNA or protein level (20,21) (Figures 144.2 and 144.3). In vitro, the addition of free radical scavengers and/or tetrahydrobiopterin, an essential cofactor of eNOS, normalized the dysfunctional eNOS activity associated with cigarette smoking (21) (Figure 144.2). In vivo, supplementation of tetrahydrobiopterin restored the EDV in cigarette smokers (28). These findings support decreased or altered eNOS activity as a viable mechanism for the decrease in NO availability in smokers.

Figure 144.2. Effects of smokers' serum on eNOS activity in vitro. Confluent (~85%) HCAECs were incubated with equal volumes of medium and serum from nonsmokers ( $n = 10$ ) or smokers ( $n = 15$ ) (with or without treatment as indicated) in 12-well plates. After 12 hours, the HCAECs were lysed. eNOS activity of the cell lysates was determined by detecting the conversion of [ $^3$ H] L-arginine to [ $^3$ H] L-citrulline. Results are presented as the mean  $\pm$  SEM after adjusting for the specific amount of eNOS protein/mg total protein. Unpaired Student's t-test: \* $p < 0.02$  versus nonsmokers' baseline; paired Student's t-test: † $p < 0.04$  versus smokers' baseline; ANOVA:  $p < 0.008$  for nonsmokers' baseline versus all treatment in smokers, Post hoc Fisher's PLSD: ‡ $p < 0.03$  versus nonsmokers' baseline. (Reproduced with permission from Barua RS, Ambrose JA, Srivastava S, et al. Reactive oxygen species are involved in smoking-induced dysfunction of nitric oxide synthase: an in vitro demonstration in human coronary artery endothelial cells. *Circulation*. 2003;107:2342–2347.)

Figure 144.3. Potential mechanism(s) for decreased NO availability in smokers. *Dashed arrows* represent potential direct and indirect pathways. *Bracket* identifies eNOS and its cofactors. Normally, eNOS utilizes L-arginine to produce NO and citrulline. Free radical such as  $O_2^-$  derived from cigarette smoke and other endogenous sources reacting with NO, not only would decrease NO availability but also would give rise to  $ONOO^-$ .  $ONOO^-$  has been shown to oxidize  $BH_4$ . With oxidation  $BH_4$ , eNOS becomes uncoupled and produces  $O_2^-$ , which would further enhance the cellular oxidative stress. NOS, nitric oxide synthase;  $BH_4$ , tetrahydrobiopterin; NADPH, nicotinamide adenine dinucleotide phosphate reduced; FAD, flavin adenine dinucleotide; FMN, flavin adenine mononucleotide;  $O_2^-$ , superoxide;  $ONOO^-$ , peroxynitrite.

In addition to its vasodilatory function, NO also plays an important role in the regulation of inflammation, leukocyte adhesion, platelet activation, and thrombosis. Therefore, an alteration in endothelium-derived NO availability is likely to be one of the important steps in the initiation and progression of atherothrombotic disease (Figure 144.4).

#### Effect of Cigarette Smoke Exposure on Endothelium-Derived Endothelin-1

ET-1 is the most potent endogenous vasoconstrictor produced by both ECs and vascular smooth muscle cells (VSMCs). Available data regarding the effects of cigarette smoke or its components on ET-1 levels have been conflicting. In vitro, HUVECs exposed to serum from smokers or controls failed to demonstrate a difference in basal ET-1 production between nonsmokers, light smokers, and heavy smokers (16). On the other hand, HUVECs treated with medium that was conditioned with monocytes from smokers demonstrated increased release of ET-1 (29). In a rat model, acute cigarette exposure (six cigarettes for 30 minutes) was shown to increase the expression of *ET-1* mRNA in heart and lung tissues, but, with chronic cigarette exposure (six cigarettes for 30 min/day, 5 days a week for 6 months), the effect on the *ET-1* mRNA in cardiovascular tissues became insignificant (30). Using lung tissue specimens from human subjects who underwent lung resection for lung carcinoma, Barbera and colleagues found that *ET-1* mRNA and protein levels in pulmonary arteries and in lung tissue extracts were similar between smokers and nonsmokers (31). In vivo studies suggested that within the first 10 minutes of active smoking, a rise occurs in plasma or serum ET-1 levels, which is followed by a decline over time (32,33). Nicotine alone had no effect on plasma ET-1 (33).

Recently, utilizing an ET A receptor (ETA) blocker (BQ-123), it was found that the vasodilatory function of the brachial artery measured by venous occlusion plethysmography did not improve in smokers, suggesting that ET-1 does not contribute substantially to vascular tone in smokers, especially via the ETA receptor (34). Thus, based on current data, the role of ET-1 in cigarette smoking-related vasodilatory dysfunction is unclear and appears to be restricted to the acute phase of smoking (10 minutes to few hours).

#### Effect of Cigarette Smoke Exposure on Endothelium-Derived Prostacyclin

Prostacyclin ( $PGI_2$ ), a vasodilatory and antithrombogenic molecule secreted by ECs, also is affected by cigarette smoking. It was reported that aortas from rats that were chronically exposed to cigarette smoke showed a reduction in  $PGI_2$  production (34). Similarly, Reinders and colleagues showed that incubation of HUVECs with cigarette smoke condensate (CSC) impaired the basal and stimulated (phorbol myristate acetate) production of  $PGI_2$  (35). Ahlsten and colleagues reported that maternal smoking significantly decreased  $PGI_2$  production in umbilical arteries from newborn infants (36). Similarly, HUVECs isolated from smoking mothers were shown to produce less  $PGI_2$  in vitro (37). On the other hand, it was reported that incubation of nicotine with HUVECs resulted a dose-dependent increase (maximum effect with  $0.05\ \mu\text{g}/\text{mL}$ ) in the basal level of  $PGI_2$  (38). However, at higher doses nicotine appears to decrease the production of  $PGI_2$  (38).

#### Proinflammatory Effects

The inflammatory change in the endothelial milieu leading to an increase in leukocyte and EC interaction is an essential component in the initiation and progression of atherosclerosis. In vitro, CSC was associated with a 70% to 90% increase in adherence between human monocytes and HUVECs (39). Shen and colleagues demonstrated that exposure of HUVECs to CSC resulted in increased nuclear factor (NF)- $\kappa$ B DNA binding activity; increased surface expression of intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and platelet-endothelial cell adhesion molecule (PECAM)-1; and a twofold induction in transendothelial migration of monocytes (40). Adams and colleagues, exposing human monocytes and HUVECs to smokers' serum, found a significant increase in adhesion between these cells, which was associated with increased expression of ICAM-1 on HUVECs (41). These authors also noted that the increased adhesion between HUVECs and monocytes was reversed by L-arginine, suggesting that smoking-related impairment of NO availability was an important determinant of increased cell-cell adhesion between endothelium and leukocytes (41). Oxidized low-density lipoprotein (oxLDL) and lipid peroxidation products have been shown to be proinflammatory and, in various experimental models (including human, animal, and cell culture models), cigarette smoke exposure was associated with

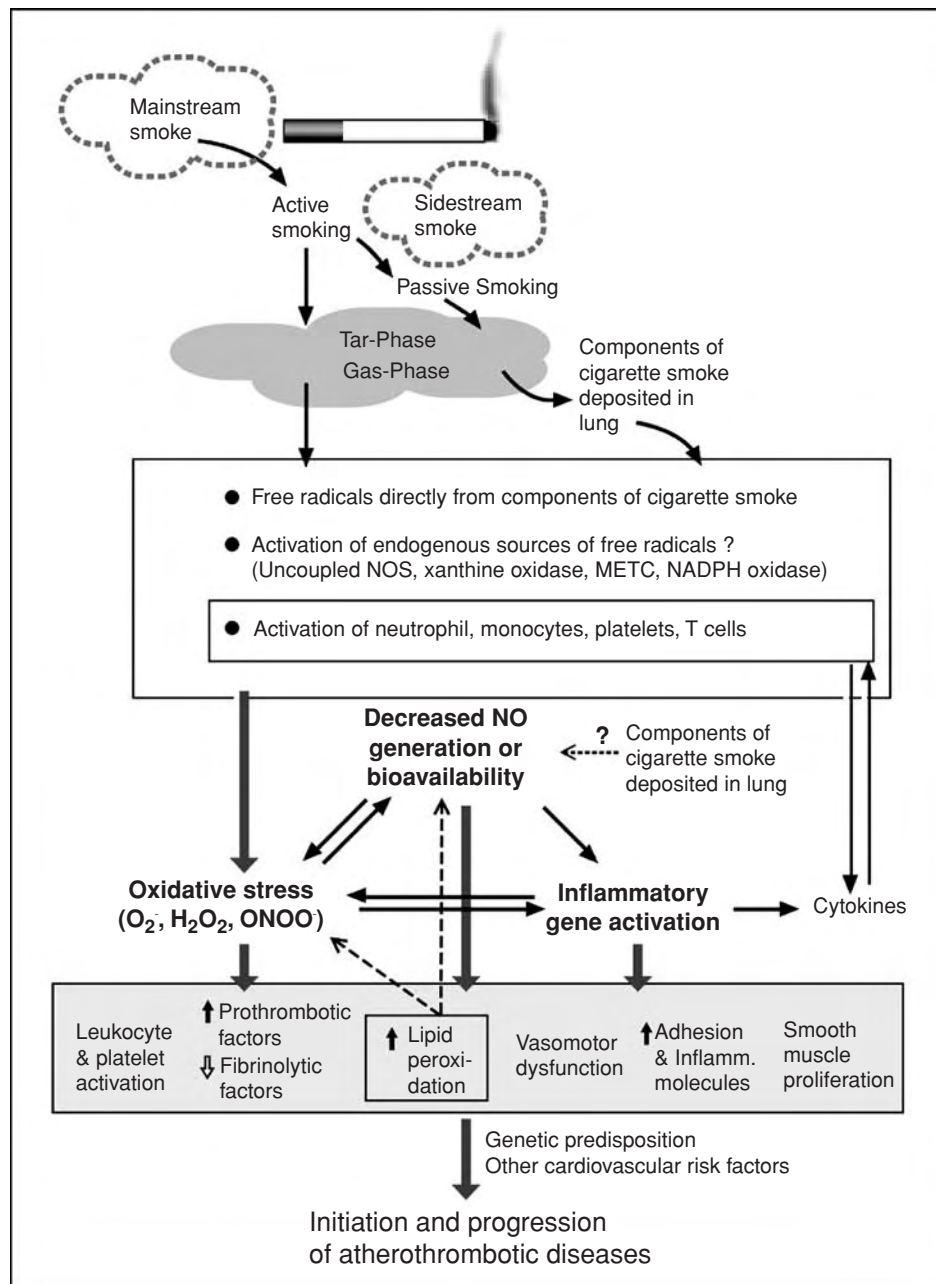

Figure 144.4. Potential pathways and mechanisms for cigarette smoking-mediated cardiovascular dysfunction. The **bold boxes** and **arrows** in the flow diagram represent the probable central mechanisms in the complex pathophysiology of cigarette smoking-mediated atherothrombotic disease. NOS, nitric oxide synthase; METC, mitochondrial electron transport chain; NADPH, nicotinamide adenine dinucleotide phosphate reduced form;  $O_2^{\cdot-}$ , superoxide;  $H_2O_2$ , hydrogen peroxide;  $ONOO^-$ , peroxynitrite. (Reproduced with permission from Ambrose JA, Barua RS. The pathophysiology of cigarette smoking and cardiovascular disease: an update. *J Am Coll Cardiol*. 2004;43:1731–1737.)

an increase in both these products (1). In humans, after controlling for multiple risk for atherosclerosis, chronic cigarette smoke exposure was found to be associated with increased levels of multiple inflammatory markers including peripheral leukocytosis, C-reactive protein (CRP), interleukin (IL)-6, and tumor necrosis factor (TNF)- $\alpha$  (1,42–45).

### Procoagulant Effects

Epidemiological studies indicate that cigarette smoking increases the risk of acute coronary events, namely acute MI and sudden death (46). These events are mediated by thrombosis on a ruptured or eroded atherosclerotic plaque. Cigarette

smokers have MI at a relatively young age, although they have fewer cardiac risk factors, and less severe underlying coronary disease on angiography, compared to nonsmokers (47,48). These data suggest that for any given degree of atherosclerosis, smokers are more hypercoagulable than are their nonsmoking counterparts.

The endothelium is a major source of both thrombotic (e.g., tissue factor) and antithrombotic (e.g., tissue factor pathway inhibitor [TFPI]-1) factors, as well as fibrinolytic (tissue-type plasminogen activator [t-PA]) and antifibrinolytic factors (plasminogen activator inhibitor [PAI]-1) (49). Thus, an imbalance in endothelial antithrombotic and fibrinolytic properties may contribute to an acute thrombotic event. In vitro, HUVECs exposed to serum from chronic smokers showed a significantly decreased TFPI-1 level, but no significant difference was found in tissue factor level (49). Atherosclerotic plaques isolated from *ApoE*<sup>-/-</sup> mice exposed to non-filtered research cigarettes showed an increased tissue factor immunoreactivity and an increase in tissue factor activity (50). In smokers, 2 hours after smoking two cigarettes, an increase in circulating tissue factor activity also has been reported in human plasma (51). In vitro, HUVECs exposed to chronic smokers' serum have significant decreases in both basal and substance-P-stimulated t-PA release as well as a significant alteration in the t-PA:PAI-1 molar ratio (49). In vivo, decreased plasma t-PA antigen and activity were observed in smokers in samples obtained from brachial and coronary arteries after pharmacological (substance P or bradykinin) stimulation (1). In addition to its prothrombotic effect on the endothelium, cigarette smoking can further enhance the prothrombotic milieu by affecting platelet activation, circulating fibrinogen levels, red blood cell counts, the hematocrit, blood viscosity, and ongoing inflammatory responses (1).

#### CIGARETTE SMOKE COMPONENTS AND MECHANISM(S) RESPONSIBLE FOR ENDOTHELIAL DYSFUNCTION

Using a standardized automatic smoking machine designed to approximate human smoking behavior, cigarette smoke can be divided into two phases: the tar or particulate phase, and the gas phase. During the tar phase, particulate material is trapped when the smoke stream is passed through the Cambridge glass-fiber filter that retains 99.9% of all particulate material with a size  $>0.1 \mu\text{m}$ . The gases of the gas phase are all materials that pass through the filter. *Mainstream smoke* is the smoke drawn through the tobacco into an active smoker's mouth; it is composed of 8% tar and 92% gaseous components. *Sidestream cigarette smoke* is the smoke emitted from the burning end of a cigarette (1,52).

In 1967, the United States Federal Trade Commission adopted this method to indicate the amount of tar, nicotine, and carbon monoxide (CO) associated with existing brands of cigarettes. These machine-generated values do not reflect the actual amount of tar and nicotine that will be inhaled

by a smoker from any particular cigarette, nor does it indicate the relative amount of tar and nicotine between any two brands. Because no two cigarette smokers smoke cigarettes exactly the same way, how much tar and nicotine an individual gets from a cigarette depends on how an individual smokes it (e.g., larger or more frequent puffs taken by a smoker of a low-tar/nicotine brand cigarette may deliver as much tar and nicotine as those by smoker of a high-tar/nicotine brand cigarette). Many cigarettes also have ventilation holes. Exposure to the harmful constituents in cigarette smoke substantially increases when the fingers holding the cigarette block these holes (52,53).

Cigarette smoke contains over 4,000 identified and over 100,000 unidentified components. About 500 of them have been identified in the gas phase (1,52,53). A few components, such as CO, nicotine, and some of the polycyclic aromatic hydrocarbons (PAHs), have been studied in isolation in relation to atherothrombotic dysfunction of the endothelium.

The effects of cigarette smoke-derived CO are equivocal. Earlier studies in animal models suggested that CO was associated with the induction and development of atherosclerosis. However, more recent epidemiological and animal studies have failed to demonstrate a relationship between CO exposure and EC morphology or the development of atherosclerosis (1,48). On the contrary, Thom and colleagues reported that CO-exposed bovine pulmonary artery ECs release a higher concentration of NO (54). Kourembanas and colleagues reported that CO suppressed the production of ET-1 by ECs (55).

Nicotine, a component of tar, is the only known addictive substance in cigarette smoke, and it is also its most studied component. Nicotine is vaporized from burning tobacco and carried proximally on tar droplets (mass median diameter 0.3 to 0.5  $\mu\text{m}$ ) that are inhaled; nicotine also is probably inhaled in gas-phase materials (56). Nicotine exerts its effect via nicotinic acetylcholine receptors (nAChRs), which are expressed in neuronal as well as non-neuronal cells (e.g., ECs and VSMCs). In neuronal cells, these receptors are thought to be involved in psychoactive action and addictive properties of tobacco. In non-neuronal cells these receptors are suggested to be involved in the regulation of mitosis, differentiation, organization of the cytoskeleton, cell-cell contact, locomotion, and migration (57). Although nicotine's role in the hemodynamic effects of smoking, such as an increase in cardiac output, heart rate, and blood pressure are well accepted, its role in endothelial dysfunction and atherothrombotic modification of the endothelium remains debatable. Lin and colleagues, utilizing en face preparations of rat thoracic aorta, showed that nicotine exposure was associated increased frequency of EC apoptosis, which resulted in enhanced transendothelial leakage of macromolecules including LDL (58). On other hand, Pittilo and colleagues reported that electron microscopic evidence of injuries in aortic endothelium from rats was minor with nicotine as compared to cigarette smoke exposure (6). In cultured ECs, low-dose nicotine ( $<10^{-8}$  M) was found to increase DNA synthesis, mitogenic activity, and endothelial proliferation

(59). In reference to EDV or NO availability, in various models, nicotine exposure alone has been reported to cause no change, a decrease or an increase in these two parameters (1). Similarly, the effect of nicotine on hemostatic factors such as platelets, fibrinogen, t-PA, or PAI-1 appears to be small in the setting of smoking (1). From the current evidence, nicotine alone probably plays only a minor role in direct atherothrombotic modification of the endothelium; however, the addictive property of nicotine is likely to play a major role in perpetuating the exposure to other more detrimental components of cigarette smoke.

PAHs are found in the tar fraction of cigarette smoke. The effects of a few of them, such as benzo(a)pyrene, 7,12 dimethyl benz(a)anthracene 1-methylanthracene, phenanthrene, acenaphthylene, and naphthalene also have been studied. In vitro, HUVECs exposed to 10  $\mu$ M benzo(a)pyrene for 90 minutes demonstrated increased endothelial DNA damage as assayed by single-cell gel electrophoresis (Comet assay) (60). In HCAECs, 1-methylanthracene, phenanthrene, and benzo(a)pyrene exposure caused significant apoptosis by the phospholipase A2/arachidonic acid-dependent pathway (61). In cockerels, weekly injections of benzo(a)pyrene and 7,12 dimethyl benz(a)anthracene caused an increase in atherosclerotic plaque development in the aorta (48). However, contrary data also exist. Vayssier-Taussat and colleagues, comparing tobacco smoke filtrate with benzo(a)pyrene, reported that tobacco smoke filtrate caused expression of the inducible heat shock protein 70 and heme oxygenase-1 in ECs, which produced loss of mitochondrial membrane potential and apoptosis. On the other hand, exposure to benzo(a)pyrene alone evoked neither stress proteins nor mitochondrial membrane potential (62). In isolated rat aorta, acenaphthylene and naphthalene dose-dependently relaxed the phenylephrine-induced contraction of rat aorta, and this vasorelaxation effect was diminished when endothelium was removed, suggesting that the relaxation effect of PAHs was endothelium-dependent. Pretreatment with the NO synthase inhibitor, L-N(G)-nitroarginine methyl ester, and the guanylate cyclase inhibitor, methylene blue, prevented the vasorelaxation induced by PAHs (62,63). These results suggested that the vasorelaxation effect of PAHs was mediated by activation of eNOS.

Cigarette smoke is a rich source of free radicals. The particulate (tar) phase of cigarette smoke contains  $>10^{17}$  free radicals/g, and the gas phase contains  $>10^{15}$  free radicals/puff. The radicals in the tar phase have a longer lifespan (hours to months), whereas the radicals in the gas phase have a shorter lifespan (seconds). In the setting of cigarette smoking, free radicals could arise not only from the gas or tar phase of cigarette smoke, but also, current evidence suggests, from endogenous sources (e.g., activated macrophages, neutrophils, and ECs) via mechanisms that include uncoupled eNOS, xanthine oxidase, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and mitochondrial electron transport chain (see Figures 144.3 and 144.4). A reaction between free radicals such as superoxide and NO not only

decreases NO availability but also generates reactive nitrogen species (peroxynitrite). Peroxynitrite has been shown to oxidize tetrahydrobiopterin, a cofactor of eNOS. With oxidized tetrahydrobiopterin, eNOS becomes uncoupled and produces superoxide anion preferentially over NO, which would further enhance the cellular oxidative stress (1) (Figure 144.3).

Current consensus suggests that free radical-mediated oxidative stress and the loss of the protective effect of NO are pivotal steps in the atherothrombotic modification of the endothelial milieu (Figure 144.4). Many of the abnormalities of the endothelium associated with cigarette smoking, including vasoregulatory dysfunction, and proinflammatory and prothrombotic effects, can largely be explained by the effects of increased oxidative stress and decreased protection from NO. Additionally, in various experimental models, antioxidants or agents that reduce the oxidative stress or increased NO availability have been shown to either improve or reverse the proatherogenic, proinflammatory, and prothrombotic attributes associated with cigarette smoking (1).

Recently, it has been proposed that genetic predisposition also could influence intersubject variability in atherogenesis in individuals exposed to cigarette smoke. Wang and colleagues proposed that certain gene polymorphisms such as *CYP1A1 MSP* (an enzyme present in the lungs that activates smoke carcinogens) or specific *eNOS* intron-4 polymorphisms increased the susceptibility to cigarette smoke exposure-related atherosclerotic diseases including multivessel CAD and MI (1,48). Because the overall prevalence of these genetic variations has not been determined, the importance of genetic variation in the general population in relation to cigarette smoke exposure remains to be established.

#### EFFECT OF ENVIRONMENTAL SMOKE EXPOSURE ON THE ENDOTHELIUM

Environmental tobacco smoke results from the combination of sidestream smoke (85%) and a small fraction of exhaled mainstream smoke (15%) from smokers (1). In 1978, Aronow was the first to highlight the effect of passive smoking on CAD by showing that passive smoke exposure exacerbated angina (8). Imaging of the carotid artery with ultrasound has shown that the intimal and medial thickness (a measure of atheromatous disease) was greater in nonsmokers living with a smoker compared to that of unexposed nonsmokers, even after controlling for diet, physical activity, body mass index, alcohol intake, education, and major cardiovascular risk factors (64). In various animal models, environmental tobacco smoke exposure has been shown either to increase the area of atheromatous plaques or to increase infarct size after ligation of one coronary artery (3). In humans, active and passive smoke exposure caused a similar degree of dysfunction in EDV of the brachial artery and the coronary artery, even though the objective evidence of exposure was significantly different (serum cotinine, a stable metabolite of nicotine or carboxy-hemoglobin level) (16). A similar degree of effect also was

observed in platelet aggregation studies *in vitro* in relation to acute and passive smoke exposure (3). Meta-analyses of existing epidemiological data have suggested that the relative risk for CAD in nonsmokers exposed to environmental tobacco smoke is about 1.3 (i.e., a 30% excess risk) compared with unexposed nonsmokers (3). Interestingly, in a recent paper, Sargent and colleagues reported that a citywide smoking ban in public places over a 6-month period in Helena, Montana, reduced the incidence of acute MI by 60% during that time period (65). All these data highlight the impact of environmental tobacco smoke on atherothrombotic modification of the endothelium.

### **SMOKING, PREGNANCY, AND ENDOTHELIUM: EFFECT ON UTERO-PLACENTAL CIRCULATION**

Cigarette smoking causes well-documented adverse effects on pregnancy and fetal health that include low birth weight, preterm delivery, perinatal morbidity, and placental complications. Even after learning that they are pregnant, 54% of women continue to smoke (66). It is estimated that smoking continues to account for 10% of all fetal mortality (67). Placental and uterine vascular dysfunction, together with thrombotic complications within these vessels, is thought to be responsible for smoking-related complications of pregnancy (68). As discussed earlier, endothelium from the umbilical arteries of babies from mothers who chronically smoked cigarettes during pregnancy showed ultrastructural evidence of endothelial injury. Utilizing Doppler ultrasonography, a significant increase of utero-placental vascular resistances was reported in chronic smokers. A direct correlation was noted between utero-placental vascular resistance and serum cotinine (a stable metabolite of nicotine often used as a surrogate marker for cigarette smoke exposure) levels in the blood from these mothers (68). Castro and colleagues reported that in habitual smokers, acute cigarette exposure significantly decreased the flow of uterine blood to the placenta (69). These observations can partly be explained by the effect of nicotine on utero-placental circulation via nicotinic receptors as well as by the decreased availability of endothelial-derived NO and PGI<sub>2</sub> in the utero-placental circulation of mothers who smoked.

### **POSITION (CHALLENGES) IN BENCH TO BEDSIDE**

Although progress has been made in understanding the effect of cigarette smoking on the endothelium, the nonbinary continuous nature of the endothelium and complex chemical composition (>4,000 known components) of cigarette smoke pose a multitude of investigative and diagnostic challenges. In the *in vitro* studies, challenges are primarily twofold. The first major challenge is to create a dynamic *in vitro* endothelial culture system. It is noteworthy that most *in vitro* studies to date have been carried out in static culture, in which ECs,

once uncoupled from their native tissue microenvironment, undergo phenotypic drift. It is unclear to what extent these findings can be translated to the *in vivo* setting. An important goal, which is not unique to studying the effects of smoking on the endothelium, is to develop novel cell culture systems in which the microenvironment is preserved and/or recapitulated *in vitro*. The second challenge is to develop an appropriate model for cigarette smoke exposure *in vitro*. The majority of *in vitro* data have involved the use of CSE or CSC. However, the concentration of CSE or CSC that simulates actual human cigarette smoke exposure is unclear, because in the circulation, cigarette smoke must first pass through the pulmonary circulation, where certain toxic components may be neutralized (e.g., by antioxidants present in the blood). Some studies have utilized serum from cigarette smokers or have isolated components of cigarette smoke as a vehicle of cigarette smoke exposure *in vitro*. It is unknown whether differences in the model of smoke exposure were responsible for the somewhat contradictory findings among the different *in vitro* models of cigarette smoking (1,6,12–20). In animal models, interspecies heterogeneity of the endothelium and differences in the behavioral pattern of cigarette smoking (habitual smoking versus control smoke exposure) must be considered when translating their relevance to humans.

In humans, various endothelium-derived biomarkers, as well as invasive and noninvasive investigative techniques, are currently being studied as research and diagnostic tools. Noninvasive evaluation of flow-mediated vasodilatory function of the brachial artery by ultrasound has been shown to be a reproducible and relatively easily applicable technique to investigate the vasoregulatory function of the endothelium in smokers. However, given the site-specific heterogeneity of the endothelium, at present, there is not enough available data to assure that this measurement of peripheral vascular endothelial vasoregulatory function would also precisely reflect the vasoregulatory function of other vascular beds, specifically the coronary circulation. New imaging techniques such as high-resolution magnetic resonance imaging and transthoracic Doppler echocardiography may improve our ability to evaluate multiple and clinically relevant vascular beds. However, to investigate the molecular mechanism(s), invasive techniques such as biopsy of the endothelium will be essential. Currently, in a living human, an ethically acceptable way to biopsy the endothelium of a clinically relevant vascular bed is not available. However, endothelium-specific evaluation of skin biopsy from smokers might provide additional insight into the potential molecular mechanism(s) underlying smoking-related endothelial dysfunction.

### **CLINICAL AND THERAPEUTIC IMPLICATIONS**

#### **Strategies to Reduce Oxidative Stress and Increase Nitric Oxide Availability in Smokers**

From existing data, it can be hypothesized that increased oxidative stress and the loss of the protective effect of NO

are the central processes responsible for cigarette smoke exposure-mediated endothelial and cardiovascular dysfunction. Therefore, increasing NO availability and reducing oxidative stress by free radical scavengers would be of potential clinical and therapeutic benefit in cigarette smoking.

As presented earlier, the *in vitro* addition of various antioxidants, including vitamin C and vitamin E, improved endothelial dysfunction, antagonized procoagulant effects, and reduced some inflammatory effects in various smoking models. However, human data from *in vivo* and prospective studies of these agents have failed to demonstrate sustained benefit. Oral vitamin C was shown to improve endothelial vasoregulatory function in healthy smokers. This effect was short-lived in smokers, and did not persist after 8 weeks of continuous vitamin C administration, despite a sustained increase of plasma ascorbate levels (70). Data on vitamin E administration in smokers are contradictory, with some studies reporting improvement in endothelial vasoregulatory function, whereas others have failed to demonstrate benefit (18,71). Similarly, prospective randomized clinical trials such as Gruppo Italiano per lo Studio della Sopravvivenza nell'Infartomiocardico (GISSI), the Heart Outcomes Prevention Evaluation (HOPE), and the Heart Protection Study failed to show any benefit of vitamin C and E in reducing cardiovascular events (72). Currently, therefore, the recommendation of antioxidants such as vitamin C and E as adjunctive therapy for primary as well as secondary prevention in smokers does not appear warranted.

In both *in vitro* and *in vivo* experimental models, several strategies have been shown to increase the NO availability in smokers, such as supplementation of L-arginine (the substrate of NO synthase) or the use of tetrahydrobiopterin, a cofactor of eNOS (1,6,26). However, long-term clinical effects of their use in smokers have not been studied. Another experimental strategy that could be useful in increasing NO bioavailability in smokers who have decreased eNOS expression in their endothelium is the utilization of viral vectors to deliver eNOS genes directly to the affected vasculature. Further research is required to determine their usefulness in the setting of smoking exposure.

### **Therapeutic Strategies for Acute Coronary Syndromes in Cigarette Smokers**

It has been observed that, among cases of MI, smokers have less severe underlying coronary atherosclerosis than do non-smokers. It also has been demonstrated that smokers with MI appear to do better after thrombolysis compared with non-smokers, with a higher percentage experiencing complete clot lysis (25). However, it also has been shown that in smokers with MI, outcomes with coronary angioplasty were equal to or better than those with intravenous thrombolysis (25). Therefore, in smokers presenting with acute MI, coronary angioplasty may be preferable to thrombolysis. Yet, when angioplasty is not immediately available, immediate thrombolysis with an intravenous clot lysing agent may be preferable to more delayed angioplasty. Combined approaches involving clot lysis

and delayed angioplasty also are being tested. Their effect in cigarette smokers is presently unknown.

### **Nonlinear Dose Effect of Cigarette Smoke Exposure**

Cigarette smoke exposure may cause a disproportionately large effect on the endothelium at a relatively small dose. It has been demonstrated that heavy and light active smoking can cause a similar decrease in brachial artery EDV, which paralleled the *in vitro* observations showing equivalent alterations in NO production, eNOS protein expression, and eNOS activity in cultured HUVECs exposed to serum from the same heavy and light smokers (16). Other studies even found that passive smoke exposure is associated with a decrease in EDV, comparable to smokers (16). These observations appear to parallel the cardiovascular risk estimation from the epidemiologic studies. A meta-analysis of large cohort studies showed that in active smokers the risk for ischemic heart disease with five cigarettes per day was not a quarter, but about half that associated with 20 cigarettes per day (3). More importantly, it has been estimated that with environmental smoke exposure, even though the exposure to tobacco smoke was less than 1% of the exposure from smoking 20 cigarettes per day, the excess risk for ischemic heart disease was about 33% of that experienced by a person who smoked 20 cigarettes per day (3).

This nonlinear dosimetry of cigarette smoking raises some interesting questions: Do underlying biochemical and cellular processes become saturated with small doses of toxic components from cigarette smoke, signifying their threshold effect? Do small amounts of cigarette smoke exposure cause changes in the endogenous cellular process that multiplies the original toxin burden (i.e., free radicals) (see Figures 144.3 and 144.4) and leads to this nonlinear effect? Or, does this observation reflect how intensively cigarettes are smoked (i.e., even though the number of cigarettes smoked may be small, with more intensive cigarette smoke inhalation, the actual exposure to tobacco smoke toxins is high) (48)? Regardless of the cause, this nonlinear dosimetry stresses the important notion that there may not be a safe level for cigarette smoke exposure. Thus, strategies to eliminate smoking-related cardiovascular disease must include complete elimination of all types of cigarette smoke exposure.

### **Therapies for Smoking Cessation**

The medications currently approved for smoking cessation are nicotine (patch and gum form) and bupropion.

As discussed earlier, nicotine exposure is the only known addictive substance of cigarettes, and it has been shown to contribute to endothelial dysfunction. Therefore, its therapeutic use raises a valid safety concern. However, nicotine alone is clearly much less hazardous compared with cigarette smoke exposure. It also has been suggested that differences in nicotine delivery between cigarette smoke exposure and pharmacotherapy also make nicotine replacement therapy less harmful. Cigarette smoke exposure delivers nicotine into the arterial

circulation quite rapidly, maximizing the pharmacologic and potentially pathological effects, whereas nicotine from pharmaceutical preparations is absorbed much more slowly, resulting in much lower peak arterial concentrations that are potentially less toxic (48). Indeed, some clinical trials found no evidence that pharmacotherapy increased cardiovascular risk in patients with cardiovascular disease (48). On the contrary, it was reported that the administration of nicotine patches to smokers with known CAD reduced the size of the myocardial perfusion defect during exercise, despite higher nicotine levels while on the patch compared with when smoking alone (48). These findings are consistent with the concept that the combustion products of cigarette smoke are much more deleterious than nicotine alone.

Bupropion is an antidepressant that stimulates dopamine release and curbs the severe withdrawal symptoms of smoking cessation. The appropriate dosing of bupropion is important in the success of smoking cessation. A dose of 300 mg or 150 mg per day over 7 weeks is associated with a significant rate of smoking cessation as compared with 100 mg per day over that time (73).

Recent data from animal as well as human studies with rimonabant, a selective cannabinoid receptor antagonist, showed encouraging results in aiding smoking cessation. Currently, prospective, randomized, multicenter, double-blind, placebo-controlled clinical trials are ongoing with this new drug (74).

Smoking cessation probably is the most important intervention in preventive cardiology. However, this continues to be a major therapeutic challenge. Only approximately 10% of all smokers who try to quit are able to do so. This low rate is in part due to the strong psychological and physiological needs of dependence. However, physicians may also be at fault, because counseling for smoking cessation is often relegated to a low level of priority (26,75).

#### KEY POINTS

- Cigarette smoke exposure has profound and multiple deleterious effects on endothelial biology, leading to cardiac and vascular diseases.
- Smoking decreases vasodilatory function, and increases the inflammatory and thrombotic potential of the endothelium.
- From the current evidence, it appears that free radical-mediated increased oxidative stress with loss of the protective effect of NO is the central step in atherothrombotic modification of the endothelial milieu associated with cigarette smoke exposure.
- However, the precise cellular and molecular mechanism(s) associated with these observations has yet to be clearly defined. Moreover, in prospective clinical

trials, some of the therapeutic strategies in smokers based on the current experimental studies have failed to show a sustained benefit. These negative results may, in part, be explained by the complexity of the endothelium – an organ that is still not completely understood. Furthermore, linear reasoning often is used to investigate or devise therapeutic strategies for endothelial dysfunction, which in itself may be too simplistic.

- The dosimetry of cigarette smoke exposure is nonlinear, which results in a disproportionately large effect with relatively small exposure. Therefore, any level of cigarette smoke exposure appears to be unsafe for health. There is a need for physicians, communities as well as legislative bodies to actively support measures that significantly reduce or eliminate any form of cigarette smoke exposure.

#### Future Goals

- To improve protocols used to isolate and investigate the endothelium
- To integrate the advances in proteomics, such as protein-based chips and molecular imaging techniques, to further strengthen our ability to investigate and diagnose smoking-related endothelial dysfunction

## Disseminated Intravascular Coagulation

---

Marcel Levi

*University of Amsterdam, The Netherlands*

Disseminated intravascular coagulation (DIC) is a syndrome characterized by the systemic activation of coagulation, leading to the intravascular deposition of fibrin in the (micro)vasculature and the simultaneous consumption of coagulation factors and platelets (1). DIC may result in the formation of microvascular thrombi and thereby compromise an adequate blood supply to various organs, which may contribute to organ failure. Simultaneous exhaustion of coagulation factors, protease inhibitors, and platelets, due to ongoing coagulation activation, may lead to serious bleeding. It is important to emphasize that DIC is not a disease in itself but is always secondary to an underlying disorder, for example sepsis, severe trauma, some forms of cancer, or serious immunologic or toxic reactions. A diagnosis of DIC can only be made when one of these underlying disorders is present and is further based on a scoring system, using laboratory results (platelet count, prothrombin time, and fibrin degradation products). Although the pathophysiology of DIC may vary according to the underlying clinical disorder, certain pathogenic mechanisms are common to most if not all cases, including the mediatory role of inflammatory cytokines, the tissue factor–dependent initiation of intravascular coagulation, and the attenuation of natural anticoagulants and fibrinolysis.

The endothelium plays a central role in all major pathways involved in the pathogenesis of DIC. Endothelial cells (ECs) release and respond to myriad proinflammatory mediators, resulting in the induction of tissue factor expression and downregulation of important physiological anticoagulant pathways (2). However, rather than being a unidirectional relationship, the interaction between inflammation and coagulation involves significant cross-talk in which the endothelium appears to play a pivotal role (3). For example, activated coagulation proteases, such as the tissue factor–factor VIIa complex, factor Xa, and thrombin not only promote fibrin deposition, but also bind to protease-activated receptors (PARs) on various cell types, including ECs, thus promoting additional proinflammatory and procoagulant responses. Activated protein C (APC) can bind to the endothelial protein C receptor (EPCR), thereby affecting nuclear factor (NF)- $\kappa$ B nuclear

translocation and subsequently influencing inflammatory gene expression and inhibition of tissue factor expression on ECs (as well as monocytes). The intricate relationship between inflammation and coagulation on the EC surface has major consequences for the pathogenesis of microvascular failure and subsequent multiple organ failure in the setting of DIC.

### INFLAMMATION AND DISSEMINATED INTRAVASCULAR COAGULATION

Acute inflammation, as occurs in response to severe infection or trauma, results in a systemic activation of the coagulation system (1). It was initially thought that this systemic activation of coagulation was a result of direct activation of the contact system by microorganisms or endotoxin. However, during the 1990s, it became apparent that the principal initiator of inflammation-induced thrombin generation is tissue factor, and that the contact system is not involved. Because tissue factor is expressed on cytokine-activated mononuclear cells, which play a pivotal role in the host response to infection, it was hypothesized that microorganism-induced activation of mononuclear cells resulted in tissue factor–mediated activation of coagulation. However, other than in severe meningococemia (4), it has proved difficult to demonstrate *ex vivo* tissue factor expression on the monocytes of septic patients or experimental animals systemically exposed to microorganisms.

It has become apparent that cytokines mediate many of the responses triggered by severe inflammation, and cells other than circulating mononuclear cells may thereby play an important role (2). Evidence has accumulated to suggest that more complex mechanisms might be involved in the relationship between inflammation and the activation of coagulation (5). ECs respond to the cytokines expressed and released by activated leukocytes but can also release cytokines themselves. Furthermore, ECs are able to express adhesion molecules and growth factors that may not only promote the inflammatory response further but also affect the coagulation response. However, it has recently become clear that, in addition to these mostly indirect effects of the endothelium, ECs interfere

directly with the initiation and regulation of fibrin formation and removal during severe infection. In fact, ECs play a prominent role in all three major pathogenetic pathways associated with coagulopathy in sepsis: tissue factor–mediated thrombin generation, dysfunctional anticoagulant pathways, and decreased fibrinolysis. Interestingly, rather than being a one-way direction of inflammation leading to coagulation, both systems intensely interact, so that coagulation also can importantly modulate inflammatory activity. Binding of coagulation proteases (like thrombin), tissue factor, or anticoagulant proteins (like APC) to specific cell receptors on mononuclear cells or ECs may affect cytokine production or inflammatory cell apoptosis. This complex cross-talk between the two systems is relevant for many disease states associated with DIC, including the systemic inflammatory response syndrome (SIRS).

### INITIATION OF COAGULATION IN DISSEMINATED INTRAVASCULAR COAGULATION

The initiation of coagulation in DIC is primarily mediated by the tissue factor–factor VIIa pathway. Tissue factor is a transmembrane protein that is constitutively expressed on a number of cells throughout the body (6), predominantly in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels and subcutaneous tissue. Tissue factor expressed at the cell surface can interact with factor VII, either in its zymogen or activated form (factor VIIa). Upon complexing in its zymogen form, factor VII is activated, and the tissue factor–factor VIIa complex catalyzes the conversion of factors IX and X (7). Factors IXa and Xa enhance the activation of factor X and prothrombin, respectively. In cells in contact with blood, tissue factor expression is induced by the action of several compounds including cytokines, C-reactive protein, and advanced glycosylated end products (8). Tissue factor expression at the surface of activated mononuclear cells can be induced in vitro by a number of proinflammatory mediators and is also detectable ex vivo in patients with severe sepsis and in experimental models of endotoxemia in humans (4,9). However, evidence is emerging that ECs also play an important role in the generation of tissue factor in DIC. Under in vitro conditions, various cytokines (such as tumor necrosis factor [TNF]- $\alpha$  and interleukin [IL]-1) have been found to induce tissue factor expression in vascular ECs, and various observations support the notion of EC involvement in tissue factor–mediated activation of coagulation during, for example, severe infection (8,10).

### REGULATION OF COAGULATION IN DISSEMINATED INTRAVASCULAR COAGULATION

Thrombin generation is limited by antithrombin (AT), the protein C system, and tissue factor pathway inhibitor (TFPI).

In DIC, all three regulatory systems are defective – primarily as a result of endothelial dysfunction.

AT is the main inhibitor of thrombin and factor Xa. In subjects with DIC, AT levels are very low due to consumption, impaired synthesis, and degradation by elastase from activated neutrophils (11). A reduction in glycosaminoglycan availability at the perturbed endothelial surface (due to the influence of cytokines on its synthesis by ECs) also may lead to reduced AT function, because glycosaminoglycans act as a physiological heparin-like cofactor of AT (12).

The involvement of endothelial dysfunction in the impaired function of the protein C system is even more apparent (13). Under physiological conditions, protein C is activated by thrombin bound to the EC membrane-associated molecule, thrombomodulin. ECs, primarily of large blood vessels, express EPCR, which augments the activation of protein C at the cell surface (14). APC then decelerates the coagulation cascade by inactivating factors Va and VIIIa through proteolytic cleavage. However, in DIC, in addition to the already low levels of protein C (as a result of impaired synthesis and consumption), a major cause of protein C system dysfunction is the downregulation of thrombomodulin at the endothelial surface. Proinflammatory cytokines, such as TNF- $\alpha$  and IL-1, may significantly downregulate the expression of thrombomodulin, as suggested by cell culture experiments (15). These data were corroborated by observations in patients with severe gram-negative septicemia, in whom decreased thrombomodulin and EPCR expression at the EC surface and impaired activation of protein C were seen (16).

A third inhibitory mechanism of thrombin generation involves tissue TFPI, which exists in several pools – either EC-associated or lipoprotein-bound in plasma. This molecule inhibits the tissue factor–factor VIIa complex by forming a quaternary complex in which factor Xa is the fourth component. Clinical studies in patients with DIC have not provided clues as to its importance because, in the majority of patients, the levels of tissue TFPI are not diminished compared with normals. The relevance of TFPI in DIC is illustrated by the fact that (a) TFPI depletion sensitizes rabbits to DIC induced by tissue factor infusion (17), and (b) TFPI infusion protects against the harmful effects of *Escherichia coli* in primates (18). TFPI not only blocked DIC, but all baboons challenged with lethal doses of *E. coli* showed a marked improvement in vital functions compared with controls and survived the experiment without apparent complications. The beneficial effects of TFPI may be due, in part, to its attenuating effect on IL-6 generation, and to its capacity to bind endotoxin and interfere with its interaction with CD14 (3). A study in healthy human volunteers confirmed the potential of tissue TFPI to block the procoagulant pathway triggered by endotoxin (19).

### FIBRINOLYSIS IN DISSEMINATED INTRAVASCULAR COAGULATION

Inhibition of the fibrinolytic system is another key element in the pathogenesis of fibrin deposition during DIC. Major

fibrinolytic activators and inhibitors are synthesized and stored in ECs. Although the initial response in bacteremia and endotoxemia is an increase in fibrinolytic activation (mediated by the almost immediate release of plasminogen activators), this is only short-lived and is rapidly shut off by a sustained increase in the main inhibitor of fibrinolysis, plasminogen activator inhibitor (PAI)-1 (20). TNF- $\alpha$  and IL-1 increase PAI-1 synthesis or release from ECs and also decrease plasminogen activator synthesis. TNF- $\alpha$  and endotoxin stimulate PAI-1 production in the liver, kidney, lung, and adrenal glands of mice (21). Furthermore, PAI-1-null mice challenged with endotoxin do not develop thrombi in the kidney (22). These experiments demonstrate that fibrinolytic action is required to reduce the extent of intravascular fibrin accumulation.

### CROSS-TALK BETWEEN COAGULATION AND INFLAMMATION

Coagulation activation yields proteases that not only interact with coagulation protein zymogens, but also with specific cell receptors to induce signaling pathways that mediate inflammatory responses. Coagulation proteins, such as factor Xa, factor VIIa, thrombin, and fibrin, can activate ECs, eliciting the synthesis of IL-6 and/or IL-8 (2). The most important mechanisms by which coagulation proteases influence inflammation is by binding to PARs, of which four types (PAR 1–4) have been identified, all belonging to the family of transmembrane domain, G-protein-coupled receptors (23). PARs are localized in the vasculature on ECs, mononuclear cells, platelets, fibroblasts, and smooth muscle cells (23). The exact role of PARs in the pathogenesis of DIC remains to be established. In vivo evidence for a role of coagulation-protease stimulation of inflammation comes from experiments showing that the administration of recombinant factor VIIa to healthy human subjects causes a small but significant three- to fourfold rise in plasma levels of IL-6 and IL-8 (24).

All three physiological anticoagulant pathways are capable of influencing inflammatory activity. This is most prominently shown for the protein C pathway, and is fully dependent on EC function (25). Indeed, APC has been found to inhibit endotoxin-induced production of TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and IL-8 by cultured monocytes/macrophages (26). Further, APC abrogates endotoxin-induced cytokine release and leukocyte activation in rats in vivo (27). Blocking the protein C pathway by a monoclonal antibody in septic baboons exacerbates the inflammatory response, as evidenced by increased levels of proinflammatory cytokines and increased leukocyte infiltration and tissue destruction at histological analysis (28). Conversely, administration of APC ameliorates the inflammatory activation in various models of DIC (29,30). An infusion of APC abrogates inflammatory activity and improves organ function and survival in an experimental *E. coli* sepsis model in baboons (29). Furthermore, in models of DIC in rats, the administration of APC resulted in a significant improvement of organ function, associated with lower levels

of inflammatory cytokines and less leukocyte infiltration (30). Mice with a one-allele targeted disruption of the *protein C* gene (resulting in heterozygous protein C deficiency) have not only a more severe DIC when challenged with endotoxin but also demonstrate significant differences in inflammatory responses, as shown by higher levels of circulating proinflammatory cytokines (31). Finally, septic patients receiving recombinant human APC have lower IL-6 levels than placebo-treated controls (32). It is likely that the effects of APC on inflammation are mediated by the EPCR, which may modulate downstream inflammatory processes (25). Binding of APC to the EPCR was shown to affect gene expression profiles of cells by inhibiting endotoxin-induced calcium fluxes in the cell and by blocking NF- $\kappa$ B nuclear translocation, which is a prerequisite for increases in proinflammatory cytokines and adhesion molecules (33). The EPCR-APC complex itself can translocate from the plasma membrane into the cell nucleus, which may be another mechanism for the modulation of gene expression, although the relative contribution of nuclear translocation and cell surface signaling is unclear at present (34). The role of EPCR in the pathogenesis of DIC is being investigated in ongoing experimental and clinical studies.

### CLINICAL RELEVANCE OF COAGULATION AND INFLAMMATION IN DISSEMINATED INTRAVASCULAR COAGULATION

The relevance of the interaction between coagulation and inflammation in severe DIC is becoming increasingly clear, and this knowledge has indeed been demonstrated to be applicable to improve the clinical management of these patients. Based on the assumption that defective physiological anticoagulant mechanisms play a pivotal role in the pathogenesis of DIC, the restoration of these pathways or the stimulation of these systems by administration of supraphysiological doses of their pivotal components may be a logical approach in the (supportive) treatment of patients. The administration of recombinant human APC has been most successful in that respect. A beneficial effect of recombinant human APC was demonstrated in two randomized controlled trials, a dose-ranging clinical trial in patients with sepsis and a large multicenter efficacy trial (35). Interestingly, the beneficial effect was most distinct in patients who had overt DIC (36). Trials using AT and TFPI were less successful, although confounding factors (such as trial design and concomitant use of anticoagulant treatment) may have influenced the outcome. Also, strategies aimed at the inhibition of tissue factor may hypothetically be effective in suppressing the activation of coagulation in DIC. This approach has been shown to be successful in experimental DIC models but this strategy has not yet been evaluated in clinical trials.

Further unraveling of the intricate relationship between coagulation and inflammation and the pivotal role of ECs in DIC will probably lead to novel potential points of impact for preventive and therapeutic strategies for DIC and other

diseases in which (micro)vascular thrombosis and inflammation are key events.

### KEY POINTS

- DIC is a syndrome characterized by a systemic activation of coagulation, leading to microvascular thrombosis and the simultaneous consumption of coagulation factors and platelets.
- Pathogenetic pathways that play a role in the development of DIC include tissue factor–dependent activation of coagulation, defective physiological anticoagulant pathways (such as the AT system and the protein C system), and impaired fibrinolysis, due to elevated levels of PAI-1. ECs occupy a prominent position in the occurrence of each of these mechanisms.
- Considerable cross-talk occurs between inflammation and coagulation in the pathogenesis of DIC, and also occurs for the major part at the EC surface.

### Future Goals

- To delineate more precisely the role of bidirectional relationship between coagulation and inflammation in DIC in vivo
- To explore the EC as a target to modulate the derangement of inflammation and coagulation leading to DIC

## Thrombotic Microangiopathy

Jeffrey Laurence

*Weill Medical College of Cornell University, New York*

The fundamental lesion in idiopathic thrombotic thrombocytopenic purpura (TTP), sporadic hemolytic-uremic syndrome (HUS), and some forms of familial HUS/TTP is a thrombotic microangiopathy (1–3). Hyaline thrombi, composed predominantly of platelets and accompanied by localized endothelial cell (EC) activation, proliferation, and detachment, are found exclusively in the microvasculature of involved tissues (1). These thrombi subserve the clinical manifestations of both disorders. Initial treatment consists of plasmapheresis and plasma infusions, often requiring over 20 liters of plasma. Failure to institute prompt plasma exchange invariably results in death from renal failure, stroke, myocardial infarction, or other thrombotic events.

Although TTP is recognized classically by the pentad of thrombocytopenia, microangiopathic hemolytic anemia, fluctuating neurological signs, renal abnormalities, and fever, and HUS by a triad of signs – the hemolytic anemia and fever seen in TTP plus prominent renal disease (4) – pathological changes overlap significantly. Sporadic HUS patients often have multiple organ involvement, including dermal, ocular, cardiac, gastrointestinal, and neurological changes, similar to that seen in TTP (1–3). In one study, cerebral microthrombi were found in 13 of 26 HUS patients at autopsy; reciprocally, renal dysfunction occurs in 40% to 80% of TTP cases (3). Only two organs are absolutely or relatively spared in classic TTP/sporadic HUS: The lung is virtually never involved (5), and the liver is an infrequent site of pathology (2).

It is critical – in terms of pathophysiology and selection of appropriate therapeutic interventions – to distinguish between two clinical syndromes commonly labeled HUS. The epidemic type, occurring primarily in children younger than 5 years of age and typically preceded by bloody diarrhea, is linked to the shiga-like verocytotoxins (4). In contrast to classic TTP/sporadic HUS, the pulmonary microvasculature can be a major site of thrombosis in this form of HUS, and also in those disorders with the clinical features of either HUS or TTP, but arising in the setting of malignancy, cancer chemotherapy, and bone marrow or organ transplantation (6). Larger vessels of all tissue lineages also may be involved. There is no clear evidence for benefit of plasma exchange in these forms of HUS

or TTP-like disorders (7,8). In contrast, most cases of sporadic HUS respond, at least initially, to plasma infusions or plasma exchange in a manner identical to idiopathic TTP (3). These distinctions are summarized in Table 146-1.

Renal microangiopathy accompanies both sporadic and epidemic, cancer- and transplant-related forms of HUS, but distinct histological patterns are found in the kidney. In epidemic (shigatoxin-associated) HUS, as in cancer, cancer chemotherapy, and transplant-linked disease, fibrin thrombi predominate, larger vessel thrombosis with cortical necrosis and inflammation is common, and no EC proliferation occurs within involved vessels (9). In sporadic HUS, as in classic idiopathic TTP, platelet thrombi predominate, with EC activation characterized by EC proliferation and expression of activation markers *in vitro* and *in vivo*, including Fas, CD54, and CD62E (10,11); severe intimal proliferation leading to luminal stenosis; and absence of inflammatory changes (5,9). The latter findings, together with EC detachment from affected microvasculature and their appearance in the peripheral blood (12), are consistent with an apoptotic process. Indeed, a high frequency of apoptotic ECs from splenic sinusoidal lumina has been described in classic TTP *in vivo* (10).

Microvascular EC (MVEC) abnormalities seen in idiopathic TTP/sporadic HUS *in vivo* (5,10) parallel findings from our laboratory with an experimental model distinguishing among types of TTP/HUS. Apoptosis could be induced *in vitro* by low levels of plasma (0.1–1%) from idiopathic TTP patients in primary human MVECs of renal, cerebral, cardiac, tonsillar, hepatic, and dermal origin, but not in pulmonary MVECs nor in large vessel ECs, such as those from human umbilical vein (13,14). This reflects the pathology and distribution of platelet thrombi in these disorders. The effects were paralleled by the induction of procoagulant features in ECs susceptible to TTP plasma-mediated apoptosis (13,14), findings that are briefly summarized later. Procoagulant properties are typical of ECs undergoing apoptosis: They become proadhesive for nonactivated platelets (15), a phenomenon enhanced by microparticle release, which is also characteristic of TTP (11).

In contrast, necrosis and inflammation are hallmarks of epidemic, cancer-, and transplant-linked HUS and TTP-like

**Table 146-1: Clinical, Pathologic, and Pathophysiological Distinctions among Thrombotic Microangiopathies**

<i>Disorder</i>	<i>Vessels Involved</i>	<i>Vessel Pathology</i>	<i>Mechanism of EC Injury</i>	<i>Response to Plasma Infusion</i>	<i>ADAMTS133 Deficiency</i>
Idiopathic and some forms of familial TTP; HIV-1-, ticlopidine-, and pregnancy-linked TTP	Microvessels; all except lung; hepatic rare	Platelets > fibrin thrombi; EC activation and proliferation, absence of inflammation; ultrastructural changes consistent with EC apoptosis	Apoptosis of susceptible vascular beds	Yes	Yes (subsets)
Sporadic HUS	Microvessels; all except lung; predominant renal, hepatic rare	Platelets > fibrin thrombi; EC activation and proliferation, absence of inflammation; ultrastructural changes consistent with EC apoptosis	Apoptosis of susceptible vascular beds	Yes	Yes (subsets)
Epidemic HUS (shigatoxin-related)	All microvessels, including lung, also larger vessels	In kidney: fibrin predominant; no EC proliferation; apoptosis, necrosis and inflammation present	Apoptosis, necrosis, and inflammation	No	No
Malignancy, chemotherapy, transplantation	All microvessels, including lung, also larger vessels	Fibrin	Necrosis and inflammation	Rare	No

disorders (5). This is reminiscent of injury by EC toxins or autoantibodies, and is consistent with the necrotic cell death observed following incubation of large-vessel or microvascular ECs with plasma from patients with shigatoxin-related HUS (9,13).

In summary, as illustrated in Table 146-1, two major forms of thrombotic microangiopathy exist: (a) plasma exchange-responsive acquired and familial TTP/sporadic HUS linked to MVEC apoptosis and platelet thrombi, and (b) HUS/TTP-like disease, including epidemic forms of HUS, resistant to plasma therapy and characterized by fibrin thrombi, inflammation, and necrosis of blood vessels of all sizes and tissue lineages.

A recently identified enzymatic abnormality may assist in discriminating between these two forms of thrombotic microangiopathy. In 2001, mutations leading to severe deficiency (<5% of control values) of this enzyme (ADAMTS13 – a disintegrin-like and metalloprotease with thrombospondin type 1 motif – a metalloprotease that cleaves ultra-high molecular weight von Willebrand factor [vWF] multimers) was shown to be the cause of some forms of familial TTP (16). Three years earlier, presence of an IgG autoantibody

to ADAMTS13, with resulting severe decrease in enzymatic activity, was shown to be specific for at least a subset of classic TTP/sporadic HUS cases (17), although the magnitude of that subset is uncertain (18). These changes were not seen in other forms of TTP/HUS, save for those linked to human immunodeficiency virus (HIV)-1 infection and ticlopidine treatment (discussed later), and pregnancy. This suggests that at least a subset of idiopathic TTP/sporadic HUS cases represents an autoimmune disorder. Indeed, for the 10% to 20% of patients who fail initial plasma therapy, and the 40% with disease recurrence, immune suppression with glucocorticoids, vincristine, anti-CD20 monoclonal antibody, or splenectomy may be effective.

The remainder of this chapter reviews evidence that EC injury is a fundamental event in classic TTP and sporadic HUS, along with studies of the prevalence of ADAMTS13 deficiency in TTP and HUS. This work suggests that development of classic TTP/sporadic HUS may require “two hits” on the endothelium: MVEC apoptosis, related to known and unknown agents, and altered activity of vWF cleaving protease(s) such as ADAMTS13 or some other platelet-specific event.

## CLUES TO PATHOPHYSIOLOGY OF THROMBOTIC THROMBOCYTOPENIA PURPURA

### Initiation of Microvascular Endothelial Cell Damage in Thrombotic Thrombocytopenic Purpura

We had hypothesized that MVEC injury is one primary event in classic TTP/sporadic HUS, and that it is induced by plasma factors that initiate a cascade leading to MVEC apoptosis, thereby obviating the inflammatory reactions typical of endemic, cancer-, and transplant-associated forms of thrombopathy. The exact nature of that apoptotic process, and the inducing agents involved, are active areas of investigation.

Large-vessel ECs respond differently than do MVECs to a variety of injuries both *in vitro* and *in vivo*, reflected by differences in EC proliferation, migration, cytokine production, and phenotype (19–21). Substantial evidence suggests EC activation in the absence of inflammation, restricted to the microvasculature, in classic TTP/sporadic HUS. Histopathology reveals increased vacuolization and aggregation of rounded ECs, with mitochondrial swelling (3). These ultrastructural changes are typical of apoptotic cells *in vitro*, indicating that our system for inducing MVEC apoptosis by TTP plasmas *in vitro* mimics at least one prominent characteristic of the disease *in vitro*. But it does not establish cause and effect.

Indeed, studies of typical TTP lesions have been unable to establish whether EC damage precedes the deposition of platelet thrombi within a vessel lumen, or whether the extensive EC activation and proliferation surrounding these thrombi is simply a response to prior platelet aggregation with vascular occlusion. Clues to the importance of initial MVEC damage may come from a study of situations in which the incidence of classic TTP/sporadic HUS is dramatically increased.

### Thrombotic Thrombocytopenic Purpura, Human Immunodeficiency Virus Infection, and Ticlopidine

Agents (biological, chemical, or both) responsible for initiating classic TTP/sporadic HUS, and the MVEC damage associated with it, remain generally unknown, save for two intriguing exceptions. Viruses have long been suspected as inciting agents. For example, TTP and HUS have occurred sporadically in association with human T cell-lymphotropic virus type 1 (22) and cytomegalovirus infections (3). But the clearest pathophysiological clues may derive from analysis of two settings associated with a marked increase in incidence of TTP clinically and pathologically indistinguishable from the idiopathic form: (a) HIV-1 infection, with TTP occurring in 1.4% of a cohort of 1,070 consecutively diagnosed patients with acquired immune deficiency syndrome (AIDS) (23) versus 0.3 per 100,000 in the general population (3); and (b) ticlopidine treatment, with 0.06% of patients taking this thienopyridine ADP receptor antagonist and antiplatelet agent developing TTP within 1.5 to 6 weeks of initiating drug therapy (24). Successful suppression of HIV viremia with highly active antiretroviral therapies has virtually eliminated the associa-

tion of thrombotic microangiopathy with HIV (25). Although ticlopidine is now rarely used clinically, its associated risk for TTP was accelerated by prior EC damage, as may occur during vascular stenting (24). Clopidogrel, a thienopyridine related structurally and functionally to ticlopidine, is a commonly prescribed antiplatelet agent and also has been linked to TTP, although with a much lower incidence compared with ticlopidine (26).

Thrombotic microangiopathies occurring in the setting of active HIV infection or ticlopidine use share three major features with idiopathic TTP and sporadic HUS: (a) they respond clinically to plasma exchange, (b) low levels of patient plasmas induce apoptosis in restricted lineages of MVECs *in vitro* (i.e., sparing pulmonary MVECs) (13,27), and (c) severe deficiency of plasma ADAMTS13 activity has been noted in these forms (17). TTP occurring in the setting of pregnancy also has been linked to ADAMTS13 deficiency, and typically responds to plasma exchange (28), but the occurrence of EC apoptosis has not been assessed *in vitro* or *in vivo*.

The underlying cause of MVEC injury in these clinically and pathologically similar disorders – idiopathic TTP/sporadic HUS, and HIV- and ticlopidine-linked thrombopathies – is important to discern. One potential shared factor is disruption of MVEC interactions with the extracellular matrix (ECM). This leads to EC apoptosis *in vitro* through a variety of mechanisms (27), including altered ECM signaling pathways linked to stress-induced mitogen-activated protein kinases (MAPKs); EC detachment from ECM-supported substrate, a form of apoptosis known as anoikis; and the expression of unligated integrin adhesion molecules. Suppression of ECM proteins linked to EC apoptosis *in vitro* has been described in HIV disease *in vivo* and ticlopidine-exposed ECs *in vitro* (27). Finally, our lab has documented similar effects of ticlopidine and plasmas from idiopathic and ticlopidine-linked TTP patients on MVEC activation, apoptosis, ECM proteins, and induction of MAPK pathways linked to ECM-based signaling (27).

In general, sustained EC activation through phosphorylation of extracellular-signal-regulated protein kinase (ERK)-1/2 is associated with cell survival, whereas prolonged stimulation through p38 MAPK leads to apoptosis. However, the outcome of activation of a particular pathway often depends on the nature of the apoptotic signal. Our lab reported that pharmacological levels of ticlopidine initiated apoptosis in primary human MVECs with size and lineage restrictions identical to that of plasmas from idiopathic and HIV-infected TTP patients. These changes were accompanied by prolonged induction of ERK1/2 and p38 MAPK only in TTP-susceptible MVECs; apoptosis initiated by ticlopidine or plasma from ticlopidine-treated patients who developed TTP was abrogated by inhibitors of these kinases (27).

In an attempt to identify the etiological agent(s) of EC activation and apoptosis in idiopathic TTP patient plasmas, our lab has undertaken genomic and proteomic approaches. Initial clues were derived from a broad search for changes in mRNA expression in dermal and renal versus pulmonary

MVECs following TTP plasma exposure. A preliminary screen using a Hu6800 GeneChip Array (Affymetrix) indicated that pulmonary MVECs had greater basal expression of three genes encoding antiapoptotic proteins for ECs: osteoprotegerin, vascular endothelial growth factor (VEGF), and VEGF receptor 2 (VEGFR2) (29), and one related to a membrane protein protective against complement-mediated EC apoptosis, CD55 (J. Laurence, unpublished data). In addition, expression of the antiapoptotic genes Bcl-xL and Bcl-2 was increased in pulmonary but not dermal MVECs on exposure to TTP plasma (29). Retrovirus-mediated gene transfer confirmed that overexpression of Bcl-2 and Bcl-xL could protect dermal MVECs against TTP plasma-mediated damage (30). In addition, our group and others have shown that interleukin (IL)-1 and tumor necrosis factor (TNF)- $\alpha$ , cytokines linked to MVEC apoptosis, ECM changes, and activation of p38 MAPK are elevated in idiopathic TTP/sporadic HUS plasmas (11,31). Although the concentrations of IL-1 and TNF- $\alpha$  found in those plasmas are much lower than are required to induce MVEC apoptosis *in vitro*, they could synergize with each other and with additional TNF superfamily members, such as TNF-related apoptosis-inducing ligand (TRAIL), also upregulated in TTP (28,29), to initiate apoptosis. In association with the Proteomics Program at Cornell-Ithaca we are utilizing matrix-assisted laser desorption ionization-time of flight (MALDI-TOF/TOF) to identify protein differences between idiopathic TTP and control plasmas, directed by findings from the gene array analyses.

#### **ADAMTS13 Deficiency and Endothelial Cell Damage: the "Two-Hit" Hypothesis**

It has been proposed that *ADAMTS13* polymorphisms might influence the expression of TTP as a phenotype in ticlopidine-treated patients (32). This could also hold true for HIV-1 infection, pregnancy, or other potential inciting agents in classic, plasma exchange-responsive TTP, and might underlie the paradox of why the incidence of TTP in the setting of HIV infection and ticlopidine use, albeit high, is not greater still. Concerns include the relatively low prevalence of severe *ADAMTS13* deficiency in some large series of patients with classic, acquired TTP (18), its lack of predictive value for response to plasma exchange (33), and the lack of a phenotype in common strains of *ADAMTS13*-null mice (34). These issues are addressed next. An excellent overview of the regulation of plasma vWF multimer size is provided in Chapter 102. Here the physiology of *ADAMTS13* is reviewed with respect to TTP.

Apart from serving as a carrier for coagulation factor VIII, vWF mediates the rapid adhesion of platelets to sites of vascular injury. A pool of ultra-large vWF multimers is released from ECs in response to EC activation; these multimers have significantly greater capacity to bind platelets than do smaller vWF units. Once immobilized, the affinity of vWF for the gpIb-IX-V receptor complex on the surface of circulating platelets is further enhanced, leading to tethering of platelets at sites of vascular damage and formation of platelet plugs (35). Normally,

vWF multimers circulate in a globular form; when exposed to increased shear forces, present normally in the microvasculature (predominantly the arterioles, and not venules or capillaries) and in damaged vessels, they unravel into string-like conformations, facilitating their platelet-tethering potential (35).

*ADAMTS13* is a zinc-dependent metalloproteinase produced by hepatic stellate cells and ECs and secreted into the blood as an active enzyme with a plasma concentration of 1  $\mu\text{g/mL}$  and a half-life of 2 to 3 days (35). Although it is unclear how this protein is regulated and localized, it cleaves vWF and its multimers very inefficiently in the absence of shear forces. In their presence, it serves to limit the build-up of platelet thrombi. It was thus logical to postulate that *ADAMTS13* deficiency, acquired via an autoantibody inhibitor, might underlie classic TTP/sporadic HUS and, indeed, initial reports found an absolute association between deficiency of this enzyme and idiopathic, HIV-, and ticlopidine-linked TTP/HUS (36). Severe decreases in *ADAMTS13* activity were not found in other forms of HUS or TTP-like disorders (36).

However, subsequent reports showed a much lower incidence of severe enzyme deficiency, regardless of the presence of anti-*ADAMTS13* autoantibody. In one large survey, severe deficiency of this vWF-cleaving protease (CP) activity was found in only 16 of 48 (33%) patients with idiopathic TTP (18). *ADAMTS13* suppression was not associated with the presence of neutralizing antibodies in the majority of patients (37). It was also recognized that partial deficiency of *ADAMTS13* (activity between 10–49% of normal) occurs in normal pregnancies and myriad disease states, and may itself be a consequence of thrombosis, not its cause. Reductions in *ADAMTS13* arise as a result of increased thrombin-dependent inactivation during the course of a thrombotic event (35).

The lack of phenotype in some *ADAMTS13*-deficient mice is also troubling. Homozygous null C57BL mice lacking all vWF-CP activity do not show microangiopathic hemolytic anemia, thrombocytopenia, or vWF-rich platelet thrombi in the microvasculature, despite the fact that circulating ultra-large vWF multimers are present in plasmas of these mice, as in acute TTP in humans (38). Challenge of the null mice with endotoxin failed to induce disease. Spontaneous thrombocytopenia does occur in a subset of CASA/Rk (a strain with elevated plasma vWF) *ADAMTS13*-null mice, and administration of the endemic HUS toxin, verotoxin-2, did cause an HUS-like syndrome in these animals (34). However, as noted earlier, shigatoxin-linked thrombotic microangiopathy is not associated with *ADAMTS13* deficiency in humans. In addition, several familial disorders cause HUS/TTP without affecting *ADAMTS13*; all relate to mutations in anticomplement factors, the most prominent being factor H and CD46 (39,40). Indeed, incubation of MVECs with plasmas of idiopathic TTP patients, all of whom had *ADAMTS13* deficiency, led to the deposition of the complement components C3 and membrane attack complex, and cell death, which was blocked by anticomplement agents (41). More research is needed to define the role of *ADAMTS13*, as well as other mutations and

polymorphisms that might contribute to a predisposition to development of TTP.

### Procoagulant Phenotype of Endothelial Cells in Thrombotic Thrombocytopenic Purpura

Virtually all properties of normal microvascular endothelium are altered in TTP. ECs synthesize many substances involved in coagulation and fibrinolysis, including vWF, thrombomodulin, tissue-type plasminogen activator (t-PA), plasminogen activator inhibitor, protein S, prostacyclin (PGI<sub>2</sub>), and nitric oxide. Alterations in levels of these substances have been reported in TTP, and correlate with disease activity, although that may simply reflect EC injury (3). Our lab examined three in vitro phenomena related to a potential procoagulant EC phenotype: PGI<sub>2</sub> production, membrane expression of annexin II, and tissue factor production (14).

Tissue factor levels were unchanged in MVEC cultures exposed to TTP plasma. Membrane expression of annexin II was suppressed by exposure of MVECs susceptible to TTP plasma-mediated apoptosis to TTP plasmas, but the consequences of altering EC annexin II binding sites – receptors for plasminogen and t-PA – in vivo are unclear. By translocating annexin II to its external surface, ECs may actively modulate plasmin generation, blocking formation of a fibrin clot. Its relative loss thus could encourage thrombus formation, but fibrin is only a small component of the TTP clot. Basal levels of PGI<sub>2</sub> (assessed by measuring its stable metabolite, 6-keto-prostaglandin F1 $\alpha$ ) were significantly lower in TTP plasma-exposed dermal versus pulmonary MVECs, with very low levels of sodium arachidonate-induced PGI<sub>2</sub> in the former (14). Failure to increase production of PGI<sub>2</sub> by apoptotic ECs may be of pathological importance, because PGI<sub>2</sub> normally suppresses platelet aggregation induced by cytokines, shear stress, and other means. In addition, as suggested earlier, apoptotic ECs are procoagulant, and may shed procoagulant membrane blebs (42).

### DESIGN OF EXPERIMENTAL THERAPEUTICS FOR CLASSIC THROMBOTIC THROMBOCYTOPENIC PURPURA/SPORADIC HEMOLYTIC-UREMIC SYNDROME

Options are limited for the treatment of TTP in patients who do not respond initially to plasma exchange, or who relapse frequently. The production of recombinant ADAMTS13 and demonstration of its efficacy in normalizing vWF-CP activity in vitro in plasmas of patients with TTP secondary to congenital absence of ADAMTS13 (43), in conjunction with methods to suppress autoantibodies to this enzyme, could aid in defining its role and potential therapeutic value in TTP. Defining the interactions among pro- and antiapoptotic factors for MVECs, their regulation by circulating triggers of EC apoptosis, and the involvement of ECM components and their MAPK-related signaling cascades may suggest the trial of novel ECM-directed

treatments and help define the nature of the apoptotic stimuli in TTP/sporadic HUS.

### KEY POINTS

- MVEC injury is a fundamental event in idiopathic as well as HIV- and ticlopidine-associated thrombotic microangiopathies. We postulate that this injury involves MVEC activation and apoptosis related to an as yet unidentified plasma factor(s). Development of clinical disease may require “two hits:” MVEC perturbation and deficiency of vWF-CP activities such as ADAMTS13.
- Idiopathic TTP, sporadic HUS, and TTP linked to HIV and ticlopidine share several features: involvement of all MVEC lineages except for the pulmonary system, sparing larger vessels; development of platelet thrombi with minimal fibrin content; EC lesions lacking necrosis or inflammation; severe deficiency of ADAMTS13 in about half of cases; plasmas capable of inducing apoptosis in MVECs in vitro; and clinical response to plasma exchange.
- Shigatoxin-associated HUS and HUS/TTP-like syndromes occurring in the setting of malignancy, chemotherapy, and bone marrow and organ transplantation have pathological and clinical features distinct from familial, acquired idiopathic TTP/sporadic HUS, and HIV-1 and ticlopidine-linked disease: involvement of vasculature of all sizes and tissues, including the lung; predominant fibrin thrombi; inflamed and necrotic EC lesions; ADAMTS13 plasma levels not severely depressed; failure of patient plasmas to induce MVEC apoptosis in vitro; and atypical clinical response to plasma exchange.

### Future Goals

- To identify apoptosis inducing factor(s) in TTP plasmas
- To define the interactions among ADAMTS13 deficiency, microvascular EC injury, and perhaps genetic polymorphisms in establishing the TTP phenotype

## Heparin-Induced Thrombocytopenia

---

Andreas Greinacher and Theodore E. Warkentin

*Institute of Immunology and Transfusion Medicine, Ernst-Moritz-Arndt-University-Greifswald,  
Germany; McMaster University, Hamilton, Canada*

Heparin-induced thrombocytopenia (HIT) is an immune-mediated adverse drug reaction that results when pathogenic immunoglobulin (Ig)G antibodies are formed that recognize neoepitopes on a “self” protein – platelet factor 4 (PF4) – after PF4 has formed complexes with heparin (1). Multimolecular complexes of heparin, PF4, and IgG form on platelet surfaces (2). Occupancy of the platelet Fc $\gamma$ IIa receptors by the resulting immune complexes induces platelet activation, with concomitant activation of coagulation (3), perhaps via the generation of procoagulant platelet microparticles (MPs). Once triggered, the prothrombotic risk persists for a time, even after stopping heparin. This scheme of pathogenesis is fundamentally unique.

Unlike HIT, other immune-mediated thrombocytopenic disorders are caused by antibodies that recognize one or more platelet surface glycoproteins. The Fc moieties of the platelet-bound antibodies are recognized by Fc receptors of the mononuclear phagocytic system; this results in the clearance (not activation) of the antibody-coated platelets and often produces severe thrombocytopenia and mucocutaneous bleeding. This is also the mechanism of all other (non-HIT) drug-induced immune thrombocytopenias, except that the antibodies bind to a drug (or drug metabolite)/glycoprotein complex.

The clinical importance of HIT derives from its high frequency (3–5%) in certain patient populations, particularly postoperative patients receiving unfractionated heparin (UFH) antithrombotic prophylaxis for 1 to 2 weeks, and because of its paradoxical strong association with thrombosis (odds ratio, 20–40) (1). The frequency of HIT is less with low-molecular-weight heparin (LMWH), compared with UFH. Venous thrombosis predominates, despite HIT being a primary platelet activation disorder. Understanding the pathophysiological basis of venous thrombosis predominance in HIT might help unravel the role that platelets play in contributing to venous thrombosis. This concept has been highlighted recently by a report (4) that venous thrombosis occurs more frequently than expected by chance in patients

with atherosclerosis, thus potentially linking arteriopathy and resulting platelet activation with systemic hypercoagulability.

In addition to their platelet-activating activities, it has been proposed that HIT antibodies induce a procoagulant shift within the endothelial cell (EC) (5). This concept is supported by in vitro evidence that HIT antibodies bind to ECs (2,6) and induce procoagulant changes on microvascular ECs (MVECs) (7). Further, HIT antibodies can activate monocytes (8) and neutrophils (9) and lead to the formation of platelet-monocyte-neutrophil aggregates (9). Thus, pancellular activation could underlie the unusual prothrombotic nature of HIT.

An important unresolved issue is whether the prothrombotic risk of HIT is explained primarily by in vivo platelet activation per se, or whether it results from additional activation of ECs or leukocytes. Table 147-1 lists arguments both pro and con. Our thesis maintains that platelets activated by HIT antibodies or their products (e.g., MPs) are critically important in mediating EC and leukocyte activation in HIT and, in turn, that EC and leukocyte activation is a key determinant of the prothrombotic and proinflammatory clinical phenotype. Thus, although EC and leukocyte alterations are important in the clinical expression of HIT (thrombosis, systemic inflammatory response-like syndrome), these are likely the result of platelet-derived MPs and other mediators produced by activated platelets, and not directly through HIT antibody binding to ECs and leukocytes. As more platelets become activated, more pronounced activation of these other cells occurs. Such a model would be consistent with the well-known association in HIT between presence of platelet-activating IgG antibodies (rather than nonactivating antibodies of IgM and IgA class) and clinical manifestations of disease, including the correlation between the magnitude of platelet count fall and risk of thrombosis. In addition, this model also could account for the unusually severe prothrombotic phenotype of HIT, because pancellular interactions augment the pathogenicity of HIT antibodies beyond mere platelet activation.

**Table 147-1: Evidence For and Against a Major Role for Endothelium in the Pathogenesis of Heparin-Induced Thrombocytopenia**

<i>For</i>	<i>Against</i>
1. Venous thrombosis (which is common in HIT) is not typical for a primary platelet activation disorder.	1. The magnitude of the platelet count fall in HIT correlates well with the risk and severity of thrombotic events.
2. Hyperplastic and proliferating ECs plus immunoglobulin deposition identified in thrombi obtained from patients with HIT.	2. Platelet-activating anti-PF4/heparin IgG antibodies strongly correlate with HIT, but not anti-PF4/heparin IgM and IgA (that presumably would bind to ECs).
3. Acute pain in vessels can be associated with intravenous heparin bolus use in a patient with HIT antibodies.	3. Activation of ECs in vitro by HIT antibodies has been shown for microvascular, not macrovascular, ECs, whereas HIT usually causes macrovascular thrombosis.
4. There is a unique distribution of arterial thrombosis (limb artery occlusion > thrombotic stroke > myocardial infarction) that differs from typical atherothrombosis.	4. Vasculitides with activating anti-EC antibodies usually evinces small/medium-sized vessels (cf. HIT).
5. HIT has higher risk of arterial thrombosis (“white clots”) than do other hypercoagulability states.	5. Renal failure is not a feature of HIT (cf. vasculitides).

## CLINICAL PICTURE

HIT is often called the *white clot syndrome* based on the typical appearance of artery-occluding, platelet-rich thrombi. Early clinicians described these as “pale, soft, salmon-colored clots” that “histologically . . . were comprised mostly of fibrin, platelets and leukocytes; red cells were rare” (1). One immunohistologic study (10) of ischemic tissues obtained from patients with HIT noted hyperplastic ECs either covering, or infiltrating into, hyaline (platelet-containing) thrombi within small arteries; in some lesions, a marked intraluminal hyperplasia of ECs with less hyaline material was seen. Immunoperoxidase staining revealed presence of immunoglobulin deposition within these platelet- and EC-containing microthrombi. Another histopathologic study (11) of HIT thrombosis reported layered (“onion skin”) accumulation of platelets with minimal fibrin content on ECs, without associated ulcerative or arteriosclerotic vessel abnormalities.

It remains uncertain whether “white clots” in HIT are pathologically distinct – reflecting a unique pathogenesis – or whether they represent an extreme degree of hypercoagulability not necessarily unique to HIT. For example, adenocarcinoma-associated disseminated intravascular coagulation (DIC) can mirror HIT in its extreme prothrom-

botic nature (e.g., high risk of bilateral deep vein thrombosis [DVT], pulmonary embolism; coumarin-associated venous gangrene).

Overall, venous thrombosis is more common than arterial thrombosis in HIT (ratio, ~4:1). However, in arteriopathic patient populations (e.g., postcardiac surgery), the ratio is about 1:1. Most thrombotic events are macrovascular, involving large veins or arteries. However, microvascular thrombosis can occur, particularly in association with coumarin therapy (3). The syndrome of venous limb gangrene complicating HIT is associated with warfarin treatment, because the vitamin K antagonist induces a protein C depletion that predisposes to thrombotic occlusion of small venules, causing acral (distal extremity) necrosis, usually in a limb already affected by large vein thrombosis.

Venous thrombosis in HIT most often involves proximal lower limb veins, with about half of these patients evincing symptomatic pulmonary embolism. Rarely, adrenal vein thrombosis (with potential for unilateral or bilateral adrenal hemorrhagic necrosis) or cerebral venous (dural sinus) thrombosis occurs. Arterial thrombosis in HIT most often involves lower limb arteries, such as the distal aortic, aortoiliac, or iliofemoral arteries. Less common arterial thrombi are thrombotic stroke and myocardial infarction, followed by mesenteric artery thrombosis, upper limb artery thrombosis, and renal artery thrombosis. The relative frequency of HIT-associated arterial thrombosis (aortic/iliofemoral > cerebral > myocardial) is the converse of that observed in typical atherothrombosis, arguing at least indirectly that the prothrombotic nature of HIT is special.

Vascular injury resulting from the use of intravascular catheters directly influences risk of thrombosis in HIT. About 10% of HIT patients who have current (or recent use of) central venous catheters develop upper-limb DVT, which invariably occurs in the same limb as the central line (12). Also, femoral artery puncture or catheter use predisposes to arterial thrombosis in patients with HIT.

A minority (about 10–20%) of patients who develop HIT while receiving subcutaneous UFH or LMWH develop skin lesions at the heparin injection sites. These lesions range in appearance from erythematous plaques to frank necrosis (13). The former lesions exhibit “eczema with spongiosis and exocytosis, without microthrombi or signs of vasculitis,” with “mild superficial dermal perivascular infiltrate” sometimes observed (14). In contrast, biopsies from necrotic dermal lesions show “epidermal and dermal necrosis with numerous intravascular thrombi in the superficial dermis, accompanied sometimes by signs of leukocytoclastic vasculitis” (14). Often, the platelet count fall is minimal (<30%) or begins a few days after the heparin is discontinued. We have observed that thrombi of large arteries, rather than of veins, are more likely to occur in patients with HIT who develop skin lesions (particularly, necrosis) at heparin injection sites, particularly when a marked platelet count fall occurs.

The pathophysiology of heparin injection site skin lesions in HIT remains poorly understood. Perhaps the presence

of Fc $\gamma$ IIa receptors within the subset of ECs found in the superficial (but not deep) dermal vascular plexus (15) plays a role. In humans, only platelets and dermal MVECs bear Fc $\gamma$ IIa receptors as their only class of Fc $\gamma$  receptors (15).

Occasionally, patients develop intense limb pain (corresponding to a concurrent or imminent site of DVT), or pain at the catheter infusion site, within minutes of receiving intravenous heparin.

### THE HIT ANTIGEN

HIT-mediated cell activation depends on antibody binding to cells. Thus, we will review the interaction of PF4 with glycosaminoglycans (GAGs), including those found on ECs.

### Structure of Heparin

UFH is a polydisperse mixture of GAGs with molecular weights (MW) ranging from 5 to 40 kDa (mean, 13 kDa, or about 40 saccharide units). It is comprised of alternating D-glucosamine residues linked 1 $\rightarrow$ 4 to either L-iduronic acid or D-glucuronic acid. Its principal repeating unit is the trisulfated disaccharide, (1 $\rightarrow$ 4)-O- $\forall$ -L-iduronic acid-2-sulfate (1 $\rightarrow$ 4)-O- $\forall$ -D-glucosamine-2,6-disulfate (1 $\rightarrow$ ), which represents 75% to 90% of the heparin chain. The remaining 10% to 25% disaccharide units differ in the number and positions of sulfate groups.

Heparin is present naturally in the liver and mast cells. Its biologic function is unknown, but it is not primarily involved in control of hemostasis. In pharmacologic concentrations, the major effect of heparin is the catalysis of antithrombin (AT)-mediated inactivation of certain activated coagulation factors. The binding of heparin to AT is mediated by a well-defined pentasaccharide sequence within heparin with a central  $\forall$ -D-glucosamine-2,3,6-trisulfate unit.

Heparin is the GAG with the highest charge density (SO<sub>3</sub><sup>-</sup>/COO<sup>-</sup> ratio, 2.0–2.5). The high density of negative charge accounts for several limitations of heparin, including osteoporosis (binding to osteoclasts), suboptimal dose-response effect (binding to von Willebrand factor [vWF] and other acute phase reactants), and also risk of HIT (charge interaction with PF4).

### Heparan Sulfate

Heparan sulfate (HS) is widely distributed throughout the vasculature. It is less-sulfated (by about 50%) than heparin, and has a major role in regulating hemostasis. It is found on EC surfaces as a proteoglycan; it consists of a protein core to which sulfated oligosaccharides are attached. Although only a minority of HS molecules have AT-catalyzing properties, most are probably capable of binding PF4, although with a lower affinity than heparin. It is unclear if, in a situation of

intense platelet activation and PF4 release (as in HIT), whether PF4 binds in large quantities to endothelial HS to localize immunoinjury to endothelium. In vitro, the addition of HS inhibits the platelet-activating effects of HIT antibodies in the presence of heparin (16).

### Structure of Platelet Factor 4

PF4 is a member of the CXC subfamily of chemokines (designated CXCL4). It is released from  $\alpha$ -granules of activated platelets and, under physiologic conditions, attaches to the endothelial surface by binding to GAGs; it also binds to specific receptors, CXCR3A and CXCR3B (17). PF4 is a compact homotetrameric globular protein with a subunit MW of 7,780 Da (70 amino acids per each of the four subunits), with net positive charge. The C-terminal  $\alpha$ -helices, which contain four lysine residues each that are involved in binding heparin, are arranged as antiparallel pairs on the surface of each extended  $\beta$ -sheet. These lysine residues are predominantly on one side, resulting in a ring of strong, positive charge that runs perpendicularly across the helices.

PF4 was the first chemokine described to inhibit neovascularization. In addition to its antiangiogenic properties, PF4 inhibits chemotaxis and hematopoiesis. It also interferes with the binding of fibroblast growth factor 2 (FGF2) and vascular endothelial growth factor (VEGF) to their receptors by competing with HS proteoglycans on the cell surface and by impairing the growth factor's ability to form homodimers (18). PF4 also can antagonize epidermal growth factor (EGF)- and VEGF-mediated EC stimulation (19).

A nonallelic variant gene of PF4/CXCL4, PF4<sub>var1</sub>/PF4<sub>alt</sub>, designated CXCL4L1, is expressed in ECs (20,21) and was recently also isolated from human platelets (22). PF4 and PF4<sub>var1</sub> differ in only three amino acids at the C-terminus. However PF4<sub>var1</sub> seems to be more potent in inhibiting chemotaxis of human MVECs toward interleukin (IL)-8/CXCL8 or FGF2 (22). In vivo, PF4<sub>var1</sub> was also more effective than PF4 in inhibiting bFGF-induced angiogenesis in rat corneas (22). However, no information is available whether PF4 and PF4<sub>var1</sub> differ in tertiary structure. It is possible that PF4<sub>var1</sub> interacts differently with ECs than does PF4, because the differences in amino acids reside in the heparin-binding region, with implications for modulating the pathogenesis of HIT.

### Platelet Factor 4-Sulfated Polysaccharide Complexes

PF4 has the highest affinity for heparin among proteins stored within platelet  $\alpha$ -granules. At low concentrations (0.1–1.0 IU/mL) of shorter heparin chains, and high concentrations of PF4, the binding capacity of a PF4 tetramer for heparin is not saturated by one heparin molecule, thus permitting simultaneous binding to more than one heparin chain. If a heparin molecule is longer than 16 monosaccharides, it is able to bind simultaneously to, and thereby bridge, two PF4 tetramers. Thus, at certain concentrations of heparin and PF4, there results the

formation of large, multimolecular PF4/heparin complexes that can be subsequently dissociated by adding very high concentrations of heparin (2,23,24). The ability of a polysaccharide to form complexes with PF4 depends on its degree of sulfation (DS); this occurs in the order: UFH > LMWH > HS > dermatan sulfate > chondroitin-6-sulfate > chondroitin-4-sulfate. In addition to the DS, other structural parameters that influence the affinity of a polysaccharide to PF4 include type of uronic acid and the location of the sulfates on the amino sugar. Although HS interacts with PF4, it does not form the HIT antigen *in vitro*, but rather inhibits its formation with heparin.

### Platelet-Activating Immune Complexes

Heparin binding to PF4 exposes one or more neoepitopes on PF4. The majority of HIT antibodies recognize a non-contiguous conformational epitope on PF4. At least two distinct antigen sites have been identified. Combining the techniques of atomic force microscopy, photon correlation spectroscopy, and quantitative immunoassays performed using three presentations of PF4 (PF4 alone, PF4/heparin, and PF4/heparin/PF4 “sandwiches”), we found evidence that the HIT antigen is formed when at least two PF4 tetramers are brought into close approximation by polysaccharide-induced charge neutralization (25).

HIT antibodies bind to PF4/heparin complexes via their F(ab')<sub>2</sub> domains, with IgG as the predominant immunoglobulin class. Thus, divalent IgG binding to multimolecular PF4/heparin complexes produces large IgG-containing immune complexes. On the platelet surface, the subsequent interaction of the HIT-IgG Fc moieties with the platelet FcγIIa receptors leads to cross-linking of these receptors and, consequently, strong platelet activation. However, by incubating ECs with HIT antibodies, we did not find EC activation (26).

### Platelet Factor 4 Interactions with Low-Molecular-Weight Heparin

HIT antigen generation depends not only on the concentration but also on the chain length of heparin. LMWH has reduced affinity for platelets, ECs, and plasma proteins such as PF4. Accordingly, LMWH is less likely to form multimolecular complexes with PF4 (27), and the complexes formed are smaller (24), possibly explaining the lower frequency of HIT with LMWH.

Whereas homogeneous heparin fragments containing 12 or more saccharide units form multimolecular complexes with PF4 that are recognized by HIT antibodies, fragments containing 10 residues induce antigen formation only weakly, and fragments containing 8 or fewer residues bind weakly (23) or not at all *in vitro* (28). However, we recently showed that the smallest heparin-like molecule used for anticoagulation, the pentasaccharide (fondaparinux), was able to induce anti-PF4/heparin antibodies *in vivo* as frequently as did LMWH (although, interestingly, these antibodies did not recognize

PF4/fondaparinux *in vitro*, although they bound well to PF4/UFH and PF4/LMWH) (29).

### Platelet Factor 4 Interactions with Nonheparin Polysaccharides

Changes in PF4 structure that lead to induction of HIT antibodies *in vivo* can be induced by polyanions other than heparin, such as pentosan polysulfate, hypersulfated chondroitin sulfate, and PI-88 (an antiangiogenic agent) (16,27). Cross-reactivity of HIT antibodies for these PF4-polyanion complexes depends on certain features of polyanion structure, particularly the DS and/or MW (16,23). We synthesized structurally well-defined sulfated polysaccharides (23) with a variety of β-1,3-glucan sulfate DS, MW, and sulfation patterns, as well as differences in glycosidic side chains. Increases in DS or in MW (or both), or branching of the polysaccharide (by glycosidic substitution) resulted in increased formation of antigen sites on PF4.

In theory, pathological conditions that increase sulfation of endothelial HS could promote PF4 binding in a way that allows the epitopes relevant for HIT to form even in the absence of pharmacologic heparin. Such a scenario could produce a prothrombotic autoimmune disorder. Indeed, in some individuals, HIT antibodies can be detected even though they had never previously been exposed to heparin.

### HIT ANTIBODIES AND ENDOTHELIAL CELLS

HIT antibodies could lead to EC activation by both direct and indirect mechanism (Figure 147.1) (30).

The first evidence that HIT antibodies might interact directly with ECs was provided in 1987, by Cines and colleagues (5). HIT serum deposited IgG, IgM, IgA, and complement to human umbilical vein ECs (HUVECs) in amounts greater than control. The addition of heparin was not necessary. PF4 most likely bound to endothelial HS, as shown by loss of IgG binding following treatment of HUVECs by heparinase. It has been suggested (6) that binding of HIT antibodies to ECs in these early studies without addition of PF4 may be explained by use of serum (rather than plasma), which contains significant levels of PF4 released from platelets during clotting.

ECs incubated with HIT serum expressed increased tissue factor-associated procoagulant activity. The authors noted that “additional increases in procoagulant activity were expressed when ECs were incubated with patients’ serum in the presence of gel-filtered platelets” (5). This is relevant to work by later investigators who noted the important role of platelets in generating endothelial procoagulant activity by HIT serum/plasma (discussed subsequently). Indeed, expression of CD40 ligand on activated platelets produces certain changes in ECs, including an inflammatory response (31).

In 1994, two studies were reported investigating the interaction of HIT antibodies, PF4, and endothelium (2,6).

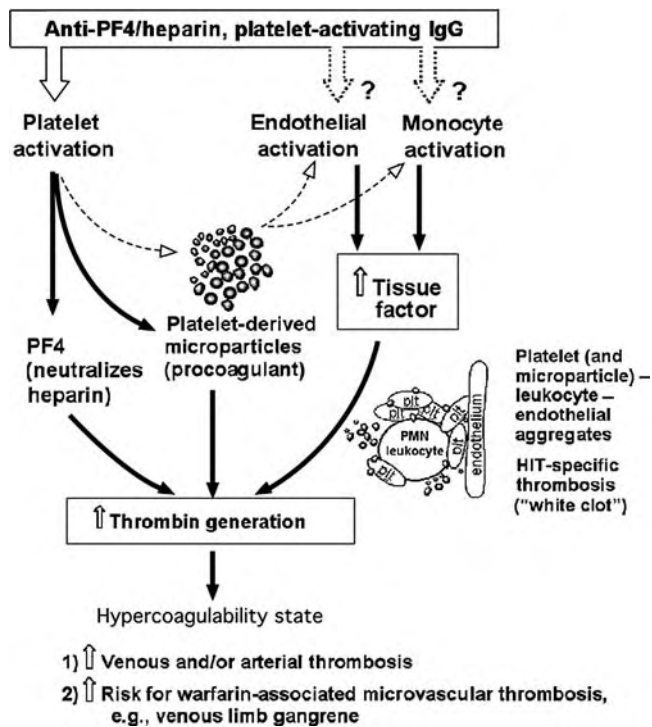

Figure 147.1. Two models for thrombosis in HIT. Activation of platelets (*Plt*) by anti-platelet factor 4 (PF4)/heparin IgG antibodies (HIT antibodies) leads to formation of procoagulant, platelet-derived microparticles, and neutralization of heparin by PF4 released from activated platelets. This leads to marked increase in thrombin (“hypercoagulability state”) characterized by an increased risk of venous and arterial thrombosis, as well as increased risk for coumarin-induced venous limb gangrene. In this model, platelet activation per se is the primary factor explaining prothrombotic risk. In contrast, unique pathogenic mechanisms operative in HIT could explain unusual thromboses, such as arterial “white clots.” For example, HIT antibodies have been shown to activate endothelium and monocytes (leading to cell surface tissue factor expression), although this stimulation may be largely “indirect” through poorly defined mechanisms involving platelet activation and, possibly, the formation of platelet-derived microparticles. Further, aggregates of platelets and leukocytes (monocytes, neutrophils) have been described in HIT. To what extent these cooperative interactions between platelets, platelet-derived microparticles, neutrophils, monocytes, and endothelium lead to arterial (or venous) thrombotic events in HIT, either in large or small vessels, remains unclear. (Reproduced, with modifications, with permission from Warkentin TE. An overview of the heparin-induced thrombocytopenia syndrome. *Semin Thromb Hemost.* 2004;30:273–283.)

Visentin and coworkers (6) showed that IgG and, sometimes, IgM from HIT plasmas bound to HUVECs in a PF4-dependent, but heparin-independent, fashion. Further, antibody binding to HUVECs could be inhibited by excess heparin, but not by an Fc receptor-blocking monoclonal antibody. These investigators hypothesized that in acute HIT, PF4 released from activated platelets binds to HS on ECs, creating the neoepitopes recognized by HIT antibodies and leading to endothelial immunoinjury and thrombosis, for example by complement activation. In such a model, HIT antibodies of

IgM class alone could be pathogenic, despite their inability to activate platelets via FcγIIa receptors.

We used classic adsorption/elution experiments to study the reactivity of HIT antibodies against HUVECs (2). Purified HIT-IgG tested positive in both platelet activation and PF4/heparin immunoassays. This IgG fraction was then adsorbed by HUVECs and, after washing, the antibodies were eluted by low pH. The eluate again tested positive in both activation and antigen assays. Thus, these experiments showed that the HIT antibodies recognize the same epitope(s) on platelets, ECs, and PF4/heparin complexes coated onto a microtiter plate. However, as we added low concentrations of UFH (0.1 IU/mL) to facilitate antibody binding to endothelium, we did not address whether endothelial HS itself permits binding of PF4-reactive HIT antibodies. In contrast to the hypothesis of Visentin and colleagues, in these experiments, no PF4 was added to the HUVEC culture. Because purified IgG fractions were also used in these experiments, this indicates that PF4 is directly expressed by ECs. A likely (though as yet untested) explanation is that the HIT antibodies bound to (EC-derived) PF4<sub>var1</sub>.

Herbert and coworkers (32) found that HIT serum, together with UFH (0.5 IU/mL) and in the presence of washed platelets, activated HUVECs, as shown by increased expression of E-selectin, intracellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and tissue factor. In addition, the activated HUVECs also synthesized and released soluble IL-1β, IL-6, plasminogen activator inhibitor (PAI)-1, and tumor necrosis factor (TNF)-α. EC lysis did not occur. A platelet glycoprotein IIb/IIIa receptor antagonist completely inhibited HUVEC activation under these conditions, as did apyrase (an adenosine diphosphate [ADP]-degrading enzyme) and ATPγS (inhibitor of ADP-induced platelet activation). Adhesion of platelets to HUVECs activated by HIT serum also was inhibited by the glycoprotein IIb/IIIa receptor antagonist. However, these studies did not address why platelets appeared necessary for the (HIT antibody-induced) endothelial activation response, nor whether the platelets were themselves activated under the experimental conditions used.

Blank and colleagues (7) reported that MVECs (derived from human bone marrow) responded differently to HIT antibodies than did HUVECs. Specifically, only MVECs could be directly activated by affinity-purified PF4-reactive HIT antibodies, thus leading to endothelial expression of E-selectin, P-selectin, and VCAM-1 (but not ICAM-1), as well as release of IL-6, vWF, and thrombomodulin (TM). In contrast, HUVECs could be activated by HIT antibodies in the presence of PF4 only if washed platelets or TNF-α had been added. Pretreatment of ECs with heparinase (which degrades endothelial-associated GAG) abolished binding of the HIT antibodies. Additional experiments showed that adhesion of a monocyte-macrophage cell line (U937) to MVECs (from human bone marrow) could be enhanced by prior treatment of the endothelium by HIT antibodies and PF4, an effect abrogated by pretreatment with a

**Table 147-2: Summary of Methodologies Used in Studies of Heparin-Induced Thrombocytopenia Involving Endothelial Cells**

cocktail of antibodies blocking E-selectin, P-selectin, and VCAM-1 (7). This study supports the concept that EC heterogeneity may have implications for the pathogenesis of HIT. However, whereas in these *in vitro* studies HIT antibodies had their most prominent effect on MVECs, macrovascular (not microvascular) thrombosis is the major clinical effect of HIT.

Asmis and colleagues (33) observed that the addition of the murine HIT antibody-mimicking monoclonal antibody, named KKO (with anti-PF4/heparin specificity), to HUVECs in the presence of heparin did not result in endothelial changes unless platelets were added that had been activated by the HIT antibodies. Under these conditions, HUVECs downregulated TM, in line with the procoagulant effects on HUVECs in the presence of platelets (32).

In our own investigations (26), HUVECs were used to study a wide variety of effects of HIT antibodies on macrovascular ECs, including procoagulant (e.g., release of vWF, cleavage of TM, inhibition of protein C generation, tissue factor upregulation), proinflammatory (upregulation of VCAM-1), and cytotoxic (complement-dependent <sup>51</sup>Cr-release) properties. Although HIT antibodies bound to HUVECs, no *in vitro* EC-activating effect was found. However, when platelets or platelet-derived MPs were added, these led to HUVEC activation, as shown by VCAM-1 upregulation. *Ex vivo* investigation found that HIT patients showed elevated serum TM levels, suggesting EC activation might occur *in vivo*. However, TM levels did not differ from those patients with non-HIT thrombocytopenia.

In summary, these studies of HIT antibody–endothelial interaction show important discrepancies (Table 147-2). In particular, there is disagreement as to whether HIT antibodies

directly activate ECs in the absence of platelets or platelet-derived MPs. These studies are difficult to compare, however, because they employed different methods and experimental conditions (e.g., use of serum versus plasma, addition of heparin, etc.).

#### ANIMAL MODELS OF HEPARIN-INDUCED THROMBOCYTOPENIA

Several challenges arise when developing animal models of HIT (34–38). For example, animals do not generate HIT antibodies with heparin treatment. Accordingly, Blank and colleagues immunized mice with affinity-purified anti-PF4/heparin antibodies obtained from patients with HIT (34,35). These mice developed specific anti-idiotypic antibodies against the human HIT antibodies, followed 2 months later by formation of anti–anti-idiotypic antibodies. Unfortunately, although these mice apparently become thrombocytopenic when treated with UFH, they do not develop thrombosis.

Other problems with a murine model of HIT include lack of platelet Fc $\gamma$  receptors and nonreactivity of human HIT antibodies against murine PF4/heparin complexes. Accordingly, Reilly and colleagues (36,37) developed a novel murine model employing double-transgenic Fc $\gamma$ RIIA/hPF4 mice – mice that express human Fc $\gamma$ RIIa on their platelets as well as human PF4. When these mice were treated with the HIT-mimicking murine monoclonal antibody, KKO, that recognizes human PF4/heparin, and then given heparin, the mice developed severe thrombocytopenia and fibrin-rich thrombi in multiple organs, including the pulmonary vasculature. Thus, several salient features of human clinical HIT were recapitulated in

this model. Interestingly, mice transgenic only for human PF4 developed neither thrombocytopenia nor thrombosis when treated with the HIT-mimicking monoclonal antibody. This is compatible with our concept that, in HIT, ECs are activated *indirectly* via mediators released from activated platelets.

Platelets obtained from nonhuman primates (*Macaca mulatta*; the Rhesus monkey) can be activated by HIT serum, suggesting that a primate animal model for HIT might be feasible (38).

### ENDOTHELIAL HETEROGENEITY

The unusually high rate of thrombosis in HIT hints toward involvement of ECs. However, the thrombotic complications manifest predominantly in large vessels, where the EC surface area to blood volume ratio is the lowest. Shedding of TM from the EC surface is a specific marker for *in vivo* activation of ECs (39). TM levels are increased in HIT patients, compared with normal controls. However, comparison with non-HIT thrombocytopenic patients shows no major difference in TM levels. Indeed, non-HIT patients have a trend to even higher TM levels, despite absence of clinical thrombosis.

PF4<sub>var1</sub> also may be important to explain the discrepant *in vitro* findings, as well as the different thrombotic manifestations in HIT. Potentially, the amounts of PF4 and PF4<sub>var1</sub> bound to the surface of ECs could differ, depending on the intravascular location of the ECs. Furthermore, inflammatory cytokines may influence PF4 binding and expression on the EC surface. Because platelet granules contain several chemokines (e.g., regulated on activation, normal T-cell expressed and secreted [RANTES]), platelets might be necessary for a change of the activation status of those ECs required for neoepitope expression on PF4.

### MULTIPLE CELLULAR ACTIVATION

Studies by Khairy and colleagues (9) suggest that HIT antibodies induce leukocyte–platelet aggregate formation. The leukocytes are comprised of monocytes and neutrophils, and are activated best together with activated platelets. High plasma myeloperoxidase levels suggest that leukocyte activation could occur *in vivo* in patients with HIT. However, histomorphology studies suggest a marked predominance of platelets and a paucity of leukocytes within the white thrombi of HIT (11).

Basic studies (not involving HIT sera) have shown that procoagulant platelet MPs lead to increased binding of monocytes to HUVECs by upregulating cell adhesion molecules, such as ICAM-1 on HUVECs and CD11a/CD18 on monocytes (40). Platelet MPs themselves, via transcellular lipid metabolism, can effect the activation of adjacent platelets, monocytes, and ECs (41). To what extent such cellular “cross-talk” pathways exist or contribute to thrombotic events in HIT remains unknown.

### KEY POINTS

- Platelets activated by HIT antibodies, or their products (e.g., MPs), are critically important in mediating EC and leukocyte activation in HIT. In turn, EC and leukocyte activation is a key determinant of the prothrombotic and proinflammatory clinical phenotype.
- Platelet activation by HIT antibodies occurs via platelet Fc $\gamma$ IIa receptors; however, ECs (except dermal MVECs) lack Fc $\gamma$  receptors.
- Increasing *in vitro* evidence indicates that pancellular activation (platelets, ECs, monocytes, neutrophils) occurs in HIT.

### Future Goals

- To establish that ECs are activated *in vivo* in patients with HIT
- To determine the mechanisms by which HIT antibodies activate ECs directly or indirectly
- To clarify the role of PF4<sub>var1</sub> for HIT antibody–EC interaction

## Sickle Cell Disease Endothelial Activation and Dysfunction

---

Robert P. Hebbel

*Vascular Biology Center, University of Minnesota, Minneapolis*

Sickle cell anemia is characterized by hemolytic anemia, acute painful episodes that are believed to be caused by vaso-occlusion, and various organ-specific complications (1). Although the fundamental molecular basis for this disease is the inherited presence of the mutant sickle hemoglobin, the pathogenesis of clinical sickle disease is exceedingly complex. The studies described here, both bedside-to-bench and bench-to-bedside, have suggested that the endothelium contributes substantially to the vascular pathobiology of sickle disease and helps govern clinical phenotype (2). Indeed, we regard sickle cell anemia as an “endothelial disease” in which the endothelium is abnormally activated and dysfunctional. It is likely that the vascular pathobiology of this disease is affected by the endothelial cell (EC)’s functions as a space-defining physical barrier, an adhesive surface, a regulator of vascular tone, a balancer of the anticoagulant and procoagulant properties of blood and vessel wall, a participant in the inflammatory response, and a responsive surface that is dynamically alterable.

### THE BEGINNING: FROM BEDSIDE TO BENCH

After the first medical literature report of a patient with sickle disease in 1910 (3), early studies identified the relationship between deoxygenation and cytoplasmic changes and red cell sickling (4), and ultimately the molecular character of the disease as being caused by an abnormal hemoglobin molecule (5). Thereafter, the traditional view of sickle disease explained pathophysiology simply via the sickling phenomenon, a view we now recognize as being highly oversimplified (6). The bedside observation of marked heterogeneity in clinical phenotype, both from person-to-person and from time-to-time for any given patient, stimulated our original interest in the endothelial biology of this disease. Specifically, we were struck by the apparent inability of traditional explanations for sickle disease genesis to explain what was observed at the bedside.

This led us to pose and investigate a series of hypotheses regarding the endothelial biology of this disease (2). The first of these, regarding red cell adhesion to endothelium, began a fundamental shift in the understanding of sickle disease pathobiology.

### Red Blood Cell Adhesion to Endothelium

The seminal endothelial biology experiments (7,8) for sickle disease demonstrated that sickle red blood cell (RBCs), even when oxygenated, are abnormally adhesive to cultured vascular ECs. This has since been verified by using various *in vitro*, *ex vivo*, and *in vivo* systems (2), including the sickle transgenic mouse itself (Table 148-1) (9). Patient-to-patient variability in red cell adhesiveness to EC (using human umbilical vein ECs [HUVECs]) *in vitro* correlates with clinical vaso-occlusive severity (Figure 148.1). Elaborate studies in rodents have indicated that sickle vaso-occlusion probably involves two steps: initiation due to endothelial adhesion of deformable red cells, followed by a propagation phase caused by log-jamming of poorly deformable RBCs (10). Flow chamber and *in vivo* observations indicate that sickle red cell adhesion occurs under low shear stresses characteristic of the postcapillary venule (2). However, endothelial adhesion of red cells increases dramatically as vessel size approaches the limiting diameter (11), so its role in capillaries requires further study. The importance of this phenomenon derives from its ability to slow microvascular transit time, fulfilling the physical-chemical requirement to allow for the delay time between deoxygenation and substantial polymer formation (12).

The mechanisms involved in the abnormal adhesion of sickle red cells to ECs have been identified largely through studies using simplified buffer systems, and relatively little is known about this event in the more physiologic, complex plasma environment. The mechanisms currently supported by the literature are depicted in Figure 148.2. These involve

**Table 148-1: Murine Models of Sickle Cell Disease**

<i>Sickle Mouse</i>	<i>Murine-<math>\alpha</math> Globin</i>	<i>Murine-<math>\beta</math> Globin</i>	<i>Trans-Gene</i>	<i>Phenotype</i>
NY1DD	+/+	Del/del	$\alpha^H\beta^S$	Mild sickle state, normal white count, elevated monocyte count, elevated serum amyloid P, low endothelial tissue factor converts to high tissue factor after H/R.
S+S-Antilles	+/+	Del/del	$\alpha^H\beta^S$ and $\alpha^H\beta^{S\text{-Antilles}}$	Moderate sickle state, elevated monocyte count, elevated serum amyloid P, moderate endothelial tissue factor.
BERK	ko/ko	ko/ko	$\alpha^H\beta^S$	Severe sickle state, elevated white count, elevated monocyte count, elevated serum amyloid P, high endothelial tissue factor

Abbreviations: del, deleted; ko, knocked out.

various adhesion molecules on the EC (e.g., CD36,  $\alpha v\beta 3$ , GPIIb, P-selectin, vascular cell adhesion molecule [VCAM]-1), on the red cell (e.g., CD36,  $\alpha 4\beta 1$ , sulfated lipids), and/or involving plasma bridging molecules (e.g., thrombospondin, von Willebrand factor [vWF], fibronectin, fibrinogen). Some

of the identified mechanisms could utilize structures displayed by the quiescent EC, whereas others would be relevant only to activated ECs. Recently, a possible role for multicellular interactions (e.g., leukocyte/EC/RBC) in this phenomenon has received some attention (13). The many mechanisms are discussed in detail elsewhere (2). It seems unlikely that any single "most important" mechanism exists. Rather, mechanisms may differ from patient to patient, or from organ to organ, or time to time for a given patient.

Flow model experiments generally have identified adhesion mechanisms that employ defined ligand-receptor interactions (2) that are high affinity and are most likely determined by on-rate of adhesion events (14). Consequently, it is often assumed that only sickle adhesion employing such high-affinity interactions is of physiological relevance. However, there could be a role for lower-affinity mechanisms that do not occur rapidly but, rather, benefit from a high number of receptors. In fact, the demonstration of a correlation between sickle red cell adhesiveness and clinical severity (Figure 148.1) was probably reflective of a low-affinity adhesion mechanism. It seems probable that sickle red cell adhesion to endothelium in pathobiology involves a variety of affinities (14). It should be noted that virtually everything known about sickle red cell adhesion to endothelium is derived from observation in a two-dimensional, flat universe (i.e., flow chambers or relatively large caliber vessels). The microcirculation, however, includes small vessels of constraining diameter. Adhesion science has not yet been able to evaluate, for example, the presumably critical interplay between adhesiveness and deformability in such a demanding, three-dimensional environment.

### THE ENDOTHELIUM: BEDSIDE, BENCH, AND MOUSE

The apparent relevance of EC activation to sickle red cell adhesion to endothelium in vitro led our group to focus on the endothelium itself.

#### Circulating Endothelial Cells

Seeking to understand the activation state of the endothelium in the living subject, we developed the approach of examining the phenotype of circulating ECs (CECs). We found that the CECs in sickle subjects are abnormally activated (even remote from any acute clinical events), being proadhesive (express-

ing VCAM-1, intercellular adhesion molecule [ICAM]-1,  $\alpha V\beta 3$ , selectins [15]), procoagulant (expressing tissue factor [16]), and oxidatively stressed (expressing heme oxygenase-1 [17]). Notably, these adhesion molecules are directly relevant to leukocyte-EC and/or erythrocyte-EC interactions. These observations are presumably instructive because CEC phenotype would be governed by the same milieu that determines the phenotype of in situ vessel wall endothelium. In support of this hypothesis, we did note a correspondence between the activated phenotype of CECs and vessel wall endothelium in the sickle transgenic mouse (18). Notably, however, the most striking feature was the observation of a marked heterogeneity in vessel wall endothelial phenotype, varying from organ to organ and between small and large vessels (18). We believe that such heterogeneity in endothelial phenotype and biology extends to humans and is highly relevant to understanding sickle disease pathobiology.

Although it has not been proven that the phenotype of CECs corresponds to that of vessel wall endothelium in humans with sickle disease, our studies of endothelial tissue

Figure 148.3. Evidence for endothelial tissue factor expression in sickle disease. (A) Tissue factor–positive endothelium in the lung of a sickle cell anemia patient. (B) A circulating EC staining positive for tissue factor antigen and tissue factor mRNA. (C) Tissue factor–positive vein in lung of a sickle transgenic mouse. A, reproduced with permission from Solovey A, Hebbel RP. *J Lab Clin Med*. 2001;137(6); Cover photo. B, Solovey A, Gui L, Key NS, Hebbel RP. *J Clin Invest*. 1998;101:1899–1904. C, Solovey A, Kollander R, Shet A, et al. *Blood*. 2004;104:840–846. For color reproduction, see Color Plate 148.3.

factor expression are consistent with this notion (Figure 148.3; for color reproduction, see Color Plate 148.3). We observed abnormal tissue factor expression on pulmonary endothelium in a sickle patient who had tissue factor–positive CECs and died of thromboembolism. We found that CECs from sickle patients are abnormally tissue factor positive (16). And we documented that the pulmonary venous endothelium in the sickle transgenic mouse is abnormally tissue factor positive (19).

### Inflammation

The activated CECs in sickle patients are indicative of an abnormal inflammatory state. Other evidence for this includes chronic elevation of leukocyte counts, shortened leukocyte half-life, abnormal activation of granulocytes and monocytes, activation of the coagulation system, and elevations of soluble VCAM-1 and platelet counts (2). Patients also have elevated numbers of microvesicles derived from monocytes and ECs (20), a probable sign of cellular activation. The blood of sickle patients reveals variably but chronically elevated levels of EC perturbants (1). Sickle mice share this inflammatory phenotype with humans (2).

Clinically, leukocytosis is a correlative risk factor for mortality (21) and several major complications of sickle disease. Notably, leukocytosis predicts which babies will subsequently develop a severe clinical course (22). The large hydroxyurea trial showed correlation between subject leukocyte counts and pain crisis rates (23). Administration of granulocytosis-inducing growth factors to sickle patients has precipitated acute vaso-occlusive crises. In acute chest syndrome and acute painful crisis, clinical benefit is derived from corticosteroids. Intriguingly, it has been noted that a recent febrile illness is an independent risk factor for stroke, implicating proximate inflammation in its genesis. Thus, it seems likely that the inflammatory state of sickle disease comprises a vicious cycle, with inflammation causing occlusion leading to further inflammation. The chronic activation state of CECs from patients with sickle cell anemia is consistent with this notion.

Two unique aspects of sickle disease may underlie this chronic inflammatory state.

### Adherent Cells and Sickled Cells

The adhesion of oxygenated sickle red cells to the endothelium triggers an injury response (not seen after normal RBC adhesion) that includes release of peroxidation byproducts, prostacyclin, 15-HETE, and endothelin-1; upregulation of adhesion molecules; inhibition of vasorelaxation; and activation of nuclear factor (NF)- $\kappa$ B (2). It is likely that interaction of sickled (i.e., deoxygenated) sickle red cells with ECs has effects as well. Interestingly, it has been observed that nocturnal blood oxygen saturation correlates inversely with a marker of EC activation, soluble VCAM-1 (24). Sickled red cells stimulate cultured ECs to produce endothelin-1 (25). Thus, it would seem that the relentless irritation of endothelium by red cells in the sickle patient may contribute to the endothelial biology of this disease. Indeed, we specifically posit that this pro-

cess results in long-range endothelial signaling. For example, the pulmonary arterial circulation is flooded with presickled red cells. The resultant “conditioned” blood would proceed to bathe the pulmonary venous endothelium and other critical downstream endothelium, such as in the Circle of Willis.

### Reperfusion Injury

We have proposed that the predominant inflammation-inciting event in sickle cell disease consists of repeated cycles of ischemia and reperfusion (2). This “reperfusion injury” physiology is a well-known pathobiological paradigm, in which events that accompany resolution of an occlusion, during reperfusion, lead to the generation of reactive oxygen species and an intense inflammatory response (26). To test this idea in sickle transgenic mice, we examined animals both at ambient air and after transient exposure to hypoxia. Although this would comprise a modest hypoxic stress for normal animals, for sickle mice it increases the occurrence of sickling and, therefore, risk for vaso-occlusion and ischemia.

In our study examining biochemical footprints of oxidative biology (27), we found evidence for abnormal oxidant generation by sickle mice even at ambient air, and this was exaggerated by hypoxia–reoxygenation (Figure 148.4). In our study using intravital microscopy to evaluate leukocyte–EC interactions in the cremaster circulation *in vivo* (28), we similarly observed abnormal leukocyte adhesion and rolling and emigration, and this was exaggerated for sickle mice by hypoxia–reoxygenation (Figure 148.4). In a third study, we found that sickle mice abnormally express tissue factor on endothelium of pulmonary veins (see Figure 148.3), and that this too was greatly exaggerated in sickle mice after hypoxia–reoxygenation (19). We believe that these observations in sickle mice are relevant to human biology and suggest that reperfusion injury physiology is a part of the vascular pathobiology of sickle disease.

### Vasoregulation and Nitric Oxide Biology

It appears that sickle disease is a state of diminished nitric oxide (NO) bioavailability, although females seem to be protected (29). In sickle disease, a deficiency of NO could result from several processes, including consumption by plasma hemoglobin (30), consumption from excessive superoxide generation due to reperfusion injury or uncoupling of endothelial NO synthase (eNOS) or activation of vessel wall xanthine oxidase, or myeloperoxidase activity from inflammatory cells. Additional roles of arginase or L-arginine availability may be relevant. There may be important regional differences (such as between resistance and conduit vessels) in vasoregulation. In general, data seem to indicate a state of vascular instability, with upregulation of both vasodilatory (possibly mediated by heme oxygenase and carbon monoxide [CO]) and vasoconstricting (possibly mediated by endothelin-1 or peroxides) processes (31). Intriguingly, an apolipoprotein A-1 mimetic has been reported to improve the vasodilatory capacity of arterial rings from sickle mice (32).

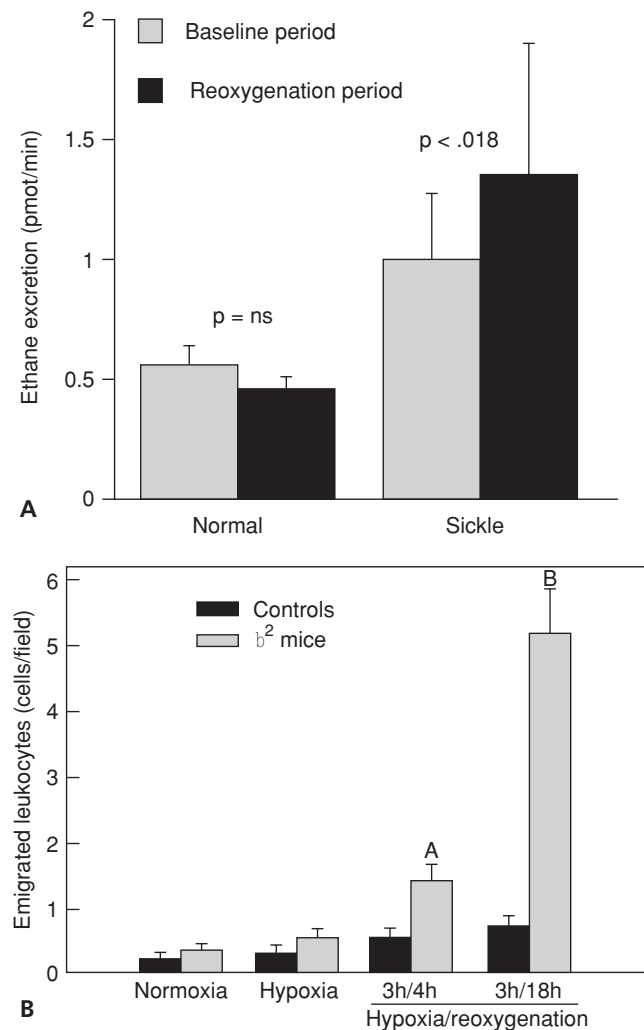

Figure 148.4. Reperfusion injury physiology in sickle transgenic mice. (A) Ethane, a marker of lipid peroxidation, in expired gas is at higher level in sickle animals at ambient air; this is exaggerated after exposure to hypoxia/reoxygenation, compared with normal animals. (Reproduced with permission from Osarogiagbon UR, Choong S, Belcher JD, et al. Reperfusion injury pathophysiology in sickle transgenic mice. *Blood*. 2006;96:314–320.) (B) Similarly, sickle mice show abnormal emigration of inflammatory cells, which is exaggerated after hypoxia/reoxygenation. (Reproduced with permission from Kaul DK, Hebbel RP. Hypoxia/reoxygenation causes inflammatory response in transgenic sickle mice but not in normal mice. *J Clin Invest*. 2000; 106:411–420.)

A deficiency of NO could have a significant impact on the endothelial biology of sickle disease. For example, NO inhibits endothelial expression of VCAM-1, interleukin (IL)-6, and tissue factor (33), and has multiple other salubrious actions.

### Angiogenic Tone

Sickle disease seems to comprise a state of heightened angiogenic “tone.” Plasma levels of vascular endothelial growth factor (VEGF), placental growth factor (PlGF), and erythropoi-

Figure 148.5. Circulating EC apoptosis correlates inversely with plasma VEGF level. (Reproduced with permission from Solovey A, Gui L, Ramakrishnan S, et al. Sickle cell anemia as a possible state of enhanced anti-apoptotic tone: survival effect of vascular endothelial growth factor on circulating and unanchored ECs. *Blood*. 1999;93:3824–3830.)

etin are elevated (2); all are promotive of angiogenesis. Studies of CECs suggest that the balance of pro- versus antiangiogenic factors in sickle blood is tipped toward angiogenesis, because CECs in sickle blood exhibit much less apoptosis than do CECs in normals, and this correlates significantly with VEGF levels (34) (Figure 148.5).

Significantly, some clinical aspects of sickle disease are consistent with heightened angiogenic tone: (a) some children who develop occlusive disease at the Circle of Willis also develop neovascular formation (moyamoya) (35); (b) sickle cell disease entails risk for neovascularizing retinopathy, and the greater risk for this in hemoglobin SC disease versus sickle cell anemia (1) is consistent with our observations of VEGF (proangiogenic) versus thrombospondin (TSP) (antiangiogenic) levels in patient plasmas (VEGF is elevated in both, but thrombospondin is concurrently elevated only in sickle cell anemia subjects) (2); and (c) pulmonary edema is likely part of the acute chest syndrome. This syndrome can result from disparate proximate events that initiate a pathobiology in which the potentially deleterious effects of hypoxia are augmented by NO deficiency and inflammatory mediators (1,2,36). We suspect that the genesis of this syndrome is promoted by pulmonary vascular permeabilization that could derive from multiple factors, including liberation of permeabilizing fatty acids, thrombin, and elevated levels of VEGF (also known as *vascular permeability factor*).

### Coagulation Activation

The clinical spectrum of sickle disease manifestations includes thrombosis. This plays a role in triggering acute stroke, as a result of underlying vessel wall changes at the Circle of Willis (35), and it accompanies pulmonary arterial wall disease (37). Underlying such complications is an abnormal stimulation of the coagulation system in sickle patients, which

tends to be activated at all times, with greater disturbance evident in conjunction with acute vaso-occlusive crisis (38). Evidence for this includes excessive generation of thrombin, alteration of plasma clotting factor levels, activation of platelets and fibrinolysis, and consumption of antithrombotic substances.

This coagulation activation presumably is related to the inflammatory state of sickle disease, reflecting the fact that the EC resides at the interface of the inflammatory and coagulation systems. Such activation implies abnormal expression of tissue factor – the trigger of the clotting cascade. In sickle blood, this is abnormally expressed by monocytes (39) and CECs (16), the latter suggesting that there may be abnormal tissue factor expression by the vessel wall endothelium. Supporting observations in human and mouse were noted earlier. A portion of the microparticles in sickle blood that are derived from ECs are also tissue factor positive (20). Thus, we suspect that abnormal endothelial expression of tissue factor may occur in human sickle disease. A number of biological modifiers elevated in sickle blood (e.g., IL-1, tumor necrosis factor (TNF)- $\alpha$ , endotoxin, and activated monocytes) are able to trigger endothelial expression of tissue factor *in vitro*.

The coagulopathy story in sickle disease is not all tissue factor-based, because the abnormally externalized phosphatidylserine of the sickle red cell membrane plays a substantial role in accelerating the coagulation (40) after it has been triggered by tissue factor.

### Chronic Vasculopathy

Sickle disease includes a component of chronic vasculopathy, with similar changes noted in multiple organs. Correspondingly, these organs show clinical disease: stroke, pulmonary hypertension, fetal growth retardation and mortality, autosplenectomy, priapism, and renal failure (1,2). Most thoroughly described is disease of large/medium vessels at the Circle of Willis, which tend to develop intimal hyperplasia, proliferative changes, and disruption of the internal elastic lamina (2,35). Small vessel disease also occurs in the sickle brain (35).

It is notable that this large-vessel vasculopathy shares a nonrandomness of location (albeit in a different distribution) and similar key pathological changes to atherosclerotic disease. However, the sickle lesions are not described as having a fatty streak (sickle patients have low blood lipids). Nonetheless, it is notable that inflammation is a key etiologic factor in both sickle disease (1,2) and atherosclerosis (41). We have speculated that the relevant process in sickle vessels is abnormal stimulation of ECs by inflammatory mediators, such as IL-1 $\beta$ , that causes the formation of the same oxidized lipid species implicated as proximate triggers of the early inflammatory process in atherosclerosis (2).

Importantly, it is not known if monocytes and inflammatory changes might be involved in the vasculopathy of sickle disease. In this regard, the current understanding of sickle

vasculopathy is analogous to the level of understanding of atherosclerosis during the 1960s, before the exhaustive use of animal models revealed the primacy of inflammation in atherogenesis (41). In sickle disease, additional factors can contribute, such as chronic hypoxia, effects of adherent blood cells, stimulation by thrombin and platelet release products, antiapoptotic effects of elevated levels of VEGF, diminished NO bioavailability, and perpetual elevation of shear rates. Nonetheless, we believe that chronic inflammation, stemming from reperfusion injury and adverse effects of adherent red cells, is probably the key etiologic factor.

### THERAPEUTIC IMPLICATIONS: FROM BENCH TO BEDSIDE

The laboratory studies of endothelial biology in sickle disease have underpinned our bench-to-bedside program of developing novel therapeutics for this disease.

One approach would be to use anti-inflammatory drugs of sufficient potency to impair endothelial transcriptional control of inflammatory surface molecules. A pilot study using sulfasalazine, a powerful (albeit nonspecific) NF- $\kappa$ B inhibitor, demonstrated the efficacy of this, by monitoring the phenotype of CECs as a surrogate marker for vessel wall endothelium (18). In addition, this drug is demonstrated to offer substantial ameliorative effects on leukocyte-endothelial interactions in the sickle mouse, thereby improving microvascular flow (42). Sulfasalazine, however, was ineffective as an inhibitor of tissue factor expression on CECs.

In studies of endothelial tissue factor expression in the sickle transgenic mouse *in vivo*, we have identified lovastatin as an effective inhibitor (19). Aside from their lipid-lowering effects, statins are anti-inflammatory, improve NO bioavailability, and have beneficial antiproliferative effects (43). Ongoing studies looking for additional effective tissue factor inhibitors in the live mouse have identified several additional small molecules for potential use (R. P. Hebbel, unpublished observations). Bedside pilot studies of some of these approaches are underway or planned.

Other strategies can be envisioned. The demonstrated involvement of reperfusion-injury physiology as an inflammation-inciting event in sickle disease raises the possibility that therapeutics aimed at this process might have benefit; possibilities would include allopurinol, antioxidants, and P-selectin blockers (27,28,42). Anticoagulation intervention might be considered, but this has not been adequately studied in the context of sickle cell disease. The role for red cell adhesion to endothelium in sickle pathobiology has stimulated interest in antiadhesive therapeutics. Given the multiplicity of adhesion mechanisms (2), we believe that to have efficacy, an antiadhesive agent will have to exhibit broad inhibitor activity. For example, nonspecifically antiadhesive “vascular lubricants” (44) are more likely to work than are agents that specifically interfere with a single adhesion mechanism.

## PHENOTYPIC DIVERSITY AND ENDOTHELIAL GENOMICS

Subjects with sickle disease exhibit marked phenotypic diversity, most of which is unexplained (1). We expect that the application of new genomics methods to sickle disease will reveal that genetically determined, person-to-person differences in endothelial biology contribute substantially to this. Using the case of Circle of Willis disease, for example, we expect that participants could include aspects of endothelial biology that help regulate coagulation biology, shear-response genes, NO biology, and inflammation signaling (among others). Preliminary data consistent with this concept have been presented using global gene expression profiling of ECs (45), whole-genome single nucleotide polymorphism (SNP) analysis (46), and quantitative trait loci (QTL) identification (47).

### KEY POINTS

- Sickle cell anemia is an “endothelial disease” with EC activation.
- All aspects of endothelial function are relevant.
- Clinical correlates are consistent with laboratory and murine data.
- The abnormal state of inflammation suggests novel targets for therapeutics.
- Therapies targeting endothelial transcriptional control may hold promise.

## The Role of Endothelial Cells in the Antiphospholipid Syndrome

Jacob H. Rand and Xiao-Xuan Wu

Montefiore Medical Center, Bronx, New York

The antiphospholipid antibody syndrome (APS) is an enigmatic autoimmune disorder in which vascular thrombosis and/or recurrent spontaneous pregnancy losses occur in patients who have positive blood tests for antibodies that recognize phospholipid-binding proteins, predominantly  $\beta_2$ -glycoprotein I ( $\beta_2$ GPI). The clinical tests that are currently available to detect the presence of APS antibodies are surrogate assays that were empirically derived from the biologic false-positive syphilis test and from unusual coagulation assays. The latter, paradoxically, report the *inhibition* of phospholipid-dependent coagulation reactions (referred to as the lupus anticoagulant [LA] phenomenon [1]). The clinical manifestations of the syndrome include venous and arterial thrombosis and embolism, disseminated large and small vessel thrombosis with accompanying multiorgan ischemia and infarction, stroke, premature coronary artery disease, and recurrent spontaneous pregnancy losses. Although the mechanism(s) of the syndrome have not yet been definitively established, a growing body of evidence supports a role for vascular endothelium in the disease process.

Formal criteria – known as the *Sapporo Investigational Criteria* – have been developed to define the diagnosis of APS (2). These criteria have been updated recently as the Sydney Investigational Criteria (3). These include a clinical history of one or more episodes of vascular thrombosis (involving any site) or history for pregnancy morbidity, together with laboratory evidence for a positive LA test or a medium- or high-titer anticardiolipin (aCL) immunoglobulin (Ig)G and/or IgM antibody measured by a standard assay for  $\beta_2$ GPI-dependent aCL antibodies. The laboratory abnormalities must be persistent – that is, present on two or more occasions, at least 6 weeks apart.

In retrospect, the first serologic evidence for the existence of this disorder had been the description of a “biological false-positive” serological test for syphilis (BFP-syphilis test) in 1952 (4). This laboratory anomaly was associated with systemic lupus erythematosus (SLE) (5) and with an anticoagulant phenomenon (6). Remarkably, it was learned

that this anticoagulant activity was not associated with bleeding manifestations *in vivo*, but rather with thrombosis, embolism (7), and recurrent pregnancy losses (8). A major step toward the recognition of this syndrome was the development, in 1983, of a quantitative test that detected antibodies against the anionic phospholipid, cardiolipin (diphosphatidylglycerol), and the major antigen in the syphilis test reagent (9).

This syndrome was proposed to be a distinct entity, the *anticardiolipin syndrome*, in 1985 (10) and was later renamed the *antiphospholipid antibody syndrome* (11). Additional terms used for the disorder are *Hughes syndrome*, the *autoimmune thrombosis syndrome*, and *the syndrome of the black swan*. APS is considered “primary” in the absence of SLE, and “secondary” in its presence.

### ETIOLOGY

The trigger that incites autoimmunity in this disorder has not yet been established. Because cells undergoing apoptosis (programmed cell death) expose phosphatidylserine on their cytoplasmic membranes (12), it has been suggested that this membrane alteration may trigger an autoimmune response in susceptible patients (13). Consistent with this idea, immunization of mice with apoptotic cells coated with  $\beta_2$ GPI can result in the generation of autoantibodies against  $\beta_2$ GPI, the major antigen recognized by APS antibodies (13). It also has been proposed that these autoantibodies arise in response to microbial infections, particularly cytomegalovirus (CMV), because  $\beta_2$ GPI shares sequence similarities with microbial pathogens (14,15). There have also been case reports of children who developed fulminant APS with thrombosis following varicella infections (16).

Antibodies against anionic phospholipids arise in response to infections such as syphilis and Lyme disease; however, these differ from those present in APS in that the former generally recognize phospholipid epitopes directly, whereas those

Figure 149.1. Structure of human  $\beta$ 2GPI. (A) Ribbon model of  $\beta$ 2GPI based on crystal structure: The protein is composed of an extended chain of five SCR domains having a “fish-hook” appearance. The structure of SCR domain V deviates from the standard fold of the four other domains and forms the putative phospholipid-binding site.  $\beta$ -strands are shown in light gray and helices in dark gray. (B) The structural data suggest a simple membrane-binding mechanism in which the cationic patch of domain V has an affinity for anionic phospholipid. The stretch of Ser 311 to Lys317 forms a hydrophobic loop that inserts into the lipid bilayer and positions Trp316 at the interface region between the acyl chains and the phosphate head groups of the lipids, thereby anchoring the  $\beta$ 2GPI in the membrane. Current data support the hypothesis that APS antibodies reactive against  $\beta$ 2GPI mainly recognize epitopes on domains I and II, and that antibody-mediated dimerization of  $\beta$ 2GPI markedly increases the affinity of  $\beta$ 2GPI for phospholipid. (Reproduced with permission from Bouma B, et al. *EMBO J* 1999;18:5166–5174.) For color reproduction, see Color Plate 149.1A.

generated in APS appear to mainly recognize epitopes on phospholipid-binding protein cofactors – primarily  $\beta$ 2GPI. However, exceptions exist to this generalization, because anti- $\beta$ 2GPI antibodies have been detected in some patients with syphilis, leptospirosis, leishmaniasis (17), and Hansen disease (18). The antiphospholipid (aPL) antibodies generated in response to infections are not associated with thrombosis, embolism, or recurrent pregnancy losses. Although it is clear that patients with the syndrome can have IgG, IgM, and IgA antibodies, the significance of isolated IgA aPL antibodies is unclear – anticardiolipin IgA antibodies appear to be associated with clinical manifestations, whereas anti- $\beta$ 2GPI IgA antibodies do not (19). There appears to be a genetic component to APS, because familial clustering of raised APS antibody levels (20) and human leukocyte antigen (HLA) linkages (21–25) have been reported. aPL antibodies can arise in response to drugs – chlorpromazine is the major culprit. Although there have been case reports associating drug-induced aPL antibodies with thrombosis (26), a statistically significant association has not to our knowledge been demonstrated.

## ANTIGENIC SPECIFICITIES

### $\beta$ 2-Glycoprotein I

The major antigenic target that is recognized by APS antibodies is  $\beta$ 2GPI – also referred to as *apolipoprotein H*.  $\beta$ 2GPI is a highly glycosylated single-chain plasma protein composed of 326 amino acids with a molecular weight of 50 kDa (27) (Figure 149.1; for color reproduction, see Color Plate 149.1A). The protein is synthesized in the liver and enterocytes (28), and also in endothelial cells (ECs), astrocytes, neurons, and lymphocytes (29).  $\beta$ 2GPI appears to behave as an acute-phase reactant (28).  $\beta$ 2GPI is a member of the complement control protein or short consensus repeat (SCR) superfamily, and it has five SCR domains (also known as “sushi domains”), each with a set of 16 conserved residues and two fully conserved disulfide bonds. The crystal structure of the protein (30,31) indicates that it is shaped like a fishhook, with the end of the hook located at the carboxy-terminus. The structure suggests that the protein inserts into phospholipid membranes via its fifth SCR domain (Figure 149.1), via a “barb” that includes a positively charged cluster at amino acids 282 through 287 (32)

and hydrophobic sequences at 313 through 316 (33), which are present near the carboxy-terminus. Binding of  $\beta$ 2GPI to phospholipid membrane may require annexin A2, and is increased by APS antibodies.

### Proposed Functions of $\beta$ 2GPI

The biological functions of the serum protein  $\beta$ 2GPI are still unknown. Although human  $\beta$ 2GPI deficiency was first described over 30 years ago (34), it is not associated with any known disease or thrombotic tendency. Heterozygosity for  $\beta$ 2GPI deficiency was found in about 6% of 812 Japanese subjects and was not associated with thrombosis (35). One patient with thrombosis and homozygous  $\beta$ 2GPI deficiency was described; however, his homozygous deficient brother and several heterozygous family members were asymptomatic (36).

$\beta$ 2GPI may play a role in the clearance of apoptotic cells by binding to them and thereby providing an “eat me” signal to macrophages (37). However, no evidence for manifestations of deficient apoptotic clearance has yet been described in humans or in animal models.  $\beta$ 2GPI-null mice appear anatomically and histologically normal (38). Impairment of thrombin generation has been detected in their plasmas in vitro. A role for the protein in the reproductive process was suggested by the finding that less than the expected percentage of offspring of the  $\beta$ 2GPI null heterozygotes were homozygous for the disrupted alleles (38).

$\beta$ 2GPI has multiple effects on coagulation, both anticoagulant and procoagulant (39). It exerts anticoagulant activity by inhibiting phospholipid-dependent coagulation reactions such as prothrombinase, tenase, and factor XII in vitro.  $\beta$ 2GPI inhibits factor Xa on activated platelets – an effect that is counteracted by APS antibodies (40) – and also binds factor XI and inhibits its activation (39). The anticoagulant effects of the protein are abolished when it is “nicked” by plasmin at Lys317–Thr318 (41), an effect that has a negative-feedback effect on fibrinolysis, because the nicked form of  $\beta$ 2GPI binds and inactivates plasminogen (39). The procoagulant properties of the protein promotes the inhibition of activated protein C (APC) (39).  $\beta$ 2GPI can also increase coagulation by inhibiting the protein Z–dependent protease inhibitor (PZI), an inhibitor of factor Xa (42); reduced inhibition of factor Xa could lead to increased thrombin generation and greater susceptibility to thrombosis.

Remarkably, aPL antibodies appear to induce a gain-of-function abnormality in  $\beta$ 2GPI by binding to nonfunctional epitopes on the molecule and thereby dimerizing it, increasing its affinity (or more formally, its *avidity*) for phospholipid bilayers. Most APS antibodies appear to recognize domain I of  $\beta$ 2GPI (43,44), and APS antibody binding to domains I and II has been shown to increase the binding of the protein to membrane phospholipid (30). It recently has been demonstrated that IgG antibodies from APS patients that recognize a specific epitope consisting of Gly40–Arg43 are at increased risk for thrombosis (45). The increased binding of IgG– $\beta$ 2GPI complexes has been demonstrated to result from the increased

affinity of the divalent complexes for the phospholipid bilayer (46). Consistent with this concept, the binding of divalent  $\beta$ 2GPI, as opposed to monovalent  $\beta$ 2GPI, also is required for endothelial activation (47).

### $\beta$ 2GPI in Endothelial Cells

There appear to be three binding sites for  $\beta$ 2GPI on the surface of ECs – the phospholipid bilayer itself, annexin A2, and heparan sulfate (HS).  $\beta$ 2GPI has been shown to bind to the apical membranes of ECs via annexin A2 (47), which also serves as a receptor for plasminogen and tissue-type plasminogen activator (t-PA) (48). It has been proposed that  $\beta$ 2GPI binding to the endothelial surface may also occur via attachment to HS, because heparitinase reduces  $\beta$ 2GPI binding (49).

### Antiphospholipid Antibody Syndrome Cofactors Other Than $\beta$ 2GPI

Additional cofactors and antigenic targets of APS antibodies include prothrombin (coagulation factor II), coagulation factor V, protein C, protein S, annexin A5, high-molecular-weight kininogen, and low-molecular-weight kininogen. Interestingly, protein C can be a target of aCL in the presence of cardiolipin and  $\beta$ 2GPI, leading to protein C dysfunction (50). Also, antibodies of some APS patients have been found to recognize heparin and inhibit the formation of antithrombin III–thrombin complexes (51).

The remarkable heterogeneity of aPL antibodies, even within a single patient (52), adds to the difficulties in defining the pathogenic antiphospholipid response(s). Oxidation of phospholipids may be necessary for APS antibody recognition (53). The epitopes for some APS antibodies appear to be adducts of oxidized phospholipid and protein such as  $\beta$ 2GPI (54). Some affinity-purified cardiolipin-binding antibodies in sera from patients with SLE appear to cross-react with oxidized low-density lipoprotein (LDL) (55). Elevated levels of these antibodies have been proposed to be markers for arterial thrombosis (56).

## PATHOGENIC MECHANISMS INVOLVING ENDOTHELIUM

### Overview

APS antibodies have been shown to have several effects on vascular endothelium that convert the endothelial–blood interface from a phenotype that promotes blood fluidity to one that is procoagulant and proadhesive (Table 149-1). The procoagulant phenotype is believed to result from a remarkable array of effects including the increased expression of tissue factor and anionic phospholipids on the apical cell membrane, the reduction of endogenous anticoagulant mechanisms such as annexin A5 shielding and the thrombomodulin/protein C/protein S system, and increased expression of cell surface adhesion molecules that result from the antibody-mediated triggering of signaling pathways.

**Table 149-1: Endothelial Mechanisms Proposed in APS***Procoagulant Effects of APS Antibodies*

---

Induction of tissue factor expression by ECs  
 APS antibody-mediated disruption of the annexin A5 shield  
 Interference with the protein C pathway  
   Inhibition of thrombin formation  
   Decreased activation of protein C by thrombomodulin-thrombin  
   Inhibition of assembly of the protein C complex  
   Inhibition of protein C activity  
   Protecting factors Va and VIIIa from proteolysis by APC  
 Antibodies against EPCR  
 Protein S deficiency  
 Inhibition of antithrombin-III activity via cross-reactivity with heparins  
 Inhibition of fibrinolysis via:  
   Elevation of PAI-1  
   Anti- $\beta$ 2GPI-mediated inhibition of the autoactivation of factor XII

*Proadhesive Effects of APS Antibodies*

---

Induction of receptors for cell adhesion molecules on endothelium  
 Vascular injury  
 Apoptosis  
 Microparticle formation  
 Increased endothelin-1  
 Altered balance of eicosanoid synthesis

---

**Procoagulant Effects of Antiphospholipid Antibody Syndrome Antibodies***Induction of Tissue Factor Expression by Endothelial Cells*

APS antibodies have been shown to increase the expression of tissue factor by cultured ECs (57,58). The upregulation of tissue factor expression in cultured ECs was inhibited by fluvastatin (59). Anti- $\beta$ 2GPI antibodies increased the expression of tissue factor in cultured ECs, a response that was associated with the redistribution of nuclear factor (NF)- $\kappa$ B. However, the time course of activation suggested that NF- $\kappa$ B is an intermediate in the process of EC activation and that its response to anti- $\beta$ 2GPI antibodies is indirect (60). APS antibodies also increase tissue factor expression in monocytes (61).

*Antiphospholipid Antibody Syndrome Antibody-Mediated Disruption of the Annexin A5 Shield*

Annexin A5 has potent anticoagulant activity in vitro, which is based on its high affinity for anionic phospholipids and its capacity to displace coagulation factors from phospholipid surfaces (62). The protein has the shape of a concave disk, with the phospholipid and calcium binding domains present on the convex surface. Annexin A5 clusters on exposed mem-

Figure 149.2. Crystal structure of annexin A5. A high-resolution atomic force image of annexin A5 that has crystallized over a phospholipid bilayer that is composed of 30% phosphatidylserine and 70% phosphatidylcholine. The highly ordered two-dimensional crystal structure is apparent. The crystals assemble via initial trimerization of annexin A5, followed by the progressive trimerization of the trimers on the bilayer.

brane phospholipid (62) and forms two-dimensional crystalline arrays (Figure 149.2) (63,64). The potent anticoagulant properties of the protein are a consequence of this crystallization of annexin A5, which shields the bilayer from availability for coagulation reactions. The affinity of annexin A5 for heparin oligosaccharides suggests that cell surface HS also may play a role in the binding of annexin A5 to the bilayer (65).

Significant data support the concept that annexin A5 has a thrombomodulatory function in the circulation. Annexin A5 is highly expressed by vascular ECs (66). The removal of annexin A5 from the EC surface by treatment with ethylene glycol tetraacetic acid (EGTA) exposes the apical membrane to circulating blood and accelerates the coagulation of plasma exposed to the cells (67). Plasma from SLE patients decreased the binding of annexin A5 to ECs, and this was associated with atherothrombosis (68). Infusion of pregnant mice with polyclonal anti-annexin A5 antibodies resulted in placental infarction and pregnancy wastage, indicating that annexin A5 is necessary for maintenance of placental integrity (69). IgG fractions from APS patients reduced the quantity of annexin A5 on cultured ECs and accelerated the coagulation of plasma exposed to these cells (67). Antibodies against annexin A5 have been observed in the majority of patients with Takayasu arteritis (70).

The APS antibody-mediated reduction of annexin A5 occurs on noncellular phospholipid surfaces via displacement by APS antibodies in the presence of  $\beta$ 2GPI (71), and results in acceleration of phospholipid-dependent coagulation reactions (71,72). This procoagulant property of the antibodies offers a plausible explanation for the LA paradox – that antibodies that can inhibit phospholipids-dependent coagulation reactions are associated with thrombotic, rather than bleeding, manifestations (Figure 149.3; for color reproduction, see Color Plate 149.3). This model was validated through experiments

Figure 149.3. Proposed mechanisms for the LA and the APS antibody procoagulant effect. (A) Anionic phospholipids, predominantly phosphatidylserine (negative charges), serve as potent cofactors for the assembly of three different coagulation complexes: the tissue factor-VIIa complex, the IXa-VIIIa complex, and the Xa-Va complex, and thereby accelerate blood coagulation. The tissue factor complexes yield factors IXa or factor Xa, the IXa complex yields factor Xa, and the Xa formed from both of these reactions is the active enzyme in the prothrombinase complex that yields factor IIa (thrombin), which in turn cleaves fibrinogen to form fibrin. (B) LA effect. aPL antibody- $\beta$ 2GPI complexes can prolong coagulation times, compared with control antibodies, when limiting quantities of anionic phospholipid are available. This occurs via antibody recognition of domains I or II on the  $\beta$ 2GPI, which results in dimers and pentamers of antibody- $\beta$ 2GPI complexes having high affinity for phospholipid via domain V. These high-affinity complexes reduce the access of coagulation factors to anionic phospholipids, thereby resulting in a LA effect in those conditions in which the antibody-cofactor has a sufficiently high affinity. (C) Annexin A5, in the absence of aPL antibodies, serves as a potent anticoagulant by crystallizing over the anionic phospholipid surface, shielding it from availability to bind coagulation proteins. (D) aPL antibody-mediated disruption of annexin A5 shield. aPL- $\beta$ 2GPI complexes with high affinity for phospholipid membranes disrupt the ability of annexin A5 to form ordered crystals on the phospholipid surface. This results in a net increase of the amount of anionic phospholipid available for promoting coagulation reactions. For color reproduction, see Color Plate 149.3.

using atomic force microscopic imaging (Figure 149.4) (73), and these findings were recently translated into clinical type assays with the demonstration that antibodies from APS patients induce resistance to annexin A5 anticoagulant activity (Figure 149.5) (74). APS antibody-mediated interference with the binding of annexin A5 also has been demonstrated using flow cytometry (75).

The available data support the hypothesis that annexin A5 has a thrombomodulatory role in vivo and that interference with its crystallization on the surfaces of vascular ECs may provide a thrombogenic mechanism for APS. This potent anticoagulant protein may play a thromboregulatory role at the vascular-blood interface by shielding anionic phospholipids, which would otherwise serve as efficient cofactors for the assembly of coagulation factor complexes, from participating in coagulation reactions.

#### Interference with Protein C Pathway

The protein C pathway, one of the major endogenous antithrombotic mechanisms, is initiated when thrombin binds to thrombomodulin on ECs (76). This binding modifies the substrate specificity of thrombin; the enzyme loses its procoagulant specificities and cleaves protein C—concentrated near the cell surface by the endothelial protein C receptor (EPCR)—to APC. APC complexes with the free form of protein S and proteolyzes coagulation factors Va and VIIIa. APS antibodies can interfere with the protein C system by: (a) inhibiting the formation of thrombin; (b) decreasing the activation of protein C by the thrombomodulin-thrombin complex; (c) inhibiting the assembly of the protein C complex; (d) inhibiting the activity of protein C, directly or via its cofactor protein S; and (e) binding to factors Va and VIIIa in a manner that protects

Figure 149.4. Atomic force imaging of effect of APS antibodies on annexin A5 crystallization. When aPL mAb and  $\beta$ 2GPI were added to the annexin A5 crystal lattice formed on the bilayer, circular pits appeared (arrows in A and B), indicating disruptions in the crystal lattice. A representative pit is shown at higher magnification in the insets. Moreover, at higher resolution (C, D) more vacancy defects (small round dark holes) in the crystalline lattice are apparent. Amplitude images (A, C) processed with a  $\times 1$  convolution, and height images (B, D) processed by “zero-order flatten.” Magnifications  $10 \mu\text{m} \times 10 \mu\text{m}$  scan (A, B);  $500 \text{ nm} \times 500 \text{ nm}$  (C, D). (Reproduced with permission from Rand JH, et al. *Am J Pathol.* 2003;163:1193–1200.)

Figure 149.5. Resistance to annexin A5 anticoagulant activity in APS. Annexin A5 anticoagulant ratios were performed as described (74) and defined as the coagulation time using normal pooled plasma of phospholipid that was exposed to patient plasma in the presence of annexin A5, divided by the coagulation time in the absence of annexin A5  $\times 100\%$ . The annexin A5 anticoagulant ratios for the antiphospholipid (aPL) syndrome with thromboembolism group (A) was significantly decreased (mean  $\pm$  SD:  $182 \pm 31\%$ ,  $n = (25)$ ) as compared to the aPL antibodies without thrombosis history group (B) ( $210 \pm 35\%$ ,  $n = (26)$ ,  $p < 0.01$ ), the non-aPL thromboembolism group (C) ( $229 \pm 16\%$ ,  $n = (15)$ ,  $p < 0.001$ ), and the normal healthy control group (D) ( $231 \pm 14\%$ ,  $n = (30)$ ,  $p < 0.001$ ). The ratio for the plasmas from the aPL antibodies without thrombosis history group (B) also was reduced significantly compared with the normal healthy control group (D) ( $p < 0.05$ ). There were no significant differences in annexin A5 anticoagulant ratio for the non-aPL thromboembolism group (C) compared with the aPL antibodies without thrombosis history group (B) and the normal healthy control group (D). Error bars are shown for mean  $+ 2SD$  of normal healthy controls (D). (Reproduced with permission from Rand JH, et al. *Blood*. 2004;104:2783–2790.)

them from proteolysis by APC (77). Interestingly, oxidation of phosphatidylethanolamine may enhance the anticoagulant activity of APC; inhibition of this process by APS antibodies may thereby promote thrombin generation (78). It recently has been shown that autoantibodies against EPCR can be detected in APS patients, and that these are an independent risk factor for fetal death (79); however, a correlation with vascular thrombosis has not yet been demonstrated. Patients with APS also frequently have protein S deficiency (80,81).

#### Additional Procoagulant Effects

Antibodies from patients with APS can inhibit tissue factor pathway inhibitor (TFPI) activity, thereby further increasing tissue factor activity and consequently factor Xa generation (82,83). The recent finding that low TFPI levels are a risk factor for deep vein thrombosis (84) supports the idea that antibody-mediated reduction of this protein may be clinically significant.

It has been demonstrated that at least some APS antibodies cross-react with heparin and heparinoid molecules (which are highly polyanionic) and inhibit the acceleration of antithrombin III activity (51). As mentioned earlier, the nicked form of  $\beta 2GPI$  inhibits fibrinolysis, which may be even further impaired in APS via the elevation of plasminogen activator inhibitor (PAI)-1 levels (80). The reason for elevated PAI-1 in APS is unclear, and may be related to the wider prevalence of the 4G/4G polymorphism (85). Additional impairment of fibrinolysis may occur via anti- $\beta 2GPI$ -mediated inhibition of the autoactivation of factor XII (86), and the ensuing reductions of kallikrein and urokinase.

#### Proadhesive Effects of Antiphospholipid Antibody Syndrome Antibodies

The binding of APS antibodies to  $\beta 2GPI$  on the EC surface through annexin A2 is associated with the activation of ECs (47). As mentioned earlier, this activation requires the antibody-mediated dimerization of  $\beta 2GPI$ , because monomeric Fab1 anti- $\beta 2GPI$  fragments inhibit this effect (47). Annexin A2 has other roles, including its serving as a platform on vascular endothelium for promoting fibrinolysis, by binding to both t-PA and plasminogen (87).

The exposure of cultured ECs to APS antibodies promoted monocyte adhesion to the cells (88), an effect mediated by  $\beta 2GPI$  (89). The proadhesive effects of APS antibodies have been shown to be mediated by intercellular cell adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and P-selectin (90). It has been demonstrated that both the APS antibody-mediated enhancement of leukocyte adhesion and increased thrombosis in the pinch injury model are reduced in transgenic ICAM-1-deficient mice, ICAM-1/P-selectin-deficient mice, and in mice infused with anti-VCAM-1 antibodies (91). In a study of VCAM-1 expression in cultured human umbilical vein ECs (HUVECs), IgG fractions from eight of 14 APS patients increased VCAM-1 expression, compared with controls; aspirin abrogated these increases (92). Treatment with APS antibodies also increased the surface expression of E-selectin on HUVECs over 400-fold and induced activation of NF- $\kappa B$  (93). A role for E-selectin was confirmed in experiments in which APS antibodies significantly increased leukocyte adhesion to ECs and increased thrombus size in C57BL/6 J mice, but not in E-selectin-deficient mice (93). The incubation of cultured ECs with APS antibodies also stimulated chemokine synthesis and secretion (94).

The signaling pathways for the increased expression of adhesion molecules have been explored. Activation of ECs by anti- $\beta 2GPI$  occurs via NF- $\kappa B$  activation (60). In one study, incubation of ECs with anti- $\beta 2GPI$  antibodies resulted in a redistribution of NF- $\kappa B$  from the cytoplasm to the nucleus after several hours (60), which contrasted with the more rapid redistribution that took place after tumor necrosis factor (TNF) incubation, suggesting that, although NF- $\kappa B$  is a critical intermediate in the process of EC activation, the response

to anti- $\beta$ 2GPI antibodies is indirect (60). Upstream signaling events were investigated using human microvascular ECs in studies that demonstrated that the signaling cascade in response to human anti- $\beta$ 2GPI IgM mAbs and polyclonal affinity-purified anti- $\beta$ 2GPI IgG was comparable to that activated by lipopolysaccharide (LPS) or interleukin (IL)-1. Because anti- $\beta$ 2GPI antibodies and LPS followed the same time kinetics as IL-1 receptor-activated kinase (IRAK) phosphorylation, it was suggested that the Toll-like receptor (TLR) family might be involved in this signaling (95). It has been hypothesized that cross-linking may occur between microbe-like epitopes on  $\beta$ 2GPI bound to annexin A2 and TLR4, and that this cross-linking may trigger signaling (96).

### Proapoptotic Effects of Antiphospholipid Antibody Syndrome Antibodies

APS antibodies have been reported to recognize and injure cultured vascular ECs (97–99). A subset of APS antibodies that recognize annexin A5 induce apoptosis in ECs (100). It also has been shown that procoagulant endothelial microparticles are generated in APS patients (101).

### Other Effects of Antiphospholipid Antibody Syndrome Antibodies on Endothelium

Plasma levels of endothelin-1, which is thought to play a role in arterial tone, vasospasm, and thrombotic arterial occlusion, were significantly increased in APS patients with arterial thrombosis (102). APS antibodies also may alter the balance of eicosanoid synthesis toward prothrombotic moieties, as indicated by the presence of an increased quantity of thromboxane metabolites in the urine of APS patients compared with controls (103). However, other studies have disputed this (104). APS antibodies may show cross-reactivity against oxidized LDL (53,105), and may thereby be associated with an increased risk of atherosclerosis (106).

## CONCLUSION

In summary, although the pathophysiological mechanisms for thrombosis in APS have not been firmly established, the accumulating evidence suggests a central role for APS antibody-mediated prothrombotic and proadhesive effects on endothelium. The adverse effects of APS antibodies are mediated by their recognition of “cofactor” proteins, primarily  $\beta$ 2GPI. The effects appear to be due to antibody-mediated dimerization of  $\beta$ 2GPI, which increases the affinity of the antibody–antigen complex for the vascular surface and thereby disrupts endogenous anticoagulant mechanisms and stimulates EC activation. The major task that lies ahead is to move the understanding of the disorder from that of a phenomenological syndrome for which the diagnosis is based on a constellation of clinical history and empirically derived surrogate tests, to a disease whose pathophysiology is understood. This will lead to more

accurate mechanistically based tests and, hopefully, to targeted treatments.

## KEY POINTS

- APS is an autoimmune thrombotic condition for which the mechanism has not yet been established.
- Current diagnosis is mainly based on empirically derived surrogate tests – the LA” phenomenon and enzyme-linked immunosorbent assays (ELISAs) for antibodies against proteins that bind anionic phospholipids.
- $\beta$ 2GPI appears to be a biologically significant antigenic target in this condition. Although its precise role is unknown, it appears likely that antibody-mediated dimerization and pentamerization of the protein cause gain-of-function abnormalities that affect vascular endothelium through the inhibition of endogenous antithrombotic mechanisms or the activation of proadhesive and procoagulant pathways.

## Future Goals

- To establish the actual mechanisms for thrombosis
- To develop mechanistically based diagnostic tests
- To develop treatments that directly target the disease mechanisms

## ACKNOWLEDGMENTS

This work was supported in part by the National Institutes of Health/National Heart Lung and Blood Institute grant #HL-61331. We appreciate the collaboration of Dr. Douglas Taatjes and Mr. Anthony Quinn of the University of Vermont Core Imaging Facility in providing the atomic force images for the figures.

## Diabetes

Angelika Bierhaus\*, Hans-Peter Hammes†, and Peter P. Nawroth\*

\*University of Heidelberg, Germany; †University of Mannheim, Germany

Patients with diabetes mellitus suffer from increased cardiovascular morbidity and mortality. The vascular endothelium forms the inner lining of blood vessels and serves as an important autocrine and paracrine regulator of vascular function. Loss of its modulatory function is thought to play a central role in the pathogenesis of late diabetic vascular complications, in both type 1 and type 2 diabetes. The increased flux of glucose under diabetic conditions results in the activation of various pathways that metabolize the excess of glucose, yet promote endothelial dysfunction. Clinical studies have consistently shown that intensive glycemic control delays the onset and progression of vascular complications in type 1 and, to a lesser extent, type 2 diabetes. Thus, hyperglycemia is an important mediator of endothelial dysfunction. However, additional factors appear to contribute to endothelial dysfunction in type 2 diabetes, and in certain patients with type 1 diabetes (e.g., those with diabetic nephropathy or obesity). In this chapter, we focus primarily on the effect of glucose on endothelial cells (ECs), but also refer to glucose-independent alterations of EC function in type 1 and type 2 diabetes.

### EFFECTS OF HIGH GLUCOSE ON ENDOTHELIAL CELLS

Hyperglycemia-induced cellular changes influence and amplify each other; therefore, activation of ECs and subsequent endothelial dysfunction is the result of interacting cellular pathways rather than a single cellular event. Accumulating data support the hypothesis that oxidative stress is a common link, because several pathways seem to contribute to the oxidative stress associated with acute or chronic hyperglycemia (1–5). The polyol pathway is one of the possible biochemical mechanisms by which hyperglycemia could impair the function and structure of ECs (6). Increased prostanoid synthesis and glucose auto-oxidation also generates reactive oxygen species (ROS). Oxidation accompanying protein glycation is another major source of oxygen free radicals (1–5). A close relationship between oxidative stress and glycemic con-

trol has been demonstrated by showing a significant positive correlation between malonaldehyde (MDA) and fasting blood glucose, glycated hemoglobin, and activation of the redox-sensitive transcription factor nuclear factor (NF)- $\kappa$ B. Moreover, the hypothesis that free radicals and subsequent oxidative stress might mediate the effects of hyperglycemia is supported by the observation that antioxidants counteract many of the injurious effects of hyperglycemia, such as excessive activation of the polyol and hexosamine pathways, induction of protein kinase C (PKC), advanced glycation end product (AGE) formation, and NF- $\kappa$ B activation (3).

ECs, however, do not only react to ROS, but also actively release ROS, thereby activating surrounding cells of the vascular wall. Hyperglycemic conditions and/or the presence of free fatty acids further induce ECs to produce free oxygen radicals via a PKC-dependent activation of nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase (7). Binding of AGEs to the receptor for AGE (RAGE) also results in increased endothelial NADPH activity. In addition to production of oxygen free radicals, depletion of antioxidative capacities may play an important role in the pathogenesis of diabetes-associated endothelial dysfunction. Consistently, high glucose and AGEs have been shown to reduce intracellular glutathione levels in cultured ECs (8,9).

### MITOCHONDRIAL SUPEROXIDE OVERPRODUCTION AS AN INTEGRATOR OF ENDOTHELIAL CELL DYSFUNCTION

Recently, Brownlee and coworkers demonstrated hyperglycemia-induced superoxide overproduction by the mitochondrial electron transport chain as one integrator of the various metabolic changes contributing to the development of endothelial dysfunction (3,4,10) (Figure 150.1). Intracellular glucose oxidation during glycolysis results in nicotinamide adenine dinucleotide (NADH) production, which donates reductive equivalents to the mitochondrial respiratory chain. In addition, pyruvate transported into the mitochondria is

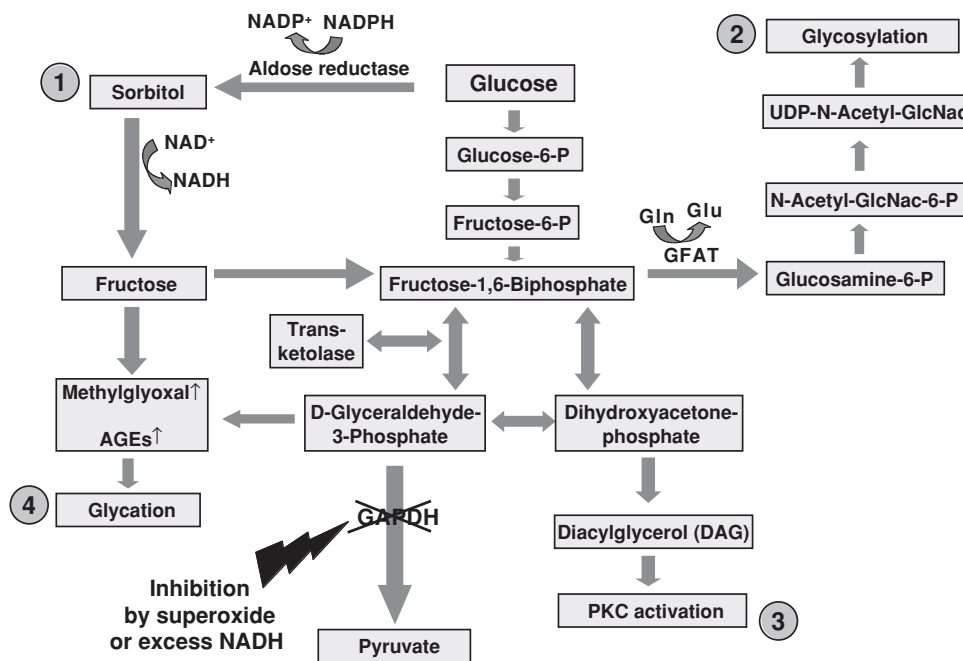

Figure 150.1. Four main molecular mechanisms have been implicated in glucose-mediated vascular damage: The polyol pathway (1), the hexosamine pathway (2), activation of PKC (3), and AGE formation (4). Hyperglycemia-induced superoxide overproduction by the mitochondrial electron transport chain acts as integrator of these various metabolic changes by inhibition of GAPDH. AGEs, advanced glycation end-products; GAPDH, glyceraldehyde phosphate dehydrogenase; GFAT, glutamine:fructose-6-phosphate amidotransferase; P, phosphate.

oxidized in the tricarboxylic cycle to form  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , NADH, and flavin adenine dinucleotide ( $\text{FADH}_2$ ). Mitochondrial NADH and  $\text{FADH}_2$  subsequently provide energy for the production of adenosine triphosphate (ATP) through oxidative phosphorylation by the mitochondrial respiratory chain. The electron flow through the mitochondrial respiratory chain is triggered by four inner membrane-associated multienzyme complexes (complex I–IV), cytochrome c, and the mobile electron carrier ubiquinone. Electron transport finally results in a difference in potential at the inner mitochondrial membrane that provides energy for ATP production. Consequently, a high mitochondrial membrane potential leads to increased half-life of the superoxide ( $\text{O}_2^-$ )-producing electron transport systems and results in the increased generation of ROS. An increased availability of glucose therefore results in increased  $\text{O}_2^-$  release and NADH formation.

Subsequently, superoxide anions can induce metabolic changes by inhibition of glyceraldehyde-3-phosphate dehydrogenase (GAPDH). During glycolysis, glucose is normally converted via glucose-6-phosphate, fructose-6-phosphate, and fructose-1,6-biphosphate to form the triose glyceraldehyde-3-phosphate. The latter is oxidized by GAPDH to form 1,3-diphosphoglycerate using  $\text{NAD}^+$  as substrate. An excess of superoxide reduces GAPDH by more than 60%. Consumption of  $\text{NAD}^+$  due to an excess of NADH also reduces GAPDH activity. Inhibition of GAPDH results in the accumulation of upstream intermediates that are metabolized in pathways of

glucose overutilization. These are: (a) the conversion of glucose to fructose by the polyol pathway; (b) the increased flux of fructose-6-phosphate through the hexosamine pathway; (c) the increased de novo synthesis of diacylglycerol (DAG), a cofactor of PKC, from dihydroxyacetone phosphate; and (d) the increased formation of reactive intracellular AGEs from accumulating trioses (see Figure 150.1). Furthermore, oxidative stress could be exacerbated by impaired endogenous antioxidant protection mechanisms. Because an excessive activation of the polyol pathway, increased PKC activation, and increased AGE formation are thought to contribute to endothelial dysfunction (discussed in a later section), blocking increased oxidative stress, including unchecked superoxide production, might at least in part restore the metabolic and vascular imbalance observed in diabetes.

### THE POLYOL PATHWAY AS ONE CAUSE OF ENDOTHELIAL DYSFUNCTION

One pathway used in the presence of glucose overutilization is the polyol pathway, in which the enzyme aldose reductase catalyses the  $\text{NADPH}/\text{H}^+$ -dependent reduction of sorbitol, before the latter is oxidized to fructose (3,4,6,10) (see Figure 150.1). This leads to depletion of NADPH and generation of reactive oxidants. Because NADPH is required for generation of nitric oxide (NO) from L-arginine, the depletion of NADPH

leads to reduced NO formation. Furthermore, the generation of NADH results in an increase in the NADH/NAD<sup>+</sup> ratio and in a pronounced cellular redox imbalance. This might be of pivotal importance, particularly for the neuronal vasculature. Increased polyol pathway flux has been linked to neuronal complications in experimental diabetes; these complications are attenuated by aldose reductase inhibitors, with defective NO-mediated vasodilation being a particular target. Another consequence is activation of the nuclear protein poly (ADP-ribose)-polymerase (PARP), that in turn synthesizes the polymer (ADP)-ribose, thereby further lowering the availability of NAD<sup>+</sup>. Because NADPH also is needed to regenerate glutathione, a hyperactive polyol pathway reduces the antioxidative defense capacities.

### INCREASED FLUX THROUGH THE HEXOSAMINE PATHWAY AS ANOTHER CAUSE OF ENDOTHELIAL DYSFUNCTION

Inhibition of GAPDH results in the accumulation of fructose-6-phosphate (10) that represents a substrate for the enzyme glutamine:fructose-6-phosphate amidotransferase (GFAT). GFAT converts fructose-6-phosphate into glucosamine-6-phosphate and thereby provides the substrate for proteoglycan synthesis and the formation of O-linked proteins (see Figure 150.1). Thus, hyperglycemia impairs the functional properties of cytosolic and nuclear proteins via O-linked glycosylation modification (O-GlcNAcylation). Consistently, O-GlcNAcylation immunoreactivity is barely detectable in control ECs from nonatherosclerotic small vessels, whereas the endothelial layer of carotid plaques from diabetic patients shows an intense signal in both cytoplasm and nuclear compartments (11).

Recently, hyperglycemia has been shown to induce a 2.4-fold increase in hexosamine pathway activity in cultured ECs and to significantly increase the O-glycosylation of the transcription factor SP1. Because the glycosylated form of SP1 seems to be more transcriptionally active than the deglycosylated form, modification of endothelial SP1 results in increased activation of SP1-regulated genes such as plasminogen activator inhibitor (PAI)-1 or NF- $\kappa$ B p65 (12). Furthermore, O-GlcNAcylation directly affects the metabolic branch of insulin signaling, such as insulin receptor (IR)-mediated activation of the IR substrate (IRS)/ phosphoinositide 3-kinase (PI3K)/Akt pathway (11). In addition, post-translational O-acetylglucosamylation of the Akt-binding site in endothelial NO synthase (eNOS) results in inhibition of eNOS activity. NO produced by eNOS is known to inhibit matrix metalloproteinase (MMP)-2 and -9 activity. Reduction of eNOS activity by activation of the hexosamine pathway in human aortic ECs was associated with increased expression of MMP-2 and MMP-9 and decreased expression of tissue inhibitor of metalloproteinases (TIMP)-3, which might contribute to the development of macrovascular disease (11).

### ACTIVATION OF PROTEIN KINASE C AS MEDIATOR OF ENDOTHELIAL DYSFUNCTION

The conversion of triose-phosphates into dihydroxyacetone phosphate and subsequently into the lipid second messenger DAG provides a cofactor for at least nine members of the PKC family (13) (see Figure 150.1). Binding of DAG in the presence of calcium induces conformational changes in the respective PKC molecules and results in opening of the active center and subsequent interaction with the substrate. Several PKC isoforms also can be activated in the absence of calcium (Ca<sup>2+</sup>). The hyperglycemia-dependent activation of PKC is enhanced in the presence of insulin, because the IR induces phosphorylation of phosphatidylinositol-(4,5)-biphosphate through PI3K, which results in the release of DAG and phosphatidylinositol-3,4,5-triphosphate (PIP3), which in turn activates the PKC-isoform PKC $\zeta$ . Excessive PKC activation induces phosphorylation, translocation, and activation of cytosolic phospholipase A2, resulting in the liberation of arachidonic acid and increased production of prostaglandin (PG)E<sub>2</sub>, which are known inhibitors of Na<sup>+</sup>,K<sup>(+)</sup>-ATPase. Furthermore, excessive PKC activation impairs phospholipase-C-mediated Ca<sup>2+</sup> signaling and reduces NO generation in ECs. Through induction of endothelin (ET)-1 activity, inhibition of the actin-linked regulatory protein caldesmon, and increased vascular leakage and loss of endothelial barrier function, PKCs enhance contractility and permeability of ECs. In addition, hyperglycemia inhibits thymidine incorporation and cell growth of cultured human umbilical vein ECs (HUVECs) via a PKC-dependent mechanism (14). The consequences are manifold, the most important for the retina being changes in blood flow and vascular permeability due to vasoactive molecules such as vascular endothelial growth factor (VEGF) and ET-1 (15,16). PKC $\beta$  overexpression in mice results in excess retinal neovascularization in a model of proliferative retinopathy, whereas mice with a genetic ablation of the gene develop less proliferation (17). Pharmacological inhibition of PKC $\beta$  normalizes hyperglycemia-induced impaired blood flow through the retina of hyperglycemic animals (15). PKC inhibition also reduces laser-induced retinal neovascularization, indicating that PKC activation is a possible therapeutic target in diabetic patients with differing levels of retinopathy (18).

In addition to these effects, high glucose levels induce ROS production via PKC-dependent activation of NADPH oxidase, which results in increased EC apoptosis (19). Expression of NADPH oxidase components not only has been shown in vitro, but also in vascular tissues in experimental diabetes models, suggesting that PKC-dependent activation of NADPH oxidase may be an essential mechanism responsible for increased oxidative stress in diabetes (7). Thus, activation of cytoplasmic oxidative stress via NADPH oxidase is a possible and likely additional stress effector in the chronic hyperglycemia-exposed endothelium. In vitro data, however, suggest that high glucose exposure of retinal ECs and Müller cells produces ROS predominantly by the mitochondria, via inhibition of complex II of the respiratory chain, but not by

inhibition of NADPH oxidase—reduced oxidative stress (20). Although long-term data on retinal outcome of the mitochondrial inhibition of ROS are not yet available, the effect of catalytic antioxidants has been tested. These compounds readily distribute to the mitochondria; have a low redox potential, which enables them to recycle virtually all redox systems; and are regenerated by hyperglycemia-induced production of NADH. They can inhibit all critical downstream biochemical pathways involved in diabetic retinopathy, and they normalize the formation of acellular capillaries and pericyte loss almost completely in diabetic rats.

In addition, PKC has been shown to activate the proinflammatory transcription factor NF- $\kappa$ B and subsequent proadhesive and prothrombotic gene expression; to induce the fibrinolysis inhibitor PAI-1, apparently by boosting the binding activity of SP1 transcription factors in the *PAI-1* promoter; and to promote synthesis of fibronectin and other proteins involved in matrix expansion.

#### **THE ROLE OF ADVANCED GLYCATION END-PRODUCTS IN DIABETIC ENDOTHELIAL DYSFUNCTION**

Intracellular precursors of AGEs affect EC function through different mechanisms (21,22). They modify intracellular proteins, including growth factors, and alter cellular function. In addition, AGEs precursors become available outside cells and modify extracellular matrix molecule proteins, thereby affecting cell–matrix signaling through interference with adhesion molecules and integrins. Proteins modified by AGEs can further bind to cell surface receptors such as RAGE, AGE-R1 (OST-48), AGE-R2 (80K-H phosphoprotein), AGE-R3 (galectin-3), and CD36, but also to other newly identified AGE-binding proteins such as N-glycans, ezrin, and megalin, and thereby induce cellular activation (23–25). Experimental proof of the relevance of AGE accumulation for vascular damage in diabetes has been provided by chemical inhibition using structurally unrelated AGE inhibitors. Long-term treatment of diabetic rodents with AGE inhibitors limited the structural damage of macrovascular and microvascular vessels in these animals to a large extent.

#### **POLY(ADP-RIBOSE)-POLYMERASE ACTIVITY AS CAUSE FOR ENDOTHELIAL DYSFUNCTION**

The simultaneous generation of  $O_2^-$  and reactive NO results in the formation of peroxynitrite, which is a potent stimulus of DNA single-strand breakage. Recent studies have demonstrated that hyperglycemia-associated oxidative stress increases DNA damage, as evidenced by increasing amounts of 8-hydroxyguanine and 8-hydroxyguanosine in plasma and tissue of diabetic rats. DNA single strands activate the nuclear enzyme PARP-1, which functions as a DNA-damage sensor and promotes inflammatory signal transduction processes

(26). PARP activation results in depletion of its substrate  $NAD^+$ , slowing of electron transport, and reduction of ATP, and finally leads to cellular dysfunction. In ECs exposed to high glucose, PARP activation appears to be involved in both promoting nitrosative and oxidative stress and upregulating adhesion molecules and inflammation (27). Most remarkably, PARP-dependent poly(ADP-ribosyl)ation of GAPDH was identified as one cause of hyperglycemia-induced GAPDH inhibition in ECs (28). Both the hyperglycemia-induced decrease in GAPDH activity and its poly(ADP-ribosyl)ation were prevented by decreasing hyperglycemia-induced superoxide through overexpression of either uncoupling protein (UCP)-1 or manganese superoxide dismutase (MnSOD).

Although PARP activity is increased in ECs of large and small vessels in diabetes, PARP protein is upregulated in the diabetic retina mostly in Müller cells. Both PARP protein expression and PARP activity are normalized by the specific PARP inhibitor PJ34. PARP protein interacts with both the p50 and the p65 subunit of NF- $\kappa$ B, affecting EC survival (but not that of pericytes) in vitro. In vivo, inhibition of PARP activity (and protein upregulation) protects ECs and pericytes from loss (29). Furthermore, PARP inhibition can affect angiotensin (Ang)-II expression, suggesting interference with several pathways that lead to retinal capillary regression in vivo.

#### **SUBNORMAL TRANSKETOLASE ACTIVITY AS A CAUSE FOR ENDOTHELIAL DYSFUNCTION**

As summarized earlier, hyperglycemia-induced overproduction of superoxide by the mitochondrial electron transport chain and subsequent inhibition of GAPDH results in the accumulation of the upstream metabolites fructose-6-phosphate and glyceraldehyde-3-phosphate, which are also end-products of the nonoxidative branch of the pentose phosphate pathway. In the pentose phosphate pathway, the thiamine-dependent enzyme transketolase diverts these metabolites into pentose-5-phosphates and erythrose-4-phosphate (Figure 150.2). Because diabetic patients have a subnormal level of erythrocyte transketolase activity, inadequate transketolase activity could be considered as one reason for triose accumulation under hyperglycemic conditions (30). Consistently, supplementation with the transketolase cofactor benfotiamine, a lipid-soluble thiamine derivate with greater bioavailability than thiamine, resulted in activation of the pentose-phosphate pathway and thereby prevented activation of pathways involved in hyperglycemia-induced vascular damage in both cultured ECs and the microvasculature of diabetic rats (31).

#### **INCREASED SYNTHESIS OF ENDOTHELIN-1 IN DIABETES**

One of the most important functions of the endothelium is the regulation of blood flow. This is achieved by tight control of pro- and anticoagulant properties, but also by regulating

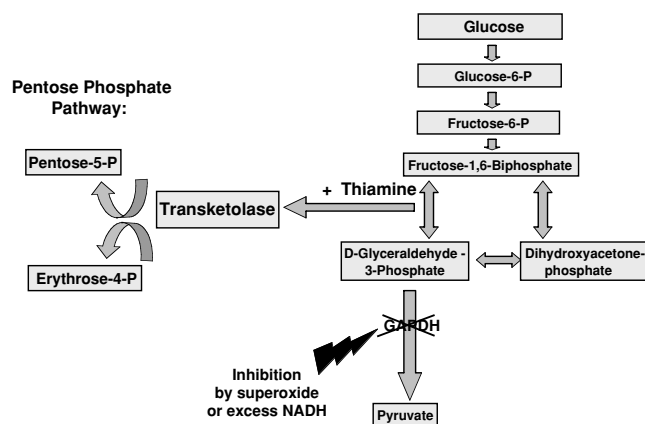

Figure 150.2. Fructose-6-phosphate and glyceraldehyde-3-phosphate are also end-products of the nonoxidative branch of the pentose phosphate pathway, in which the thiamine-dependent enzyme transketolase diverts upstream metabolites from glycolysis into pentose-5-phosphate and erythrose-4-phosphate. GAPDH, glyceraldehyde phosphate dehydrogenase; P, phosphate.

cell-cell interaction and vascular tone. ET-1 is both a potent vasoconstrictor and mitogenic factor that has been implicated as a cause of micro- and macrovascular complications in diabetes mellitus. Upregulation of ET-1 appears to be a consequence of the NO-Ang-II imbalance that contributes to end-organ injury (32). In addition, *in vitro* data have shown that oxidative stress, high glucose levels, and AGEs induce ET-1 expression via NF- $\kappa$ B activation (33). However, the pathway by which the high-glucose environment of diabetes mediates increased levels of ET-1 has still not been completely elucidated. Recent data indicate that endothelin-converting enzyme (ECE)-1, which converts inactive big ET-1 to active ET-1 peptide may play an important role, because high glucose induces PKC-mediated induction of ECE in cultured ECs (34). Thus, ECE may be another factor contributing to the elevated ET-1 peptide levels observed in diabetes. Increased ET-1 levels have been described in type 2 diabetic patients with increased intima media thickness (IMT) (35), providing further support for the role of ET-1 in late diabetic vascular disease. In addition, elevated circulating levels of ET-1 have been found in patients with microvascular disease. Consistently, ET receptor antagonists restore blood flow and nerve conduction velocity in experimental models of diabetes (36).

## REDUCED AVAILABILITY OF VASCULAR NITRIC OXIDE

One of the most important mediators of vascular homeostasis leading to vascular relaxation is NO, a small, short-lived, highly reactive radical and the metabolic product of L-arginine by the enzyme NO synthase (NOS). Its complex interaction with the autocrine and paracrine systems, particularly Ang-II, modulates vasoconstriction and vasodilatation as well as the architectural remodeling of the vascular bed (37).

To date, three forms of NOS (eNOS, inducible NOS [iNOS], and neuronal NOS [nNOS]) have been described, of which eNOS is constitutively expressed in ECs. eNOS, which is located in membrane caveolae and the cytoplasm, requires tetrahydrobiopterin (BH<sub>4</sub>), NADPH, FADH<sub>2</sub>, and flavin mononucleotide (FMN) as additional cofactors for its activity. The L-arginine required for NO synthesis is derived from a membrane-associated compartment distinct from the bulk intracellular amino acid pool, such as "lipid rafts" or caveolae (38). Under physiological conditions, the vascular endothelium constitutively releases NO and mediates relaxation of smooth muscle cells and regulation of the vascular tone (Figure 150.3). Consistently, loss of NO bioavailability due to reduced synthesis and increased scavenging by ROS is a feature of endothelial dysfunction in vascular disease. Endothelial dysfunction in diabetes is characterized by decreased NO bioactivity, increased superoxide production, and oxidation of BH<sub>4</sub> (39). Particularly, ROS generated by NADPH oxidases have been shown to promote oxidation of BH<sub>4</sub>. Oxidized BH<sub>4</sub> uncouples eNOS, resulting in decreased production of NO and generation of superoxide instead. Thus, uncoupling of eNOS in diabetes results in ROS production instead of NO-dependent vascular protection (Figure 150.3). Consistently, diabetic mice transgenic for guanosine triphosphate-cyclohydrolase (GTPCH)-1, the rate limiting enzyme for BH<sub>4</sub>-synthesis, present with selective augmentation of endothelial BH<sub>4</sub> levels, reduced endothelial superoxide production, and preservation of NO-mediated vasodilatation (40). This indicates that BH<sub>4</sub> is an important mediator of eNOS regulation in diabetes and that alteration of the balance of bioactive radicals in addition to a defective antioxidative defense (8) further promotes oxidative stress and vascular complications.

Although high concentrations of peroxynitrite (ONOO<sup>-</sup> >100  $\mu$ M) also uncouple eNOS and inactivate prostacyclin synthase in diabetes (41), low concentrations of ONOO<sup>-</sup> (1–10  $\mu$ M) activates c-Src-PI3K to generate an unknown molecule or a second messenger, which recruits AMP-activated protein kinase (AMPK) to form an active complex, resulting in AMPK activation and increasing AMPK-dependent eNOS-Ser<sup>1177</sup> phosphorylation. ONOO<sup>-</sup>-concentrations needed for AMPK activation are much lower than those conferring eNOS uncoupling, indicating that ONOO<sup>-</sup> will preferentially activate AMPK (42). Notably, the antidiabetic drug metformin also activates AMPK and thereby prevents oxidative stress in cultured ECs exposed to high glucose. This implies that low concentrations of ONOO<sup>-</sup>, as generated by clinically relevant concentrations of metformin, activate AMPK and thereby precondition the endothelium to reduce excessive oxidant stress induced by hyperglycemia (42).

## FLOW-MEDIATED DILATATION IN INSULIN RESISTANCE AND DIABETES

A noninvasive method to determine endothelial dysfunction is the determination of postischemic vasodilatation in the

Figure 150.3. Under physiological conditions, the vascular endothelium constitutively releases NO and mediates relaxation of smooth muscle cells and regulation of the vascular tone. Endothelial dysfunction in diabetes caused by uncoupling of endothelial NO results in decreased NO bioactivity and increased superoxide ( $O_2^-$ ) production, and thus promotes inflammation and atherosclerosis. AGEs, advanced glycation end products; eNOS, endothelial nitric oxide synthase; NO, nitric oxide; RAGE, receptor for AGEs.

forearm, which results in enhanced flow in the brachial artery and shear stress-induced vasodilatation. This flow-mediated (endothelial-dependent) dilatation (FMD) depends on the ability of the endothelium to produce vasodilator-endowed substances, mainly NO. Patients with a lower level of FMD are thought to have a lower production of NO, indicating endothelial dysfunction (43). Consistently, FMD decreases with increasing age and in patients with diabetes mellitus. Hyperglycemia is sufficient to change FAD, because acute hyperglycemia attenuates endothelium-dependent vasodilation in healthy adults without diabetes (44). In healthy postmenopausal women, a decrease in FMD is associated with a significantly increased risk for diabetes (45). Furthermore, nonobese women with polycystic ovary syndrome (PCOS) demonstrated an association of reduced FMD with both insulin resistance and mild chronic inflammation (46).

Insulin resistance also impairs endothelial function in young nondiabetic men. Although these young subjects exhibit a marked reduction in peripheral endothelial function early in life, no differences in IMT are observed (47). This indicates that endothelial dysfunction already is evident at an early stage, when morphological changes of the vessel wall are not apparent. In contrast, however, obesity, increased waist-to-hip ratio, and a higher percentage of body fat content were associated with increased IMT early in life and were paralleled by chronic subclinical inflammation and dysfunctional fibrinolysis independent of impaired glucose and lipid metabolism (48). Remarkably, impaired FMD response is also

a common manifestation in children with type 1 diabetes, and is associated with increased carotid artery IMT, implying that endothelial dysfunction in children with type 1 diabetes may predispose for early atherosclerosis (49).

It is not known whether insulin resistance, hyperglycemia, and genetic factors affecting endothelial dysfunction are pathogenetically related or different entities. Because healthy relatives of patients with type 2 diabetes exhibit impaired FMD (43), however, there might be an independent genetic component in endothelial dysfunction. Therefore, insulin resistance could be a cause, rather than a consequence, of endothelial dysfunction.

#### ENDOTHELIAL DYSFUNCTION INFLUENCES INSULIN ACTION

It is not clear to what extent endothelial dysfunction is a cause or consequence of diabetes. A recent prospective study of 840 apparently healthy, nonobese, postmenopausal women demonstrated that endothelial function significantly influences the future development of diabetes, independent of age and several other risk factors for diabetes (45). This is consistent with the hypothesis of Pinkney, who defined the endothelium as the principal controlling factor of insulin concentrations in the interstitium and the amount of insulin effectively reaching the target organ (50). Because IRs are expressed on ECs of large and small blood vessels, they are thought to

participate actively in insulin-regulated glucose homeostasis. It is hypothesized that the endothelium is a barrier controlling the contact between insulin and insulin-sensitive cells. Consistently, dysfunctional endothelium would be accompanied by progressive insulin resistance. Transendothelial insulin transport is believed to be a determinant of insulin action on glucose disposal. Although whether transendothelial insulin transport occurs *in vivo* is controversial, *in vitro* studies have demonstrated an IR-mediated insulin transport across the endothelial barrier (51).

When mice with a vascular EC-specific knockout of the IR (VENIRKO) were studied, glucose homeostasis under basal conditions was comparable with wild-type mice (52). *eNOS* and *ET-1* transcription, however, was significantly reduced in ECs. VENIRKO mice presented with insulin resistance, indicating that inactivation of the IR on ECs affects maintenance of the vascular tone and regulation of insulin activity. Furthermore, studies in VENIRKO mice and mice with vascular endothelial insulin-like growth factor (IGF) receptor knockout (VENIFARKO) indicate a role of endothelial insulin and IGF-1 in retinal neovascularization (53). Notably, however, these mice exhibit a normal blood–brain barrier (BBB) and a normal blood–retinal barrier (BRB) function, indicating that neither insulin nor IGF-1 signaling in vascular ECs is required for development and maintenance of the BBB or BRB (54).

Insulin-dependent stimulation of NO production is mediated by PI3K signaling, which activates Akt, which in turn phosphorylates *eNOS* on serine<sup>1177</sup> and induces *eNOS* transcription (55). The impairment of those signaling pathways mediating potentially protective insulin effects by insulin-resistant states might contribute to the accelerated atherosclerosis associated with impaired insulin sensitivity. In addition, inhibition of insulin-dependent PI3K either by the hexosamine pathway (55) or by inhibitors such as wortmannin (56) enhances insulin-induced mitogenic effects by induction of mitogen-activated protein kinase (MAPK). Activation of the MAPK pathway, in turn, mediates activation of proinflammatory, proadhesive, prothrombotic, and profibrotic mechanisms.

### ENDOTHELIAL DYSFUNCTION THROUGH VESICULATION AND INCREASED PERMEABILITY

An increase in vessel wall permeability is a common occurrence in hyperglycemia, in particular in diabetic nephropathy and retinopathy. Breakdown of the BRB is a frequent and characteristic lesion in the diabetic retina. From fluorescein angiograms in human diabetic retinas, microaneurysms can appear leaky, and have venous beading and retinal neovascularizations (57). Macular edema, the most characteristic indicator of BRB breakdown, shows several features of increased transition of intravascular elements into retinal tissues. The underlying mechanisms that contribute to increased vascular permeability are complex, and they comprise activation

of permeability-enhancing factors, transendothelial transport mechanisms, and junctional protein changes. Among the many growth factors involved during the evolution of diabetic retinopathy, VEGF plays a predominant role (58). Its vasopermeation-enhancing function is well-characterized. VEGF is upregulated early during the course of nonproliferative diabetic retinopathy, both in humans and in experimental animals, and it has been correlated with increased vessel permeability. VEGF-mediated induction of vascular permeability occurs through endothelial fenestration, vesicular transport, and transport through intercellular clefts. Hyperglycemia, AGEs, ROS, and hypoxia are all well documented stimulators of VEGF in the diabetic retina. Diabetes and VEGF also share the propensity to affect paracellular permeability in association with changes in occludin distribution. Several other molecules of junctional families are likely involved in affecting permeability, such as zona occludens (ZO)-1 and claudin-5.

The tightness of the BRB also depends on the presence of perivascular cells, in particular pericytes. It has been proposed that the exceptionally dense capillary coverage with pericytes is the cause for the tightness of the BRB. As an indirect indication, mice with a homozygous deletion of platelet-derived growth factor (PDGF)-B, a pericyte recruiting factor, die near the time of birth from cerebral hemorrhages and edema, indicating severely altered BBB function. The absence of pericytes is associated with an increase in VEGF levels. In turn, intravitreal injection of angiostatin reduces VEGF expression and corrects increased permeability in early diabetic rat retina (59).

Alterations in the glomerular basement membrane are likely to affect the permeability characteristics of the glomerular capillaries and may contribute to proteinuria, glycosuria, and hypertension. At later stages of disease, mesangial and glomerular expansion results in collapse of the glomerular capillaries and subsequent glomerulosclerosis. The pathways leading to disturbed endothelial permeability and enhanced leakiness seem to be related to the pathways involved in endothelial activation and dysfunction. ROS and AGEs seem to play a major role, since blockade of RAGE interaction with soluble RAGE reduced hyperpermeability in diabetic mice. Consistently reducing AGE formation by using aminoguanidine reduced albumin excretion in experimental and clinical diabetes.

### OXIDIZED LOW-DENSITY LIPOPROTEIN AND ENDOTHELIAL DYSFUNCTION

Binding of oxidized low-density lipoproteins (LDL) to the lectin-like oxidized LDL receptor (LOX)-1, which is upregulated in response to oxidative stress, induces ROS production and decreases NO released from ECs (60). Engagement of LOX-1 further induces the expression of ET-1, AT(1) receptor, and cell adhesion molecules. In addition, LOX-1 works as an adhesion molecule for activated platelets and neutrophils. Activated platelets and oxidized LDL in turn induce the

generation of endothelial-derived microparticles (EDMPs), which are elevated in diabetic patients, in particular in those with diabetic nephropathy. Thus, elevated EDMPs may be a sign of vascular complications in type 2 diabetic patients. Statins have been shown to inhibit upregulation of LOX-1 and to increase eNOS expression in human coronary artery ECs.

### THE ROLE ADIPOCYTOKINES IN REGULATION OF VASCULAR ENDOTHELIAL FUNCTION

Cytokines known to play a pivotal role in the immune response and inflammation possess additional endocrine and metabolic functions. Consistently, several of these cytokines are regarded as independent risk factors for vascular disease. Because visceral and subcutaneous adipose tissues are the major sources of cytokines (adipokines), increased adipose tissue mass is associated with alteration in adipokine production, such as overexpression of tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-6, and PAI-1, and reduction in the plasma protein adiponectin (61). Recent experimental and clinical studies provide evidence that reduced circulating levels of adiponectin in visceral adiposity not only contribute to insulin resistance and dysglycemia, but also promote endothelial dysfunction. Although forearm blood flow in human subjects during reactive hyperemia (a model for endothelium-dependent vasodilation) is negatively correlated with adiponectin, circulating adiponectin levels are positively associated with arterial vasodilation in response to nitroglycerin (a measure of endothelium-independent vasodilation). The proinflamma-

tory status associated with these changes provides a potential link between insulin resistance and endothelial dysfunction in patients with type 2 diabetes. Several clinical studies have proven that weight reduction and physical activity followed by adipose tissue reduction reduces adipokines, increases adiponectin, reduces inflammation, and improves insulin sensitivity and endothelial function. Thus, adiponectin might link obesity, endothelial dysfunction, and diabetic vascular complications.

### THE INFLAMMATORY COMPONENT OF ENDOTHELIAL DYSFUNCTION

ECs participating in the inflammatory response undergo a number of changes that finally result in loss of vascular integrity, activation of proinflammatory transcription factors such as NF- $\kappa$ B, cytokine expression, increased expression of leukocyte adhesion molecules, and a change from an antithrombotic to a prothrombotic phenotype (61–64) (Figure 150.4). In diabetes, initial inflammatory activation by increased oxidative stress, high glucose, oxidized LDLs, and PKC activation is perpetuated by engagement of RAGE, which in turn upregulates the receptor and initiates a cycle of sustained cellular perturbation. One unique feature of RAGE is sustained NF- $\kappa$ B activation due to de novo synthesis of p65 mRNA, which results in a constantly growing pool of excess transcriptionally active NF- $\kappa$ B p65 (65). Increased NF- $\kappa$ B transcription, expression, and activity has been shown in the microvascular endothelium of patients with type 1 diabetes

Figure 150.4. Initial inflammatory stimuli such as oxidative stress, high glucose, or cytokines induce activation of the proinflammatory transcription factor NF- $\kappa$ B. Subsequently, enhanced expression of NF- $\kappa$ B-regulated adhesion molecules on ECs promotes leukocyte adhesion, which in turn results in further NF- $\kappa$ B activation. NF- $\kappa$ B activation is perpetuated by engagement of RAGE, which upregulates the receptor and initiates sustained cellular perturbation and chronic inflammation.

(65). One of the cytokines induced by NF- $\kappa$ B is IL-6, which in turn activates C reactive protein (CRP). Low-grade inflammation determined by serum hs-CRP already is observed in children with type 1 diabetes and increased IMT of the common carotid arteries, implying that the proatherogenic effects of CRP were potentiated in the presence of hyperglycemia (66).

Platelet-activating factor (PAF), a phospholipid mediator of inflammation released by activated ECs, is significantly increased in patients with diabetes (67). In addition to changing the permeability of the glomerular basement membrane (GBM), PAF induces and enhances NF- $\kappa$ B activation. Enhanced expression of NF- $\kappa$ B-regulated adhesion molecules by the endothelium may further account for vascular damage in diabetics. Neutrophils from diabetic animals have been shown to exhibit higher levels of surface integrin expression and integrin-mediated adhesion. Blocking the surface integrin subunit CD18 has been shown to lead to decreased leukostasis in the diabetic retinal microvasculature, implying a central role of  $\beta$ 2 integrins and their counter-receptors – intercellular adhesion molecule (ICAM)-1 and RAGE – in mediating endothelial dysfunction. The expression of ICAM-1, RAGE, and the very late activation antigen (VLA)-4 (integrin  $\alpha$ 4b) receptor vascular cell adhesion molecule (VCAM)-1 is significantly increased in animal models of diabetes. In accordance with the hyperglycemic induction of adhesion molecules in experimental diabetes, E-selectin, VCAM-1, and ICAM-1 levels are significantly higher in patients with type 1 (68) and type 2 (69) diabetes. Moreover, sera from diabetic patients significantly enhance leukocyte adhesion to cultured ECs, despite normal levels of IL-1 $\beta$  and TNF- $\alpha$  (70). Monocytes from patients with diabetes mellitus also demonstrate increased adhesion to ECs in culture, further indicating that hyperglycemia promotes leukocyte adhesion to the endothelium.

#### **DISTURBANCES OF THE COAGULATION EQUILIBRIUM OF BLOOD IN DIABETES MELLITUS**

Thrombogenesis depends on the balance between coagulation and fibrinolysis in the vasculature. Diabetes mellitus is characterized in part by major disturbances of the blood's fluid-coagulating equilibrium (63,64). The reduced synthesis of factors protecting the endothelium, such as prostacyclin and NO, is accompanied by increased adhesion and aggregation growth of platelets on dysfunctional and/or injured endothelium. Furthermore, the activated platelets promote other steps in hemostasis, in particular coagulation, and thereby promote hypercoagulability in diabetes mellitus. While quiescent ECs under physiological conditions provide an antithrombotic surface not expressing tissue factor, stimulation of ECs with glucose, AGEs, or cytokines results in tissue factor expression and generation of a prothrombotic surface. Although excessive tissue factor expression in patients with type 1 diabetes is most likely the result of hyperglycemia, tissue factor expression in patients with type 2 diabetes might further be promoted by

inflammatory mediators. Consistent with the tissue factor-mediated hypercoagulability, coagulation activation markers, such as prothrombin activation fragment 1+2 and thrombin-anti-thrombin complexes, are elevated in diabetes. The plasma levels of many clotting factors including fibrinogen, factor VII, factor VIII, factor XI, factor XII, kallikrein, and von Willebrand factor (vWF) are also augmented in patients with diabetes mellitus (71). Conversely, the levels of the anticoagulant molecules such as thrombomodulin and protein C (PC) are decreased. Although vascular ECs normally synthesize activators for fibrinolysis, such as tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), the fibrinolytic system and thereby the primary means of removing clots is relatively inhibited in diabetes (72). This is due to both abnormal clot structures that are more resistant to degradation and to the increase in PAI-1 synthesis, which is at least in part mediated by excessive PKC and/or hexosamine pathway activation (12).

#### **ENDOTHELIUM, ANGIOGENESIS, AND VASCULAR REPAIR**

VEGF is the most prominent member of the class of growth factors involved in repair or response-to-injury type of neovascularization (73). It is present at low levels in the normal retina. Several cells in the eye are able to constantly produce VEGF, such as ECs, pericytes, Müller cells, and ganglion cells (74). Local VEGF production in the vasculature has been found to be associated with a fenestrated capillary phenotype, such as in the glomerulus of the kidney or the choroid. In the inner retina, the local production of VEGF may have different functions, as indicated in the upcoming discussion (75).

VEGF is upregulated several-fold in the vitreous and aqueous of patients with active ocular neovascularization, irrespective of the cause of retinopathy. Several animal models of hypoxia-induced proliferative retinopathy exhibit high retinal VEGF levels. Many studies have confirmed and extended these findings, indicating that retinal diseases associated with ischemia of a certain degree are associated with hypoxia-induced VEGF upregulation. VEGF is also a permeability-enhancing factor within the eye, thus possibly contributing to the pathogenesis of macular edema. Intravitreal injection of VEGF into the eyes of rodents and primates mimics some early features of nonproliferative diabetic retinopathy, such as increased vascular permeability and microaneurysm formations. Thus, it is possible that VEGF may be responsible for some of the changes observed during the earliest stages of retinopathy (76). However, from retinal digest preparations of diabetic rats, it is known that a focal increase in the numbers of ECs and an increase in the deposition of PAS-positive material occurs within the vessel wall, which is suggestive of increased vascular permeability and proliferative activity of the retina in the absence of occlusive vascular changes. The expression of VEGF was therefore studied in these models that do not develop proliferative retinal changes, and it was

found that VEGF is upregulated in association with its receptors FLK-1 and FLT-1 (77). Two important questions arise from this and the concomitant studies: What is the stimulus for VEGF upregulation? And, why is VEGF upregulated? With the available data, it appears that VEGF is induced by hyperglycemia-induced ROS production. Other likely inducers during the early course of retinopathy, in which ischemia due to capillary dropout may not yet be a significant contributor, are AGEs, which are also known to induce intraocular VEGF production and ROS. For the second question, it is more difficult to find a definitive answer. VEGF, among other growth factors, may promote endothelial resistance to oxidative stress. As mentioned earlier, VEGF is also a survival factor for ECs (78). Chronic hyperglycemia induces a comprehensive stress, not one limited to vascular ECs in the diabetic retina. An imbalance between survival factor demand and provision can induce programmed cell death. In fact, apoptosis has been observed in both vascular and neuroglial structures in diabetic retinas, which can be reduced either by the application of growth factors or by inhibitors of oxidative stress. The upregulation of VEGF in the early diabetic retina may represent a stress-induced cell response.

The recent discovery of circulating endothelial progenitor cells (EPCs) has substantially altered our understanding of new blood vessel formation. EPCs can differentiate from both bone marrow and circulating cells carrying hematopoietic stem cell markers. In vivo, they take part in vasculogenesis after ischemia in different animal models of limb ischemia, myocardial infarction, and wound healing. In metabolic disease, the outgrowth and function of EPCs in vitro is defective, and numbers of EPCs correlate with classical risk factors for vascular complications. EPCs from patients with diabetes are reduced in number and function (79). Similarly, EPCs from type 2 diabetes exhibit impaired proliferation, adhesion, and incorporation into vascular structures (80). As a consequence, EPC dysfunction may reduce the vascular regenerative potential of diabetic patients and contribute to the pathogenesis of vascular complications. Remarkably, Ang-II subtype 1-receptor blockade has been shown to increase the number of EPCs in patients with type 2 diabetes mellitus (81), demonstrating potential options for regenerating impaired repair mechanisms, although the mechanisms resulting in impaired EPC function under hyperglycemic condition are still poorly understood.

#### **THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME AND ENDOTHELIAL DYSFUNCTION**

Endothelial function and vascular inflammation play major roles in the pathogenesis and clinical outcome of patients with systemic lupus erythematosus (SLE) and antiphospholipid antibody syndrome (APS), characterized by premature atherosclerosis of the legs as a first symptom. Recent studies indicate that abnormal ankle-brachial indexes (ABIs) are more common in primary APS than in healthy subjects. Con-

sistently, patients with primary APS have a high prevalence of carotid artery IMT and a decreased lumen diameter, which might be promoted in the presence of diabetes. However, a linkage of APS to type 1 diabetes mellitus has not yet been established, and the association with type 2 diabetes is rare. Therefore, further studies are needed to clarify the relationship between diabetes and APS (82).

#### **ENDOTHELIAL DYSFUNCTION IN DIABETIC MACROVASCULAR DISEASE**

The term *microangiopathy* summarizes the fact that large-vessel disease in diabetes involves not only atherosclerosis, but also a form of diabetic angiopathy (82,83). Although the histology of lesions in the arterial wall of diabetic subjects and the classical risk factors for these alterations resemble those observed in the general population, diabetes seems to enhance the impact of the various risk factors. A small prospective study measuring carotid IMT in pancreas transplant recipients recently has shown an IMT improvement after transplantation within 2 years (84), paralleled by normalization of HbA1c and improved renal function. Because amelioration of IMT was independent of changes in body mass index, smoking, lipid levels, and use of hypolipidemic drugs, these data imply that glucose improvement might be an important factor in diabetic macrovascular disease. However, a variety of studies has shown that the correlation of macroangiopathy with the duration of diabetes and HbA1c is rather weak. This indicates that the different mechanisms described earlier, such as increased oxidative stress, disturbed blood flow, inflammation, activated hemostasis, AGE formation, and the generation of abnormal lipoproteins, all contribute to diabetic macroangiopathy. A central role for ECs is suggested due to the observation of elevated plasma levels of vWF, a marker of vascular endothelial dysfunction, in type 2 diabetes patients with macrovascular disease (85).

#### **ENDOTHELIAL DYSFUNCTION IN DIABETIC NEPHROPATHY**

Diabetic nephropathy is characterized by progressive excretion of urinary protein and loss of filtration, resulting in reduced clearance of metabolic waste products and finally leading to uremia (86). Mesangial expansion due to cytokine-induced proliferation of cells and matrix overproduction correlates with albuminuria and seems to contrast with another focus of microvascular damage, namely retinopathy.

However, clear evidence suggests that the diabetic renal ECs, both in the glomeruli and in the peritubular space, are responsive to chronic hyperglycemia (86). Earlier studies have indicated intraglomerular neovascularization in fenestrated vessels. Microvascular endothelial loss both in glomerular and peritubular capillaries of progressive renal disease is directly linked to impaired blood flow, the development

of renal ischemia, and scarring. Important effectors of progressive glomerulosclerosis are transforming growth factor (TGF)- $\beta$ , induced by transcriptional changes involving the hexosamine pathway, and the renin-angiotensin-aldosterone-system (RAAS). The RAAS is stimulated by hyperglycemia and also by autocrine mechanisms, involving growth factors, such as VEGF. VEGF is constitutively expressed in glomerular ECs to maintain fenestration as one hallmark of this vascular bed. Acute and chronic hyperglycemia both induce VEGF upregulation in a variety of glomerular cells, including the endothelium. Podocytes covering the filtration barrier from the outside, and which are heavily involved in the maintenance of the barrier function, are an important source of VEGF. As in the retina, the loss of VEGF from one cell source (such as podocytes) impairs the development and function of glomerular capillaries.

### ENDOTHELIAL DYSFUNCTION IN DIABETIC NEUROPATHY

Because vasoregulation of nerve microvessels is regulated at the arteriolar, venular, and EC level, the etiology of diabetic neuropathy seems to have a large vascular component. Therefore, the pathophysiology of nerve dysfunction in diabetes can at least in part be explained by reduced endoneurial microcirculation, impaired blood flow due to perturbed NO levels, prostanoid metabolism, and alterations in endoneurial metabolism (87,88) (Figure 150.5).

Experimental diabetic models have demonstrated that the infusion of glucose or induction of diabetes results in abnormal vasodilatation by NO and prostacyclin. Because the reduced NO release can be improved in the presence of antioxidants, it is likely that increased oxidative stress is one major factor inhibiting NO release. However, it is not known whether antioxidants primarily improve nerve blood flow or normalize endoneurial oxidative metabolism. An overactive polyol pathway and the presence of AGEs able to quench NO may further promote the depletion of NO. Elevated plasma homocysteine levels, which are strong predictors for diabetic neuropathy in patients with type 2 diabetes, increase asymmetrical dimethylarginine (ADMA), an endogenous inhibitor of NO synthase, and thereby also decrease NO generation by ECs.

In addition to impaired NO-mediated vasodilation, upregulation of NF- $\kappa$ B is likely to support endoneurial ischemia by inducing NF- $\kappa$ B-regulated proinflammatory and procoagulant gene products, including tissue factor and ET-1. Recent studies demonstrate that ligation of AGEs to the surface receptor RAGE perpetuates activation of NF- $\kappa$ B in cultured ECs and neuronal cells. In sural nerve biopsies, ligands of RAGE, RAGE, activated NF- $\kappa$ B p65, and IL-6 colocalized in the microvasculature of patients with diabetic neuropathy, but not in controls (89). Activation of NF- $\kappa$ B and NF- $\kappa$ B-dependent gene expression was upregulated in peripheral nerves of diabetic mice, induced by AGEs and prevented by RAGE blockade. NF- $\kappa$ B activation was blunted in diabetic RAGE<sup>-/-</sup> mice compared with robust enhancement in strain-matched diabetic controls. Loss of pain perception was largely

Figure 150.5. Pathways contributing to vascular dysfunction in diabetic neuropathy. AGEs, advanced glycation end-products; AR, aldose reductase; GFAT, glutamine:fructose-6-phosphate amidotransferase; PARP, poly(ADP-ribose)-polymerase; PKC, protein kinase C; RAGE, receptor for AGE.

prevented in *RAGE*<sup>-/-</sup> mice, although *RAGE*<sup>-/-</sup> mice were not protected from diabetes-induced loss of PGP9.5 positive planar nerve fibers. In addition, diabetic neuropathy-associated loss of pain perception was reversed in wild-type mice treated with sRAGE (89). Although RAGE is known to induce NF- $\kappa$ B activation, it is not clear if this pathway underlies RAGE-dependent neuronal dysfunction in diabetes. It is speculated that NF- $\kappa$ B activation in cells of the vessel wall of the vasa nervorum results in vascular dysfunction and leads to subsequent neuronal dysfunction. An association between microangiopathy and neuropathy has long been considered, and the AGE-RAGE axis could be one mechanism by which vascular changes ultimately lead to neuronal damage. Thus, chronic vascular dysfunction might directly mediate sensory deficits.

The vasa nervorum expresses ET-1 receptors and thus is susceptible to ET-1-dependent vasoconstriction, which results in prolonged nerve ischemia and infarction. Microvascular ischemia might be further promoted by a reduction in vascular endothelial thrombomodulin expression recently observed in the nerve microvasculature of diabetic patients. Restoring vascularization of the vasa nervorum through VEGF-induced angiogenesis in mice results in reversal of experimental diabetic neuropathy, thereby supporting the concept that microvascular ischemia in the vasa nervorum might promote diabetic neuropathy (90). When intravascular oxygen saturation and blood flow was determined in human sural nerves using microlight-guide spectrophotometry, a reduced nerve oxygenation and impaired blood flow in patients with mild-moderate sensory motor diabetic neuropathy was observed. Remarkably, intravascular oxygen saturation was higher in patients with painful neuropathy, compared with those without pain, indicating that hemodynamic factors also could play an important role in the pathogenesis of neuropathic pain (91).

### ENDOTHELIAL DYSFUNCTION IN DIABETIC RETINOPATHY

Small-vessel damage in the eye, termed *retinopathy*, affects every patient with longstanding diabetes, provided that he has had an extended period of insufficient glycemic control. The disease is divided into an early nonproliferative stage, during which progressive vascular occlusion occurs, and an advanced stage, during which new vessels are formed by angiogenesis. Predominantly in the elderly, a diabetic maculopathy is distinguished; this condition also arises from the stimuli following progressive capillary dropout and reflects an increase in retinal permeability around the macula. The term *nonproliferative diabetic retinopathy* is misleading from a vessel-oriented standpoint, because there is already significant formation of new blood vessels, although they are not growing beyond the retina borders. The clinical stages of diabetic retinopathy are shown in Table 150-1.

The two most characteristic features of incipient diabetic retinopathy are increased vascular permeability and progres-

**Table 150-1: Clinical Stages of Diabetic Retinopathy**

<b>Nonproliferative Diabetic Retinopathy</b>	
<i>Stage</i>	<i>Fundus characteristic</i>
Mild	Microaneurysm, retinal hemorrhage
Moderate	+ venous beading + IRMAs present
Severe	(4-2-1 rule) Microaneurysms + retinal hemorrhages in four quadrants Venous beading in two (or more) quadrants IRMAs in one (or more) quadrant(s)
<b>Proliferative Diabetic Retinopathy</b>	
	Neovascularization from the disc (NVD)
	Neovascularization elsewhere (NVE)
	Preretinal/vitreous hemorrhage
	Retinal detachment

IRMA, intraretinal microvascular abnormalities

sive vascular occlusion (92). The time course of hyperglycemic retinal damage has been studied in diabetic animal models (92). The very first sign of hyperglycemic damage is a transient breakdown of the BRB. Structural defects start with the loss of intramural pericytes. With progressive hyperglycemic exposure, ECs disappear focally, leaving completely acellular capillaries behind (Figure 150.6). In areas unaffected by capillary dropout, EC numbers increase over time, suggesting a dual response to hyperglycemic injury. Acellular capillaries are the most significant lesions in the diabetic retina, because they represent the universal phenotype of hyperglycemia-induced vascular cell damage and are the triggers of subsequent vascular changes (Figure 150.6). Earlier studies in humans correlating in vivo perfusion (by fluorescein angiography) with post-mortem retinal vascular digest preparations demonstrated that acellular capillaries represent capillary nonperfusion, and that microaneurysms (which are the earliest clinically detectable signs of diabetic retinopathy in a patient with diabetes), cluster around areas of capillary dropout (94). Leaky microaneurysms, focal hard exudates, and dot-blot

Figure 150.6. Retinal digest preparation of a normal (A), and a diabetic (B) rat retina, showing acellular capillaries upon exposure to hyperglycemia of <25 mmol/L glucose over a period of 30 weeks. Arrows indicate acellular capillaries. In the normal rat retina, a homogenous distribution of ECs (e) and pericytes (p) is present.

hemorrhages are direct indicators of a breakdown of the BRB. With increasing disease duration, and greater formation of nonperfused retinal areas, the retina responds to progressive capillary dropout with the formation of new blood vessels that penetrate through the inner limiting membrane into the vitreous body. In general, the number of newly formed vessels often correlates with the extent of nonperfusion in the retina. These neovascularizations tend to spread within the preretinal vitreous and are prone to rhexis and preretinal bleeding.

### TARGETING DIABETIC VASCULAR COMPLICATIONS – REVERSIBILITY OF ENDOTHELIAL DYSFUNCTION

A number of drugs that improve endothelial function have been shown to significantly lower the risk for developing late diabetic vascular complications (95,96). Insulin-sensitizing drugs that improve endothelium-dependent FMD also reduce the risk for vascular disease (45,95,97,98). Other promising strategies include inhibition of ROS by antioxidative drugs (88,95,99), blockade of receptors that initiate the cellular response to hyperglycemia (100), and targeting “supporting enzymes” such as transketolase, cofactors such as BH4 (95), and detoxifying mechanisms such as glyoxalase-1. For example, activating transketolase has been shown to reduce AGEs, lower elevated hexosamine pathway metabolites, and activate PKC in ECs kept in high-glucose conditions. Furthermore, in vivo, long-term administration of benfotiamine, the lipid-soluble prodrug of vitamin B<sub>1</sub>, reduced retinal AGEs, NF- $\kappa$ B activation, hexosamine pathway metabolites, and PKC activation to near normal levels. The result of these biochemical improvements was a major reduction in retinal capillary damage. The numbers of acellular capillaries were reduced by 80% in diabetic animals treated for 9 months.

#### KEY POINTS

- Although type 1 and type 2 diabetes are diseases of a different etiopathogenesis, both are characterized by disorders of glucose metabolism, alterations in insulin action (even patients with type 1 diabetes demonstrate decreased glucose disposal rates), and multifaceted endothelial responses to injury. The underlying biochemical abnormality, referred to as the *unifying concept*, seems to be the mitochondrial overproduction of ROS; however, the mechanisms leading to tissue-specific damage, such as vessel wall inflammation in large vessels, fibrosis in kidneys, thickening of endoneurial vessel basal lamina in neurons, and proliferation in the eye are not completely understood.

- In light of the considerable success of modern therapies for lowering blood glucose, lipid levels, and hypertension, it is even more fascinating to see that nonpharmaceutical interventions such as lifestyle changes and psychosocial stress relief management also improve endothelial dysfunction in diabetic patients. The latter implies that we are still far from understanding endothelial dysfunction in diabetes. In particular, results from pancreas transplantation but also from initial experiments using stem cell therapy approaches imply that ECs have a high potential to regenerate from hyperglycemic damage.
- Thus, diabetes research, with a focus on EC biology is beginning to recognize that the future will involve not only a better understanding of mechanisms underlying vascular complications, but also a more detailed knowledge of endogenous protective and repair mechanisms. This will provide the basis for a pathogenesis-oriented treatment that not only targets the underlying damaging mechanism, but also supports the cellular defense.

## The Role of the Endothelium in Normal and Pathologic Thyroid Function

---

Jamie Mitchell, Anthony Hollenberg, and Sareh Parangi

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Angiogenesis, the formation of new blood vessels from existing vessels, has been recognized as playing an important role in the pathophysiology of many benign and malignant diseases (1,2). This chapter focuses on the role of the endothelium in the thyroid gland and explores the advances that have been made in our understanding of how the process of angiogenesis is involved in the pathophysiology of benign and malignant diseases of this gland.

### HISTORY OF ENDOTHELIAL BIOLOGY IN THE THYROID

The structure and function of the thyroid gland has been the intense focus of study by physiologists, anatomists, surgeons, and basic scientists. Most attention has focused on the thyroid follicular cell, one of the most thoroughly studied cells in the human body. By comparison, the thyroid endothelium has received little attention. In the mid 1970s, there was increasing recognition that the endothelium of endocrine organs, including the thyroid, played an important role in homeostasis. At first, microscopy was used to study the structural detail of the fenestrated endothelium present in normal rat thyroid (3) as well as benign and malignant human thyroid tissue (4). The importance of angiogenesis in the progression of malignant disease was recognized during the early 1970s, with the realization by Folkman and colleagues that, for malignant tumor growth to progress beyond approximately 2 mm in diameter, the development of a vascular supply must occur (5). The role of endothelial cell (EC) proliferation in thyroid disorders was appreciated as early as 1978, with work performed by Wollman and colleagues (6). Using an experimental model of goiter induction by thiouracil and low-iodine diets in rats, they showed that capillaries within the thyroid enlarged by the third treatment day, with an increase in EC mitoses and fusion of capillaries, as seen by electron microscopy. These changes in blood vessel morphology were not observed in extrathyroid tissue, suggesting that they were directly related to goiter for-

mation. Additionally, in this model, EC proliferation preceded that of the thyroid epithelial cells, suggesting that angiogenesis may be an important initiating event in goitrogenesis, rather than a response to an increased metabolic demand caused by epithelial cell proliferation.

Additional insights into the importance of EC regulation in thyroid disease came during the subsequent two decades, but nearly all were related to angiogenesis in the thyroid gland. Little research was undertaken into the structure and function of the normal thyroid endothelium. One study performed by Goodman and colleagues showed that epithelial follicular cells in vitro released a growth factor into the medium that promoted EC growth and migration (7). High endothelial venules in the thyroid gland were studied in humans and rats, and thought to be the site of immunological responses in some autoimmune diseases of the thyroid (8). In 1998, Ishiwata and colleagues made the observation that increased microvessel density in papillary thyroid cancers was predictive of a worse prognosis in the form of disease-free survival (9), and Segal and colleagues determined that the degree of angiogenesis occurring in follicular tumors of the thyroid predicted frequency of intrathyroid tumor spread (10). As these and other studies began to reveal a direct relationship between angiogenesis and thyroid disease, it became increasingly clear that this process played an important role in the pathogenesis of benign and malignant disorders of the thyroid gland.

As interest in angiogenesis and its role in the malignant disease intensified, a great deal of effort was directed at characterizing the molecular mechanisms involved in the regulation of this process. One of the primary driving forces behind this research was the premise that therapeutic inhibition of blood vessel formation would selectively interfere with tumor growth. It is now well established that angiogenesis is tightly regulated by both stimulatory and inhibitory factors. Under normal conditions, these factors are well balanced, maintaining an equilibrium that prevents angiogenesis from occurring. Once this balance becomes disturbed, either via an increase in stimulatory signals, and/or a decrease in

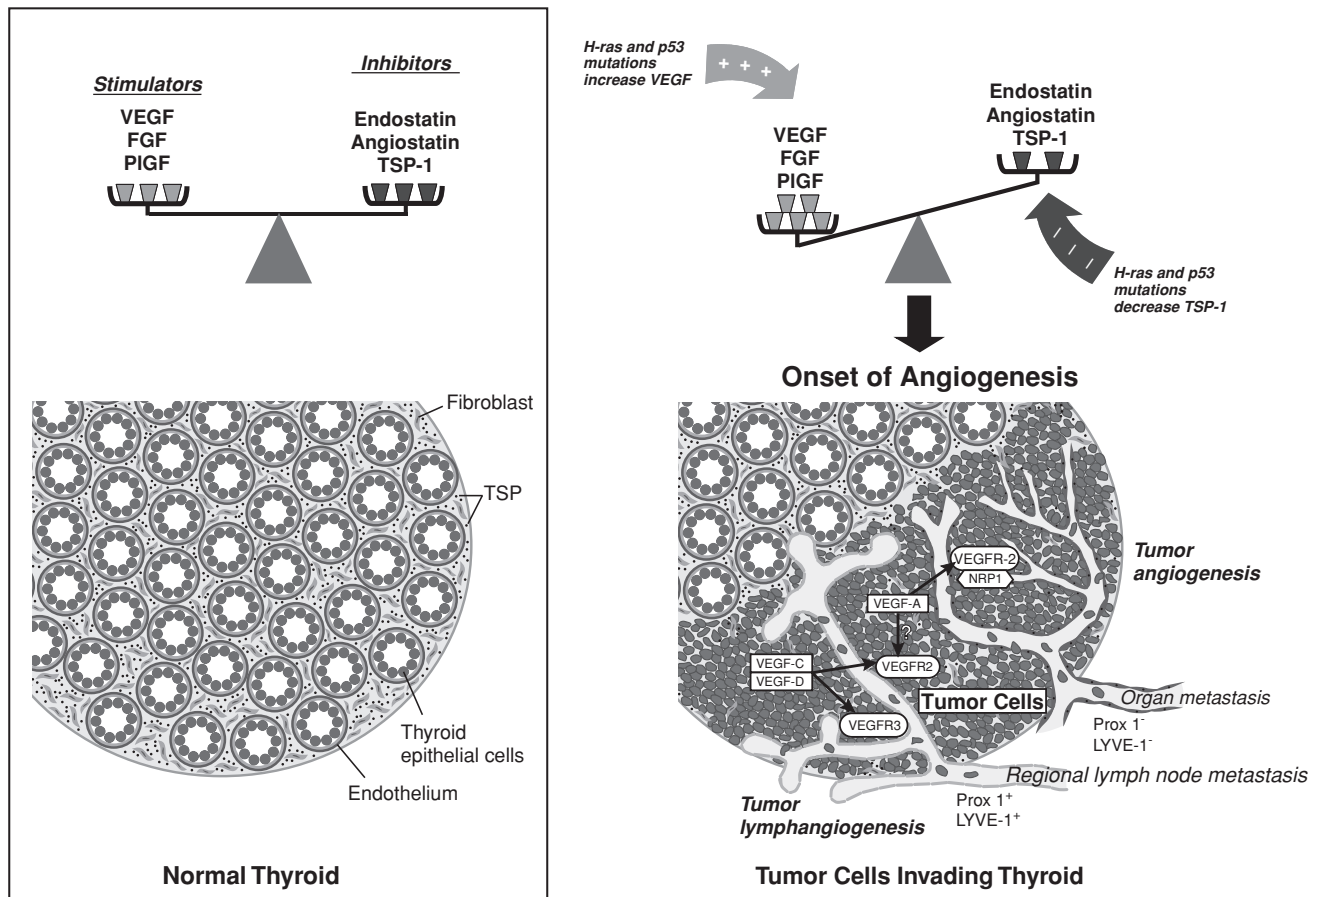

Figure 151.1. The balance of stimulators and inhibitors of angiogenesis is important in the normal thyroid gland. Disturbance of this balance, for example by Ras and p53 mutations, can lead to increases in vascular endothelial growth factor (VEGF), decreases in thrombospondin (TSP-1), and the onset of angiogenesis. Thyroid tumor cells and stromal cells provide pro- and antiangiogenic signals that are important for thyroid angiogenesis and lymphangiogenesis.

inhibitory signals, angiogenesis occurs (Figure 151.1). This has been referred to as the *angiogenic switch*, and is considered critical in the pathogenesis of malignant tumors (1). Subsequent studies demonstrated that angiogenesis is regulated by tissue-specific balances of pro and antiangiogenic factors. These findings provide a powerful rationale for developing tumor-type-specific antiangiogenesis therapies.

## STRUCTURE AND FUNCTION

The thyroid gland has a rich blood supply, with an estimated flow rate of 5 mL/g tissue per minute. The entire blood volume (approximately 5 liters), which moves through the lungs approximately once every minute and through the kidneys once every 5 minutes, moves through the thyroid approximately once every hour. While the thyroid represents only 0.4% of total body weight, it accounts for 2% of total blood flow. The principal arterial supply of the thyroid is derived from the paired superior and inferior thyroid arteries (Figure 151.2). Additional arterial supply to the gland is provided

by the thyroidea ima, and small branches from laryngeal and tracheoesophageal arteries. The inferior thyroid arteries arise from the thyrocervical trunk off the subclavian artery in most cases. They then run superiorly behind the common carotid artery before turning medially and entering the thyroid gland. The superior thyroid arteries arise as the first branch of the external carotid artery. They course inferiorly to enter the superior poles of the thyroid gland. Frequently, the artery branches at this point, with the main branch coursing over the anterior surface of the superior pole, and the smaller branch running posterior to the superior pole before entering the thyroid gland. The thyroidea ima artery is encountered in less than 10% of patients but, when present, arises from the aorta or brachiocephalic artery and courses superiorly along the anterior aspect of the trachea, finally entering the isthmus or one of the lower poles. Branching of the large paired arteries occurs on the surface of the thyroid, where several orders of branching results in a large vascular network. Only after a significant degree of branching do small arteries penetrate deep into the thyroid parenchyma. The penetrating vessels arborize among the follicles, ultimately sending a follicular artery to each follicle.

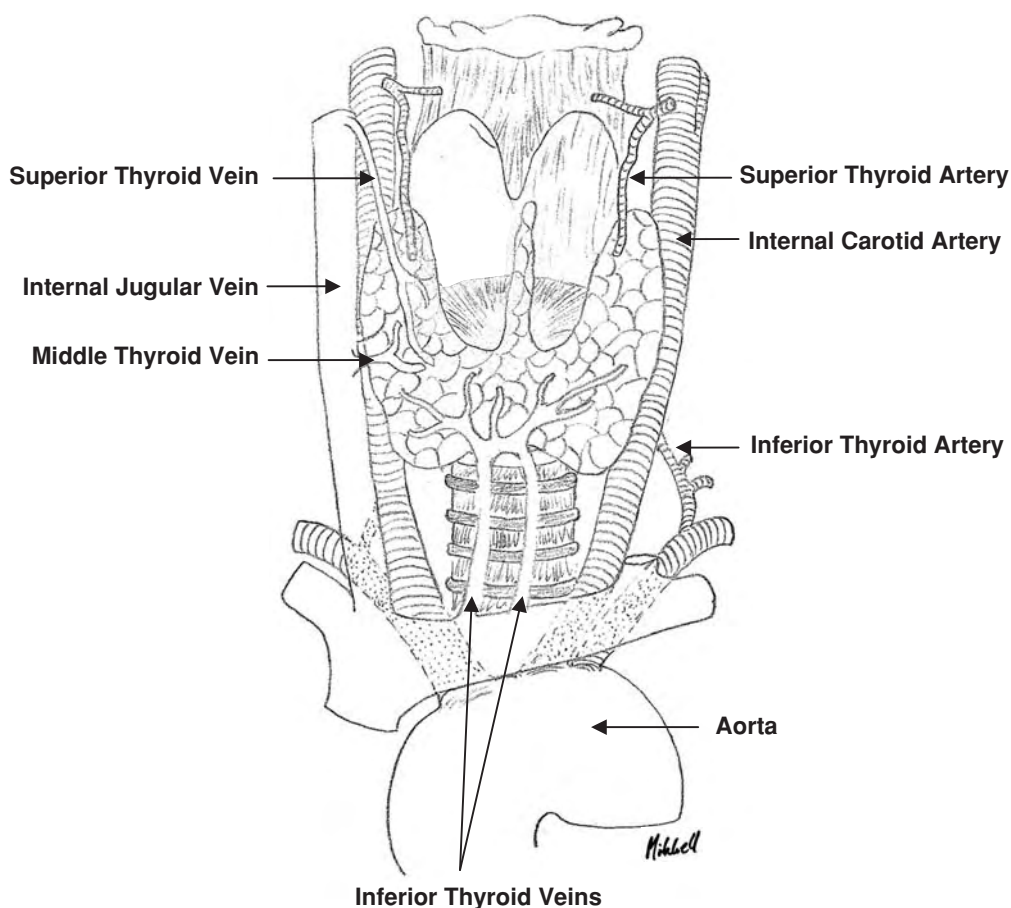

Figure 151.2. Vascular anatomy of the thyroid gland.

Venous drainage of the thyroid occurs through the superior, middle, and inferior thyroid veins (see Figure 151.2). The superior thyroid veins are formed from a confluence of vessels from the upper pole and course superiorly, crossing the carotid artery high in the neck to drain into the internal jugular veins. The middle thyroid veins drain into the internal jugular veins as well, after crossing the carotid artery anterior to the inferior thyroid artery. The inferior thyroid veins descend from the inferior poles and isthmus and drain into the brachiocephalic veins.

With the advent of transmission electron microscopy, a great deal was revealed about the structural characteristics of the ECs in the thyroid gland. The basement membrane of the follicular cells is separated from the basement membrane of adjacent ECs by a space of only a few Å (3,11). The membrane of the ECs is interrupted frequently by fenestrae of approximately 450Å in diameter. At these points, the lumen of the capillary appears to be in direct contact with the basement membrane of the thyroid follicular cells. This structural arrangement, which is thought to be similar to other endocrine organ endothelium, is believed to allow free diffusion of materials (e.g., thyroid hormone) out of the cell and into the intravascular space (Figure 151.3).

Although much of what is known about thyroid endothelial structure and function is similar to that seen in other

vascular beds, recent discoveries have hinted at the fact that endothelial structure and/or function may be more tissue- or organ-specific than previously believed. A new member of the vascular endothelial growth factor (VEGF) family of angiogenic proteins has been discovered that is specific for endocrine organs, called endocrine gland VEGF (EG-VEGF). Although thus far this protein is believed to be primarily expressed in steroidogenic endocrine glands (such as the adrenal gland), these findings suggest that there may be other endothelial factors as yet undiscovered that are specific for different organ systems in the body (12,13).

Recent studies have begun to clarify the role of thyroid hormone ( $T_4$  and  $T_3$ ) in angiogenesis in the thyroid gland. For example, Davis and colleagues demonstrated that physiologic concentrations of  $T_4$  promote angiogenesis. Their results suggest that this effect is initiated at the plasma membrane of ECs. According to their model,  $T_4$  is converted to  $T_3$  by cellular 5'-deiodinase activity;  $T_3$  enters the cell and cell nucleus, forms a complex with nuclear thyroid hormone receptor ( $TR\beta 1$ ), and initiates transcription of one or more genes relevant to angiogenesis. The presence of propylthiouracil (PTU) in the assay system did not diminish the action of  $T_4$ , however, indicating that production of  $T_3$  via deiodination of  $T_4$  did not contribute to the action of  $T_4$  and occurs via activation of the extracellular-signal-regulated kinase 1 (ERK1) and

Figure 151.3. (A) CD31 staining of mouse ECs in normal mouse thyroid and orthotopically implanted follicular carcinoma of the thyroid CD31. Note the regular pattern of ECs in the remaining normal thyroid macrofollicles (*black arrow*) versus irregular CD31 pattern of the neovessels in the tumor (*black arrowhead*). (B) Medium-magnification electron microscopic image of human thyroid tumor microvessel shows the EC nucleus (N), basal lamina (b), cytoplasmic folds (e), junction (j), and fenestra (f). -2/mitogen-activated protein kinase (MAPK) signal transduction pathway. This ultimately leads to increased expression of the proangiogenic factor fibroblast growth factor 2 (FGF2) at the EC membrane (14) with EC release of FGF2 and enhancement of the autocrine effect of released FGF2 on angiogenesis. This pathway remains to be proven *in vivo*.

### ANGIOGENIC BALANCE IN THYROID

Studies investigating angiogenesis in the thyroid gland began with attempts to determine which of the known angiogenic stimulators and inhibitors were present in follicular cells and ECs of this organ. Several groups of researchers have shown that many of the proangiogenic factors and angiogenic inhibitors listed in Table 151-1 also exist in the thyroid

gland. Studies using human thyroid tissue have determined that FGF1 and -2, as well as fibroblast growth factor receptor (FGFR)1, the receptor for these factors, are all expressed by follicular cells (15). Sato and colleagues demonstrated that normal rat thyroid follicular cells express VEGF and the VEGF receptors VEGFR1 (also known as FLT-1) and VEGFR (also known as FLK-1). Exposure to elevated levels of thyroid stimulating hormone (TSH) resulted in increased VEGF mRNA expression as well as increase in the mRNA expression of the VEGFR1 and VEGFR2. These *in vitro* and *in vivo* findings suggest that VEGF is produced by thyroid follicles in response to stimulators of TSH receptors, via the protein kinase A and C pathways. VEGF, a secretable angiogenesis factor, subsequently stimulates VEGFR1 on ECs in a paracrine manner, leading to their proliferation and producing hypervascularity of the thyroid gland, as seen in patients with Graves disease (16). Follicular cells from the thyroid gland of rats have been shown to express angiopoietin 1 (Ang1) (17), whereas ECs purified from human thyroids have been reported to express Tie1, the receptor for Ang1 (18). Members of the matrix metalloproteinase (MMP) family of proangiogenic proteins also have been characterized in human primary thyroid follicular cell cultures (19). These proteins have been found to be secreted by fibroblasts present in the thyroid (20).

In addition to these proangiogenic factors, several angiogenic inhibitors have been found to be expressed in the thyroid. Ramsden and colleagues determined that primary cultured human follicular cells secrete angiostatin (19), whereas other studies have shown that thrombospondin (TSP)-1 is secreted from the basolateral pole of thyroid follicular cells (21). Collectively, the data from these and other studies provide compelling evidence for a functional role of many of the known angiogenic stimulators and inhibitors in regulating thyroid gland angiogenesis. Moreover, they lay a strong foundation

for investigating the nature and mechanisms of the imbalance that underlies the development of benign and malignant diseases of the thyroid.

## THYROID ENDOTHELIUM IN DISEASE

### Benign Disease

The thyroid gland is one of the most common sites of benign epithelial hyperplasia, affecting nearly 15% of the adult population. Although these conditions, unlike malignancies, are generally not life-threatening, they nevertheless frequently require surgical intervention to relieve compression of the trachea or laryngeal nerves (22). Therefore, the ability to prevent these conditions or better treat them could potentially be of significant clinical benefit. Increasing evidence suggests an important role of angiogenesis in mediating benign thyroid disease. Thus, an understanding of the mechanisms underlying new blood vessel formation in these diseases may have therapeutic implications. Two benign diseases of the thyroid gland are associated with an increase in vascularity: hyperplastic goiter (multinodular goiter) and thyroiditis. As previously mentioned, the study by Wollman and colleagues in 1978 provided some of the first evidence that angiogenesis was important in the pathogenesis of benign diseases of the thyroid (6). Since then, many more studies have been conducted to examine the role of angiogenic factors in these conditions.

#### *Hyperplastic Goiter*

Both in vivo and in vitro studies in rats and humans have shown that the FGFs are important in goitrogenesis. For example, treatment of rats with systemic FGF1 has been shown to induce goiter formation (23). It also has been shown that follicular cells from human nontoxic multinodular goiters display increased expression of FGF1 and -2 compared with follicular cells from normal thyroid glands. The receptor for these factors, FGFR1, was also shown to be upregulated in these follicular cells (15). Additional evidence for the importance of FGF in goitrogenesis came from a study performed by Logan and colleagues, which showed that rats treated with methimazole and a low-iodine diet (a goitrogenic treatment) displayed upregulation of FGF2 expression in the follicular cell nuclei as well as the stroma of the thyroid, and that neovascularization accompanied this upregulation (24). The data from these and other studies provide strong evidence for the concept that FGF1 and -2 play an important role in goitrogenesis.

Evidence also exists for the other proangiogenic factors, with VEGF and the angiopoietins playing an important role in the pathogenesis of benign thyroid epithelial cell hyperplasia. Studies performed in rats have shown that, after chemical induction of goiter with methimazole, expression of VEGF, placental growth factor (PlGF; another member of the VEGF family of proteins), and its receptors VEGFR1 and -2 were upregulated in ECs (16,25,26). Similar studies have shown

that Ang1 and its receptor Tie2 are also upregulated in the ECs of experimentally induced goiters in rats (27).

In addition to the upregulation of proangiogenic factors, the angiogenic inhibitor TSP-1 has been shown to be downregulated after the induction of goiters with methimazole and a low-iodine diet in rats, and this downregulation is concurrent with the stimulation of angiogenesis (28). These studies strongly suggest that angiogenesis is important in the pathophysiology of goitrogenesis, involving a disruption in the normal balance of angiogenic stimulators and inhibitors in the thyroid follicular cells and ECs. The mechanisms by which the normal balance of angiogenic stimulators and inhibitors is altered leading to angiogenesis and goitrogenesis remain unclear.

#### *Autoimmune Thyroid Disease*

As previously mentioned, angiogenesis is implicated in the development of several pathologic conditions, including inflammatory disorders of the thyroid such as thyroiditis (29,30). Several studies have demonstrated an important role for angiogenic factors in the pathogenesis of benign inflammatory diseases of the thyroid, including Graves disease and Hashimoto thyroiditis. For example, studies comparing healthy subjects and patients with Hashimoto thyroiditis showed a significant upregulation of VEGF gene expression in the serum from Hashimoto subjects, which correlated with increased vascular flow on ultrasound vascular flow studies, as well as an increase in VEGF protein levels in the thyroid gland (31,32). Another study found that primary human thyroid follicular cells in vitro showed increased expression of VEGF mRNA after incubation with Grave immunoglobulin(Ig)G (16). Serum levels of VEGF have been shown to be significantly elevated in patients with Graves disease and Hashimoto thyroiditis compared with healthy controls (33). In this study, the thyroids of those patients with thyroiditis were shown to have significantly increased vascularity compared with the thyroids of healthy subjects (31).

Another study examining the role of various angiogenic growth factors in thyroids from patients with subacute thyroiditis (often caused by an inflammatory reaction to a viral infection) suggested a complex process whereby increased expression of VEGF, FGF2, transforming growth factor (TGF)- $\beta$ , and epidermal growth factor (EGF) in infiltrating monocytes and macrophages and thyroid follicular cells regulate endothelial and follicular proliferation (as measured by increased bromodeoxyuridine (BrdU) uptake in thyroid follicular cells after treatment with EGF) (34). As with goitrogenesis, regulation of angiogenesis appears to play an important role in the pathophysiology of inflammatory conditions of the thyroid.

In summary, a growing body of evidence supports a role for angiogenesis in the pathogenesis of hyperplastic goiter formation and inflammatory disorders of the thyroid (see Table 151-1). The extent to which the imbalance in pro- and antiangiogenic factors is an initiating event that drives follicular cell growth or is a secondary response to paracrine-mediated

follicular cell-derived signals remains to be determined. Whereas the early studies by Wollman and colleagues showed that neovascularization preceded follicular cell proliferation in an animal model of goitrogenesis, suggesting that angiogenesis may be the initiating event rather than a response to follicular cell growth (6), additional studies are needed to further elucidate the mechanisms at work here. Whatever the primary mechanism, it seems clear that angiogenesis is necessary for sustaining the follicular cell hyperplasia in animal models, thus providing a rationale for testing antiangiogenesis therapy in animal models. In fact, very recently Ramsden and colleagues (35) have demonstrated that inhibition of angiogenesis in rats with chemically induced goiters was possible with use of three combined antiangiogenic gene-therapy adenoviral vectors (RAAd-sTie2, RAAdDN-FGFR1, and RAAd-sVEGFR1). In thyroids from animals treated with all three antiangiogenic vectors, there was marked, significant inhibition of Tie2, FGFR1, VEGFR1, FGF2, and VEGF expression compared with control goiters. When used individually, RAAdDN-FGFR1 partially prevented goiter and RAAd-sVEGFR1 partially reduced vascular volume. Their effects were not additive. RAAd-sTie2 did not reduce goiter mass or vascular volume when used alone, but was essential for complete goiter inhibition. Therefore, inhibitors of angiogenesis may prove to be useful clinical tools in the future treatment of these benign disorders of the thyroid gland.

### Malignant Disease

Although therapeutic manipulation of the angiogenic balance holds promise for controlling benign thyroid conditions, its greatest potential lies in the treatment of thyroid cancer. Malignancies of the thyroid encompass many different histotypes, with varying phenotypic characteristics and clinical behaviors (36). Papillary carcinomas are thyroid malignancies (derived from follicular thyroid cells) that most commonly metastasize via lymphatics to cervical lymph nodes. Follicular carcinomas of the thyroid are generally more aggressive tumors that may give rise to hematogenous metastases. Anaplastic cancers of the thyroid are extremely aggressive tumors that possess a significant potential to become invasive, and are almost invariably fatal. Each of these tumors of the thyroid arises through malignant transformation of thyroid follicular epithelial cells. Another malignant tumor, medullary thyroid carcinoma, arises from neural crest-derived C cells present in small numbers in the thyroid. These cancers generally have a worse prognosis if not diagnosed when the primary tumor is small (<1 cm) and metastasize via both lymphatic and hematogenous routes (37).

As mentioned previously, it has been recognized that, for malignant tumors to progress, they must establish a new vascular supply through angiogenesis (5). A great deal of energy has focused on attempting to discern which angiogenic factors are involved in the pathogenesis of the various thyroid malignancies, how these differences may explain their unique clinical behavior, and how this knowledge can be utilized for the

development of new, potentially curative therapies for these malignancies.

Studies analyzing human thyroid malignancies have shown that expression of several isoforms of VEGF is significantly upregulated in papillary, follicular, medullary, and undifferentiated carcinomas compared with normal thyroid tissue (37). Expression of the VEGF receptor VEGFR2 also is upregulated in the ECs of all tumor types. Other *in vitro* studies using cultured thyroid cancer cells have provided some evidence that, in some thyroid cancers, insulin-like growth factor (IGF)-1 induced upregulation of VEGF production, associated with activation of activator protein (AP)-1 and hypoxia-inducible factor (HIF)-1 $\alpha$  via signaling through the phosphoinositide 3-kinase (PI3K)/Akt kinase cascade is important (38). These data indicate that IGF-1 stimulates VEGF synthesis in thyroid carcinomas by an Akt-AP-1/HIF-1 $\alpha$ -dependent pathway, thus providing the framework for clinical use of small-molecule inhibitors, including geldanamycin analogs, to abrogate proangiogenic cascades in thyroid cancer. VEGF levels have been correlated with pathologic stage and progression, suggesting their potential prognostic significance.

Ang2 also has been shown to be upregulated in all thyroid tumor types, except microscopic papillary carcinomas (37). The fact that neither VEGF nor Ang2 was upregulated in microscopic papillary carcinomas, a hypovascular stage of thyroid neoplasia, reinforces the notion that these proangiogenic factors are critical for the progression of tumors from early to more advanced stages. Ang2 was originally believed to antagonize the proangiogenic function of Ang1 (39), and these findings speak to the complex nature of interactions between various angiogenic factors and their regulation.

Because members of the VEGF and Ang family are upregulated in both benign and malignant diseases of the thyroid, these factors are clearly not sufficient for the angiogenic switch to a malignant phenotype. The hallmark of malignancy is the ability to metastasize via blood or lymphatics. This requires the ability of the malignant cells not only to stimulate neovascularization, but also to invade existing blood and lymphatic vessels. In addition to the obvious molecular and genomic changes in the follicular cells themselves, other groups of proteins also may be involved in angiogenesis. For example, one member of the VEGF family of proteins, VEGF-C, is believed to be involved specifically in lymphangiogenesis, because its receptor, VEGFR3, is expressed only by lymphatic endothelium (40–42). Studies of human thyroid malignancies have provided evidence that VEGF-C and VEGFR3 are strongly upregulated in the majority of tumors with a propensity for lymphatic dissemination, including papillary, medullary, and undifferentiated thyroid cancers (37,43).

The MMP family is another group of proteins involved in angiogenesis that may be particularly important in the ability of tumors to invade lymphatic and blood vessels. These proteins include more than 26 zinc-dependent endopeptidases that are thought to be tightly regulated by a group of naturally occurring inhibitors (tissue inhibitor of metalloproteinase

[TIMP]) and by interactions with other MMPs (44,45). These proteins play an important role in angiogenesis through their ability to degrade the basement membrane of ECs, allowing remodeling to occur for new vessel formation. These same properties make them important in the pathologic processes of tumor invasion into lymphatics and blood vessels. Certain MMPs, including MMP-2 and -9, which are known to be important in vascular invasion, have been shown to be upregulated in certain thyroid tumors, including papillary, medullary, follicular, and anaplastic carcinomas, compared with normal thyroid tissue (46,47). Although all studies are not in agreement, mounting evidence suggests that these factors may be the key to developing a malignant phenotype for some thyroid neoplasms. This is reinforced by the fact that upregulation of these factors has not been described in benign thyroid disease. Certainly, additional studies are required for further elucidation of the exceedingly complex regulatory mechanisms involved in the process of angiogenesis, as well as those disturbances in this regulation that lead to pathologic conditions in the thyroid. It is clear that angiogenesis and lymphangiogenesis are key processes involved in the pathogenesis of benign and malignant diseases of the thyroid. Although a great deal is still to be discovered, what is currently known is already being utilized to develop new therapies for thyroid diseases.

#### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Routine assays for the thyroid endothelium do not exist. Lymphovascular or capsular invasion (as observed by the pathologist) is considered a sign of malignant diseases of the thyroid and is often used to differentiate between benign and malignant conditions. Thyroid malignancies with a high incidence of lymphovascular invasion seen on routine histochemical staining are considered more clinically aggressive. However, the use of endothelial markers (e.g., CD31) to measure vascular density or vascular invasion is not standard.

The endothelium of the thyroid represents a potential therapeutic target in both benign and malignant thyroid conditions. At one time, Lugol's iodine solution was used to treat patients with large goiters. Although this therapy reduces thyroid vascularity, there is no evidence that it functions at the level of the endothelium (48). Ramsden and colleagues showed that adenoviral-mediated dominant negative inhibition of Tie2, VEGFR1, and FGFR1 resulted in complete inhibition of goiter formation in a mouse model of goiter (35). When used alone, recombinant FGFR1 adenoviral vector prevented goiter, recombinant VEGFR1 adenovirus partially reduced vascular volume, and Tie2 recombinant adenoviral vector failed to reduce goiter mass or vascular volume.

More attention has been paid to the potential of endothelial-directed therapies in malignant diseases of the thyroid. Recent exciting studies have shown that papillary carcinomas of the thyroid often are initiated by a set of transforming events with rearrangements of the rearranged during trans-

fection (RET) receptor or activating mutations of the BRAF or RAS oncogenes that target proteins that act along a linear signaling cascade, resulting in upregulation of chemokines and their receptors (49). It is interesting that these genes seem to act cooperatively in autocrine and paracrine loops that are relevant of the establishment of the neoplastic phenotype, including autonomous proliferation, motility, and angiogenesis. The therapeutic potential of interfering with the process of angiogenesis in malignant tumors has been recognized for some time. Even though research has focused on the discovery and characterization of the effectors of angiogenesis, it is the endothelium itself and its response to these signals that is central to that potential. Three primary strategies exist for accomplishing this: (a) use of vascular targeting agents to destroy existing vessels, (b) stimulating endogenous inhibitors of angiogenesis or administering angiogenic inhibitors (antiangiogenic agents), and (c) inhibiting the production of factors that activate or promote angiogenesis. These strategies can of course also be combined, especially when compelling clinical or molecular evidence suggests that such an approach may be synergistic.

#### Vascular Targeting Agents

One strategy that exploits the endothelium to treat malignancies involves the use of vascular targeting agents that cause directed destruction of tumor vessels. Vascular targeting agents differ conceptually from antiangiogenic agents in that, whereas the goal of the latter is to stop the formation of new blood vessels, the goal of the former is to destroy existing tumor vessels. Vascular targeting agents exploit pathophysiological differences between normal and tumor ECs and result in a characteristic central tumor necrosis (50).

One example of a vascular targeting agent is combrestatin A4 prodrug (CA4P), which aims to destroy the tubulin cytoskeleton required for rapidly proliferating and immature tumor ECs, resulting in cell death. Studies have shown that this agent was directly cytotoxic against human anaplastic thyroid cancer cell lines *in vitro*. Additional *in vivo* studies using CA4P in a xenografted nude mouse model of anaplastic thyroid cancer resulted in significant reductions in tumor volumes (likely via both direct tumor and vascular toxicity), but also showed significant toxicity to the animals (51).

Additional strategies using vascular targeting agents include those that selectively bind to components in the endothelium unique to tumor blood vessels. The targeting moiety is usually an antibody or peptide directed against a marker that is selectively upregulated in the endothelium of tumors compared with that of normal tissues. Proteins involved in angiogenesis or vascular remodeling, such as VEGF receptors and  $\alpha V\beta 3$  integrins, and cellular adhesion molecules, such as vascular cell adhesion molecule (VCAM)-1 and E-selectin, are examples of endothelial components targeted in this fashion (52). Such strategies have been shown to result in thrombosis of tumor vessels, EC death, alterations in EC shape, and the redirection of host immune defenses to attack tumor

endothelium (53,54). Other investigators have attempted to utilize vascular targeting agents to deliver toxins to tumor endothelium. For example, studies have been performed using diphtheria toxin and gelonin conjugated to VEGF-A to induce regression of tumors in mouse models (55,56). One limitation of these vascular targeting strategies is that many of the targeted markers upregulated in tumor endothelium also are upregulated in the endothelium of vessels at sites of inflammation, tissue remodeling, and physiologic angiogenesis.

### Antiangiogenic Agents

Many studies using animal models are being performed examining the efficacy of antiangiogenic agents in the treatment of thyroid cancers, with encouraging results. Many of these have used models of anaplastic thyroid cancer, given the poor prognosis of this disease and the lack of alternative treatments available to this patient population. Bauer and colleagues administered an anti-VEGF monoclonal antibody (mAb) recognizing VEGF isoforms 121, 165, and 189 in a subcutaneous nude mouse model of thyroid cancer. They showed a 60% reduction in tumor size after treatment compared with untreated controls (57).

Another study performed by Xu and colleagues examined the use of manumycin, a farnesyl transferase inhibitor, which also is known to inhibit angiogenesis by reducing VEGF production, and paclitaxel, which inhibits endothelial migration, in the treatment of anaplastic thyroid cancer in a mouse model. They found that, when used in combination, manumycin and paclitaxel significantly inhibited tumor growth compared with controls (58). Pietras and colleagues showed that treatment of a xenograft mouse model of anaplastic thyroid cancer with STI 571 (Gleevec), which selectively blocks the platelet-derived growth factor (PDGF) receptor kinase, the c-Kit receptor kinase, and the Abl and Arg nonreceptor kinases, in combination with tamoxifen (Taxol) resulted in a significantly increased antitumor effect compared with Taxol alone (59).

Other studies examining the efficacy of inhibition of endogenous angiogenic factors have been performed using animal models of follicular thyroid cancer. One study used PTK 787/ZK222584 (PTK/ZK, Novartis and Schering), an inhibitor designed to block the VEGF receptor tyrosine kinase. Nude mice implanted subcutaneously with follicular thyroid cancer cells treated with PTK/ZK had 41% less tumor growth compared with controls, as well as reduced microvascular staining (60). Another study by Soh and colleagues showed that treatment of follicular thyroid cancer in a xenograft mouse model with mAb to VEGF resulted in significant reductions in both tumor volumes and blood vessel density compared to controls (61). Subcutaneous delivery of the angiogenic inhibitor endostatin in a mouse xenograft model of human follicular thyroid cancer was shown to result in an 84% reduction in tumor volume compared with saline controls (62).

In an *in vitro* and *in vivo* model of medullary cancer in severe combined immunodeficiency mice, treatment with STI571 resulted in inhibition of RET phosphorylation, cell

proliferation, and inhibition using the small-molecule FGFR inhibitor. PD173074 also was tested and resulted in abrogation of FGF1-mediated FGFR4 phosphorylation in TT cells, an effect that was accompanied by significant arrest of cell proliferation and tumor growth *in vivo*. Moreover, the combination of STI571 and PD173074 resulted in greater suppression of cell proliferation *in vitro* and tumor control *in vivo* than that achieved using either agent alone. These data highlight RET and FGFR4 as therapeutic targets and suggest a potential role for the combined use of tyrosine kinase inhibitors in the management of inoperable medullary thyroid cancers (63).

### Current Clinical Trials

All these preclinical studies have been encouraging as to the potential of some of these agents to contribute significantly to the future treatment of thyroid cancers. In a thorough search of the National Institute of Health PDQ clinical trials database (May 2005), approximately one dozen current phase II clinical trial are using strategies that are partially or entirely antiangiogenic in their scope against any form of thyroid cancer. They cannot all be listed here due to page constraints but some agents will be reviewed.

One trial involves the use of combrestatin A4 phosphate (CA4P), a microtubule depolymerizing agent that leads to endothelial cytoskeletal changes by binding to tubulin and, in animal studies, can lead to extensive ischemic necrosis in tumors resistant to conventional anticancer treatments. In the first phase I clinical trial using CA4P (64) three patients with anaplastic thyroid cancer and two with medullary cancer were treated. One patient with anaplastic thyroid cancer with pretreatment-persistent disease in the thyroid bed and a 3-cm cervical lymph node with metastatic anaplastic thyroid cancer achieved a complete response and was disease free 30 months post-therapy (dose level 3). Surgical exploration of the neck in this patient post CA4P therapy revealed a complete pathologic response. Of note, acute coronary syndrome, with EKG changes that resolved without negative sequelae, was seen in a number of patients undergoing treatment with CA4P, including one patient with anaplastic thyroid cancer (65). Currently, a phase II trial of CA4 P is accruing patients with anaplastic thyroid cancer.

Another phase II trial is examining the role of ZD6474, a low-molecular-weight tyrosine kinase inhibitor (an anilinoquinazoline compound) originally identified as a chemical inhibitor of VEGFR2, with additional activity against the EGF receptor (EGFR) (66). This compound also has been found to inhibit RET/PTC transformed fibroblasts injected into nude mice (67). This combination might prove to be effective, especially in medullary carcinoma of the thyroid in which both angiogenesis and RET/PTC mutations play an important role in the development and spread of this malignancy. In a recent study by Vidal and colleagues (68), RET-mediated eye phenotypes in a *Drosophila* model of multiple endocrine neoplasias type 2A and 2B were suppressed by use of oral ZD6474, with high efficacy and low toxicity.

Another agent under current study is bortezomib (PS-341, Velcade), the first proteasome inhibitor evaluated in human clinical trials. It has been approved by the U.S. Food and Drug Administration for use in patients with refractory or relapsed multiple myeloma. Preclinical study results show that bortezomib suppresses tumor cell growth, induces apoptosis, overcomes resistance to standard chemotherapy agents and radiation therapy, and inhibits angiogenesis (69).

BAY-43-9006, is a novel bi-aryl-urea that is a potent inhibitor of Raf-1, a member of the RAF/MEK/ERK signaling pathway. It also has been shown to be effective against several tyrosine kinases involved in neovascularization, such as VEGFR2 and VEGFR3, PDGF receptor B (PDGFRB), FLT-3, and c-kit (70). Given the recent developments indicating the importance of both RAF signaling and angiogenesis in thyroid cancer, it is logical that this agent is being rapidly tested in phase II clinical trials for patients with locally advanced, metastatic, or locally recurrent thyroid cancers.

## CONCLUSION

This chapter has focused on the role of the endothelium in the thyroid gland and explored the advances that have been made in our understanding of how the process of angiogenesis is involved in the pathophysiology of benign and malignant diseases of this gland. The thyroid follicular cell has been one of the most studied cells in the human body, and the thyroid endothelium has been clearly the focus of less intense study than it deserves. However, every day, new advances are being made in understanding the cross-talk between thyroid follicular cells, stroma, and thyroid endothelium; these advances will undoubtedly lead to logically combined therapeutic agents to treat both benign and malignant thyroid conditions.

## KEY POINTS

- Angiogenesis and ECs play an important role in the pathogenesis of benign and malignant disorders of the thyroid gland, but they are understudied.
- Proangiogenic factors such as FGF1, FGF2, VEGF, and the angiopoietins play an important role in the pathogenesis of benign thyroid epithelial cell hyperplasia and goitrogenesis.
- Regulation of angiogenesis appears to play an important role in the pathophysiology of inflammatory conditions of the thyroid.
- Studies analyzing human thyroid malignancies have shown that the expression of several isoforms of VEGF is significantly upregulated in papillary, follicular, medullary, and undifferentiated carcinomas compared with normal thyroid tissue.

- Studies of human thyroid malignancies have provided evidence that VEGF-C and VEGFR3 are strongly upregulated in the majority of tumors with a propensity for lymphatic dissemination, including papillary, medullary, and undifferentiated thyroid cancers.
- The endothelium of the thyroid represents a potential therapeutic target in both benign and malignant thyroid conditions.
- Many phase II clinical trials directed against thyroid cancer are currently using strategies that are partially or entirely antiangiogenic in scope.

## Endothelial Dysfunction and the Link to Age-Related Vascular Disease

Jay M. Edelberg\* and May J. Reed†

\*Weill Medical College of Cornell University, New York;

†University of Washington, Seattle

Vascular pathology and its associated clinical entities have a broad impact on the health of older persons. Specifically, cardiovascular disease and stroke account for the majority of morbidity and mortality in individuals over the age of 65 (1). Other conditions related to vascular pathology, such as erectile dysfunction (ED) and impaired wound healing, also have a significant effect on the lives of older persons. Understanding the changes in the vasculature that occur with aging may provide insights into many disorders that affect the elderly.

Aging is associated with multiple changes in endothelial cell (EC) function that limit the capacity of older blood vessels to dynamically regulate and restore blood flow (Table 152-1). Although older persons have higher vascular risk factor profiles as a result of cumulative environmental exposures (e.g., smoking) and an increased prevalence of endogenous pathological conditions (e.g., diabetes and hyperlipidemia), inherent age-related changes in endothelial function contribute significantly to subsequent vascular dysfunction. Accordingly, it is important to emphasize that, although many factors have a role in the development of EC dysfunction, the normal aging process is itself an independent risk factor for developing vascular diseases. The overall goal of this chapter is to focus on changes in endothelial function related to “normal” aging in the general population, and to discuss the interaction between aging and other cardiovascular risk factors in promoting vascular disease in the elderly.

### THE AGED ENDOTHELIAL CELL

Little is known about how “normal aging” affects ECs in the absence of disease and/or age-related physiologic changes impacting vascular and endothelial function. Many of the observations are extrapolated from experiments using fibroblasts that have incurred numerous population doublings in vitro (2,3). When ECs are examined, they are usually late-passage human umbilical vein ECs (HUVECs) or other lines

that grow easily in culture (4,5). It is important to note that in vitro studies usually result in the loss of features that reflect differences in the function of large- versus small-vessel ECs.

Spontaneous changes that have been observed in cells aged in culture, and that are relevant to aging in vivo, include attrition of telomeres leading to unstable chromosomes and subsequent inhibition of cell cycle progression (6). The resultant senescent EC phenotype is defined by decreased proliferation, expression of  $\beta$ -galactosidase at pH 6, accumulation of cellular/chromatin debris, and increased expression of cell cycle inhibitors (7). Senescent cells also have stress-induced alterations, including stabilization of p53 and hypophosphorylation of Rb with subsequent activation of cell cycle inhibitors (8,9). In addition, whereas senescent cells produce less nitric oxide (NO), they accumulate reactive nitrogen and other toxic free radical species that can activate the apoptotic pathway (10,11). To this end, the endothelial regulatory pathways governing apoptosis and senescence are not mutually exclusive. The choice of one pathway over the other is a complex balance determined by the type and concentration of exogenous stress, as well as the presence or absence of proteins, such as caspase inhibitors, that control cell survival (12).

### ENDOTHELIAL FUNCTIONS/DYSFUNCTIONS

In vivo ECs orchestrate multiple functions, which collectively serve to regulate vascular supply to tissues. For example, the finely tuned balance between coagulation and fibrinolytic pathways maintains optimal hemostasis/blood fluidity within the intravascular space. Endothelial-mediated vasodilation and vasoconstriction serve to adjust flow from one moment to the next according to the needs of the local tissue, and to rapidly respond to major disruptions in supply or demand brought about by thrombosis and/or end-organ damage. The endothelium also plays a central role in angiogenesis, which supports additional blood flow requirements by ischemic tissues.

**Table 152-1: Endothelial Dysfunction and Aging**

<i>Disease/ Pathophysiology</i>	<i>Thrombosis</i>	<i>Vasodilation/ Constriction</i>	<i>Angiogenesis</i>
Coronary artery disease	+	+	+
Stroke	+		
Wound healing			+
Erectile dysfunction		+	

Age-related endothelial dysfunctions correlated with vascular diseases affecting older persons.

In addition, ECs modulate immune and inflammatory activities, impacting on overall host defense mechanisms and vascular homeostasis. In the aging blood vessel, these and other endothelial functions are altered, contributing to an increase in the severity of vascular pathology in older persons.

### Thrombotic Regulation

Hemostatic regulation is one of the central properties of the vascular endothelium. The normal endothelial lining provides a dynamic antithrombotic surface that suppresses procoagulant enzyme activity and platelet aggregation in the local circulation. The anticoagulant properties of unactivated, quiescent ECs are maintained to a large degree by the expression of the glycosaminoglycan, heparan, and the enzymatic cofactor, thrombomodulin (TM) as well as tissue factor pathway inhibitor (TFPI) and the endothelial protein C receptor (EPCR). One of the significant actions of endothelial heparan is to promote the inactivation of thrombin and factor Xa by antithrombin III (ATIII). TM acts as a substrate-modulating cofactor for activated protein C (APC) to direct the inactivation of factors Va and VIIIa.

Vascular injury induced through acute stimuli (such as vessel trauma) and chronic conditions (such as atherosclerosis) reverse the hemostatic regulatory pathways and induce a procoagulant milieu. Disruption of the endothelial lining also exposes tissue factor and the collagen of the subendothelial extracellular matrix to activate thrombin and platelet aggregation. Activation of the intact endothelium may result in increased adhesion of platelets and leukocytes, secretion of von Willebrand factor (vWF), expression of tissue factor, and downregulation of natural anticoagulant mechanisms such as TM.

Quiescent ECs also contribute to the resolution of thrombi, secreting enzymes (tissue-type plasminogen activator [t-PA] and urokinase-type plasminogen activator [u-PA]) that activate plasminogen to plasmin, an enzyme that degrades fibrin. In addition, ECs release inhibitors that quench activating enzymes as well as plasmin itself (plasminogen activator inhibitors [PAI]-1, and  $\alpha$ 2-antiplasmin, respectively). The EC membrane also provides a surface for the regulation of the

enzymes that bind to annexin-2 (plasminogen receptor) and the urokinase receptor.

Previous studies have shown that aging is associated with increased coagulability and decreased fibrinolysis due to changes in endothelial- and nonendothelial-mediated functions, suggesting a potential basis for the predisposition of older individuals to thrombotic coronary and cerebrovascular events. Large-scale population-based studies have found a correlation between advanced age and increased levels of plasma coagulation factors and D-dimers (13,14). Moreover, older persons demonstrate longer thrombolysis time compared with younger individuals (15,16). Mechanistically, this may be related to increases in PAI-1, which is found to be upregulated in vitro in aged human ECs (4) as well as in the in vivo endothelium of "Klotho" mice, a genetic murine model of aging (17). Notably, however, in studies of lipopolysaccharide (LPS)-induced thrombosis, older mice revealed an increase in PAI-1 that was restricted to perivascular cells, including hepatocytes and renal glomerular cells, but not ECs (18). This increase in PAI-1 was linked to elevations in tumor necrosis factor (TNF)- $\alpha$  (18), which suggests that age-associated changes in TNF receptor-1 pathways may contribute to the increase in PAI-1 and thrombosis in the aging vasculature (19). In addition, the production of coagulation inhibitors, such as APC and ATIII, has been shown to be altered in some groups of elderly (20,21). Similarly, heparan, the endogenous template for ATIII, has been shown to be structurally altered in aging (22). Although age-related changes have been described only with respect to its interactions with vascular growth factors, changes in heparan could impact endothelial hemostatic regulation either directly or indirectly through modulation of coagulation enzymes and growth factors.

The clinical impact of senescent shifts in coagulation and fibrinolytic pathways is complex in the aging population. An increase in prothrombotic function is associated with an increased risk of acute coronary events, which is the major cause of morbidity and mortality in the elderly (1). Conversely, however, the serum of centenarians shows increased expression of biomarkers for hypercoagulability (14), including high levels of PAI-1 (23). These data suggest that longevity-related genes may counter and/or redirect the coagulant pathways to promote healthy aging in long-lived individuals.

### Vasomotor Tone

ECs govern blood flow by regulating the constriction and dilation of blood vessels. Changes in local oxygen consumption or disruption of end-organ blood flow due to vascular thrombosis triggers EC pathways aimed at acutely compensating for the dynamic needs of tissue beds. Through the balance of local factors, including NO and endothelin (ET)-1, ECs can govern smooth muscle tone in the expansion and constriction of blood vessels to adjust the delivery of oxygenated blood to specific organs.

Age-associated changes in ECs as well as smooth muscle cell function can limit the capacity of older blood vessels to

regulate local blood flow. The altered regulation of vascular tone impairs the vasodilation of both coronary and peripheral blood vessels in older persons. Clinical studies often have employed forearm brachial blood flow as a surrogate index for coronary vascular dynamics. In this model, older persons have decreased brachial endothelium-dependent vasodilation, as compared with younger individuals with otherwise matched clinical characteristics and risk factors (24). These data correlate with impaired acetylcholine-induced endothelium-dependent coronary vasodilation *in vivo* (25), but are not uniform throughout the aged vasculature (26). For example, aging may have a greater impact on smaller blood vessels of the mesenteric tree relative to larger conduits such as the aorta (27). The larger arterial beds, however, are more affected by age-related decreases in viscoelastic properties, causing increases in arterial stiffness (28). Such findings highlight that vascular changes in the aged often reflect events that are specific to the local vasculature.

Mechanistically, the changes in endothelium-mediated vasoactive function have been linked to alterations in two integral mediators of these respective functions: NO and ET-1. Coronary basal and stimulated NO production is decreased with aging (29). Moreover, studies in rodent models reveal that NO-dependent aortic vasodilation is diminished (30). ET-1-induced coronary vasoconstriction is increased in the aged (31,32). Functionally, aging rodent hearts have less resistance to myocardial ischemia and reperfusion injury in association with decreased coronary NO production (33). Age-related deficits in hypoxia-inducible factor (HIF)-1-mediated expression of vascular endothelial growth factor (VEGF) may impair the codependent vasodilatory actions of NO and VEGF (34). The compromise in early compensatory actions and regulation of vascular tone contributes to impaired angiogenesis and can increase the subsequent risk of apoptosis and necrosis of dependent tissues.

In addition to changes in vasoactivity, large arteries in the aged demonstrate increased stiffness due to protein cross-linking and deposition of advanced glycation end-products (AGEs) in the extracellular matrix. The decreases in elasticity limit the dynamic recoil of the arterial system (28). The resultant elevation in blood pressure required to compensate for the increase in conduit stiffness could, in turn, lead to further endothelial dysfunction in the aging vasculature. Novel agents developed as AGE cross-link “breakers” improve cardiovascular function in aging animal models and offer the potential for countering the effects of aging, as well as diabetes, on the arterial system (35).

### Angiogenesis

Disruption of blood flow due to injury, thrombosis, or vasoconstriction induces a cascade of growth factors that enhance cell proliferation and migration. Specifically, the resulting hypoxia promotes the expression of a set of genes regulated, in part, by HIF. HIF stimulates the expression of VEGF, which in turn promotes EC proliferation and migration as well as

local vasodilation. Other factors induced in the hypoxic state include fibroblast growth factor 2 (FGF2) and platelet-derived growth factor (PDGF), which function synergistically with VEGF to promote angiogenesis. Endothelial precursor cells (EPCs) also are recruited from the circulation and contribute to angiogenesis and the expression of growth factors.

Physiological and pathological angiogenesis is depressed in most older tissues including the heart, peripheral vascular beds (36), and select disease-matched tumor beds (37,38). Indeed, cardiac angiogenesis induced by myocardial hypertrophy is significantly depressed in the aging heart, as evidenced by 20% less capillary growth (39,40) and subsequent impaired myocardial blood flow (41,42). Angiographic studies of risk factor-matched subsets of patients with coronary artery disease reveal decreased collateral circulation in older individuals (43).

The age-related impairment of angiogenesis is due to deficits in growth factor synthesis and dysregulation of angiogenic cytokine pathways, both in peripheral ECs and EPCs. Experimental models have demonstrated impairments in the expression and function of a number of angiogenic factors, including VEGF (34,36), FGF2 (44,45), transforming growth factor (TGF)- $\beta$  (46), and PDGF (47). Age-associated decreases in the concentration and function of EPCs compound this dysfunction (48,49). Functionally, the replacement of deficient angiogenic growth factors, such as FGF, VEGF, and PDGF, improves the migration and proliferation of aged, multipassaged ECs and ECs isolated from aging mice (50,51). Moreover, treatment of aged tissues (both in the basal state and after ischemic injury) with angiogenic growth factors (36,52) or EPCs from transplanted young bone marrow cells increases subsequent capillary density and improves vascular function.

It is important to note that age-related macular degeneration, a common cause of blindness in the elderly, is an exception to the rule regarding a lack of angiogenesis in aged tissues. In the vascularized form of this condition, high levels of VEGF and alterations in other growth factors from the retinal pigmented epithelium contribute to excessive neovascularization and subsequent increased risk of blindness (53). To this end, the recent use of VEGF inhibitors for the treatment of this disease reveals the importance of tissue-specific regulation of angiogenesis in the clinical manifestations of endothelial angiogenic function and dysfunction in the elderly (54).

### AGE-ASSOCIATED DISEASES – THE LINK TO ENDOTHELIAL DYSFUNCTION

The combined impairments in hemostasis, vasodilation, and angiogenesis increase the risk of associated vascular diseases in older persons. For example, the prothrombotic tendency may lead to stroke and myocardial infarction (MI), alterations in vascular tone predispose to endothelial dysfunction, and depressed angiogenesis might contribute to delayed tissue repair in older persons.

### **Cardiovascular Disease: Link to Multiple Endothelial Dysfunctions**

Ischemic cardiovascular disease is the most common cause of morbidity and mortality in the U.S. population over age 65 (1). MIs in the elderly result in poorer outcomes and are associated with higher rates of infarction-related mortality, compared with younger individuals. In addition, those surviving initial cardiac events are more likely to develop congestive heart failure, suggesting that age-related changes in the vasculature predispose older individuals to an increased risk of clinically significant pathology.

Endothelial dysfunction is one of the most important predictive factors for cardiovascular disease in the general population (55), and its impact is heightened with age. For example, age-associated increases in antifibrinolytic parameters, such as endothelial-derived PAI-1 (56), could contribute to the increased incidence of cardiovascular disease in the aging population. Mechanistically, however, PAI-1's role as an acute phase reactant, like C-reactive protein, also could be the basis of the association between cardiovascular disease and increased inflammatory mediators.

Physiologically, the response of the aging heart to coronary occlusions is impaired, leading to increased myocardial injury, when compared with similar arterial compromise in younger hearts. Previous studies have demonstrated that episodes of cardiac tissue hypoxia caused by transient coronary occlusion induce vasodilatory actions that result in cardioprotection in the young rodent heart (57). In the aged heart, this ischemic preconditioning can be significantly depressed (58–60). This deficit, which reflects inherent endothelial dysfunction and impaired vasodilation, contributes to worse clinical outcomes for older persons after MI.

Age-related decreases in angiogenesis may also contribute to increased pathology following myocardial injury in older persons. Angiographic studies have shown that subgroups of older patients with diabetes have decreased collateral circulation relative to younger counterparts otherwise matched for clinical characteristics (43). Experimental studies aimed at reversing these age-related changes have demonstrated that restoration of PDGF-based pathways at the time of acute coronary occlusion can significantly reduce the extent of myocardial injury in the aging rodent heart (61). Interestingly, the PDGF-induced angiogenic factors (including VEGF and angiopoietin 2 [Ang2]) rapidly suppress myocardial apoptosis. These data suggest that restoring angiogenic pathways in the aging heart may have clinical utility in conjunction with present reperfusion therapies (e.g., thrombolytics and primary angioplasty) for acute MI.

### **Stroke: Link to Prothrombotic Predisposition**

Advanced age has been shown to be a risk factor for stroke and its complications (62,63). Indeed, stroke is the single greatest source of major morbidity in older persons. The neu-

ropathology resulting from stroke can contribute to cognitive impairment in older persons. Often seen in the setting of systolic hypertension, "subclinical" strokes are a major cause of dementia and functional decline in aging (64). Thromboembolic occlusion of a vessel is the primary pathophysiology of stroke and, similar to cardiovascular disease, is related in part to endothelial dysfunction. Consequently, age-associated changes in endothelial pathways may contribute directly to the increased risk of stroke in the geriatric population.

In addition to hypertension and aging itself, atrial fibrillation and diabetes are the greatest risk factors for stroke in older persons. Each of these conditions is more prevalent in older persons and is associated with impaired endothelial function. Hypertension has been linked to impaired vasodilation. Atrial fibrillation has been associated with increased endothelial activation (65). Diabetes results in greater degrees of oxidative stress and release of inflammatory mediators, which are detrimental to endothelial function and increase the risk of vascular damage (66). Thus, due to the coexistence of multiple risk factors in many elders, optimal prevention of stroke in the aged requires control of hypertension, minimization of thrombus formation in the large vessels and atria, and improved management of diabetes.

### **Aging and Delayed Wound Healing: Link to Impaired Angiogenesis**

Aging is associated with delayed wound healing in the skin and other organs. In the basal state, there are fewer capillaries in aged skin and other tissues (67), and the rate of capillary growth in wounds is decreased in older animals (68). The decline in neovascularization has been attributed to decreases in both the proliferation and migration of ECs in the wound bed (69). This deficit is due, in part, to reduced levels and function of endothelial angiogenic factors, such as the growth factors TGF- $\beta$  and VEGF (36,70,71). Other age-related defects in EC behavior during injury include increased adhesion to leukocytes, enhanced response to TNF- $\alpha$ , and greater interleukin (IL)-1 production (72–75).

It has been shown that the replacement of deficient angiogenic growth factors can increase the growth of capillaries in aged tissues (36,52). However, the extrapolation to enhanced wound repair (as a direct result of increased neovascularization, as opposed to the numerous other changes induced by the application of these angiogenic factors) remains to be proved. Notably, in animal models, treatment with inhibitors of angiogenesis had inconsistent effects on cutaneous wound repair and has been shown to modulate functions other than the growth of new vessels (76–78). The importance of angiogenesis to wound healing may be tissue-specific: A lack of newly formed vessels has been shown to be detrimental to repair of intestinal anastomoses (79). It is important to note that none of the studies using inhibitors of angiogenesis were performed on aged animals. In this context, it is likely that a limitation on capillary growth that is not detrimental to healing in a young

animal may have significant consequences for an aged animal, wherein multiple other impairments coexist.

**Erectile Dysfunction: Link to Impaired Vasodilation**

ED, which has received an unprecedented amount of public attention in recent years, is a primary defect of endothelial-mediated vasodilation. Aging, diabetes, hypertension, and smoking are independent risk factors for ED. Accordingly, men with ED also have an increased risk of developing cardiovascular diseases (80,81), demonstrating that the manifestations of endothelial dysfunction are broad with respect to clinical presentations of vascular pathology in older persons.

One of the underlying mechanisms of ED is a lack of NO, in conjunction with increased ET-1, in the aged penile endothelium. Acetylcholine-mediated endothelial vasodilation is impaired in the aged penile vasculature, similar to brachial arterial studies that correlate with an increased risk of impaired endothelial function (24). Mechanistically, this decrease in NO may be related to an age-related suppression in penile expression of VEGF (82). Experimental approaches to restore these pathways through VEGF gene therapy have shown increased endothelial NO synthase (eNOS) expression and improved penile function in an aging rat model (83). Moreover, diabetic models suggest that VEGF may act through the suppression of apoptosis in the penile cavernosa (84), a role potentially analogous to the antiapoptotic actions of exogenous angiogenic growth factors on the ischemic myocardium (61).

Notably, it is the pharmacological treatment of ED that represents the most significant advance in the development of therapies aimed at reversing the age-associated impairment in endothelial/vascular function. Specifically, the role of sildenafil, an inhibitor of phosphodiesterase (PDE)-5 activity in human corpora cavernosa (85), restores vasoactive erectile function and has revolutionized the treatment of ED. Moreover, the benefits of PDE-5 inhibition extend beyond ED to improve vascular function in other beds. Early trials have shown beneficial actions of sildenafil in the pulmonary arterial system to treat pulmonary hypertension (86,87). Similarly, PDE-5 inhibition improves cutaneous microcirculation in patients with coronary artery disease (88). Mechanistically, the actions of PDE-5 inhibition extend beyond vasodilation, potentially improving angiogenesis (89) and inducing cardiac preconditioning (86,90). The expanded understanding gained from the targeting of PDE-5 suggests that clinical pharmacology developed to counter age-associated endothelial vascular impairment in a specific vascular bed may have broader applications for reversing senescent endothelial dysfunction. Deficits in function in different regions of the vasculature may share common pathways in endothelial dysfunction and that development of interventions aimed at improving EC function in one organ may have utility in the treatment of other tissues in older persons.

**KEY POINTS**

- Those endothelial functions that are altered with aging – vasodilation, hemostasis, and angiogenesis – have a significant influence on many clinical conditions that affect older persons.
- In aging ECs, thrombosis and activation are increased, and vasodilation and angiogenesis are decreased.
- By improving the understanding of the mechanisms that relate endothelial dysfunction with age-related pathology, future therapies may be developed to specifically reverse the predisposition to vascular diseases in the elderly.

## Kawasaki Disease

---

Jane C. Burns

*University of California, San Diego School of Medicine*

Kawasaki disease (KD), an acute vasculitis of infancy and early childhood, affords a unique opportunity to study acute endothelial cell (EC) damage in the setting of previously healthy arteries unaffected by underlying disease processes such as atherosclerosis, hypertension, or diabetes. KD is now the most common form of acquired heart disease in children in the United States and Japan (1,2). The vasculitis presents with clinical signs that include fever, rash, conjunctival injection, edema and erythema of the extremities, and mucosal erythema (3). The vasculitis is self-limited, but without treatment, one in four children will develop coronary artery aneurysms occasionally accompanied by aneurysms of other medium-sized, muscular, extraparenchymal arteries (4). Echocardiography during the first 2 months after onset of fever is used to classify patients as having normal, dilated, or aneurismal coronary arteries. Long-term sequelae of the coronary artery aneurysms include ischemic heart disease and myocardial infarction. The acute inflammation can be abrogated in the majority of patients with a single dose (2 g/kg) of intravenous immunoglobulin (IVIG) and aspirin (80–100 mg/kg/day), which reduces the aneurysm rate to 3% to 5% (5).

The etiology of KD remains unknown, although an infectious cause is suspected based on seasonality and clustering of cases (2) and the similarity of clinical signs to other infectious diseases. In addition, the peak incidence in infants and children younger than 5 years, coupled with the rare occurrence of KD in adults and infants younger than 3 months of age, is consistent with infection with a widely disseminated agent that causes asymptomatic infection in most hosts and the acquisition of protective immunity and passage of transplacental antibodies. The finding of immunoglobulin (Ig)A-secreting plasma cells infiltrating into the trachea and small airways, coupled with molecular evidence of an oligoclonal IgA response, suggests a pathogen with a respiratory portal of entry (6,7). Genetic factors likely influence disease susceptibility because the disease is over-represented in children of Asian descent and among siblings and other family members of an index case (8,9). Study of the pathophysiology of KD is hampered by lack of a convincing animal model, inability to sample affected tissues during life, and the paucity

of autopsy material due to the rare occurrence of fatal cases. In this chapter, we review the evidence for acute EC injury associated with KD and discuss studies that address whether EC dysfunction is also a late complication of KD in children and young adults.

### **PATHOLOGY OF THE VESSEL WALL IN KAWASAKI DISEASE**

Our understanding of the pathology of KD is based largely on autopsy data due to the inability to biopsy affected arteries during life. Initial autopsy studies focused on similarities between KD and infantile polyarteritis nodosa, a systemic vasculitis of young infants recognized only at autopsy (10,11). The hallmark of the arteritis observed in autopsy tissues in both disease entities is the presence of lesions within the same patient at different stages in the evolution of the vasculitis, as outlined in Table 153-1 (12,13). The earliest changes are observed in the endothelium of the musculo-elastic arteries and include swelling, proliferation, enlarged nuclei, and frank degeneration with adherent platelets entrapped in fibrin (14). The endothelium of the vasa vasorum of larger arteries can be similarly involved. More advanced lesions show edema and inflammatory cell infiltrate in the subendothelial space. This progresses to destruction of the media, with necrosis associated with infiltration of monocytes and lymphocytes of the memory T cell (CD45RO<sup>+</sup>) and cytotoxic/suppressor T cell (CD8<sup>+</sup>) phenotypes extending from lumen to adventitia, which results in a transmural vasculitis (15). Replacement of the intima and media with fibrous connective tissue, thinning of the media with aneurysm formation, scarring, and stenosis complete the progression of the vascular lesion. Coronary artery rupture is extremely rare but can occur during the subacute phase. Stenosis occurs over a period of months to years, and these lesions may remain silent until the moment of acute thrombotic occlusion, often decades after the initial acute illness (16,17).

Remodeling of the arterial wall may be followed by gradual thrombotic occlusion and recanalization of the vessel. In a

**Table 153-1: Progression of Arterial Lesions in Acute KD as Deduced from Autopsy Data**

---

Intimal mononuclear cell accumulation with intimal thickening  
 Mixed inflammatory cell infiltration of outer adventitial sites  
 Lymphocytic infiltration of luminal side of intima  
 Progressive medial disruption with a mixed inflammatory infiltrate and edema  
 Intimal fibrinoid necrosis  
 Luminal thrombosis and aneurismal dilatation

study of arterial lesions after KD, high levels of growth factors, including transforming growth factor (TGF)- $\beta$ 1, platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) were noted in the muscular layers, whereas vascular endothelial growth factor (VEGF) was strongly expressed by the ECs of these neomicrovessels (18). Presumably, the artery recanalizes by proteolysis of the thrombus with seeding of endothelium via migration and proliferation of endothelial progenitor cells. Thus, KD provides not only a model for acute EC destruction but also neoangiogenesis and EC proliferation.

The state of the endothelium in the microvasculature during acute and convalescent KD in living patients has been studied in three different vascular beds: skin, conjunctiva, and right ventricular myocardium. In the skin, nonspecific degenerative changes were noted in the endothelium of both subcutaneous venules and arterioles (19). Direct evidence of EC activation during acute KD comes from examination of skin biopsies that demonstrated high levels of intercellular adhesion molecule (ICAM)-1, endothelial adhesion molecule (ELAM)-1 (also known as E-selectin), and human leukocyte antigen (HLA) DQ expression on capillary ECs (20). Study of conjunctival biopsies by electron microscopy revealed areas of vacuolated endothelial cytoplasm with adherent platelet clumps, suggesting focal EC damage (21) (Figure 153.1).

In a study of right ventricular biopsies in 201 KD patients studied 1 week to 11 years after onset of acute KD, all patients had some degree of EC degeneration detected by light microscopy (22). In addition, all patients had evidence of myocarditis with lymphocytic infiltrates and varying degrees of fibrosis. Disarray, abnormal branching, and hypertrophy of cardiac myocytes also was noted. A second study of right ventricular biopsies obtained 2 months to 23 years after disease onset in 54 KD patients revealed changes in the endothelium by electron microscopy that included atrophy, degeneration, and fresh thrombus attached to damaged ECs of the microvessels (23). ECs in the arterioles and small arteries showed proliferation, swelling, vacuolization, and projection into the lumen. These findings were noted in six (20%) of 30 age-matched

Figure 153.1. Electron photomicrograph of conjunctival biopsy obtained on illness day 4 from a 3-month-old patient with KD prior to intravenous gamma globulin treatment. ECs have areas of vacuolated cytoplasm with adherent platelet clumps suggesting focal EC damage (21). Magnification  $\times 14,280$ . controls with nonvasculitic heart disease as compared with 26 (48.1%) of 54 KD patients. Disturbingly, these changes also were noted in KD patients who had normal coronary arteries as assessed by echocardiography during their acute and subacute stages.

In a histologic study of coronary arteries in a child with normal echocardiograms during the acute and subacute phase of KD who died 13 months later, expression of PDGF-A and inducible nitric oxide synthase (iNOS) was elevated in the regenerating intima. This suggests that persistent inflammation and repair of EC injury continues for months after the acute illness has subsided (24).

#### ROLE OF ANTIENDOTHELIAL CELL ANTIBODIES

Early observations by Leung and coworkers suggested that circulating anti-EC antibodies (AECAs) might be involved

**Table 153-2: Noninvasive Assessment of Endothelial Cell Function in Children Following Acute Kawasaki Disease**

Method	Population of KD Subjects	Results*	Conclusion	References
BAR	20 British subjects age 11–19 yrs	Reduced flow-mediated dilation; normal response to NTG	Abnormal EC function in KD subjects	44
BAR	39 Chinese subjects age 3–14 yrs	Reduced flow-mediated dilation reversible with IV infusion of vitamin C; normal response to NTG	Abnormal EC function in KD subjects	46
BAR	24 Canadian subjects, mean age 14.3 ± 1.8 yrs	No difference in flow-mediated dilation between KD subjects and controls ( <i>n</i> = 11)	Normal EC function in KD subjects	55
BAR	24 Japanese subjects, mean age 8.3 ± 4.1 yrs	Reduced flow-mediated dilation with greatest decrease in KD subjects with aneurysms	Abnormal EC function in KD subjects	52
PET	27 Japanese subjects age, 17.2 ± 3.2 yrs	Decreased myocardial flow reserve; reduced response to cold pressor challenge; normal response to adenosine triphosphate	Abnormal EC function in KD subjects	56
LDF	27 U.S. subjects age 0.33–16 yrs	Normal hyperemic response to acetylcholine iontophoresis	Normal EC function in micro-vasculature in convalescent KD subjects	53

\*Compared to age-matched normal controls

BAR, brachial artery reactivity; NTG, nitroglycerin; LDF, laser Doppler fluximetry. Studies assessed both children with aneurysms, transient dilation, and normal echocardiograms during the acute illness.

in the pathogenesis of the vasculitis of KD. Patient sera incubated with interleukin (IL)-1- or tumor necrosis factor (TNF)- $\alpha$ -stimulated human umbilical vein ECs (HUVECs) caused cell lysis in the presence of complement, whereas incubation with unstimulated HUVECs had no effect (25). This suggested that, in acute KD, cytokine-mediated activation of ECs leads to the expression of neoantigens that are targeted by cytotoxic antibodies. However, subsequent studies of AECAs in KD yielded conflicting results (26–28). Some investigators detected AECAs during the acute phase and demonstrated cytotoxicity in the absence of HUVEC stimulation with cytokines (28,29). The current consensus is that anti-EC antibodies also are present in the serum of children suffering from a variety of different febrile illnesses and that such antibodies are a nonspecific epiphenomenon associated with generalized immune activation rather than important mediators of the vasculitis in KD (30,31).

#### ENDOTHELIAL CELL BIOMARKERS IN ACUTE KAWASAKI DISEASE

Several studies have measured circulating biomarkers of EC activation and injury during the acute phase of KD, and these conclude that both processes occur. Studies have documented

increased plasma levels of von Willebrand factor (vWF) during the acute phase of KD (32–35). Many studies have examined levels of circulating soluble adhesion molecules, selectins, and integrins as markers of EC activation. Biomarkers of activation including ICAM-1, vascular cell adhesion molecule (VCAM)-1, E-selectin, and P-selectin all have elevated levels during acute KD (36,37). Elevated circulating levels of ICAM-1 also have been correlated with increased TNF- $\alpha$  levels and increased severity of coronary artery lesions resulting from KD (37). The finding during acute KD of elevated levels of S100 proteins, specifically S100A8, S100A9, and S100A12, which interact with the receptor for advanced glycation end-products (RAGE) on ECs and are potent chemotactic agents, may be one mechanism by which increased expression of adhesion molecules and activation of ECs occurs (38–40).

The finding of circulating ECs during the acute and subacute phase of KD, coupled with the detection of endothelial progenitor cells in highest numbers during the subacute phase, is further evidence of EC injury and repair (18,41). Levels of circulating progenitor cells were highest in patients who developed coronary artery dilatation or aneurysms, thus suggesting that the number of circulating cells may correlate with the severity of vessel wall injury (42). Assays of EC microparticles in plasma as a measure of EC activation have not been performed.

## ENDOTHELIAL CELL FUNCTION LATE AFTER KAWASAKI DISEASE

Classic methods for studying EC function *in vivo*, including response to acetylcholine infusion in the coronary arteries, brachial artery flow-mediated dilatation, myocardial blood flow following cold challenge, and laser Doppler fluximetry have yielded an overall impression of subclinical EC dysfunction even in individuals without coronary artery damage detected by echocardiogram during the acute illness (43–56). The most reproducible of these studies has been the direct infusion of acetylcholine into the coronary arteries at the time of angiography. Results from four studies demonstrated failure to vasodilate in response to acetylcholine in coronary artery segments with either persistent or regressed aneurysms, whereas coronary artery segments without previous aneurysms vasodilated normally in these same subjects (47–49,51). A case report of a 21-year-old woman who had suffered KD at age 19 months described coronary artery spasm in response to acetylcholine infusion despite a history of normal echocardiograms during the acute illness and angiographically normal coronary arteries prior to infusion of acetylcholine (54). Whether this isolated case is an anomaly or whether EC dysfunction occurs in a subset of patients with normal echocardiograms during the acute phase of KD must be studied in a larger population of these patients as young adults.

Although invasive methods of assessing EC function in KD patients have yielded consistent results, studies using noninvasive methods have yielded conflicting results, perhaps due to technical issues (44,46,52,53,55,56) (Table 153-2). None of the four studies reporting assessments of flow-mediated dilation of the brachial artery used high-resolution transducers (>10-MHz linear-array transducer) nor did they provide assessments of inter- and intraobserver variability in a comparable population of children, as recommended by an international task force (57). Studies in Chinese, Japanese, and British children found reduced brachial artery flow-mediated dilation (EC-dependent response) in patients with a history of KD regardless of their coronary artery status during the acute disease and normal responses to nitroglycerin (EC-independent response) when compared with age-matched control subjects (44,46, 52). This suggested diffuse EC dysfunction in children and young adults with a history of KD 5 to 17 years prior to testing. In contrast, a third study in Canadian children found no evidence for EC dysfunction using essentially the same study design (55).

Further studies using noninvasive techniques have included <sup>15</sup>O-water positron emission tomography (PET) following adenosine triphosphate administration (EC-independent response) and cold pressor challenge (EC-dependent). Based on reduced myocardial blood flow following cold challenge, the authors concluded that KD patients had impaired EC function regardless of their coronary artery status during their acute disease (56) (see Table 153-2). A single study using laser Doppler fluximetry before and after acetylcholine iontophoresis found normal EC responses in the microcirculation in the

skin 0.9 to 11 years after KD (53). If confirmed by further studies, these data suggest that EC dysfunction late after KD may be restricted to medium-sized muscular arteries.

## CONCLUSION

KD is characterized by acute EC activation and injury, which in some cases is associated with transmural inflammation and destruction of the vessel wall architecture. This leads to the formation of coronary artery aneurysms, the hallmark of this disease. Emerging evidence suggests that EC injury may continue for years following the acute illness in children who develop aneurysms. Thus, KD provides a model to study both acute and chronic EC injury and recovery in a population of otherwise healthy young subjects.

### KEY POINTS

- KD provides a model to study both acute and chronic EC injury and recovery in a population of otherwise healthy young subjects.
- Acute EC injury occurs early in the vasculitic process.
- Recovery from acute EC damage may take months to years.
- Abnormal EC function may occur in a subset of patients years after recovery from the acute illness.

### Future Goals

- To understand the environmental (probably infectious) trigger for acute KD and the mechanism by which this causes acute EC injury
- To understand the complex genetics that influence susceptibility to disease and disease outcome

## Systemic Vasculitis

### Autoantibodies Targeting Endothelial Cells

‡*Tel-Aviv University, Israel*

The vasculitides are defined by the presence of leukocytes in the vessel wall, producing reactive damage to mural structures. Compromise of the lumen leads to tissue ischemia and necrosis. In general, affected vessels vary in size, type, and location in association with the specific vasculitic disorder. In recent years, substantial progress has been made in identifying the attributes of specific types of vasculitis, thus allowing for accurate diagnosis. One approach to classifying vasculitides categorizes them, in part, on the basis of the predominant type of vessel affected (Table 154-1). Accordingly, vasculitides are classified into large-vessel vasculitis, medium-sized vessel vasculitis, and small-vessel vasculitis. Large-vessel vasculitis primarily affects the aorta and its primary branches, but medium-sized arteries may also be affected. Medium-sized vessel vasculitis is a disease of small and medium-sized muscular arteries. Small-vessel vasculitis affects vessels smaller than arteries, such as arterioles, venules, and capillaries. It is important to note that small-vessel vasculitis sometimes also affects arteries, and thus the vascular distribution overlaps.

The exact mechanisms underlying these disorders are unclear. Three different pathogenic models of disease have been advanced to help explain why the lesions of a particular vasculitic syndrome are found only in specific vessels. First, the distribution of the antigen responsible for the vasculitis may be differentially distributed. Second, the recruitment and accumulation of the inflammatory infiltrate is likely to be determined by site-specific properties of the endothelial cell (EC), including the expression of adhesion molecules, the secretion of mediators, peptides and hormones, and the specific interaction with inflammatory cells. Finally, nonendothelial structures of the vessel wall may be involved in controlling regional inflammatory processes. All three mechanisms are likely to contribute to the site-specific nature of endothelial injury and vasculitis.

Several causes exist for EC stimulation and injury associated with vasculitis. For example, giant-cell arteritis is caused by pathogenic immune responses that are ultimately controlled by T cells (1). The typical lesions, granulomas in the vessel wall, are formed by CD4<sup>+</sup> T cells and macrophages. CD4<sup>+</sup> T cells undergo in situ activation in the adventitia, where they interact with indigenous dendritic cells. Tissue injury is mediated by several distinct sets of macrophages. Wegener granulomatosis (WG) is characterized by an early lesion involving neutrophils and ECs as both targets and active participants, and antineutrophil cytoplasmic antibodies (ANCA), which may enhance immunoinflammatory events that contribute to disease (2). Another group of autoantibodies, anti-EC antibodies (AECAs), were found in many autoimmune diseases showing vasculitis.

#### ANTI-ENDOTHELIAL CELL ANTIBODIES

Antibodies that react with EC structures were first reported during the early 1970s. Sera from patients with various rheumatic diseases, including systemic lupus erythematosus (SLE) and scleroderma, were reactive with capillaries in the mouse kidney specimens (3). Since then, several methodological approaches have demonstrated the existence and potential pathogenic role of AECAs in a wide variety of inflammatory diseases (4). AECAs bind to different structures on endothelial membranes, mainly through the F(ab)<sub>2</sub> portion of the immunoglobulin (Ig). IgG, IgM, and IgA isotypes of those antibodies have been reported. AECAs target antigens have not yet been defined, but there are likely to be many of them. AECA-positive sera has been shown to display broad reactivity against ECs from different species (mouse, bovine, and human) and multiple vascular beds, including aorta, umbilical

**Table 154-1: Classification of Primary Systemic Vasculitis**

<i>Vasculitic Type</i>	<i>Classification</i>	<i>Antigens Targeted by AECA</i>
Large vessel	Giant cell (temporal) arteritis Takayasu arteritis	70-kD protein; proteins range of 60–65 kD
Medium-sized vessel	Classic polyarteritis nodosa Kawasaki disease	
Small vessel	Wegener granulomatosis Churg-Strauss syndrome Microscopic polyangiitis (microscopic polyarteritis) Henoch-Schönlein purpura Essential cryoglobulinemic vasculitis Cutaneous leukocytoclastic angiitis	PR3, human lysosomal associated membrane protein 2 (h-lamp-2); range of 25-, 68-, 125-, 155-, 180-kD proteins Myeloperoxidase

cord vein, saphenous vein, and small vessels from kidney, skin, omenta, and brain (4,5). One interpretation of these findings is that AECAs are nonspecific and target commonly expressed endothelial antigens. However, increasing evidence suggests that AECAs demonstrate specificity for microvascular or macrovascular ECs, and that this specificity correlates with the clinical pattern of vasculopathy.<sup>1</sup>

#### DISEASE ASSOCIATION AND PREVALENCE OF ANTIENDOTHELIAL CELL ANTIBODIES

AECAs can be detected in various clinically distinct, immunologically mediated diseases in which the common factor appears to be immune/inflammatory-mediated damage to the vessel wall. The largest disease group in which AECAs have been detected includes patients with systemic vasculitides. AECAs also are associated with other systemic autoimmune diseases. In the next sections, we discuss the occurrence of AECAs in these various syndromes and, where possible, emphasize the correlation between site-specific pathology and in vitro AECA specificity.

#### Small-Vessel Vasculitides

##### *Wegener Granulomatosis and Microscopic Polyangiitis*

WG and microscopic polyangiitis (MPA) are systemic disorders in which inflammation and fibrinoid necrosis of small-vessel walls may affect several organs. WG and MPA share many common pathological features including pulmonary

capillaritis and pauci-immune focal necrotizing and/or crescentic glomerulonephritis. However, an important difference between the two diseases is the presence of granulomatous inflammation in WG, which is not observed in MPA. Several investigative groups have reported the occurrence of AECAs in both WG and MPA sera, which are distinct from antineutrophil cytoplasmic antibodies (ANCA), the other serologic marker present in the majority of these patients.

The presence of AECAs in WG has been reported to correlate with disease activity and risk for relapse (6). For example, a prospective analysis of patients with ANCA-negative WG showed that persistence of AECAs after remission was associated with a high risk of relapse, and that a rise in AECA titers preceded the development of relapse (6).

Several in vitro studies have demonstrated that AECAs from the sera of patients with WG are able to activate ECs (7–9). Incubation of human umbilical vein ECs (HUVECs) with AECA IgG from WG patients resulted in increased expression of E-selectin, intercellular adhesion molecule (ICAM)-1, and vascular cell adhesion molecule (VCAM)-1 (7). The upregulation of adhesion molecules was followed by increased leukocyte adhesion. Once bound to ECs, AECAs also induced a parallel increase in interleukin (IL)-1, IL-6, and chemokines (IL-8 and monocyte chemoattractant protein [MCP]-1). Each of these studies employed similar methods to detect AECAs and to evaluate EC phenotype, and thus collectively provide compelling evidence for AECA-mediated activation of HUVECs.

More recently, it was demonstrated that AECAs from patients with WG and MPA react more strongly with human microvascular ECs (MVECs) cultivated from unaffected target organs such as the nose, kidney, and lung, compared with HUVECs. Thus, HUVECs may not always be the suitable target in AECA assays (10). Vascular bed-specific AECAs did not result in EC lysis. Interestingly, the same profile of AECAs persisted despite clinical remission of the disease, albeit at lower titers. Binding of WG-AECAs to kidney and nasal ECs was lost upon treatment with interferon (IFN)- $\gamma$  and tumor necrosis

<sup>1</sup> In these assays, HUVECs (until passage 4) or microvascular cells are grown in 96-well ELISA plates for about 48 hours until confluent. Half the plate of monolayer cells is fixed with 0.4% glutaraldehyde; the other half undergoes no fixation. The plates are blocked with 3% BSA at 37°C. The antibodies are added at different concentrations in triplicate for 2 hours of incubation and probed with antihuman IgG/IgM conjugated to alkaline phosphatase and appropriate substrate. The data are read at 405 nm.

Figure 154.1. Generation of mouse AECAs following immunization with human AECAs. Based on Jerne theory, mice immunized with antibody-1 (Ab1), will develop anti-anti-Ab1 (Ab2) and later anti-Ab2 (Ab3), which will resemble the binding properties of Ab1. Naïve mice such as BALB/c or C3H were immunized with human AECAs or human anti-PF4/heparin complex emulsified in adjuvant and booster 3 weeks later. Eight weeks later, the immunized mice developed anti-human-AECA (Ab2, anti-idiotypic Abs), and 3 to 4 months later anti-anti-idiotypic Abs (Ab3), which had the biological activity of Ab1 (human AECAs or human anti-PF4/heparin). The generation of Ab3 was followed by the development of clinical manifestation similar to vasculitis or HIT respectively.

factor (TNF)- $\alpha$ . However, these two cytokines were cytotoxic (30%) to nasal and lung ECs, an effect that was accentuated (60%) by addition of WG and MPA serum. This increased sera effect may be a result of combined cytokine effect and complement-dependent cytotoxicity (10). These findings suggest that AECAs are not directly involved in destruction of the vessel wall but may instead sensitize ECs to the effects of other host factors involved in the initiation of the disease.

A previous study demonstrated the capacity of human AECAs to induce vasculitis-like lesions in mice (11). Naïve BALB/c mice, injected with IgG fractions from patients with WG, developed histopathologic signs of renal and pulmonary vasculitis. These IgG fractions were shown to contain both anti-proteinase 3 (PR3; the target antigen of cytoplasmic ANCA) and AECA activity. To demonstrate an independent pathogenic role for AECAs, naïve mice were immunized with human WG IgG depleted of anti-PR3 antibodies but still displaying AECAs. These animals developed anti-human-IgG (Ab2) and later anti-antihuman-IgG (Ab3) (characterized as murine AECA; Figure 154.1), which was followed by glomerular vascular inflammation (12). This experimental model, therefore, supports a direct connection between the occurrence of autoimmune AECAs and the appearance of vasculitic histologic lesions.

Together with the Churg-Strauss syndrome (CSS), WG and MPA represent a triad of small-vessel vasculitides characterized by the presence of ANCAs in patient serum. ANCAs are a family of antibodies directed against enzymes that are stored in primary granules of polymorphonuclear neutrophils and lysosomes of monocytes. Based on immunofluorescence patterns, a distinction is made between cytoplasmic ANCAs (c-ANCAs), which target PR3, and perinuclear ANCAs (p-ANCAs), which target myeloperoxidase (MPO). The immunofluorescence pattern in MPA and CSS is usually perinuclear with specificity for MPO. The presence of

c-ANCAs, with antibodies to PR3 has a nearly 95% specificity for WG, and the titer correlates with disease activity. In addition to being a serological marker for WG, substantial evidence points to a pathogenic role of ANCAs. In vitro, sera or purified IgG from ANCA-positive patients, as well as monoclonal antibodies directed against MPO or PR3, have been found to induce an oxidative burst in healthy human neutrophils that are pretreated with inflammatory cytokines, such as TNF- $\alpha$ , or bacterial lipopolysaccharide (LPS) (13). Furthermore, it has been shown that ANCAs stimulate neutrophils to damage human ECs. For example, neutrophil-derived PR3 and elastase released at sites of neutrophil and/or monocyte infiltration may signal in a paracrine manner to induce apoptosis of ECs (13). Proinflammatory cytokines also can induce PR3 expression on the surface of ECs, thereby converting these cells into ANCA targets (14).

#### *Antineutrophil Cytoplasmic Antibodies–Positive Necrotizing and Crescentic Glomerulonephritis*

Among the first reports of vascular bed–specific antibodies were studies of patients with ANCA-positive necrotizing and crescentic glomerulonephritis (NCGN) (15). ANCA-positive sera from patients with NCGN reacted with glycoproteins from a membrane preparation of neutrophils, designated as gp170/80–110 and verified to be identical with human lysosomal-associated membrane protein 2 (h-lamp-2). Unexpectedly, these sera also cross-reacted with a 130-kDa EC membrane glycoprotein (gp130) of the renal microvasculature. This latter glycoprotein is also present on the surface of ECs of intestinal capillaries and placental capillaries, but not on ECs of arteries and arterioles. Monoclonal antibodies against gp170/80–110 as well as rabbit anti-gp130 failed to bind unstimulated or IL-1–treated HUVECs. Interestingly, 14 of 16 patients with NCGN had IgG that was specific for gp130 and gp170/80–110. The relationship between gp130 and h-lamp-2 has not been established yet. A possible explanation is that the 130-kd antigen shares one or several epitopes with h-lamp-2. It is also possible that the 130-kd membrane protein is an isoform of h-lamp-2, which differs primarily in its carbohydrate side chain (15).

#### **Large-Vessel Vasculitides**

Kawasaki disease (KD) is an arteritis of large, medium, and small arteries, particularly the coronary arteries (see Chapter 153). The disease usually occurs in children, and is often associated with a mucocutaneous lymph node syndrome. IgM AECAs were detected in up to 72% of patients with KD, whereas the prevalence of IgG ranged from 12% to 42% (16,17). Antibody titers, measured by cyto-enzyme-linked immunosorbent assay (ELISA) with nonfixed HUVECs, correlated with disease activity and, in some instances, disappeared in patients with convalescent KD (18). AECAs in KD are cytotoxic to HUVECs and human saphenous vein ECs in the absence or presence of prestimulation with IFN- $\gamma$ , IL-1, and TNF- $\alpha$  (16). IFN-inducible neoautoantigens expressed on

ECs appear to be distinct from IL-1- and TNF- $\alpha$ - inducible neoautoantigens. We have shown recently that mice immunized with AECAs from a patient with KD develop murine AECAs (see Figure 154.1) (17). The murine AECAs increased monocyte adhesion to ECs in vitro, similar to the AECAs used for immunization. Furthermore, all mice that developed AECAs had proteinuria and IgG deposition in the renal mesangium. No histological or immunofluorescence evidence of cardiac vasculitis was detected. These findings suggest that AECAs may play a pathophysiological role in certain KD manifestations.

AECAs have been detected in other large-vessel diseases such as giant-cell arteritis and thromboangiitis obliterans. TA primarily affects the aorta and its primary branches. The inflammation may be localized to a portion of the thoracic or abdominal aorta and branches, or may involve the entire vessel. Giant-cell arteritis and temporal arteritis (TA) are chronic vasculitides of large- and medium-sized vessels. Although it may be generalized, vessel inflammation most prominently involves the cranial branches of the arteries originating from the aortic arch. Thromboangiitis obliterans is a nonatherosclerotic, segmental, inflammatory disease that most commonly affects the small and medium-sized arteries, veins, and nerves of the extremities. AECAs derived from patients with TA have been shown to activate ECs (discussed in the next section) (19). In another study, TA-derived AECAs were reported to mediate complement-dependent cytotoxicity of ECs (20). Patients with active thromboangiitis obliterans had significantly higher AECA titers than did those with inactive disease (21). Taken together, these studies support a pathogenic role for AECAs in most large-vessel vasculopathies. AECAs also were detected in a large proportion of patient with giant-cell arteritis, but the association with disease activity was not evaluated (22).

We have shown that AECAs from TA patients preferentially bind and activate macrovascular, compared with microvascular ECs (19). Monoclonal antibodies were selected, the mixture of which produced 100% inhibition of binding of the original IgG from the patient with TA to HUVECs. All monoclonal antibodies possessed high activity against macrovascular ECs (i.e., anti-HUVEC activity), but none had significant anti-MVEC activity. Four of the six monoclonal antibodies activated ECs, as evidenced by increased IL-6 and von Willebrand factor (vWF) secretion. The four monoclonal antibodies induced EC expression of adhesion molecules and increased adhesion of monocytes to ECs. In addition, these monoclonal antibodies stimulated the nuclear translocation of the nuclear factor (NF)- $\kappa$ B transcription factor (23). Moreover, immunohistochemical studies demonstrated considerable antihuman aortic EC activity of the monoclonal antibodies, whereas antihuman MVEC antibodies (from patients with heparin-induced thrombocytopenia [HIT]) or normal human IgG did not react with human aorta. Again, the distinct predilection of TA-derived AECA monoclonal antibodies for macrovascular antigens corresponds with the distribution of pathological lesions in this large artery vasculitis.

### Systemic Lupus Erythematosus and Antiphospholipid Syndrome

A high prevalence of AECAs has been described in patients with clinically active SLE (up to 80%) (22). However, AECA binding was not specific to ECs, since binding reactivity was partially absorbed by both fibroblast and peripheral blood mononuclear cell membrane suspensions (24). The high prevalence of nonspecific AECAs in that study may have been due to the method utilized for AECA detection, namely ELISA with HUVEC membranes. It is difficult to completely rule out any contamination of cytoplasmic structures in the cell membrane preparation. Furthermore, the high percentage of AECA-positive patients may reflect a referral bias, with a greater representation of severe clinical cases. In other studies, an association between the AECA titer, SLE disease activity, and lupus nephritis (25) or SLE-associated psychiatric manifestations (26) was reported, but the prevalence of AECAs in SLE patients (as detected by cyto-ELISA with HUVECs) in the last quoted study was lower and ranged from 29.4% in patients without psychiatric manifestation to 64.7% in patients with psychiatric manifestation. No association was found between anti-DNA antibodies and AECAs in SLE patients (27).

Binding of AECAs to ECs was reported to be unrelated to the presence of circulating immune complexes and antinuclear antibodies in the serum (5,24). Antigens recognized by AECAs in SLE sera have been partially characterized by immunoblotting techniques that have demonstrated large numbers of bands (24,28). Moreover, analysis of the antigens on EC surface membrane immunoprecipitated by AECA-positive SLE sera identified several constitutive proteins with molecular weights ranging from 25 to 200 kDa. Although most of the endothelial antigens were also recognized by AECAs from patients with WG or MPA, some were precipitated by SLE sera alone (29). These data point to the existence of both disease-specific and disease-nonspecific antibodies. Other studies have implicated constitutively expressed sulfate proteoglycan or heparin-like molecules as antigenic determinants for AECAs in a subset of SLE patients (24). SLE-derived AECAs also may recognize antigens in the subendothelial matrix, including collagen (30).

Antibodies directed against constitutive endothelial antigens, both anti-DNA and anti- $\beta_2$ -glycoprotein I (anti- $\beta_2$ GPI) antibodies, can display antiendothelial activity due to their ability to recognize their respective molecules adhered on the EC surface (25,31). Recently, binding of antiphospholipid IgG or both polyclonal and monoclonal anti- $\beta_2$ GPI antibodies has been shown to induce phenotypic changes in cultured HUVECs (32), including upregulation of E-selectin, ICAM-1, and VCAM-1; increased secretion of proinflammatory cytokines such as IL-1 and IL-6; and increased procoagulant activity. In addition, mononuclear leukocytes, adhering to activated endothelium, can be activated by endothelial inflammatory cytokines and induced to display a procoagulant phenotype, further contributing to the thrombophilic state in antiphospholipid antibody syndrome (APS). Similar

induction of a proinflammatory phenotype *in vitro* was also shown in the anti-EC IgG fraction from SLE patients, which did not react with either double-stranded DNA or  $\beta_2$ GPI (8,31). Indeed, true AECAs directed against constitutive endothelial antigens and distinct from anti- $\beta_2$ GPI antibodies also have been found in the sera of patients with both APS and SLE-associated APS (31).

An analysis of AECA specificity in primary APS and SLE revealed differences in both the pattern of antibody binding and band intensity between membrane antigens on HUVECs and those on human MVECs (33). Of 17 primary APS sera, antibody binding to HUVEC membranes was found in nine sera and to human MVEC membranes in seven sera. Binding at 72 to 79 kDa was confined to HUVECs. In 32 SLE sera, binding to HUVECs and human MVEC membranes was detected in 17 and 22 sera, respectively, with binding at 135 to 155 kDa being confined to human MVECs. As already mentioned, some anti-EC reactivity in APS may be directed to epitopes on phospholipid-binding proteins, especially  $\beta_2$ GPI.

### Antiendothelial Cell Antibodies in Transplantation

Progressive narrowing and ultimate luminal occlusion of the arteries and arterioles of a transplanted organ are the hallmark of chronic rejection. Immunologically mediated injury of ECs may be the initiating event. Indeed, increasing evidence suggests that AECAs are associated with transplant rejection (34). AECAs can recognize major histocompatibility complex (MHC) antigens in MHC-mismatched allografts, but even in well-matched allografts, antibodies can be targeted to antigens of the EC/monocyte system or to EC-specific determinants (34). It was shown that serum AECA titers increase significantly in renal transplant recipients with acute rejection, but decrease after formal rejection (immunosuppressive) therapy. In recipients with acute rejection, the prerenal transplant AECA titer was higher than in those without acute rejection, leading to the conclusion that pre- and postrenal transplant AECA titers may be useful for predicting and monitoring acute rejection, respectively (35). Recent studies of cardiac allograft recipients support an association between AECAs and transplant-induced coronary artery disease (36). In one study, these antibodies were shown to be directed against vimentin, a cytoskeletal protein with a molecular mass of 56 to 58 kDa (37), whereas another report implicated triose phosphate isomerase (molecular weight of 28 kDa), the 85-kd human CD36 antigen (a cell surface glycoprotein), and a 50-kDa keratin-like protein (a member of the intermediate filament protein expressed in epithelial cells) as target antigens (37). Although these antibodies may prove useful as diagnostic markers for post-transplantation coronary artery disease, which, if any, play a direct pathogenic role in mediating this complication remains unknown (36).

Cytomegalovirus (CMV) infection is associated with an increased incidence of acute and chronic allograft rejection in renal and cardiac transplant recipients. There are reports suggesting that AECA levels, as determined by cyto-ELISA with

HUVECs, are elevated during CMV infections in transplant recipients. These observations support the concept that CMV infections are associated with an increased humoral immune response to EC antigens, which may in turn increase the risk for vascular rejection. However, further investigations have shown that AECAs induced by CMV infections are not specific to ECs and react with multiple cell types such as fibroblasts, keratinocytes, platelets, peripheral blood mononuclear cells, and Burkett lymphoma Raji B cells (38). Consequently, elevated AECA levels seen in CMV-infected transplant recipients may reflect a polyclonal activation of the humoral immune response, which is of uncertain pathogenic significance.

### Other Diseases

AECAs have been found in other autoimmune disease in addition to systemic vasculitis and SLE. For example, antibodies are often detected in the sera of patients with thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS). CD36 has been proposed as a target antigen in TTP (39). In four consecutive patients with TTP, affinity-purified AECA F(ab)<sub>2</sub> bound and activated human bone marrow ECs (HBMECs), but not HUVECs (40). The activation was manifested by enhanced thrombomodulin, IL-6, and vWF release from the EC, followed by raised levels of adhesion molecules (E-selectin, P-selectin, VCAM-1) and CD36 expression as well as monocyte adhesion to ECs. It is noteworthy that TTP is characterized by small-vessel thrombosis only (in the brain, kidney, or skin), whereas thrombosis of large blood vessels is never observed.

AECAs also have been described in patients with HIT (41). HIT is a complex clinical syndrome in which individuals sensitized to heparin develop thrombocytopenia, which may be associated with severe thrombotic events. HIT is mediated by antibodies to epitopes formed by complexes between heparin or other glycosaminoglycans and platelet factor 4 (PF4) (see Chapter 147). In addition, sera from patients with HIT and thrombosis contain antibodies that react with ECs (42). Using a model of active immunity, we studied the effect of IgG anti-PF4/heparin antibody *in vivo* (43). Naïve BALB/c mice actively immunized with human anti-PF4/heparin antibodies subsequently developed thrombocytopenia after administration of unfractionated heparin (see Figure 154.1). The results of this study support the importance of anti-PF4/heparin antibodies in the pathogenesis of HIT. Because the thrombotic phenomena in HIT occur in large vessels (arteries and veins) as well as in capillaries, we investigated the interaction of affinity-purified anti-PF4/heparin antibodies in cultured microvascular HBMECs and macrovascular HUVECs from six patients with HIT (19). HIT antibodies directly activated unstimulated MVECs, causing release of IL-6, vWF, and soluble thrombomodulin; increased expression of the adhesion molecules P-selectin, E-selectin, and VCAM-1; and enhanced monocyte adhesion. In contrast, the HIT antibodies reacted with macrovascular ECs only after pretreatment of the cells with TNF- $\alpha$ .

Behçet disease affects primarily small vessels, although large-vessel involvement is observed in 15% to 35% of patients. However, when sera from the same patients were exposed to microvascular (omental) or macrovascular (human umbilical vein) ECs with the use of a cyto-ELISA, the binding to MVECs was seen in 43% of patient sera versus 26% of patient sera recognizing HUVECs (44,45).

### Naturally Occurring Antiendothelial Cell Antibodies

The occurrence of IgG AECAs in the circulation of healthy individuals and in pooled normal human Ig has been demonstrated by ELISA using fixed HUVECs (46). Further characterization by immunoblotting revealed that natural AECAs recognize a restricted and conserved set of endothelial antigens, with almost no differences between healthy individuals (46). Analysis of AECAs in the serum of SLE patients in the same experiment revealed a higher amount of activity and wider spectrum of antigenic specificities. Recent observations support the concept that natural AECAs increase the anti-inflammatory properties of ECs through selective inhibition of thromboxane A<sub>2</sub>, endothelin-1, and metalloproteinase (MMP)-9 secretion, as well as through inhibition of the EC proinflammatory response to TNF- $\alpha$  (36).

### IDENTIFICATION OF ANTIENDOTHELIAL CELL ANTIBODY TARGET ANTIGENS

A major challenge in elucidating the mechanisms of AECA-mediated EC activation is to identify the culprit antigen(s). As mentioned earlier, many candidate antigens have been identified, including those that are constitutively expressed (e.g., sulfate proteoglycan- or heparin-like molecules), upregulated by inflammatory mediators, or adherent to ECs (e.g., DNA or DNA-histone complexes,  $\beta_2$ GPI, PF4-heparan complexes, PR3 and/or myeloperoxidase) (4,35).

In a recent study, a molecular cloning strategy was used to isolate a panel of candidate EC antigens in patients with SLE (47). The candidate autoantigens identified included EC-specific plasminogen activator inhibitor, the classic lupus antigen, ribosomal P protein PO, and proteins that have never been described as putative antigens in SLE, such as ribosomal protein L6, elongation factor 1 $\alpha$ , adenylyl cyclase-associated protein, profilin II, and two novel proteins. Furthermore, it was shown that a patient with active disease and nephritis had autoantibodies that recognized a spectrum of EC autoantigens different from those recognized by the autoantibodies of another patient who had active disease without nephritis. The authors pointed out that these different autoantigen profiles may help to explain the wide clinical spectrum seen in SLE (47). In a recent study, heat-shock protein 60 (Hsp60) was recognized as a new antigen on ECs. Namely, most of the SLE tested sera (73%) bound to a 60-kDa EC surface polypeptide that was identified as human Hsp60. Incubation of ECs

with these anti-Hsp60 antibodies induced apoptosis in a time- and dose-dependent manner (48). It also has been observed that IgM AECAs from patients with Behçet disease recognized human  $\alpha$ -enolase on human dermal MVECs (49).

The observation that certain antibodies preferentially target microvascular or macrovascular ECs (and that such patterns mirror the clinical phenotype) suggests that AECAs may recognize vascular bed-specific antigens (50,51). It is well established that ECs display marked heterogeneity in structure, mRNA and protein expression, and function. Antigenic heterogeneity is evident between vessels of different sizes, between same-sized vessels from different organs, and even between neighboring ECs. An important goal for the future is to map the site-specific antigenic determinants for AECAs, and to determine which – if any – of these antigens are involved in the pathophysiology of vasculitis.

### CIRCULATING ENDOTHELIAL CELLS AND VASCULITIS

Several investigators have reported that circulating ECs were detected in peripheral blood in various conditions with vascular injury (52). These cells are probably detached from the vascular wall, but the mechanism of detachment remains enigmatic. It is well established that the number of circulating ECs increases in small-vessel vasculitis and KD, reflecting the extent of the disease activity (53). In coronary artery disease, circulating ECs were detected in patients with acute myocardial infarction and unstable angina. These findings were well in line with current concepts of plaque vulnerability, and patients with stable angina did not exhibit elevated cell number (54). It is not known whether circulating ECs might be capable of causing an inflammatory response on their own. In addition to circulating ECs, endothelial microparticles (EMPs) have recently emerged as markers of vascular activation. They result from an exocytotic budding process that translocates phosphatidylserine from the inner to the outer leaflet of the cell membrane. This inversion of membrane polarity is followed by blebbing of the membrane surface, leading to the formation of microparticles and their release in the extracellular environment. Even if there is no real consensus on microparticle definition, it is accepted that they are submicron elements (from 0.1 to 1  $\mu$ m) that express at their surfaces phosphatidylserine and membrane antigens characteristic of their cell of origin. It was demonstrated in a recent *in vitro* study that EMPs were able to express adhesive receptors similar to those expressed by activated ECs. In the interaction with human monocytes, EMPs also were able to stimulate tissue factor-mediated procoagulant activity, suggesting a novel mechanism by which EMPs may participate in the dissemination and amplification of procoagulant cellular response. EMPs may be involved in target-organ damage in severe hypertension, diabetes, the procoagulant state in pregnancy, and systemic vasculitis (55,56).

## CONCLUSION

Increasing evidence points to a pathogenic role for AECAs (and ANCAs) in the inflammatory process that leads to vasculitis. The differences found between ECs from large and small vessels, and the consequent reactivity of AECAs in small and large vessel diseases and ANCA in small-vessel vasculitis, underscore the importance of using cells derived from vessels of appropriate size when studying macro- or microangiopathies. The wide range of AECA frequencies in a defined disease may therefore be attributed to the various sources of ECs used for their detection. Some sera apparently negative for AECAs may be reactive if ECs of appropriate types are used. Consequently, it is rational to classify AECAs into one of two groups of antibodies, against either microvascular or macrovascular ECs.

### KEY POINTS

- EC injuries in vasculitis can be phenotyped into microvascular and macrovascular involvements, based on targeting specific EC molecules by anti-EC antibodies.
- These polyclonal populations of antibodies cause activation of the ECs into procoagulation or other pathophysiological states.

### Future Goals

- To better understand the mechanisms that cause involvement of macrovascular ECs in some diseases, and microvascular endothelium in others
- To use gene array and proteomics approaches to better understand the signaling cascades provoked by the diverse subclasses of anti-EC antibodies on the different phenotypes of ECs, with the goal of developing more site-specific therapies

## High Endothelial Venule-Like Vessels in Human Chronic Inflammatory Diseases

Jean-Philippe Girard

*Institute of Pharmacology and Structural Biology, Toulouse, France*

### HISTORY OF HIGH ENDOTHELIAL VENULE-LIKE VESSELS IN RHEUMATOID ARTHRITIS AND OTHER HUMAN CHRONIC INFLAMMATORY DISEASES

High endothelial venules (HEVs) are anatomically distinct postcapillary venules found in lymphoid organs. They support high levels of lymphocyte extravasation from the blood (1–3). The precise relationship between the structure and function of these specialized blood vessels has intrigued and fascinated many investigators over the past 100 years. The peculiar structure of HEVs in lymph nodes from *Macacus cynomolgus* was first observed by Thome in 1898 (4). He described these vessels as being composed of plump, cuboidal endothelial cells (ECs) whose surface strongly bulges into the vascular lumen. These ECs looked like columnar epithelial cells and Thome wrote that, at first notice, one is more inclined to think of the duct of a gland rather than that of a blood vessel. It is this cuboidal or columnar appearance that has given rise to the names *high ECs* and *high endothelial venules*. The observations of Thome were confirmed in other species, including human, by von Schumacher, who was the first to note the presence of numerous lymphocytes within the wall of HEVs (5). Vessels of the HEV type, characterized by a plump endothelial lining with many adherent and infiltrating lymphocytes, were later observed in Peyer patches and tonsils. Although the occurrence of lymphocytes within HEV walls was first noted in 1899 (5), the direction and physiological significance of lymphocyte migration through HEVs was not fully appreciated until the classical autoradiographic experiments of Gowans and Knight (6). In their landmark paper, published in 1964, these authors demonstrated that radioactively labeled small lymphocytes that were transfused into the blood of rats migrated rapidly into lymph nodes and Peyer patches by crossing the walls of HEVs. These experiments conclusively showed that HEVs are the site of a large-scale migration of lymphocytes from the blood into secondary lymphoid organs. Evidence accumu-

lated over the past 25 years indicates that HEV-like vessels develop in chronically inflamed tissues and appear to share with HEVs this unique capacity to recruit large numbers of circulating lymphocytes (1). The structure, phenotype, and functional role of these HEV-like vessels in human chronic inflammatory diseases is the focus of this chapter.

In rheumatoid arthritis (RA), a chronic systemic inflammatory disease affecting the joints, small blood vessels with HEV characteristics were first described during the 1980s by Antony J. Freemont (7) and Morris Ziff (8). Freemont noticed that areas of lymphocyte aggregation in the diseased synovia ( $>150$  lymphocytes/mm<sup>2</sup>) contained small blood vessels easily distinguished by the plump, cuboidal appearance of their ECs (Figure 155.1), the unusual thickness of their perivascular sheaths, and the presence of numerous lymphocytes within their walls. These HEV-like vessels were never observed outside areas of lymphocytic aggregation in the diseased synovia or in normal tissues (7). Although the most striking feature of the ECs from the HEV-like vessels found in RA was their unusual height, ultrastructural analysis also revealed certain additional features, including a prominent Golgi complex, abundant mitochondria closely associated with rough endoplasmic reticulum, numerous ribosomes, and a large oval nucleus contrasting with the flattened nuclei from the usual squamous ECs. This indicated an intense biosynthetic activity generally not observed in ECs from other vessels, which typically have a poorly developed Golgi apparatus. In addition, several different membrane-bound vesicular structures were seen in the cytoplasm, including secretory vesicles, Weibel-Palade bodies, and multivesicular bodies that are also characteristic of lymph-node HEV ECs. Altogether, these ultrastructural findings showed that the plump ECs of HEV-like vessels in RA exhibit features that allow them to be regarded as metabolically active, with a predominantly biosynthetic and secretory function.

In his pioneering study, Freemont observed that the ECs from the HEV-like vessels in diseased synovia were less plump

Figure 155.1. HEV-like vessel in RA synovium. HEV-like vessels in the inflamed synovium always are found in association with dense accumulations of lymphocytes. The plump, cuboidal morphology of the ECs can be discerned easily. Staining of the cuboidal ECs with HEV marker MECA-79 is more intense on the side of the leukocyte infiltrate.

when the lymphocyte count was less than  $150/\text{mm}^2$  (7). A few years later, in 1986, Iguchi and Ziff used electron microscopy to perform morphometric analysis of blood vessels in RA synovial membrane and found a strong correlation between the “tallness” or “plumpness” of the ECs and the number and percentage of perivascular lymphocytes (8). This confirmed the intimate relationship between plump endothelium and lymphoid aggregation in RA and strongly suggested that lymphocytes emigrated through the HEV-like vessels to form perivascular lymphoid aggregates in the RA synovium. This latter possibility was further supported by functional studies published the same year (1986) by Sirpa Jalkanen and Eugene Butcher (9), who demonstrated, using the Stamper-Woodruff assay of lymphocyte adhesion to frozen sections *in vitro* (see Chapter 170 for a description of the assay), the capacity of HEV-like vessels in the RA synovium to support lymphocyte adhesion. Freemont extended these studies by showing that the capacity of HEV-like vessels in frozen sections of RA synovium to bind lymphocytes *in vitro* was strongly correlated with the plumpness of the ECs and their capacity to incorporate large amounts of radioactive sulfate, a unique metabolic property shared with HEV ECs from lymphoid tissues (10). He proposed that HEV-like vessels may be responsible for the selective accumulation of lymphocytes in the RA synovium and that these observations could be exploited therapeutically “by using antibodies to inhibit selective lymphocyte adhesion to synovial blood vessels or by interfering with synthesis of the sulfated macromolecule implicated in endothelial control of lymphocyte traffic it may be possible to

reduce lymphocyte accumulation within diseased synovium” (10).

As early as 1983, Freemont extended the observations made in RA to other diseases and described the presence of HEV-like vessels exhibiting plump ECs and numerous lymphocytes within their walls in many human chronic inflammatory diseases (11). In several completely unrelated disease states affecting distinct tissues (stomach, dermis/subcutaneous tissue, thyroid, liver, kidney, muscle), he found that infiltrates containing significant numbers of lymphocytes ( $>150$  lymphocytes/ $\text{mm}^2$ ) always contained HEV-like vessels with plump endothelium that mediated sulfate uptake and *in vitro* lymphocyte adhesion (12). These observations strongly suggested that changes in the local venous microvasculature to a type capable of promoting lymphocyte traffic into the tissue were not disease- or organ-specific but were probably a universal finding in sites of lymphocyte accumulation in chronically inflamed tissue. Freemont also made several interesting observations about the mechanisms that govern the formation of HEV-like vessels in diseased tissues. First, recognizable HEVs developed only after lymphocyte migration had been initiated, suggesting that their formation was not the primary event in lymphocyte migration. Second, HEVs developed in sites that, under normal conditions, contained no such vessels. Third, plump ECs from HEV-like vessels did not show mitotic activity. He concluded from these observations that HEV-like vessels developed from remodeling of existing vessels, and their development was a response to, or a consequence of, lymphocyte accumulation in the tissue. However, once developed, these HEV-like vessels were likely to participate in a positive feedback mechanism for increasing lymphocyte entry into the diseased tissue, thus contributing to the amplification and maintenance of chronic inflammation.

#### PHENOTYPE AND FUNCTION OF HIGH ENDOTHELIAL VENULE-LIKE VESSELS IN HUMAN CHRONIC INFLAMMATORY DISEASES

##### High Endothelial Venule Markers MECA-79, HECA-452, and 6-Sulfo Sialyl Lewis x Ligands for Lymphocyte L-Selectin

Many studies performed over the past 15 years have revealed that HEV-like vessels induced by chronic inflammation in extralymphoid sites are phenotypically similar to HEVs from lymphoid tissues (1). This is illustrated by the results obtained using monoclonal antibodies MECA-79 and HECA-452, two of the best HEV markers currently available (Table 155-1). These two antibodies, which recognize carbohydrate epitopes found on the 6-sulfo sialyl Lewis X (sLe<sup>x</sup>; NeuAc $\alpha$ 2-3Gal $\beta$ 1-4[Fuc $\alpha$ 1-3]GlcNAc $\beta$ 1-) ligands for the lymphocyte homing receptor L-selectin (Figure 155.2), were initially produced in the laboratory of Eugene C. Butcher in 1988 (13,14) and, since that date, have been widely used for the identification and characterization of HEVs and HEV-like vessels in human tissues and chronic inflammatory diseases.

**Table 155-1: MECA-79<sup>+</sup> HEV-Like Vessels in Human Chronic Inflammatory Diseases**

<i>Affected Organs</i>	<i>Diseases</i>	<i>HEV Markers</i>	<i>HEV-Associated Chemokines</i>	<i>Other Features</i>	<i>References</i>
Synovium	Rheumatoid arthritis	MECA-79 <sup>+</sup> HECA-452 <sup>+</sup> 2F3 <sup>+</sup>	CCL21 <sup>+</sup> CXCL13 <sup>+</sup> CXCL12 <sup>+</sup> CCL19 <sup>+</sup>	Cuboidal endothelium Sulfate uptake	7, 10, 15, 41, 50–54

**High Endothelial Venule Marker MECA-79**

MECA-79 stains all HEVs within lymphoid tissues (both luminal and abluminal surfaces of HEV ECs) and does not react with human umbilical vein ECs (HUVECs), nor with ECs of postcapillary venules in spleen, thymus, or nonlym-

phoid tissues (13,15). MECA-79 antibody inhibits both lymphocyte migration through HEVs in vivo and lymphocyte adhesion to human lymph node and tonsil HEVs in vitro. Although initially produced against mouse HEVs, MECA-79 shows a wide species cross-reactivity and, in both mouse and

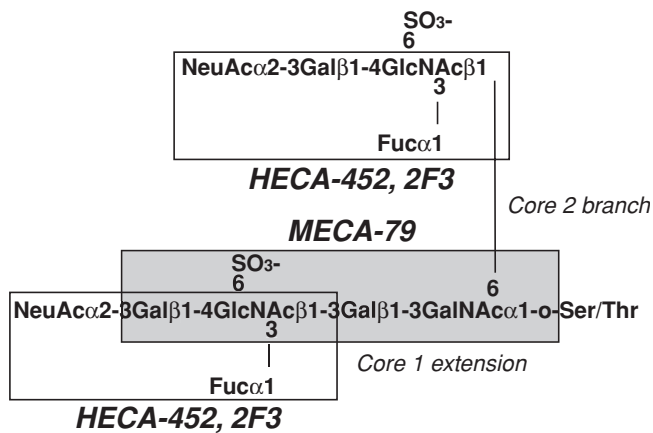

Figure 155.2. Structure of the carbohydrate epitopes recognized by HEV markers MECA-79, HECA-452, and 2F3. The three antibodies react with 6-sulfo sLe<sup>x</sup> ligands for lymphocyte L-selectin, displayed in HEVs from lymphoid tissues and HEV-like vessels from chronically inflamed human tissues. The 6-sulfo sLe<sup>x</sup> epitope, which is a major capping group of L-selectin ligands, is shown both on extended core 1 and core 2 branched structures, formed respectively by core 1 extending  $\beta$ 1,3-N-acetylglucosaminyltransferase and core 2 branching  $\beta$ 1,6-N-acetylglucosaminyltransferase. HECA-452 and 2F3 antibodies recognize the sialic acid (NeuAc) and fucose residues of the 6-sulfo sLe<sup>x</sup> structure (*white boxes*). MECA-79 reacts with a sulfate-dependent epitope on the extended core 1 structure (*gray box*).

human, recognizes a sulfate-dependent carbohydrate epitope (see Figure 155.2) decorating a set of heavily O-glycosylated sialomucin-type HEV counter-receptors for lymphocyte L-selectin, referred to as peripheral node addressins (PNAds, see Chapter 170) (13,15,16). Recent work from the groups of Minoru Fukuda and John B. Lowe has revealed that the minimal carbohydrate epitope recognized by MECA-79 corresponds to an extended core 1 O-glycan structure modified with 6-sulfo N-acetylglucosamine (17). Moreover, MECA-79 also can bind to the sialylated and fucosylated derivative of this structure, which constitutes the 6-sulfo sialyl Lewis X epitope displayed on PNAd (see Figure 155.2) and is recognized by lymphocyte L-selectin (16–18). An HEV-specific sulfotransferase enzyme designated LSST/HEC-GlcNAc6ST (GlcNAc6ST-2/CHST4) has independently been characterized by the groups of Minoru Fukuda and Steven D. Rosen, and shown to be essential for the elaboration of the MECA-79 epitope and the generation of functional L-selectin ligands within the lumen of HEVs (16,19–21). In addition, a second HEV-expressed GlcNAc-6-O-sulfotransferase identified by Takashi Muramatsu and colleagues and designated GlcNAc6ST-1 (CHST2) also has been found to contribute to the generation of the MECA-79 epitope in HEVs (particularly the abluminal one) and the synthesis of 6-sulfo sialyl Lewis ligands for lymphocyte L-selectin (22). Mice lacking both GlcNAc6ST-1 and GlcNAc6ST-2 demonstrated complete elimination of MECA-79 and 6-sulfo sialyl Lewis X epitopes in HEVs and considerably reduced L-selectin mediated lymphocyte adhesion to HEVs (23,24).

Induction of MECA-79 in HEV-like vessels from RA and other human chronic inflammatory diseases was first reported by Butcher and colleagues in 1993 (15). They observed MECA-79<sup>+</sup> vessels with plump endothelium in many cutaneous sites of chronic inflammation, including allergic contact dermatitis, psoriasis, lichen planus, and cutaneous lymphomas. Most importantly, the venules that reacted with MECA-79 were nearly always associated with lymphoid infiltrates, and the degree of MECA-79 expression correlated with the extent of mononuclear cell infiltration present in each lesion. Although MECA-79 reacted with entire vessel segments in most instances, occasional examples of partial reactivity were observed in which only one side of the vessel or even a single EC was MECA-79<sup>+</sup>. Similar observations were made by Butcher and colleagues in extracutaneous sites of chronic inflammation, particularly synovium in RA and thyroid in lymphocytic thyroiditis, in which vascular MECA-79 reactivity was most pronounced in association with extensive lymphoid infiltrates (Figure 155.3). These studies have been extended by Risto Renkonen and coworkers, who have carried out systematic

Figure 155.3. Selective induction of HEV marker MECA-79 on HEV-like vessels in RA. Although MECA-79 reacts with the entire vessel segment in the center of the leukocyte infiltrate, partial reactivity is observed at the periphery. Very often, only one side of the vessel (the one close to the infiltrate) is MECA-79<sup>+</sup>, and a single vessel contains both MECA-79<sup>+</sup> cuboidal ECs and MECA-79<sup>-</sup> flat ECs. As previously described in lymphoid tissues, a reticular pattern of MECA-79 staining is seen around the HEV-like vessel in the leukocyte infiltrate.

surveys in humans, involving large numbers of independent samples. Immunohistochemical staining with MECA-79 was performed on more than 400 specimens from chronically inflamed tissues and their corresponding noninflamed tissues (25). The endothelial expression of the MECA-79 epitope in postcapillary venules was absent in control tissues but induced de novo in inflamed tissues from patients with thyroiditis, psoriasis, ulcerative colitis, bronchial asthma, and heart and kidney allograft rejection (25–28). Induction of MECA-79 was found both on HEV-like and flat-walled vessels, and the intensity of staining and percentage of MECA-79<sup>+</sup> vessels were strongly correlated with the degree of lymphocytic infiltration in the inflamed tissues (25,26). Moreover, differences were observed between the inflammations associated with lymphocytic (MECA-79<sup>+</sup> vessels) or neutrophil (MECA-79<sup>-</sup> vessels) infiltrations in the same organs, such as between psoriasis and vasculitis in the skin (25), or bronchial asthma and adult respiratory distress syndrome in the lungs (27), further supporting the possibility that MECA-79 induction is a hallmark of lymphocyte infiltration in inflamed human tissues.

Interestingly, expression of MECA-79 has been shown to correlate with progression of inflammation in several diseases. During heart and kidney allograft rejection, MECA-79 expression was induced at the onset and, during acute rejection episodes, correlated with the severity of rejection; it decreased to background levels as the rejection resolved (26,28). Similar observations were recently reported by Fukuda and colleagues, who studied a large series (>140) of chronic inflammatory gastritis human specimens associated with *Helicobacter pylori* infection of the gastric mucosa (29). The number of MECA-79<sup>+</sup> HEV-like vessels and the number of patients exhibiting MECA-79<sup>+</sup> HEV-like vessels were both highly correlated with the progression of inflammation. In addition, analysis of gastric biopsies obtained from 17 patients with chronic active gastritis before and after eradication of *H. pylori* infection revealed that eradication of *H. pylori* is associated with the disappearance of MECA-79<sup>+</sup> HEV-like vessels and lymphocyte infiltration in the gastric mucosa.

The molecular mechanisms involved in the induction of the MECA-79 epitope in human chronically inflamed tissues remain poorly characterized. However, recent data from Rosen and colleagues suggest that the HEV-specific sulfotransferase HEC-GlcNAc6ST is likely to be key. Double staining of human RA samples with MECA-79 and an antibody to the HEV sulfotransferase revealed that all the MECA-79<sup>+</sup> vessels were also positive for the sulfotransferase (30). In contrast, MECA-79 staining and the HEV sulfotransferase were not observed in synovial vessels from osteoarthritis patients, used as controls for RA.

A complete list of human inflammatory diseases for which MECA-79<sup>+</sup> HEV-like or flat-walled vessels have been observed can be found in Table 155-1. In addition to the aforementioned diseases, these include Crohn disease (31), glomerulonephritis (32), inflammatory myopathies (33), lung bronchiectasis (34), experimentally induced allergic rhinitis (35), cutaneous lupus erythematosus (36), and conjunctival inflammation induced

by cataract surgery (37). The diversity of diseases and affected organs suggest that MECA-79<sup>+</sup> HEV-like vessels may appear in most (if not all) human nonlymphoid tissues after long-standing chronic inflammation.

#### *High Endothelial Venule Marker HECA-452*

Another monoclonal antibody recognizing a carbohydrate epitope expressed on human HEV and HEV-like vessels but not on HUVECs or ECs from other flat-walled vessels was described by Butcher and colleagues in 1988. Elegant studies by Reiji Kannagi and coworkers have revealed that this antibody, HECA-452, belongs to a group of variant-type anti-sLe<sup>x</sup> antibodies (HECA-452, 2F3, 2H5) which, unlike the classical type anti-sLe<sup>x</sup> antibodies (CSLEX-1, FH-6), recognize the 6-sulfo sLe<sup>x</sup> ligands for L-selectin on human HEVs (18,38). HECA-452 recognizes both the sialic acid and fucose residues of the 6-sulfo sLe<sup>x</sup> ligand and, similar to the other anti-sLe<sup>x</sup> antibodies (including 2F3), does not cross-react with rodent HEVs, likely because of species-specific modifications of sialic acid residues. Expression of HECA-452 and related sLe<sup>x</sup> epitope 2F3 in ECs has been shown to be induced by the  $\alpha$ 13 fucosyltransferase Fuc-TVII (38), which is specifically expressed by HEVs in secondary lymphoid organs (39) and known to play a key role in the synthesis of HEV-specific L-selectin ligands in vivo (40). It should be noted that the  $\alpha$ 13 fucosyltransferase Fuc-TVII also controls fucosylation of selectin ligands in leukocytes (40), which may explain the cross-reaction of HECA-452 with monocytic cells, dendritic cells, and the cutaneous lymphocyte antigen (CLA) subset of skin-homing memory lymphocytes (14,41,42).

Induction of the HECA-452 epitope on HEV-like vessels was first described in Crohn disease (14), autoimmune thyroiditis (14,42) and RA (41). HECA-452<sup>+</sup> vessels in these chronically inflamed tissues resembled HEVs seen in lymphoid organs; they had, however, a more variable appearance, with irregularity in the morphology of the endothelium, from flat to cuboidal. In all these diseases, HECA-452<sup>+</sup> vessels always were found in association with dense accumulations of lymphocytes, and positive vessels were never observed in acutely inflamed tissues lacking intense local infiltration of lymphocytes. The presence of diffusely distributed lymphocytes in these acutely inflamed conditions indicated that induction of the HECA-452 epitope at the EC surface was not an absolute requirement for low levels of lymphocyte extravasation. In RA, the morphological and phenotypic changes of the endothelium from HECA-452<sup>-</sup> flat-walled vessels to HECA-452<sup>+</sup> HEV-like vessels were found to follow the influx of dendritic cells in the synovium (41).

Induction of HECA-452 and related sLe<sup>x</sup> epitope 2F3 in human inflammatory diseases has been further characterized through immunohistochemical analyses of large series of patient specimens. Similarly to MECA-79, HECA-452 and/or 2F3 were significantly upregulated on small blood vessels (HEV-like and/or flat-walled) in inflamed tissues from patients with thyroiditis, ulcerative colitis, bronchial asthma, conjunctival inflammation induced by cataract surgery,

glomerulonephritis, and heart and kidney allograft rejection (25–28,32,37), and their expression was found to correlate with progression of inflammation during acute heart and kidney rejection episodes (26,28). The staining patterns observed with the two anti- sLe<sup>x</sup> antibodies in the diseased tissues were similar but not identical because, for example, HECA-452 was induced in 25% of vessels from psoriatic lesions, whereas 2F3 remained completely negative in skin (25). Interestingly, induction of the two epitopes during heart allograft rejection was associated with the upregulation of fucosyltransferase Fuc-TVII (26).

In *H. pylori*-associated chronic inflammatory gastritis, HECA-452 was found to be coexpressed with MECA-79 on the same HEV-like vessels, and its expression on these vessels was dependent on continuous *H. pylori* infection and highly correlated with progression of inflammation (29). Moreover, the HEV-like vessels detected by MECA-79 and HECA-452 in *H. pylori*-associated gastritis appeared to be functional for recruitment of L-selectin-expressing lymphocytes, because they bound a soluble recombinant form of L-selectin (L-selectin/IgM chimera). Indeed, a large number of B and T lymphocytes were recruited in the gastric mucosa infected with *H. pylori*. Together with those other studies showing simultaneous induction in many diseases of the sulfate-dependent epitope MECA-79 and the sialic acid and fucose-dependent epitopes HECA-452 and/or 2F3 (see Table 155-1), these later results suggest that functional 6-sulfo sLe<sup>x</sup> ligands for L-selectin (see Figure 155.2) are induced on HEV-like vessels in many human chronic inflammatory diseases. Therefore, HEV-like vessels are likely to be fully competent for L-selectin-mediated lymphocyte tethering and rolling, the first essential steps of the multistep lymphocyte recruitment cascade (see Chapter 170).

The mucosal HEV-specific EC adhesion molecule mucosal addressin cell adhesion molecule (MAdCAM)-1, a ligand for both L-selectin (when decorated with the MECA-79 epitope) and lymphocyte  $\alpha 4\beta 7$  integrin, known to mediate the initial interaction of lymphocytes with mucosal HEVs in Peyer patches, also has been shown to be induced on HEV-like vessels in chronic inflammatory bowel diseases (Crohn disease, ulcerative colitis) and *H. pylori* gastritis (43,44). This suggests that MAdCAM-1 is likely to cooperate with the 6-sulfo sLe<sup>x</sup> ligands for L-selectin in the initial capture and rolling interactions of lymphocytes in chronic inflammatory diseases associated with the gastrointestinal tract.

### Chemokines and Lymphocyte Migration Through High Endothelial Venule-Like Vessels

Chemokines and chemokine receptors support lymphocyte migration through HEVs by triggering the integrin-mediated arrest of rolling lymphocytes (2,3). Circulating B and T lymphocytes express multiple chemokine receptors, including CCR7, the receptor for chemokines CCL21 (SLC) and CCL19 (ELC); CXCR4, the receptor for CXCL12 (SDF1); and, in the case of B lymphocytes, CXCR5, the receptor for

CXCL13 (BLC/BCA-1). The so-called *lymphoid chemokines* (or HEV-associated chemokines) CCL21, CCL19, CXCL12, and CXCL13 have all been found to be associated with the luminal surface of HEVs in lymphoid tissues (45–48). However, only CCL21 is produced by the HEV ECs themselves (49). The three other chemokines are produced by non-ECs in the lymphoid tissues and subsequently transported to the HEVs, transcytosed, and displayed on the HEV lumen (46–48). A similar scenario seems to apply to the RA synovium, where the four lymphoid chemokines have been detected on HEV-like and flat-walled vessels (50–54). The ECs in chronically inflamed synovium acquire the ability to synthesize CCL21, a property that is normally restricted to HEV ECs from lymphoid tissues (50). In contrast, although CXCL12 was displayed on RA synovial endothelium (54), *in situ* hybridization revealed that ECs did not express the corresponding mRNA, which was mainly produced by fibroblast-like synoviocytes (52). Similarly, CXCL13 was found on ECs but was thought to be produced by follicular dendritic cells and synovial fibroblasts (51).

Among the four lymphoid chemokines induced on endothelium in chronic inflammatory diseases (see Table 155-1), CCL21 and CXCL13 are likely to be the most important for recruitment of T and B lymphocytes, respectively. In RA synovium, Uli von Andrian and colleagues observed induction of CCL21 both on MECA-79<sup>+</sup> HEV-like vessels and MECA-79<sup>-</sup> flat-walled vessels (50). Indeed, 85% of blood vessels in the inflamed synovium were found to express CCL21. Similarly, most blood vessels (66%) in tissue samples from patients with ulcerative colitis expressed CCL21. CCL21 is highly potent for attracting naive T cells, and CCL21 induction in blood vessels correlated positively with the influx of CD45Ra<sup>+</sup> naive T cells in the inflamed tissues from patients with RA or ulcerative colitis (50). Together, these findings suggest that induction of CCL21 on HEV-like vessels and flat-walled vessels is an important determinant for naive T-cell migration into chronically inflamed human tissues. In addition, CCL21 induction on endothelium during chronic inflammation also may be critical for recruitment of memory lymphocytes. For example, in T-cell autoimmune infiltrative skin diseases (atopic dermatitis, lichen planus, etc.), expression of CCL21 was highly induced in ECs from venules, and the receptor for CCL21, CCR7, also was found to be highly expressed on the infiltrating T-cells, the majority of which expressed the memory CD45Ro<sup>+</sup> phenotype (55). CXCL12 also may participate in the recruitment of memory lymphocytes during chronic inflammation, particularly in the RA synovium, where endothelial expression of CXCL12 was associated with the presence of large numbers of perivascular CXCR4<sup>+</sup> CD45Ro<sup>+</sup> lymphocytes (54).

In a number of other chronic inflammatory diseases, the induced expression of CCL21 in ECs may cause abnormal recruitment of T cells from the circulation to sites of pathologic inflammation. These include chronic *H. pylori* gastritis (56), chronic inflammatory liver disease (57), and autoimmune thyroiditis (58), in which CCL21 was shown to be induced on HECA-452<sup>+</sup> HEV-like vessels. In addition, CCL21 also

was found to be induced on blood–brain barrier venules in experimental autoimmune encephalomyelitis (EAE), an animal model for multiple sclerosis and, together with CCL19, appeared to be important for aberrant T-cell infiltration into the inflamed brain (59).

CXCL13 has been found to be induced on endothelium both in RA and ulcerative colitis (51,60). In vitro, CXCL13 is a strong chemoattractant for B lymphocytes. Endothelial induction of CXCL13 in chronically inflamed tissues is therefore likely to mediate recruitment and transendothelial migration of large numbers of CXCR5<sup>+</sup> B lymphocytes. Indeed, in ulcerative colitis, Per Brandtzaeg and coworkers have found that induction of CXCL13 on HEV-like vessels was associated with infiltration of numerous CXCR5<sup>+</sup> B lymphocytes in irregular lymphoid aggregates (60).

In addition to mediating lymphocyte recruitment into chronically inflamed tissues, CXCL13 and CCL21 also may participate in the development of HEV-like vessels and ectopic lymphoid tissue in these inflamed sites, in collaboration with the tumor necrosis factor (TNF)/lymphotoxin pathways.

#### MECHANISMS GOVERNING THE DEVELOPMENT OF HIGH ENDOTHELIAL VENULE-LIKE VESSELS IN CHRONIC INFLAMMATION

The development of specific protocols for the isolation of HEV ECs from fresh human tissues (61) has opened the way to the molecular characterization of these specialized ECs, allowing for example, the identification of genes involved in HEV sulfation pathways (62) or genes encoding nuclear and secreted factors preferentially expressed in human HEVs (61,63). Most importantly, the use of HEV ECs freshly purified from human tonsils has demonstrated that HEV ECs exhibit a remarkable plasticity and rapidly lose their specialized characteristics outside the lymphoid tissue microenvironment (64). Although the mechanisms governing the development of HEV-like vessels in chronically inflamed human tissues are not yet completely understood, the latter study strongly suggested that lymphoid cells surrounding HEVs, and the soluble cytokines/chemokines produced by these cells, were likely to be key for the induction of HEV-like vessels during chronic inflammation.

Because HEV-like vessels are always associated with dense lymphocytic infiltration in sites of chronic inflammation, lymphocytes are likely to play an important role in the induction of the specialized HEV phenotype. However, the loss of HEV characteristics in mouse lymph nodes deprived of afferent lymphatics, despite normal numbers of recirculating lymphocytes in the blood, clearly shows that recirculating lymphocytes are not sufficient to induce the HEV phenotype (1). This also is supported by the fact that generalized induction of HEV-like vessels has not been reported in human diseases characterized by uncontrolled lymphocyte overpopulation (e.g., chronic lymphocytic leukemia, acute lymphoblastic leukemia, etc.). Therefore, cooperation between lymphocytes and other

cell types found in the infiltrates may be required for the induction and maintenance of HEV-like vessels. Dendritic cells are likely to be key in this respect, because studies of HEV-like vessel development in RA or autoimmune thyroiditis, and HEV induction during development of the human immune system, have revealed that the appearance of dendritic cells always precedes the development of HEVs (1).

A key role for soluble mediators (cytokines, chemokines) in HEV-like vessel development during human chronic inflammatory diseases is supported by the results obtained in transgenic and knockout mice models, which indicate that lymphoid chemokines cooperate with TNF/lymphotoxin cytokines for the induction of HEV-like vessels in chronically inflamed nonlymphoid tissues. Transgenic expression in pancreatic islets of cytokines TNF- $\alpha$ ; lymphotoxin- $\alpha$  (TNF- $\beta$ ); membrane-bound lymphotoxin  $\alpha 1\beta 2$  (65–67); or lymphoid HEV-associated chemokines CCL21 (68), CXCL13 (69) and, to a lesser extent, CCL19 or CXCL12 (70), induced chronic inflammatory infiltrates containing HEV-like vessels expressing HEV markers MECA-79 and/or MAdCAM-1. These vessels closely resembled lymph nodes with respect to both cellular composition and organization. This process of de novo formation of organized lymphoid tissue in chronic inflammation was named *lymphoid neogenesis* by Ruddle and colleagues in 1996 (65–67,71,72). Over the last 10 years, lymphoid neogenesis has been described in many human chronic inflammatory diseases (72), including RA (50,51,53), inflammatory bowel diseases (60), autoimmune thyroiditis (58), *H. pylori*-induced gastritis (56), and chronic inflammatory liver disease (57). Although not observed in all patients, lymphoid neogenesis is believed to be a key determinant in the pathogenesis of these diseases by allowing local production of autoantibodies and direct priming of autoreactive naive T and B lymphocytes at the site of inflammation (50,71,72).

The membrane-bound lymphotoxin  $\alpha 1\beta 2$  and the chemokines CCL21 and CXCL13 are the most potent inducers of lymphoid neogenesis (66,69,70), and both CCL21 and CXCL13 have been proposed to act through recruitment and upregulation of lymphotoxin  $\alpha 1\beta 2$  on T and B lymphocytes, respectively (69,70). Ectopic expression of lymphotoxin  $\alpha 1\beta 2$  in pancreatic islets has been shown to be sufficient for induction of HEV-like vessels expressing the HEV sulfotransferase HEC-GlcNAc6ST and luminal MECA-79<sup>+</sup> PNA<sup>d</sup> ligands for L-selectin, as well as MAdCAM-1 and chemokine CCL21 (66). In addition, lymphotoxin  $\alpha 1\beta 2$  was recently proposed to bind to the lymphotoxin receptor (LT $\beta$ R) expressed on HEV ECs, and to regulate HEV-specific gene expression through the alternative nuclear factor (NF)- $\kappa$ B pathway (73). An intriguing possibility is that continuous stimulation of LT $\beta$ R on HEV ECs by lymphotoxin  $\alpha 1\beta 2$  expressed at the surface of recirculating lymphocytes and/or dendritic cells may be required for induction and/or maintenance of HEVs in lymphoid tissues and HEV-like vessels in chronically inflamed tissues. This would explain why HEV-like vessels are always found in association with extensive lymphoid infiltrates in human chronic inflammatory diseases, and why HEV markers such as

MECA-79 are only induced in ECs that are in direct contact with the leukocyte infiltrate (Figure 155.3).

Nuclear transcription factors acting downstream of the  $LT\beta R$  in ECs are likely to be key for the induction and maintenance of HEV-like vessels. Studies in mice indicate that binding of lymphotoxin- $\alpha\beta$  to the  $LT\beta R$  may activate expression of MECA-79<sup>+</sup> PNAd and other HEV-specific genes (sulfo-transferase HEC-GlcNAc-6ST, chemokine CCL21) through the alternative NF- $\kappa B$  pathway, which is known to regulate NF- $\kappa B$ -inducing kinase (NIK) and I $\kappa B$  kinase complex- $\alpha$  kinase (IKK $\alpha$ ) activities and the subsequent processing of NF- $\kappa B2$  p100 to p52, resulting in nuclear translocation of RelB:p52 heterodimers (66,73,74). NF- $\kappa B2$  and RelB, two members of the NF- $\kappa B$  transcription factor family, may therefore play a key role in HEV-specific gene expression (73,74). Because NF- $\kappa B$  transcription factors regulated by the TNF/lymphotoxin pathway also can be activated in a variety of other cell types, other EC- or microenvironment-specific cues must exist that work together with the aforementioned signaling to elicit a HEV-specific phenotype. For example, nuclear transcription factors regulated by other pathways and/or encoded by HEV master control genes might also exist and participate in the development of HEV-like vessels. An attractive candidate is NF-HEV, a homeodomain-like nuclear factor preferentially expressed in human HEVs, which may regulate HEV-specific genes (63). In addition, signals originating from the extracellular matrix (ECM) also may play important roles in the induction and/or maintenance of HEVs (1). Possible candidates include the matricellular proteins Hevin and Mac-25, which are preferentially and abundantly expressed in HEVs (61,75).

### HIGH ENDOTHELIAL VENULE-LIKE VESSELS IN DISEASE: THERAPEUTIC IMPLICATIONS

The development of HEV-like vessels in chronic inflammatory diseases is tightly associated with the recruitment of large numbers of lymphocytes into the diseased tissues, thus favoring the expansion and perpetuation of an autoimmune response. Therefore, interfering with the development and/or maintenance of these HEV-like vessels or with the function of HEV-associated molecules that control lymphocyte recruitment (e.g., HEV-specific adhesion molecules PNAd and MAdCAM-1, HEV-associated chemokines CCL21, CXCL13), is likely to provide therapeutic benefits in many distinct human chronic inflammatory diseases (see Table 155-1).

As previously discussed, the presence of HEV-like vessels and/or associated markers (MECA-79, HECA-452, 2F3) in diseased tissues is strongly correlated to the progression of inflammation. The example of *H. pylori* gastritis is particularly interesting in this respect, because the disappearance of MECA-79<sup>+</sup>HECA-452<sup>+</sup> HEV-like vessels after treatment was strikingly correlated with the disappearance of lymphocyte infiltration in the gastric mucosa (29). Similar clinical observations have been reported in heart or kidney allograft rejection episodes (26,28), and in RA, in which HEV-like ves-

sels are observed in the rheumatoid synovium of patients with active untreated disease, whereas tissue samples from patients whose disease has been modified by treatment exhibit a flatter endothelium (76). Altogether, these clinical observations indicate that the formation of HEV-like vessels – and thus recruitment of lymphocytes to chronic inflammatory sites – can be reversed.

In view of the critical role played by the TNF/lymphotoxin cytokines in the induction and/or maintenance of HEVs, specific inhibitors of these cytokines are likely to be useful to inhibit the formation and/or maintenance of HEV-like vessels in chronic inflammatory human diseases. Indeed, the soluble TNF receptor Etanercept, which blocks both TNF- $\alpha$  and lymphotoxin- $\alpha$  and has notable efficacy in the treatment of RA, may act, at least in part, at the level of the endothelium by inhibiting the expression of HEV-associated adhesion molecules and chemokines. Antagonists of membrane lymphotoxin- $\alpha\beta$  currently in development are likely to be even more efficient and specific for the inhibition of HEV-like vessel development in clinical settings. Interestingly, one of these lymphotoxin- $\alpha\beta$  antagonists – the soluble  $LT\beta R$ -immunoglobulin fusion protein, which blocks development of HEV-like vessels induced by transgenic expression of chemokines CXCL13 (69) or CCL21 (70) – has shown therapeutic efficacy in various preclinical models of human chronic inflammatory diseases (77).

Lymphoid chemokines, such as CCL21 and CXCL13, are potent inducers of HEV-like vessels and ectopic lymphoid tissue in transgenic mice. Therefore, induction of these lymphoid chemokines at sites of inflammation in human diseases could convert the lesion from an acute to a chronic state, and blocking their activity or receptors on lymphocytes might have significant therapeutic value in human chronic inflammatory diseases. Small-molecule inhibitors of CCR7 and CXCR5, currently in development, may be useful for that purpose. However, the four HEV-associated lymphoid chemokines (see Table 155-1), as well as several inflammatory chemokines, are induced on HEV-like and flat-walled vessels in RA synovium, and it is unclear at present whether blocking the activity of a single chemokine (such as CCL21 or CXCL13) will be sufficient for therapeutic efficacy. The use of broad spectrum or promiscuous chemokine inhibitors may avoid this problem of chemokine redundancy.

HEV-specific adhesion molecules MECA-79<sup>+</sup>PNAd and MAdCAM-1 constitute other interesting therapeutic targets to block lymphocyte infiltration into chronically inflamed human tissues. Indeed, the mucosal HEV-specific MAdCAM-1 is a validated target for inflammatory bowel diseases. A therapeutic antibody targeting lymphocyte  $\alpha 4\beta 7$  integrin (natalizumab), which disrupts  $\alpha 4\beta 7$ MAdCAM-1-mediated lymphocyte/endothelium interactions, has shown therapeutic efficacy in phase I clinical trials for Crohn disease (78). Disruption of L-selectin/MECA-79<sup>+</sup>PNAd interactions also may provide significant therapeutic benefits. Indeed, targeting MECA-79<sup>+</sup>PNAd recently has been shown to have therapeutic efficacy in a sheep model of human asthma (79).

Although detrimental in chronic inflammatory diseases, the development of HEV-like vessels and lymphoid neogenesis could be beneficial in other diseases such as cancer, in setting up a local site for antigen presentation. Indeed, targeting of lymphotoxin to a tumor in mouse has been shown to induce functional HEV-like vessels within the tumor, thus allowing naive lymphocyte recruitment, priming, and expansion in the ectopic lymphoid tissue induced at the tumor site (80). Interestingly, tumor venules with HEV-characteristics have been observed in areas of lymphocytic infiltration into human tumors (81). ECs from these venules exhibited a plump, cuboidal morphology, and expressed the HEV-specific marker MECA-79 (81,82). HEV-like vessels therefore may play an important role not only in human chronic inflammatory diseases but also in human cancer.

## CONCLUSION

The HEV endothelium is unique among vascular endothelium due to its capacity to recruit large numbers of lymphocytes. HEV-like vessels induced by chronic inflammation in non-lymphoid tissues appear to be structurally, phenotypically, and functionally similar to HEVs from lymphoid tissues. A better understanding of the mechanisms controlling development and maintenance of HEV endothelium could therefore provide the basis of novel therapeutic approaches for the treatment of human chronic inflammatory diseases (RA, inflammatory bowel diseases, autoimmune thyroiditis, *H. pylori* gastritis, asthma, atopic dermatitis, psoriasis, etc.) in which HEV-like vessels facilitate large-scale influx of lymphocytes, leading to amplification and maintenance of chronic inflammation.

### KEY POINTS

- HEV-like vessels in human chronic inflammatory diseases affecting distinct tissues (synovium, colon, thyroid, stomach, skin, lung, etc.) have been shown to express HEV-specific molecules (MECA-79, MAdCAM-1, HECA-452, and 6-sulfo sLe<sup>x</sup> ligands for lymphocyte L-selectin), which mediate the initial capture and rolling interactions of lymphocytes.
- These HEV-like vessels also express HEV-associated lymphoid chemokines (CCL21, CCL19, CXCL13, and CXCL12), which induce integrin-mediated arrest, transendothelial migration, and recruitment of lymphocytes into the inflamed tissues.
- HEV ECs exhibit a remarkable plasticity, and rapidly lose their specialized characteristics outside the lymphoid tissue microenvironment. Studies in trans-

genic and knockout mice models indicate that lymphoid chemokines CCL21 and CXCL13 may cooperate with cytokines of the TNF/lymphotoxin family, particularly membrane-bound lymphotoxin  $\alpha 1\beta 2$ , for the regulation of HEV-specific gene expression through the alternative NF- $\kappa$ B pathway. Therefore, cytokines and chemokines produced by lymphoid cells are likely to be key for induction and maintenance of HEV-like vessels in human chronic inflammatory diseases.

### Future Goals

- Because interfering with the development and/or maintenance of HEV-like vessels, or with the function of HEV-associated molecules that control lymphocyte recruitment, is likely to provide therapeutic benefits in many distinct human chronic inflammatory diseases, future studies should aim at developing biological therapeutic agents (antibodies, soluble receptors) targeting membrane lymphotoxin and HEV-associated lymphoid chemokines, which appear to control development of HEV-like vessels and associated ectopic lymphoid tissues, or HEV-specific adhesion molecules such as MECA-79<sup>+</sup>PNAd and MAdCAM-1, a therapeutic target already validated in Phase I clinical trials for Crohn disease.
- To further characterize the ECs from HEV-like vessels at the molecular level: Application of high-throughput genomic and proteomic approaches to these ECs, freshly isolated from RA synovium or other human chronically inflamed tissues, is likely to reveal a treasury of as-yet-unknown genes and molecules with potential clinical importance. These may include HEV master control genes that would have considerable applications to control the development of HEV-like vessels in clinical situations, permitting therapies that either inhibit formation of HEV-like vessels in human chronic inflammatory diseases (in which these vessels are detrimental), or stimulate HEV-like vessel development in other clinical settings, such as human cancer (in which these vessels could be beneficial by allowing massive lymphocyte recruitment within the tumors).

## Endothelium and Skin

Peter Petzelbauer, Marion Gröger, Robert Loewe, and Rainer Kunstfeld

*Medical University Vienna, Austria*

The skin surface sets the boundary between the body and the external environment and serves three main functions. It protects against outside damage from physical, chemical, or infection-related stress, and it regulates body temperature and fluid balance. To fulfill these diverse functions, the skin has three anatomic layers: the epidermis, dermis, and subcutis, which serve independent and joint functions.

The epidermis, the outmost coating of the skin, is formed by a multilayer of keratinocytes. The epidermis is nonvascularized and separated by a basement membrane from the underlying zone of highly vascularized connective tissue, called the dermis. The dermo-epithelial zone is not linear, but rather is an interdigitated interface. Keratinocytes form the rete ridges, which protrude into the dermis. Concurrently, between these rete ridges, the dermis extends upward and forms the papillae. Morphologically and functionally distinct from this so-called papillary dermis is the deeper portion of the dermis, the reticular dermis, which harbors eccrine and apocrine glands (for sweat and scent production, respectively). The subcutaneous fat layer (subcutis) below resides on the muscle fascia. Terminal hairs root in the fat layer; the sebaceous glands pertinent to the hair follicle reside within the dermis (Figure 156.1; for color reproduction, see Color Plate 156.1).

### VASCULAR ARCHITECTURE

The knowledge about the structure and organization of the cutaneous vasculature has been developed over the past 25 years. Before that, it was assumed that cutaneous vessels form a random network. Irwin Braverman was the pioneer in setting up a model for the complex vascular network of the skin (1). This chapter focuses on skin blood vessels; the characteristics of the lymphatic vascular system are described in Chapter 169.

The structure and organization of the microvasculature in developing human skin was analyzed by light and electron microscopy in conjunction with computer reconstructions. At embryonic day (E)35 to 40, simple, capillary-like vessels are

morphologically identifiable in the presumptive dermis. A single plane of vessels and discontinuous vascular segments are seen in specimens at E40 to E50, whereas two planes and a capillary network emerge at E50 to E75. By electron microscopy, endothelial junctions appear similar to those in adult endothelial cells (ECs), but little or no basal lamina surrounds the vessel. By the end of the first trimester, the major vascular organization of the dermis appears defined, but the basal lamina still consists of amorphous deposits and eventually thickened segments (2).

In adult skin, blood vessels follow anatomic structures. Within the papillary dermis, paired arterioles and venules form an interconnected network of vessels. They run on a plane parallel to and just beneath the epidermis and are called *superficial vascular plexus* (SVP) (3). Capillaries arise from the arterioles, extend upward within the papillary dermis between the epidermal rete ridges, and then loop back down to the venules, forming arcade-like structures. In normal skin, most of this capillary loop is invested with a homogeneous basement membrane that resembles the segment of the arteriole. The capillaries acquire a venular-like investiture (multilayered basement membrane) only at the level of the deepest rete, just proximal to the anastomosis with the venule of the SVP (see Figure 156.1). Arterioles and venules within the SVP do not possess an internal or external elastic membrane.

Vessels of the SVP are connected by short, straight connections to the arterioles and venules of a deeper planar network of anastomosing vessels called the *deep vascular plexus* (DVP), which resides within the reticular dermis (see Figure 156.1). The plane of the DVP is parallel to that of the SVP and runs above the boundary between the reticular dermis and the underlying subcutis. The DVP is fed through penetrating vessels from the subcutis and drained by valve-containing veins into the subcutaneous fat. Valves are positioned at sites where the small vessels connect to larger ones and imply a mechanism involved in forward propulsion of blood. The DVP contains arterioles and venules of larger caliber consisting of three layers: an intima, media, and adventitia. Capillary networks connecting the arterioles and venules of the DVP

Figure 156.1. Schematic drawing of skin architecture. For color reproduction, see Color Plate 156.1.

provide nourishment for the adnexial structures within the reticular dermis.

Dermal microvessels are surrounded by flat adventitial cells, ultrastructurally most closely resembling a fibroblast, called *veil cells*. They are found in the dermis and infrequently around capillaries of the subcutis. Veil cells are probably specific for skin vessels. These cells are negative for T- or B-cell markers and negative for human leukocyte antigen (HLA)-DR and CD1a expression. They express GPIIb $\alpha$ , von Willebrand factor (vWF), and factor XIIIa, a coagulation transglutaminase; these cells are called *XIIIa-positive dendrocytes* (4,5). Interestingly, factor XIIIa-positive dendrocyte rarefaction is found in the classic type of Ehlers-Danlos syndrome, but the significance of this finding is not clear.

Unlike veil cells, pericytes are an integral component of the vessel wall. They extend long cytoplasmic processes over the surface of ECs and form interdigitating contacts. They cover small arterioles, capillaries, and venules on their abluminal surfaces. In the microvasculature, ECs and pericytes are anatomical and functional neighbors. They are separated by the EC basal lamina, which is not completely dense and allows punctuate direct contact and interdigitation. Pericytes are best identified by immunohistochemistry using antibodies to the cell surface 3G5 ganglioside antigen, which reacts with pericytes of several different tissues (6). A subpopulation of 3G5-positive pericytes coexpress smooth muscle antigen (SMA) (6). The coverage of ECs by pericytes varies considerably between different microvessel types, and the location of pericytes on the microvessel is not random but appears to be correlated with function. At points of pericyte-EC contact, communicating gap junctions, tight junctions, and adhesion plaques are present. In large venules, the pericytes only partially encircle the EC cell tube and are more randomly placed. In postcapillary venules, pericytes completely encircle and grip ECs through multiple contact points from their lateral processes, with one pericyte making contact to two to four ECs (7).

Pericytes are rich in contractile proteins. Based on their complex interdigitation with ECs of postcapillary venules, it can be assumed that they are responsible, at least in part, for gap formation in response to factors including histamine or

bradykinin (although cultured ECs are capable of contraction in the absence of pericytes). Moreover, interactions between pericytes and endothelium are important for the maturation, remodeling, and maintenance of the vascular system via the secretion of growth factors or modulation of the extracellular matrix.

## PHENOTYPIC FEATURES OF SKIN ENDOTHELIAL CELLS

ECs of the skin share most biochemical/molecular features common for all ECs in the body. They express vWF, the single most widely used marker for vascular endothelium, which is found in Weibel-Palade bodies or in the biosynthetic organelles. Differences in levels of vWF expression in different vascular segments of the skin have not been reported. Skin ECs uniformly express the pan-endothelial marker CD144 (vascular endothelial [VE]-cadherin). CD31 (platelet-endothelial cell adhesion molecule [PECAM]-1) expression is shared by endothelium and platelets, but also is found on circulating leukocytes. As in all endothelium, skin ECs can be recognized by their ability to take up acetylated low-density lipoprotein (acLDL) via the “scavenger cell pathway” of LDL metabolism. At least four different types of scavenger receptors exist; some are shared with or are unique to macrophages, whereas some are probably unique to endothelium. Like ECs of other organs, skin ECs secrete CD143 (angiotensin-converting enzyme [ACE]); this characteristic is shared with macrophages. Moreover, normal skin ECs express the anticoagulant protein CD141 (thrombomodulin). This feature is shared with trophoblast cells of the placenta, which, like endothelium, form a blood-compatible surface that prevents coagulation. Interestingly, thrombomodulin expression by skin ECs is significantly downregulated in patients with meningococcal sepsis, which correlates with low endothelial protein C receptor expression and with low plasma protein C levels (8).

Human vascular ECs express blood group H antigens recognized by the lectin *Ulex europaeus* agglutinin (UEA)-1. This antigen also is expressed on erythrocytes and on certain specialized epithelia; for example, in the skin it is expressed on keratinocytes.

In the skin, as in other organs, blood capillaries are the terminal segment of the arterial tree, and consist of tubes formed by a continuous string of elongated ECs, each curved to form a segment of a hollow cylinder. The arterial capillary connects with the venular capillary, which empties out into the postcapillary venule. Electron microscopic examinations of skin sections distinguish between these vascular segments. The arterial capillary is surrounded by a dense basement membrane, which develops lamellae in the venular capillary. The postcapillary venule has an increased external diameter, as compared with the capillary segments. Moreover, pericytes form two to three layers around postcapillary venules, as opposed to only one layer in the venular capillary (1). Phenotypic evaluations of these particular vascular segments of the skin commonly use

the term *microvessel* without a precise assignment of a certain molecular phenotype to one of these three microvascular beds. In keeping with this convention, we use the term *microvascular EC* (MVEC) to refer to all three vascular segments.

In 1985, Schlingemann and colleagues described an antibody called *Pathologische Anatomie Leiden-endothelium* (PAL-E), which bound to virtually all capillary ECs of the body and to most venules, but not to arterioles, arteries, and large veins (9). The molecular identity of PAL-E appears to be a glycoprotein associated to caveolae, which has homology to human fenestrated endothelial-linked structure protein (FELS) and to rat plasmalemmal vesicle (PV)-1 (10). The capillaries of most tissues, including those of the skin, are positive for CD34, a molecule that also is found on immature hematopoietic cells. Interestingly, monoclonal antibodies to different CD34 epitopes variably recognize hematopoietic cells, but uniformly bind to blood capillaries. Skin blood capillaries (and capillaries from most other organs) express vascular endothelial growth factor receptor (VEGFR)-1, -2, and -3 proteins, whereas arterioles, arteries, venules, and veins do not (at least as tested by immunohistochemistry) (11). Skin MVECs constitutively express class II major histocompatibility (MHC) molecules, implying that they function in antigen presentation (12). So far, in addition to skin ECs, constitutive HLA class II expression has been described only in renal peritubular and glomerular capillaries. CD36, a receptor for collagen, thrombospondin, and *Plasmodium falciparum*, is found on virtually all capillaries. The situation is different in the skin; within the SVP, there exists a small subpopulation of microvessels that is CD36 negative, but the functional relevance of this finding is unknown (13). The SVP is unique also with regard to expression of the low-affinity Fc $\gamma$  receptor CD32 (14). The CD32<sup>+</sup> population appears to reside within the CD36<sup>-</sup> EC population of the papillary dermis. CD32 expression also has been described on liver MVECs. Blood capillaries of the SVP are typically negative for mannose macrophage receptor (CD206) expression. At this site, CD206 is found on lymphatic capillaries. In contrast, in the DVP of the skin, a fraction of medium-sized blood vessels are CD206<sup>+</sup> (15).

MVECs in different organs may express a unique profile of sialomucins. Sialomucins are a heterogeneous class of highly O-glycosylated sialic acid-rich glycoproteins that are easily accessible on the cell surface. Depending on the mode of glycosylation, they can either prevent or support adhesion, or even accomplish both functions. During the adhesive steps between inflammatory cells and endothelial surfaces, they largely mediate tethering and rolling. As an example of an antiadhesive sialomucin, skin ECs may express podocalyxin. Proadhesive sialomucins include the L-selectin ligands glycosylation-dependent cell adhesion molecule (GlyCAM)-1, mucosal addressin cell adhesion molecule (MAcCAM)-1, and CD34, as well as endomucin, endoglycan, and other members of the CD34 family of proteins (16,17). Among these L-selectin ligands, skin ECs express CD34, endomucin, and endoglycan, but expression of these proteins is certainly not restricted to the skin (18–20). All sialomucins acquire their adhesive function

**Table 156-1: Phenotype of Postcapillary Venules of the Superficial Vascular Plexus**

Normal Skin	Acute Inflammation	Chronic Inflammation
vWF	E-selectin (CD62E) high	E-selectin (CD62E)
PECAM-1 (CD31)	P-selectin(CD62P)	P-selectin (CD62P)
CD34	VCAM-1 (CD106) low	VCAM-1 (CD106) high
VE-cadherin (CD144)	CXCR4 downregulated	MECA-79-reactive epitopes
PAL-E	CCR10 high	HECA-452-reactive epitopes
CXCR4		
CD32		
CCR10 low		
CD36 negative		

only when decorated with appropriate carbohydrate epitopes. Two main epitopes have been described, namely sialyl Lewis X (sLe<sup>x</sup>) (NeuAc $\alpha$ 2–3Gal $\beta$ 1–4[Fuc $\alpha$ 1–3]GlcNAc $\beta$ 1–) epitopes, and sulfo-sLe<sup>x</sup> epitopes.

sLe<sup>x</sup> epitopes are carbohydrates decorated with sialylated and fucosylated lactosamines, which can be detected by antibody HECA-452. Under normal conditions, skin endothelium shows only minimal reactivity with antibody HECA-452 (21). The sialomucin carrying this epitope in skin ECs is not known. On lymphocytes, the HECA-452-reactive epitope has been described as a sLe<sup>x</sup>-like carbohydrate displayed on P-selectin glycoprotein ligand (PSGL)-1; this epitope is also called *cutaneous leukocyte-associated antigen* (CLA), and is typically expressed on skin-homing T cells.

Sulfo-sLe<sup>x</sup> epitopes are carbohydrates decorated with sialylated, fucosylated, and sulfated lactosamines, which can be detected with the antibody MECA-79. They are collectively called *peripheral node addressins* and function as L-selectin ligands. In the skin, under normal conditions, MECA-79-reactive vessels are found only in proximity to hair follicles. Here, the majority of MECA-79 reactivity is displayed by CD34 molecules (22). Interestingly, a direct association exists between MECA-79 reactivity of skin endothelium and the appearance of naïve T cells within the draining lymphatic vessel, indicating that MECA-79 plays a role in the recirculation of naïve T cells through the skin (23). Whether this indicates that the skin may function as a secondary lymphoid organ remains to be clarified. In situations of skin inflammation, expression of HECA-452 as well as MECA-79 epitopes on ECs can be dramatically induced (21,22,24) (Table 156-1).

MVECs of the skin can express E- and P-selectin. E-selectin is absent in normal skin, but is significantly induced in inflammatory reactions by cytokines like tumor necrosis factor (TNF)- $\alpha$  or interleukin (IL)-1. When expressed, it is typically found on the venule-like portions of the capillaries (13). This is the site where inflammatory cells enter the tissue. On activated

skin endothelium in cell culture, E-selectin expression is more robust and persistent, compared to large-vessel endothelium. This appears to be a general feature of MVECs and not a skin-specific reaction pattern (25). P-selectin also is found on endothelium. In the endothelium of normal skin, analogous to the endothelium of other organs, P-selectin is prestored in Weibel-Palade bodies. In response to mediators such as histamine or thrombin, these storage organelles are degranulated, and P-selectin is released and transported to the cell surface.

In inflammation, ECs show induced expression of intercellular adhesion molecule (ICAM)-1 (CD54) and de novo expression of vascular cell adhesion molecule (VCAM)-1 (CD106). VCAM-1 plays a role in rolling and – more importantly – in tight adhesion of lymphocytes as well as monocytes, eosinophils, and basophils. In contrast to E-selectin, TNF- $\alpha$ -induced VCAM-1 expression on skin endothelium is relatively weak in cell culture as well as in tissue organ culture, compared with large vessel-derived ECs (13). Glomerular ECs behave similarly (26). Robust VCAM-1 induction in skin ECs requires the presence of TNF- $\alpha$  plus interferon (IFN)- $\alpha$  or IFN- $\gamma$  (24). It is not clear whether this is a skin-specific phenomenon. Because the skin is naturally exposed to high amounts of exogenous toxins or antigens, one could speculate that the requirement for IFN plus TNF- $\alpha$  for efficient VCAM-1 expression by skin ECs might be a protective mechanism to raise the threshold for chronic inflammation.

Other endothelial molecules involved in tight adhesion of inflammatory cells are ligands for  $\beta$ 2 integrins. They appear pivotal for lymphocyte homing to the skin. In mice lacking the  $\beta$ 2 integrin subunit, CD18, allergic contact dermatitis and delayed-type hypersensitivity reactions were impaired (27). These experiments did not specify the type of  $\beta$ 2 integrin responsible for impaired skin inflammation. The  $\beta$ 2 integrin family is composed of four members: CD11a/CD18 (lymphocyte function-associated antigen-1 [LFA-1]), CD11b/CD18 (Mac-1), CD11c/CD18 (p150,95), and CD11d/CD18 (28). Ligands for LFA-1 and Mac-1 expressed on ECs include ICAM-1, -2, and -3, and junctional adhesion molecule (JAM)-A and JAM-C. For CD11c/CD18, no direct endothelial ligands are yet described. CD11c/CD18 is a fibrinogen receptor expressed on neutrophils, monocytes, and macrophages, and on subsets of lymphocytes. CD11c indirectly interacts with VE-cadherin expressed on ECs through interposed fibrin fragments (29). Ligands for CD11d/CD18 expressed on ECs include VCAM-1 and ICAM-3.

To visualize chemokine-binding sites on skin endothelium, *in situ* binding assays for the association of radioiodinated chemokines with structures in normal human skin have been performed. These assays demonstrated the presence of specific and saturable binding sites for IL-8 (CXCL8), regulated on activation, normal T-cell expressed and secreted (RANTES; CCL5), monocyte chemoattractant protein (MCP)-1 (CCL2), and MCP-3 (CCL7) on venules and small veins but not on arterioles, arteries, or capillaries (30). Constitutively expressed chemokine receptors on normal skin endothelium include CCR2, -3, -4, and -8, and CXCR1,

-2, -3, and -4 (31,32). Expression of D6, a nonsignaling CC chemokine receptor, was found on afferent lymphatics in skin and not on blood vessels (33).

For transmigration, inflammatory cells must cross the multilayered molecular zipper of interendothelial junctions. In skin microvessels (as with vessels of other organs), molecules configuring this zipper include JAMs, PECAM-1 (CD31), CD99, and VE-cadherin (CD144). Each of these molecules is constitutively expressed and participates in zipper formation by homophilic adhesion with neighboring ECs. PECAM-1 and CD99 contribute to leukocyte transmigration by building homophilic and/or heterophilic adhesion to leukocytes (34,35). VE-cadherin interacts with leukocytes through an interposed fragment of fibrin, which is formed through thrombin-induced fibrinogen activation followed by plasmin or urokinase digestion (29).

Finally, it should be noted that in normal skin *in vivo*, ECs investing blood capillaries can be differentiated from ECs investing lymphatic vessels. The former express markers like N-cadherin or CXCR4; the latter are positive for Prox-1, lymphatic vessel endothelial hyaluronan receptor (LYVE-1), podoplanin, and VEGFR3. However, at least in cell culture, expression of the lymphatic markers podoplanin and Prox-1 is induced by IL-3 even on blood vessel ECs. Conversely, antibodies blocking IL-3 function downregulate podoplanin and Prox-1 on lymphatics, indicating that transdifferentiation between blood and lymphatic endothelium may occur (36).

## SKIN ENDOTHELIUM IN THERMOREGULATION

The regulation of the core temperature is vital to maintain normal physiological body functions and is thus adjusted within a very narrow range. Because the skin forms the strategic boundary between the body and the thermal environment, it plays a key role in thermoregulation and serves as both a source of thermal information and an effector organ for controlling thermal homeostasis. Vasoconstriction of cutaneous vessels allows conservation of body heat, whereas vasodilation and secondary elevation of blood flow to the skin promotes convective heat transfer from the core to the periphery of the body.

In glabrous skin (i.e., the palms, soles, and lips) the dermis contains arteriovenous anastomoses, which are absent in nonglabrous skin. These anastomoses shunt blood from the arterial directly into the venous beds, thereby bypassing capillary loops. This anatomic difference is the basis for the vigorous ability of glabrous skin to autoregulate blood flow, which is not a feature of nonglabrous skin.

Nonglabrous skin is subject to reflex thermoregulation of blood flow. This process is mediated by two branches of the sympathetic nervous system: a noradrenergic vasoconstrictor system and a cholinergic vasodilatory system. The noradrenergic vasoconstrictor system is tonically active, is further induced by cold exposure, and can mediate subtle modulations in vascular tone under normothermic conditions. In response to body heating, an initial vasodilation is achieved by reflex

removal of active vasoconstrictor tone. With further heating, and usually coincident with the onset of sweating, a profound active vasodilatation is mediated through the release of vasodilator transmitters (predominantly acetylcholine) from the parasympathetic cholinergic nerves. It should be noted that additional neuromediators are secreted by autonomic nerve fibers as well as by sensory nerve fibers of the skin, such as substance P, calcitonin gene-related peptide, vasoactive intestinal peptide, and pituitary adenylate cyclase activating polypeptide, which directly or indirectly induce vasodilation (37). In addition to neural control, local factors such as venous congestion, increased transmural pressure, or local alterations in temperature are capable of modulating skin blood flow. The response to thermal stress may be profound. Under thermoneutral conditions, skin blood flow is approximately 250 mL/min. Heat exposure may result in cutaneous blood flows of up to 6 L/min (~60% of the cardiac output) (38). This change requires increased cardiac output and redistribution of blood flow from other areas such as the splanchnic vasculature.

Dysregulation in the skin thermoregulatory system is characteristic of several dermatological conditions. For example, postmenopausal hot flashes appear directly related to changing estrogen levels. In these individuals, estrogen replacement relieves hot flashes and also reduces resting body temperature by 0.5°C (39). The loss of body temperature by estrogen is thought to be based on the active vasodilator function of estrogens (38). Because the precise mechanism underlying postmenopausal hot flashes is not known, it is unclear how estrogen relieves these flashes (38).

Evidence suggests that diabetic patients have an impaired thermoregulatory response of skin vessels, which correlates with an increased risk of heat illness (38).

Two cutaneous microvascular disorders that may be related to pathologic reflex or local thermoregulation are Raynaud phenomenon and erythromelalgia. Neither disorder is well understood with regard to etiology or pathophysiology. Patients with Raynaud disease suffer from an exaggerated vasospastic response to cold or emotion resulting in ischemia of digits. Abnormalities in Raynaud include impaired vascular function, impaired release of vasoconstrictors and dilators, and impaired neuronal function. This has been recently reviewed by Herrick (40). The sympathetic nervous system is a major player in thermoregulation. The  $\alpha_{2c}$ -adrenoreceptor is most important in thermoregulation (41). Indeed, isolated dermal arterioles from patients with Raynaud exhibited abnormal contraction in response to  $\alpha_2$ -adrenergic agonist UK 14,304 at 31°C, compared with arterioles derived from controls (42). Another study attributed this increased  $\alpha_2$ -adrenoreceptor reactivity to the smooth muscle cell component and not to ECs of the dermal arterioles (43). Another dysregulation potentially contributing to the impaired thermoregulatory response in patients with Raynaud has been related to calcitonin gene-related peptide, a very potent vasodilator and the predominant neurotransmitter in capsaicin-sensitive sensory nerves. Reduced numbers of calcitonin gene-related peptide-immunoreactive nerve fibers have

been found in digital skin from patients with Raynaud, and intravenous application of calcitonin gene-related peptide has been reported to improve blood flow in a small number of these patients (44). Finally, elevated circulating levels of asymmetrical dimethylarginine (an endogenous inhibitor of endothelial nitric oxide synthase) and of the vasoconstrictor endothelin-1 have been found in patients with Raynaud phenomenon (45).

Erythromelalgia is a condition of intermittent erythema of peripheral acral skin associated with the sensation of burning pain. The redness and the warmer temperature of the affected limb is accompanied by a massive increase in blood flow. It has been assumed that symptoms are due to a distal small-fiber neuropathy resulting in sudomotor abnormalities (i.e., absent or markedly reduced sweat production) and in reduced vasoconstriction in response to reflex stimulation of the adrenergic vasoconstrictor system (38).

## ANGIOGENESIS IN THE SKIN

Cutaneous angiogenesis occurs in wound healing, inflammation, and tumorigenesis. New vessels form by the sprouting of ECs from pre-existing vascular structures. The term *vasculogenesis* refers to the formation of blood vessels in embryos by the recruitment of endothelial progenitor cells to sites of new vessel formation. Endothelial progenitor cells also exist in the adult and contribute to new vessel formation, a process that has been termed *postnatal vasculogenesis*. These phenomena are not specific to skin, and are thus not discussed in the chapter. The general role of growth factors in orchestrating angiogenesis is discussed in Chapter 157; those of chemokines and their receptors have been reviewed recently (46).

Skin angiogenesis differs in interesting ways from that occurring in other organs. Skin harbors hair follicles, which, in addition to their role in forming hair shafts, appear to play a role in new vessel formation. The follicle contains a distinct population of presumptive follicular stem cells that express nestin, also a marker for neural stem cells. These nestin-expressing follicle cells are located in the follicular bulge region. During the follicular growth cycle, they differentiate into the various cell types of the hair follicle and, in addition, can form a variety of epidermal cells (47). Recently, it has been shown that these nestin-positive cells also can develop into cutaneous blood vessels that originate from hair follicles and form a follicle-linked vascular network (47). The quantitative contribution of "hair follicle-derived" angiogenesis to "conventional" angiogenesis through local sprouting and/or hematogenic seeding of endothelial progenitors is still unknown.

Skin endothelium is also unique by virtue of its close proximity to keratinocytes, which form the epidermal coating. Keratinocytes have been shown to express a wide range of angiogenic factors, including members of the fibroblast or transforming growth factor (TGF) protein family, platelet-derived growth factor, or vascular endothelial growth factor

Figure 156.2. In wild-type (*left image*) or in K14/VEGF-A transgenic mice (*right image*), delayed-type hypersensitivity reactions (DTH) were induced by oxazolone (animals and methods are described by Kunstfeld et al. [85]). Seven days later, ears were subjected to immunofluorescence labeling. DTH reactions were strongly enhanced and prolonged in VEGF-A transgenics. Note the increased numbers of blood vessels and the dilated lymphatics in transgenic animals as compared with controls. All nuclei are labeled using Hoechst stain. (Photos courtesy of M. Detmar, unpublished.) For color reproduction, see Color Plate 156.2.

(VEGF) (48). The pathogenic potential of aberrant growth factor expression by epidermal cells is exemplified in psoriasis. This disease is characterized by a distinct pattern of vascular remodeling. Psoriatic vessels become tortuous and elongated. The well-defined boundary between arteriolar endothelium resting on a homogenous basement membrane and venular endothelium resting on a laminated basement membrane becomes vague. Specifically, the intrapapillary portions of capillaries elongate and acquire a venular phenotype. Light microscopic investigations of eruptive psoriatic lesions reveal that vascular alterations are the first ultrastructurally detectable changes within the dermal compartment. These alterations consist of gap formation within postcapillary venules, EC hypertrophy (they acquire a cuboidal shape similar to that seen in high endothelial venules), and compression of the vascular lumen, all of which precede the invasion of inflammatory cells into the tissue. Gene expression studies have demonstrated that VEGF-A is typically overexpressed in lesional psoriatic keratinocytes (49). This situation can be mimicked in a transgenic animal model, in which VEGF-A is overexpressed within the epidermal compartment. In this model, the dermis shows enhanced vascularity (Figure 156.2; for color reproduction, see Color Plate 156.2). Subsequently, inflammation occurs in a very similar manner to that seen in true psoriasis (50). In humans, a linkage between psoriasis and a single nucleotide polymorphism of VEGF-A has been described (51). Specifically, the G to C polymorphism at position +405, which promotes the translation of large VEGF isoforms, is frequently found in psoriatic patients.

Transgenic mice overexpressing signal transducer and activation of transcription 3 (STAT3) within the epidermis also display a psoriasis-like phenotype, which includes increased numbers of dermal blood vessels (52). Although STAT3 overexpression results in enhanced VEGF-A expression in transgenic keratinocytes, it is not clear whether the proliferation of dermal vessels in these animals is mediated by VEGF or by another angiogenic pathway, for example, induction by fibroblast growth factors (FGFs) or by metalloproteinases.

In addition to proangiogenic factors, keratinocytes have been shown to express inhibitors of angiogenesis, such as thrombospondin (TSP)-1 (53). In a transgenic mouse model, targeted overexpression of TSP-1 within the basal layer of the epidermis, and in the outer root sheath of the hair follicle, resulted in impaired granulation tissue formation and angiogenesis following wounding. In these animals, TSP-1 overexpression inhibited wound angiogenesis even in the presence of high VEGF-A expression *in vivo* and *in vitro* (54). The molecular mechanisms of TSP-1-mediated inhibition of angiogenesis remain to be established.

These examples show that skin angiogenesis is under the control of keratinocyte-derived factors. Thus, skin angiogenesis may be indirectly influenced by environmental factors, such as ultraviolet (UV) irradiation, which leads to pronounced downregulation of TSP-1 and an upregulation of VEGF in keratinocytes. Increased expression of VEGF-A has been shown to increase the cutaneous damage that occurs after UVB exposure, suggesting that the VEGF signaling pathway might serve as a novel target for the prevention of UVB-induced photo-damage (55).

## SKIN ENDOTHELIUM IN DISEASE

The dermatologist classifies skin inflammation by eye and describes inflammatory skin diseases according to body distribution, color, and shape of the lesions. The clinical pattern of the individual lesion is mainly determined by the type of inflammatory cell involved (e.g., neutrophils or lymphocytes) and the layer(s) of skin affected (epidermis, dermis, and/or subcutis). For example, pronounced edema and sparse leukocyte recruitment in the superficial dermis presents as a wheal (e.g., the primary lesion seen in urticaria). By contrast, pronounced lymphocyte accumulation around vessels of the SVP produces a flat, red papule (e.g., the primary lesion seen in eczema or psoriasis). Lymphocyte accumulation in the superficial and deep dermis manifests as a nodule (e.g., the primary lesion seen in lupus erythematosus). These

different clinical patterns of skin lesions correspond to distinct microscopic features seen by light microscopy in biopsy specimens. The dermatopathologist, like the clinician, applies an algorithmic method based on pattern analysis to establish a diagnosis. Pattern analysis involves correlating the type of inflammatory cell and the location of the inflammatory infiltrate within the skin.

**Site and Cell Type-Specific Patterns of Inflammation**

As shown in Table 156-2, many skin diseases are associated with a signature pattern. Such “compartmentalization” of inflammation strongly favors the concept that distinct segments of the skin vascular system respond differently to pathogenic stimuli, thereby providing specific “ZIP codes” for inflammatory cells.

**Eczema and Psoriasis**

In eczema and in psoriasis, inflammatory cells exit postcapillary venules of the superficial vessels and migrate upward into the epidermis, but fundamental differences exist in terms of the anatomic location of inflammatory cells in relation to the vascular system (Figure 156.3; for color reproduction, see Color Plate 156.3). In eczema, postcapillary venules of the SVP exhibit EC hypertrophy, mitosis, and basal lamina alterations. At this site, lymphocytes exit the vascular system and migrate upward into the epidermis without any preference to rete ridges. Vessels within the tips of the papillary dermis typically are not the site of lymphocyte evasion (56). The epidermal involvement appears random. Endothelial adhesion molecule expression (e.g., E-selectin) usually is confined to the SVP and absent from vessels within the tips of the papillae.

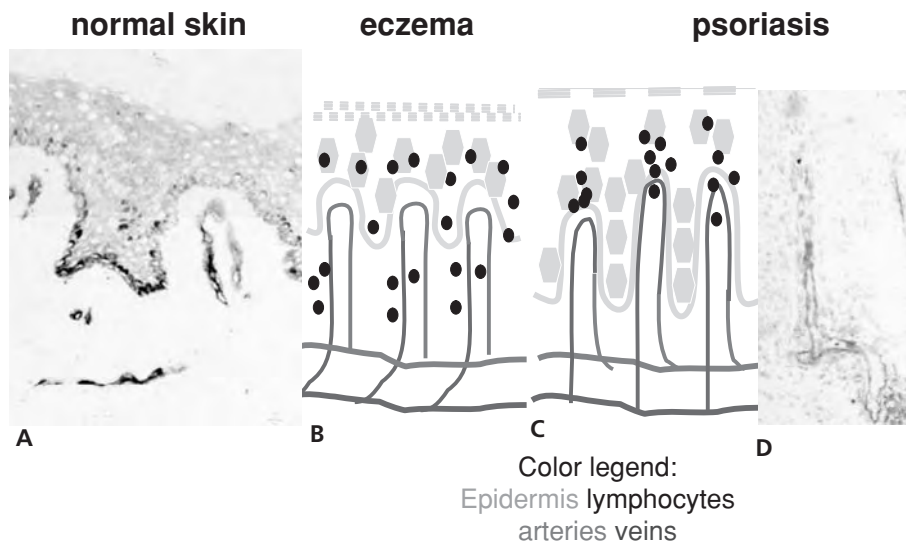

Figure 156.3. (A) A normal skin specimen treated ex vivo with TNF for 4 hours. As a result, postcapillary venules of the superficial vascular plexus express E-selectin. All vessels are labeled using *Ulex europaeus* agglutinin. The capillary loop within the tip of the papillae does not express E-selectin and is arteriolar by morphology. (B) A schematic diagram of the skin in eczema. The morphology of papillary loops is comparable to that of normal skin; lymphocytes escape the postcapillary venules of the superficial vascular plexus and randomly migrate upward into the epidermis. (C) Psoriatic skin. The papillary loops are venular, and express E-selectin and VCAM-1. Lymphocytes and neutrophils evade the capillaries within the tips of the papillae (where the blood vessel “kisses” the epidermis) and produce the phenomenon of “squirting papillae.” (D) An immunohistochemistry of psoriatic skin using an anti-VCAM-1 antibody. The vessel within the papillae shows VCAM-1 reactivity along its entire length. For color reproduction, see Color Plate 156.3.

In psoriasis, the pathology typically is found within the tips of the papillae. ECs of the venular portion of the capillary loop proliferate (57), and the venules become elongated and dilated. At the turnaround point, capillaries touch the epidermal compartment (called the *kissing* phenomenon). At these sites, lymphocytes and neutrophils exit the vessel lumen and migrate up into the epidermis. Dermatopathologists have termed this impressive image “squirting papillae,” which are overlaid by mounds of parakeratosis and permeated by neutrophils at their summits. As the morphologic substrate of this phenomenon, the capillary loops become venular, and express adhesion molecules like E-selectin and VCAM-1 (58). The pathogenic role of the aberrant adhesion molecule expression in vessels within the tips of the papillae is supported by immunohistochemistry studies of lesional skin in cyclosporine-treated psoriatic plaques. In these lesions, the first sign of regression is loss of EC adhesion molecule expression within the tips of the papillae (59).

### Leukocytoclastic Vasculitis

In leukocytoclastic vasculitis, vessel destruction occurs, predominantly involving postcapillary venules of the superficial, but not the DVP. This disease has striking similarities to the Arthus reaction. The Arthus reaction is severely suppressed in *Fcγ receptor*-knockout mice. Based on that analogy, it has been proposed that *Fcγ* receptors play a crucial role in initi-

ating vasculitis. Indeed, skin MVECs express *Fcγ* receptor IIa (CD32), which is largely confined to vessels of the SVP. This is the same site at which vessel destruction occurs in leukocytoclastic vasculitis (14,60).

### Experimental Models for Skin Inflammation

Compartmentalization of inflammatory reactions may be modeled in severe combined immune-deficient (SCID) mice. In one study, these animals were grafted either with superficial or deep portions of human skin, and then injected intravenously with human T cells (61). Although circulating human T cells alloreactive to the human skin migrated equally into both human grafts, they were phenotypically distinct. T cells entering skin grafts containing the epidermis and the SVP were  $CLA^+$  positive, whereas T cells entering skin grafts containing the DVP were  $CLA^-$  negative (61). This indicates that vessels of the SVP have a certain address for  $CLA^+$  cells that is not present in deep vessels.  $CLA$  has been shown to interact with endothelial E-selectin (62), but E-selectin was expressed equally on ECs of grafts containing the superficial as well as the DVP. Thus, additional regulatory pathways for the recruitment of  $CLA^{hi+}$  T cells to the SVP of the skin must exist.

A potential candidate is the chemokine cutaneous T cell-attracting chemokine (TARC or CCL17), which is produced by cutaneous venules, induced in inflamed skin, and absent on

intestinal vessels (63). Its receptor, CCR4, is expressed on the CLA<sup>+</sup> memory T cells. The interaction of TARC and CCR4 triggers E-selectin-mediated adhesion of CLA<sup>+</sup> T cells (63). However, skin infiltration in *CCR4*<sup>-/-</sup> mice is not impaired, indicating that additional regulatory pathways exist (63).

Another candidate for SVP-specific recruitment of CLA<sup>hi</sup> T cells is the chemokine thymus and activation-regulated chemokine (CTACK or CCL27). In immunohistochemical studies, CTACK is constitutively expressed by basal keratinocytes, and is detectable on ECs and fibroblasts of the papillary, but not of the reticular dermis (64). In contrast, cultured dermal MVECs (derived from SVP) and fibroblasts do not express CTACK. One explanation for the discrepancy between the in vivo and in vitro findings is that CTACK is expressed and secreted by keratinocytes in the epidermis, and then captured and presented by dermal cells through glycosaminoglycans or through its receptor, CCR10.

The precise role for CTACK in mediating site-specific homing of lymphocytes is controversial. In an animal model of contact hypersensitivity, skin homing of CD4/CLA/CCR10<sup>+</sup> T cells is blocked by neutralizing anti-CTACK antibodies (64). This experiment points toward CTACK as the major component for conferring skin specificity for CLA<sup>+</sup> cells. However, in another model of contact hypersensitivity, involving adoptive transfer of T lymphocytes, anti-CTACK antibodies impaired skin homing of *CCR4*<sup>-/-</sup> T cells only but had no effect on homing of wild-type cells (63). The situation is further complicated when diverse chemokine receptor expression profiles of T<sub>H1</sub> or T<sub>H2</sub> subsets of T cells are taken into consideration (65).

### Cell Adhesion Molecules in Acute and Chronic Inflammation

EC adhesion molecule expression profiles differ not only among diseases, but they also show a striking diverse pattern in acute compared with chronic disease. In acute dermatitis, ECs express high levels of E-selectin, P-selectin, moderate amounts of VCAM-1, and are largely nonreactive with antibody MECA-79 (i.e., they are negative for sialylated, fucosylated, and sulfated carbohydrate moieties corresponding to peripheral node addressins). The inflammatory infiltrate consists mainly of CD45RO<sup>+</sup> memory T cells with some neutrophils and eosinophils intermingled. In line with this observation are experiments with *L-selectin*<sup>-/-</sup> mice, in which allergen-induced skin inflammation was not impaired during the first 20 hours after challenge (66). This indicates that L-selectin ligands do not play an important role during the early phase of the inflammatory reaction. In more chronic lesions, such as those of psoriasis, ECs express E-selectin and high amounts of VCAM-1 (13). Moderate amounts of ECs react with antibody HECA-452 and MECA-79 (21). In longstanding lesions, such as those in chronic lupus erythematosus or mycosis fungoides (cutaneous T-cell lymphoma), MECA-79 reactivity on ECs plays a dominant role (22,67). The role of L-selectin and its ligands in chronic inflammation is also supported by experiments in *L-selectin*-knockout mice. In a model for chronic

graft rejection, skin inflammation is delayed and attenuated in *L-selectin*<sup>-/-</sup> mice (68).

### Epidermal-Dermal Communication

The role of keratinocytes in eliciting skin inflammation is highlighted by experiments using genetically modified animals. It should be noted that the interpretation of data derived from mouse skin must take into consideration that the mouse dermis is less complex than that of the human. No clear distinction exists between the superficial and DVP, and the capillary loops within the tips of the papillae are absent. Thus, distinct features of certain skin diseases do not exist in mouse skin. Moreover, the composition of inflammatory infiltrates differs. For example, in allergic contact dermatitis in humans, the infiltrate is predominantly composed of lymphocytes, whereas in mice the majority of cells are neutrophils. Within the mouse epidermis even accumulations of neutrophils may occur (spongiotic neutrophilic abscesses).

Results from mouse models shown in Table 156-3 highlight the fact that the epidermal compartment has profound effects on the function of dermal ECs. Overexpression of genes targeted to keratinocytes may result in vessel alterations and spontaneous skin inflammation as shown, for example, in VEGF-A or STAT3 transgenic animals (50,52). On the other hand, deletion of genes within the epidermis also may cause vessel alterations and spontaneous skin inflammation, as seen for example, in mice with inducible epidermal deletion of JunB and its functional companion c-Jun. These animals also suffer from arthritis (69). Other overexpression systems also may show skin disease. Conditional overexpression of Tie2 from its minimal promoter drives expression in ECs, keratinocytes, and epithelial cells of the hair follicle. These mice show spontaneous skin inflammation, which can be "cured" by treating animals with cyclosporine (70). Genes listed in Table 156-3 are more or less functionally unrelated, although endothelial and inflammatory responses show overlapping patterns. This indicates that several different genes, when aberrantly expressed within the epidermis, can be the driving force for dermal skin inflammation. Moreover, these models show that, once inflammation has been established, a gene expression analysis may reveal many up- and downregulated factors and the starting point of the inflammatory reaction may be obscured. Finally, these models indicate that chronic skin inflammation must not necessarily be antigen-driven.

These findings mirror the situation in chronic skin diseases in humans, in which many genes are found activated or inhibited, although the primary cause of the disease remains obscure. In fact, for psoriasis, a scenario could be envisioned in which there is a genetic aberrant expression or function of one or more genes in the epidermal or vascular compartment of the skin, which does not lead to pathology under normal situations. However, cofactors like trauma, toxic irritation, or altered bacterial skin flora may induce persistent activation or insufficient counter-regulation and precipitate disease. Such a possibility is exemplified in the chemokine

receptor D6-knockout mouse (71). D6, a nonsignaling decoy receptor, internalizes and degrades  $\beta$ -chemokines. Expression is restricted to nonhematopoietic cells such as ECs lining lymphatics of skin. The knockout mouse is born and develops normally, but following topical application of phorbol esters, persistent inflammation occurs with similarities to psoriasis. In humans, mutations have been found that, by themselves, do not cause disease, but are pathogenic in the context of cofactors. This has been shown for some point mutations in proteins of the Ras oncogene family, which in context with other hits serve as cofactors in oncogenesis. For psoriasis, TNF or IL-10 promoter polymorphism and VEGF-A point mutations have been found associated with psoriasis (51), and psoriasis susceptibility loci have been identified; it can be expected that the list will extend.

#### KEY POINTS

- The skin vasculature is unique in several aspects. The skin has several functionally distinct vascular units, the loops within the tips of the papillae, the SVP, the DVP, and the subcutaneous plexus. These vascular segments may respond to exogenous or endogenous triggers individually or conjointly, thereby “modeling” clinical skin disease expression.

- Due to the close proximity to the epidermis, keratinocytes can shape the reaction patterns of skin vessels; ECs of the SVP may respond to keratinocyte-derived factors like CTACK or VEGF, resulting in an altered vascular architecture, phenotype, and function.
- Due to their proximity to the epidermis, skin vessels are indirectly exposed to and may react to environmental factors that then may induce and/or maintain EC pathology (e.g., UV irradiation or infection).
- Skin ECs have certain unique features that may account for skin-specific pathologies. Examples are expression of CD32 and peripheral node addressins (recognized by antibody MECA-79), or the presentation of keratinocyte-derived CTACK. These skin-specific features may represent novel targets for the treatment of skin diseases.

#### Future Goals

- To develop therapies that inhibit keratinocyte-derived CTACK or VEGF production, or prevent sialylation or sulfation of endothelial sialomucins in chronic skin diseases such as atopic dermatitis, psoriasis, or cutaneous lupus erythematosus

ACKNOWLEDGMENTS

We are indebted to our teacher Dr. Klaus Wolff, chairman emeritus of the Department of Dermatology / Medical University of Vienna to whom we wish to devote this chapter. This work was -in part- supported by the Austrian science foundation (grant #S94).

# Angiogenesis

---

Helmut G. Augustin

*University of Heidelberg, and the German Cancer Research Center (DKFZ)*

The formation of blood vessels, or vascular morphogenesis, is a fundamental biological process (Figure 157.1). In fact, the cardiovascular system is the first organ that develops in the mammalian embryo. Consequently, genetic manipulation of key regulators of the angiogenic cascade often yields dramatic phenotypes that are not compatible with life and lead to early embryonic lethality. This in turn implies that the process of blood vessel formation is under strong evolutionary pressure, and that every living animal with a closed circulation that has successfully made it through embryonic development is capable of executing the angiogenic program. As such, the formation of blood vessels is a conserved, hierarchically structured process with a high degree of similarity, both molecularly as well as functionally, in such diverse species as zebrafish (1), frog (2), mouse (3,4), and man (3,4). The goals of this chapter are to discuss: (a) the history of vascular morphogenesis research, (b) the basic principles of physiological and pathological growth of blood vessels, (c) concepts of the induction and inhibition of blood vessel growth (angiogenic switch, angiogenic balance), (d) techniques and strategies to quantitatively and qualitatively assess the structural and functional status of neovasculature, and (e) established and emerging avenues for therapeutically interfering with the growth of blood vessels (antiangiogenesis, therapeutic angiogenesis). The topic of lymphangiogenesis is reviewed separately in Chapter 169.

## DEFINITIONS

The term *angiogenesis* is widely used when referring to the process of blood vessel formation (Table 157-1). Yet, more specifically, angiogenesis denotes the formation of new capillaries from pre-existing ones (see Figure 157.1). This occurs primarily through classical sprouting angiogenesis. Alternatively, nonsprouting angiogenesis (also called *intussusception* or *intussusceptive microvascular growth* [IMG]) (5) describes the formation of a vascular network from an endothelial cell

(EC)-lined vessel by focally inserting a tissue pillar or by longitudinal fold-like splitting of a vessel (6,7) (Figure 157.1).

In contrast to the formation of capillary networks via mechanisms of sprouting and nonsprouting angiogenesis, the term *arteriogenesis* describes the mechanisms of adaptive vessel growth whereby larger arteries are formed from a pre-existing network of collateral arterioles in response to changes in blood flow that lead to increased biomechanical forces (shear stress), for example, as a consequence of a local ischemic event (7,8). Arteriogenesis refers primarily to the pathology-associated remodeling of the adult vasculature associated with an intense inflammatory response (9). This type of postnatal adaptive response should be distinguished from developmental arteriogenesis, in which the neovascular capillary network is physiologically remodeled to form large arteries. A combination of genetic determinants (10) and biomechanical forces (11) is believed to be responsible for the physiological program that leads to the formation of larger arteries and veins.

The third basic mechanism of vascular morphogenesis is called *vasculogenesis*. Vasculogenesis describes the primary in situ differentiation of ECs from mesodermal precursor cells (angioblasts) and their subsequent organization into a primary capillary plexus (see Figure 157.1) (12). Angioblasts share a common lineage with hematopoietic cells (hemangioblasts), reflecting the close relationship between resident vessel wall cells and the mobile cells in the circulation (13). Vasculogenesis is primarily a developmental process that precedes and occurs concomitantly with the angiogenic phase of vessel growth. Yet, the identification of endothelial progenitor cells (EPCs) in the adult circulation in 1997 (14) has opened a whole new field of research aimed at exploring the mechanisms and contribution of vascular stem and progenitor cells to vascular morphogenic processes in the adult, as well as their therapeutic potential (15). Although the quantitative contribution of *adult vasculogenesis* to vascular morphogenic processes in the adult is the focus of intense research and the subject of some controversy, it is widely recognized that cells originating in stem cell niches within the bone marrow and

Figure 157.1. Principles of vascular morphogenesis. Vasculogenesis, angiogenesis, and arteriogenesis contribute to the formation of a structured network of blood vessels. Vasculogenesis occurs during development by the coalescence of in situ differentiating angioblastic cells that form the first primitive vascular plexus. Adult vasculogenesis refers to the recruitment of endothelial stem and progenitor cells from the bone marrow and other angioblastic niches. Angiogenesis can occur as classical sprouting angiogenesis or as nonsprouting angiogenesis (intussusception). Arteriogenesis is characterized by adaptive growth of arterioles in response to increased, flow-mediated biomechanical forces.

other parts of the body can, in principle, contribute to the growth of blood vessels in the adult.

### HISTORY OF VASCULAR MORPHOGENESIS RESEARCH

In 1787, the British surgeon John Hunter first used the term *angiogenesis* to describe the growth of blood vessels in the reindeer antler (16). One hundred and fifty years later, Arthur Hertig described the growth of new blood vessels in the placenta of pregnant monkeys (17). Modern angiogenesis research dates back to 1971, when Judah Folkman of Harvard Medical School introduced the hypothesis that the growth of tumors is angiogenesis-dependent (18). In fact, a PubMed search employing the key term *angiogenesis* yields less than 10 published papers prior to Dr. Folkman’s seminal article in the *New England Journal of Medicine*, in contrast to the almost 30,000 angiogenesis-related publications that have been published in the 35 years since. Of these, 18 original publications have so far been cited more than 1,000 times, qualifying them as angiogenesis citation classics (Table 157-2).

Dr. Folkman’s original hypothesis was slow to gain acceptance. Except for cartilage and cornea, blood vessels are found in all tissues of the body and almost any cell of the body is within 100 to 150  $\mu\text{m}$  of the next capillary (maximal effec-

tive diffusion distance for oxygen). It was therefore widely believed that tumors grow along pre-existing blood vessels, a concept that has recently been revived and named *vessel cooption*<sup>1</sup> (20). Although the angiogenesis dependency of tumor growth is solidly established, the relative contribution of vessel cooption to tumor vascularization remains to be determined.

A major research goal during the 1980s was to identify and therapeutically block a putative tumor angiogenesis factor (TAF) (18). We now know that TAF is not a single factor. Indeed, a long list of angio-stimulatory and angio-inhibitory molecules has been identified (Table 157-3). The nature of the “angiogenic cocktail” that drives the angiogenic cascade during the physiological and pathological growth of blood vessels is far from being understood.

Several angiogenesis factors were identified during the 1980s. These include the fibroblast growth factors (FGFs), the transforming growth factors (TGFs), platelet-derived EC growth factor (PD-ECGF, thymidine phosphorylase), and tumor necrosis factor (TNF)- $\alpha$  (21). The search for angiogenesis-inducing growth factors during these years was strongly stimulated by the discovery that many growth factors bind heparin, a property that facilitated their purification (22). All the angiogenic growth factors identified during these years are capable of inducing angiogenesis in specific in vitro and in vivo assays. Yet, they are not vascular-specific in their activity. Instead, they act pleiotropically to regulate the function of many cell types. This lack of specificity limited their potential as therapeutic targets.

The identification of the first specific vascular growth factor, vascular endothelial growth factor (VEGF) in 1989 (23–25) revolutionized the field of angiogenesis research. Whereas a total of <1,000 angiogenesis-related articles were published prior to 1990, over 3,500 papers are now published every year. Indeed, angiogenesis research has been (and continues to be) one of the fastest growing fields in all of biomedicine (Figure 157.2).

The EC mitogen VEGF (26) had been identified 6 years earlier as vascular permeability factor (VPF) (27). Yet, its association with the angiogenic process was not noted at the time. The molecular mechanisms underlying VEGF/VPF-mediated permeability and mitogenicity remain poorly understood to this day.

VEGF exerts its vascular-specific functions through the almost EC-specific expression of its receptors, VEGFR1 (28) and VEGFR2 (29). The importance of the ligand and receptors was established during the mid-1990s through genetic inactivation experiments that identified VEGF and its receptors as strictly rate-limiting for the developmental vascular

1 Vessel cooption describes the process whereby growing tumors prey on the pre-existing vasculature to grow along these vessels and to remodel pre-existing vessels for their vascularization purposes. Although it is generally accepted that angiogenesis is the primary mode of tumor vascularization, vessel cooption has been described to occur in at least 20% of lung tumors (19). Likewise, vessel cooption may be one of the reasons for limited efficacy of antiangiogenic therapies.

**Table 157-1: Vascular Morphogenesis**

<i>Biological Process</i>	<i>Definition</i>	<i>Embryonic</i>	<i>Adult – Physiology</i>	<i>Adult – Pathology</i>
Vasculogenesis	In situ differentiation of ECs from mesodermal precursor cells	Generation of primary capillary plexus	Bone marrow–derived EPCs may contribute to physiological vascular morphogenesis	Bone marrow–derived EPCs may contribute to the formation of new vessels during pathology (tumors, ischemic events)
Angiogenesis	Formation of new capillaries from pre-existing capillaries	Expansion of vasculogenesis-derived vascular plexus	Female reproductive system	Tumors, wound healing, inflammation
Arteriogenesis	Formation of larger arteries from a pre-existing network of collateral arterioles	Remodeling of neovascular capillary network	Not described	Adaptive remodeling of adult vasculature following local ischemia (e.g., heart)
Vessel wall assembly	3D assembly of growing vasculature	Formation of anastomosing vascular network; recruitment of mural cells	n.s.	n.s.
Acquisition of vessel identity	Formation of different types of vessel structures	Formation of different caliber blood vessels and development of arteriovenous asymmetry	n.s.	n.s.
Organotypic differentiation	Molecular and anatomical differentiation of assembled vasculature	Formation of continuous and discontinuous endothelia; expression of organotypic molecular phenotype	n.s.	n.s.

n.s., not studied in much molecular and mechanistic detail. Yet, it can be implied that the later steps of the angiogenic cascade are similarly regulated as during developmental vascular morphogenic processes. However, the differences between the formation of a regular and fully differentiated vascular network in normal organs and the chaotic vascular network associated with pathological neovascularization are mechanistically poorly understood.

morphogenesis (28–31). Their genetic inactivation consequently leads to early embryonic lethality. In fact, the heterozygous early embryonic lethal phenotype of VEGF-deficient mice is to this day the most dramatic phenotype of the many thousands of knockout mice that have been generated during the last 15 years (30,31).

VEGF may be viewed as a hierarchically high master switch of the angiogenic cascade. Indeed, 11 of the 18 all-time angiogenesis citation classics focus on VEGF (23,24,27–34) or its regulation (35) (see Figure 157.1). The finding that VEGF expression is induced by hypoxia (35) may be conceptually among the most important angiogenesis-related discoveries, because it linked a pleiotropic milieu factor (hypoxia) to the expression of a specific angiogenesis growth factor (i.e., VEGF). Moreover, the discovery paved the way for significant advances in hypoxia research, culminating in the identification of prolyl hydroxylases as a molecular candidate for the long-sought-after oxygen sensor (36).

Despite its requisite role in angiogenesis, VEGF acts in concert with other growth factors. The angiopoietins (Ang1 and Ang2) were discovered as ligands of the EC receptor tyro-

sine kinase Tie2 less than 10 years ago (37). Gene ablation experiments in mice suggested a role for Ang1/Tie2 signaling in remodeling and stabilization of the growing neovasculature (38). Ang1 acts as an agonistic Tie2 ligand and is involved in regulating vessel maturation and remodeling by acting as a survival factor for ECs and controlling the association of ECs with mural cells (pericytes and smooth muscle cells) (37). Low-level Ang1-dependent constitutive Tie2 phosphorylation appears to be involved in maintaining the quiescent phenotype of the resting vasculature (39). Ang2 functions are more complex. Ang2 acts as a functional antagonist of Ang1 by binding to Tie2 without exerting signal transducing functions (40). Intriguingly, Ang2 is produced almost exclusively by ECs and acts as an autocrine regulator of vessel stabilization and destabilization (41,42). As such, Ang2 may facilitate angiogenesis in the presence of angiogenic activity (e.g., VEGF stimulation) or induce vessel regression in the absence of angiogenic activity (e.g., during regression of the cyclic ovarian corpus luteum) (43).

The Eph receptor tyrosine kinases comprise the largest known family of tyrosine kinase receptors and interact in a

\*This list includes all angiogenesis-related original publications that have been cited more than 1,000 times (out of approximately 30,000 original publications [based on Science Citation Index – ISI Web of Science as of February 2007]).

specific, yet somewhat promiscuous manner with their corresponding ephrin ligands (44). Although initially characterized as regulators of axonal outgrowth in the nervous system, gene inactivation experiments in mice have revealed key roles for ephrinB2 and its EphB2, EphB3, and EphB4 receptors during vascular development (44). Mouse embryos lacking ephrinB2 or EphB4 (or the combination of EphB2 and EphB3) suffer dramatic defects in early angiogenic remodeling that are similar to those seen in mice lacking Ang1 or Tie2 (45). Moreover, ephrinB2 and EphB4 display remarkable asymmetric arteriovenous expression patterns, with ephrinB2 selectively marking arterial vessels and EphB4 preferentially being expressed by

venous ECs (45). This asymmetric expression pattern suggests a critical role of ephrinB2 and EphB4 in establishing arterial versus venous identity of the growing vasculature. The identification of vascular morphogenic functions of ephrinB2 and EphB4 has led to the development of two rapidly growing novel fields of vascular biology research, namely the molecular analysis of the structural and functional mechanisms of arteriovenous differentiation (46), and the molecular study of the commonalities between vascular and neuronal guidance and patterning mechanisms (47).

Angiogenic activation induces a complex gene expression program in ECs, enabling the cells to execute the molecular

VEGF, vascular endothelial growth factor; HB-EGF, heparin-binding epidermal growth factor-like growth factor; PD-ECGF, platelet-derived EC growth factor; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte macrophage colony stimulating factor; TIMP, tissue metalloproteinase inhibitor; IP-10, interferon- $\gamma$ -inducible protein-10.

tasks required for new blood vessel formation (48). The invasive ingrowth of angiogenic ECs involves the upregulation of a distinct set of adhesion molecules including the integrin heterodimers  $\alpha v \beta 3$  and  $\alpha v \beta 5$  (49,50) as well as homotypic interactions involving vascular endothelial (VE)-cadherin and other junctional molecules (51). Likewise, invading ECs (also

called *tip cells*, in contrast to following cells, which are called *stalk cells*) (52) display a shift of their proteolytic balance toward a proinvasive phenotype with upregulated expression of plasminogen activators (tissue-type plasminogen activator [t-PA] and urokinase-type plasminogen activator [u-PA]) and downregulation of plasminogen activator inhibitor (PAI)-1

Figure 157.2. Number of angiogenesis-related articles published in *Medline*. The annual number of angiogenesis-related publications has increased by more than a factor of 10 in the last 10 years.

(53). Angiogenic ECs deposit their own extracellular matrix, rearrange their cytoskeleton, and activate their proliferative machinery. Importantly, each of these steps represents a potential molecular target for antiangiogenesis therapy (54).

Although much remains to be learned about the angiogenic process, it is reasonable to conclude that the primary molecular building blocks for angiogenesis have been identified. In contrast, the mechanisms underlying physiological angiogenesis and angioregression are less well understood. The first endogenous antiangiogenic activity from cartilage was isolated in 1975 (55). Thrombospondin (TSP)-1 was identified in 1978 (56), but its antiangiogenic activity was not recognized until 1990 (57). In the mid-1990s, the discovery of the polypeptides angiostatin (58) and endostatin (59) provided new insights into the endogenous balance of angiogenic factors (see Table 157-2). Angiostatin and endostatin are cryptic fragments of plasminogen and type XVIII collagen, respectively, that are liberated through the activities of cleaving proteases. These prototypic endogenous inhibitors of angiogenesis have stimulated the systematic search for other endogenous inhibitors of angiogenesis, many of which are cryptic fragments of larger molecules with different functions (mostly molecules of the extracellular matrix and coagulation system) (60). Although the molecular mode of action of most of these molecules remains to be elucidated, endogenous angiogenesis inhibitors are being increasingly validated in complex *in vivo* model systems, as has been demonstrated for TSP-1, endostatin, and tumstatin in gene ablation experiments (61,62).

Today, the field of vascular morphogenesis with its three primary avenues of investigation – vasculogenesis, angiogenesis, and arteriogenesis – is solidly established and still growing (see Figure 157.2). Future studies will likely lead to the identification of additional specific regulators of the angiogenic cascade. For example, the cytokine endocrine gland-derived (EG)-VEGF and the chemokine stromal cell-derived factor (SDF)-1 control vascular morphogenesis in only selected vas-

cular beds (63,64). Additional organ- and caliber-specific vascular growth factors are likely to be discovered. Likewise, the study of the molecular basis of vascular assembly, network formation, organotypic differentiation, control of directional flow, and vascular maturation is in its nascence.

## PHYSIOLOGICAL AND PATHOLOGICAL GROWTH OF BLOOD VESSELS

The growth of blood vessels is primarily a physiological developmental process. As such, the first primitive vasculogenesis-derived capillary plexus expands by angiogenesis and intussusceptive microvascular growth (65). Sprouting and nonsprouting angiogenesis contribute to an increasing complexity of the growing vascular network. The network assembles and matures by the recruitment of smooth muscle cells and pericytes, eventually allowing directional flow of blood. The morphogenic events leading to a mature vascular network involve several additional steps, including vessel wall assembly, maturation, acquisition of vessel identity and organotypic differentiation. Vascular remodeling is a distinct process that describes the adaptive reorganization of an existing, mature vasculature in a physiologically or pathologically challenged microvascular bed.

Angiogenesis in the adult is normally downregulated (an exception is the female reproductive system). ECs cells in quiescent<sup>2</sup> blood vessels have very low turnover rates and divide only once every few months or years. Yet, they are not postmitotic cells; they may be rapidly recruited into the cell cycle in response to angiogenic stimuli (66). In fact, there may be few cell types in the human body with such a pronounced capacity to switch reversibly between resting and proliferating states. For example, many cell populations such as intestinal epithelial cells or keratinocytes are programmed for continuous turnover. In contrast, postmitotic cells such as neurons and cardiomyocytes have a very limited regenerative capacity. The fact that most adult ECs are quiescent, yet have the potential to rapidly proliferate, points to the existence of tonically active, although reversible antiangiogenic mechanisms. Although these mechanisms remain poorly understood, evidence suggests an autocrine role of the endothelium in this process. For example, the activin/follistatin system has been shown to control EC activity in an autocrine manner (67). Similarly, the inhibitor of the vascular maintenance and quiescence regulating Ang1/Tie2 system, Ang2, is almost exclusively expressed by ECs, suggesting a primarily autocrine mode of action (41).

Unlike other organs in the healthy adult, the female reproductive system displays angiogenic activity. The ovary and uterus undergo distinct endocrine-mediated morphological changes during the reproductive cycle; these are associated with discrete phases of tissue growth, maturation, and

2 Here we use the term *quiescent* narrowly to describe nonproliferating ECs.

regression. Concomitantly, blood vessel growth, maturation, and regression accompany and to some extent even precede the reproductive cycle, making angiogenesis a critical and rate-limiting prerequisite for normal reproductive function (68). Indeed, inhibition of key regulators of the angiogenic cascade leads to disruption of the reproductive cycle and female infertility (69).

The female reproductive system notwithstanding, angiogenesis in the adult is almost always associated with pathological processes. According to PubMed, approximately 90% of research papers related to pathological angiogenesis focus on tumor angiogenesis. However, a growing appreciation exists for the role of angiogenesis in other pathological processes, including disorders of the eye (e.g., diabetic retinopathy, retinopathy of prematurity [ROP], age-dependent macular degeneration [AMD]), acute and chronic inflammatory reactions (e.g., osteoarthritis, atherosclerosis, hypertensive vascular remodeling), and wound healing. Adaptation to changes in oxygen tension may be a primary molecular determinant underlying each of these processes (70).

Pathological angiogenesis is widely considered to result from the activation of the same molecular program that governs physiological angiogenesis during embryonic development. As such, tumor angiogenesis is considered to be an *oncofetal mechanism*, in which a normal developmental process is reactivated in the course of adult disease. Oncofetal mechanisms are attractive therapeutic targets because their inhibition – at least in nonpregnant patients – should be associated with tumor-specific effects. Indeed, extensive experience in clinical trials indicates that antiangiogenic therapies are well tolerated and do not appear to cause major unwanted side effects. For example, although prolonged anti-VEGF treatment may be associated with an increase in blood pressure, other side effects are rare (71).

The concept of an oncofetal mechanism, although conceptually helpful, belies important differences between mechanisms of developmental and tumor angiogenesis. Unlike physiological angiogenesis, pathological angiogenesis often is associated with an inflammatory response, and cells recruited during inflammatory reactions are well known to exert angiogenesis-modulating activities (72). Likewise, tumor growth involves numerous interactions with the body's immune system that may similarly modulate the angiogenic program. Physiological angiogenesis follows a well-coordinated, hierarchically structured program that leads to the formation of a stable, anatomically structured vascular network whose pattern is optimized in an organ-specific manner to meet the demands of the underlying tissue. In contrast, tumor angiogenesis is an uncontrolled and unidirectional process (i.e., the tumor has no built-in program for vascular stabilization or vascular regression), and leads to a highly dense, chaotic, and poorly organized vasculature. These considerations have led to the notion that a pruned, *normalized* vasculature with fewer blood vessels (e.g., resulting from an antiangiogenic therapy) may in fact be functionally more effective (73).

Genetic studies have provided further evidence for differences in regulatory mechanisms underlying developmental and tumor angiogenesis. Genetic inactivation of many angiogenic growth factors and their corresponding receptors (e.g., VEGF, VEGFR1, VEGFR2, Ang1, Tie1, Tie2, ephrinB2, EphB4) leads to embryonic lethality, pointing to the rate-limiting importance of these molecules for developmental angiogenesis. Knockouts of other candidate angiogenic molecules have failed to demonstrate embryonic lethality and were thus widely ignored as angiogenesis factors throughout much of the 1990s. However, it is now clear that many such factors may play a selective role in pathological angiogenesis in the adult. For example, although placenta growth factor (PlGF)-deficient mice develop normally and are viable and fertile, adult *PlGF*<sup>-/-</sup> mice have impaired angiogenesis, plasma extravasation, and collateral growth during ischemia, inflammation, wound healing, and cancer (74). Similar discrepancies between developmental and adult angiogenesis have been established for regulatory molecules of the proteolytic balance during angiogenesis, for example, plasminogen activators (t-PA and u-PA) and PAI-I (53). It is widely recognized that specific (e.g., PlGF) and pleiotropic (e.g., fibrinolytic mediators, FGF) angiogenic growth factors that are not rate-limiting for developmental angiogenesis may nevertheless be important and even rate-limiting regulators of adult pathological angiogenesis.

## INDUCTION AND INHIBITION OF BLOOD VESSEL GROWTH

The identification of molecules with angio-stimulatory and angio-inhibitory activity (see Table 157-3) has supported the concept that angiogenesis – like most biological processes – is controlled by a balance of positive and negative regulatory factors. The angiogenic balance dictates the net angiogenic phenotype, namely induction of angiogenesis or vessel regression (75). Most angiogenesis stimulators have a short half-life and act locally. In contrast, many angiogenesis inhibitors are long-lived and appear to act systemically. The concept of an angiogenic balance is attractive and plausible. Yet, few experiments to systematically manipulate this balance locally or systemically have been performed. Moreover, the molecular mechanisms of most angio-inhibitory molecules are still poorly understood.

Inhibitors of angiogenesis fall under two classes. The first includes a small number of molecules that act by inhibiting proangiogenic factors. For example, transmembrane EC surface receptors of angiogenic cytokines (e.g., VEGFRs and Tie2) transduce signals that allow angiogenically activated ECs to execute the angiogenic program. In contrast, soluble receptor derivatives (sVEGFR1 [sFLT-1] and sTie2) act as ligand traps that bind the corresponding growth factor and thereby inhibit angiogenesis (76). Similarly, Ang1 acts as a stimulating ligand of Tie2, whereas Ang2 acts as an

inhibitor of Ang1/Tie2 signaling (37). The second, larger group of molecules comprises those endogenous angiogenesis inhibitors (see Table 157-3) that act independently of the angiogenesis-inducing molecules through poorly defined mechanisms. Examples of the latter include the collagen XVIII and plasminogen fragments endostatin and angiostatin, respectively (59,77).

The best example of a dynamically regulated angiogenic balance in physiology is found in the female reproductive system. Angiogenesis in the cyclic corpus luteum is initiated following ovulation by massive induction of VEGF, which shifts the balance in favor of proangiogenic activity (68). Conversely, angioregression during luteolysis is initiated by a combination of VEGF downregulation and induction of Ang2 expression (78). Thus, physiological vessel regression in the corpus luteum is initiated by concomitant downregulation of the stimulator (VEGF) and an upregulation of the inhibitor (Ang2). The role of other endogenous angiogenesis inhibitors during reproductive angiogenesis has yet to be studied.

A shift of the angiogenic balance toward the induction of angiogenesis also occurs during tumor growth and progression. This *angiogenic switch* occurs during the transition from an avascular tumor toward an angiogenic tumor (79). The induction of angiogenesis becomes a prerequisite for the growth of the tumor if its size exceeds a diameter that allows nourishment of the tumor by diffusion. A malignant primary tumor or a small micrometastasis can persist for months or even years as dormant tumor as long as the tumor has not activated the angiogenic switch (80). The switch can result as a consequence of the increasing hypoxia within the growing avascular tumor or as a consequence of a specific angiogenic gene program activated by the tumor cells during tumor progression; for example, by specific mutations that affect angiogenesis-regulating oncogenes or tumor suppressor genes. The molecular mechanisms of the angiogenic switch during tumor progression are still poorly understood (75,79). This is largely due to the limited availability of suitable experimental models to study the angiogenic switch. The angiogenic switch does occur in *natural* tumor models (i.e., spontaneous carcinogenesis animal models, chemical carcinogenesis or genetic carcinogenesis models [e.g., RipTag]). Transplantation models with injected tumor cells are poorly suited for studying the angiogenic switch, because most established tumor cell lines are angiogenic and therefore have a committed angiogenesis phenotype.

#### QUANTITATIVE AND QUALITATIVE ASSESSMENT OF A NEOVASCULATURE

The demonstration of a correlation between an increase in microvessel density (MVD) and tumor progression by Weidner and colleagues in 1991 is the most frequently cited publication in the field of angiogenesis research (see Table 157-2) (81). This publication has inspired much research, and

MVD counting studies have been performed for many different types of malignant and benign tumors (82). To date, more than 1,500 MVD studies have been published. Collectively, these studies have firmly established the relationship between angiogenesis and tumor progression. Yet, they also have led to the widely held misconception that MVD counts are equated with angiogenesis. MVD counts, which are typically based on immunohistochemical analyses of pan-endothelial markers (CD31, CD34, von Willebrand factor [vWF]), describe the average intercapillary distance in tumors, and are thus reflective of the angio-architectural properties of the tumor vasculature. This is an important parameter, because it is the goal of an antiangiogenic tumor therapy to reduce the intercapillary distance such that it becomes rate-limiting for the growth of the tumor.

In 1972, Brem and colleagues proposed a microscopic angiogenesis grading system (MAGS) to quantify the angiogenic status of tumors (83). The score, which incorporates measures of vascular density, number of EC nuclei, and cytological properties of tumor-associated ECs, was used to establish an angiogenic rank order in different human brain tumors (83). As an alternative approach, MVD counting of marker molecules that are specific to proliferative ECs (e.g., CD105 or VEGFR2) has been used to assess the angiogenic status of tumors. However, it is not clear whether the latter approach is an improvement over MVD counting based on pan-endothelial marker molecules. A number of investigators have measured EC proliferation by double-labeling immunohistochemical techniques as a kinetic parameter of the tumor neovasculature. In fact, given the extremely low turnover of quiescent ECs in normal tissues (months to years), EC proliferation may be the most reliable marker of active angiogenesis in a tumor (66). Other advanced microscopic techniques to study angiogenic blood vessels (e.g., fluorescence, confocal, multiphoton and electron microscopy, and casting techniques) have been extensively studied in experimental models for high resolution two-dimensional and three-dimensional assessment of angiogenic vascular networks, but have been used only sparingly in the analysis of human tumor neovasculature (84).

An alternative to pathology-based, invasive examination of the tumor vasculature is the measurement of circulating soluble or cellular biomarkers (*surrogate markers*) of angiogenesis (85). A number of activation-associated endothelial-derived molecules can be detected in the circulation either as specific soluble splice forms of corresponding EC surface receptors and adhesion molecules or as a consequence of proteolytic shedding of EC surface molecules (86). These include the soluble forms of the angiogenic EC surface receptors VEGFR1 (sFLT-1), VEGFR2 (sKDR) and Tie2 (sTie2); and soluble forms of inflammatory markers, such as sE-selectin, soluble intercellular adhesion molecule (ICAM)-1, and soluble vascular adhesion molecule (VCAM)-1 (87). Similarly, circulating concentrations of the angiogenic factors VEGF and FGF2 are upregulated in many cancer patients (88).

An emerging novel biomarker of angiogenesis is the circulating EPC. Quantitative analysis of circulating EPCs may prove to be a useful readout for the intensity of local angiogenesis (89). Similarly, the transcriptome of peripheral blood cells – assayed by DNA microarrays – has been proposed as a surrogate biomarker for cancer, and may be useful for following the response to antiangiogenic therapies (90).

The widespread use of pathological specimens and the emerging use of surrogate marker assays to assess tumor angiogenesis are complemented by rapid developments in the field of noninvasive imaging (84). Positron emission tomography, x-ray computed tomography, magnetic resonance imaging, ultrasound, and optical imaging all are being extensively explored as imaging modalities in tumor angiogenesis. These techniques are capable not only of imaging the neovasculature, but also of functionally assessing the neovasculature (e.g., determination of blood flow, blood volume, empirical semiquantitative hemodynamic parameters, and quantitative hemodynamic parameters from pharmacokinetic modeling) (91).

#### THERAPEUTIC STRATEGIES TO INTERFERE WITH THE GROWTH OF BLOOD VESSELS

Translational prospects in the field of angiogenesis revolve around the therapeutic inhibition of abnormal vessel growth in several disease states, most notably cancer. The clinical approval of the anti-VEGF antibody Avastin (bevacizumab) for use in combination with chemotherapy for the first-line treatment of colorectal cancers in 2004 has established antiangiogenesis as the first therapy directed against the tumor stroma that complements established surgical, chemotherapeutic, and radiotherapeutic tumor approaches (92).

Tumor angiogenesis is a particularly attractive therapeutic target for a number of reasons: (a) angiogenesis is downregulated in normal healthy tissues, thus therapy is associated with minimal side effects even after prolonged treatment; (b) the tumor vasculature is not clonogenic, but rather is derived from normal blood vessels, and thus its pharmacological inhibition should not lead to the development of resistance; (c) each tumor capillary may supply hundreds of tumor cells, a ratio that provides for amplification of drug effect; and (d) in contrast to the interstitial location of tumor cells, direct contact of the vasculature to the circulation allows efficient access of therapeutic agents.

A number of approaches have been employed to inhibit pathological angiogenesis (93). Pharmacological inhibition of angiogenesis is aimed at interfering with the angiogenic cascade or the immature neovasculature. Pharmacological agents may be synthetic or semisynthetic substances, endogenous inhibitors of angiogenesis, or biological antagonists of the angiogenic cascade. In contrast to the direct inhibition of angiogenesis, vascular targeting is aimed at utilizing specific molecular determinants of the neovasculature for the delivery of a biological, chemical, or physical activity that will then

locally act angiocidal or tumoricidal (94). A comprehensive website summarizing the status of tumor antiangiogenic compounds in various stages of clinical trials is maintained by the National Cancer Institute at: [www.cancer.gov/clinicaltrials/developments/antiangio-table](http://www.cancer.gov/clinicaltrials/developments/antiangio-table).

Clinical experience has established that antiangiogenic tumor therapies work most effectively in combination with chemotherapy or radiotherapy. Conceptually, this is somewhat surprising. An antiangiogenic therapy is, in principle, aimed at starving the tumor, which should lead to less effective delivery of a concomitantly given chemotherapeutic drug. The mechanisms for the synergy between antiangiogenesis and chemotherapy are not well understood. Yet, increasing evidence suggests that antiangiogenic tumor therapy *prunes* the immature and chaotic tumor vasculature to lead to less, but more normal appearing and functioning tumor blood vessels. This *normalization* effect is believed to allow more effective access of chemotherapeutic drugs to their respective therapeutic target (73). As surprising as the synergy between antiangiogenesis and chemotherapy is the observed synergy between antiangiogenesis and radiotherapy (95,96). Antiangiogenesis should, in principle, be a prohypoxic therapy. Yet, hypoxia is the primary cause for radioresistance of tumors. Thus, a tumor vessel *normalization* effect must similarly be responsible for the synergy between antiangiogenesis and radiotherapy.

Antiangiogenesis research has driven the field. Yet, a number of indications may benefit from an *induction* of angiogenesis, including wound healing, cardiac ischemia, and peripheral limb ischemia (97). Various approaches have been taken to therapeutically deliver angiogenic cytokines such as VEGF and FGF2. These include the local administration of recombinant proteins and gene therapeutic delivery of angiogenic cytokines. Individual cytokine therapy may have limitations, because it may be capable of inducing a neovascular response, but it may not induce the growth of a patent neovascular network that is stable for prolonged periods of time. This notion has led to alternative strategies aimed at inducing the complex endogenous angiogenic program and not just a single cytokine. For example, experiments are under way to locally induce hypoxia-inducible factor (HIF)-1, a key regulator of the hypoxia response program, which is able to control the complex endogenous program of angiogenesis induction (98).

#### KEY POINTS

- Angiogenesis is a fundamental developmental biological process that is critically associated with the growth of tumors and other important human diseases. Manipulation of angiogenesis (antiangiogenesis, therapeutic angiogenesis) holds the promise of novel therapeutic avenues for some of the most devastating human diseases.

- Angiogenesis is a physiological process of embryonic and postnatal development largely downregulated in the adult. As an oncofetal mechanism, it is associated with the growth of tumors, and can be considered one of the most important tumor progression and metastasis-enabling mechanism.
- The VEGF/VEGFR system acts as a hierarchically high master switch of the angiogenic cascade.
- As an intricately regulated process, angiogenesis is controlled by a balance of angio-stimulatory and angio-inhibitory molecules.
- Clinical translation of angiogenesis research is limited by the lack of appropriate angio-diagnostic tools and procedures and the limited availability of reliable biomarkers.
- The first antiangiogenic tumor therapy has received clinical approval. Others are to follow. Non-neoplastic indications of antiangiogenic and proangiogenic therapies are intensely explored in as diverse disciplines such as ophthalmology, dermatology, gynecology, and cardiology.

## Tumor Blood Vessels

Harold F. Dvorak

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

It has been known for more than a century that tumors have their own blood supply and, for the better part of that time, that the tumor vasculature is highly abnormal, differing from that of normal tissues with respect to organization, structure, and function (1). At one time it was thought that tumors had a vasculature that was superior to that of normal tissues; this misconception arose because tumor vessels are often of large size and were therefore more readily visualized by angiography and macroscopy than the smaller but more numerous and functionally superior capillaries of normal tissues. By the late 1970s, it also was clear that tumor vessels were heterogeneous, hyperpermeable to plasma and plasma proteins, and that tumor blood flow was unevenly distributed and, overall, significantly lower than that in normal tissues. Further, it was known that tumor vessels were induced by tumor-secreted products, although the tumor angiogenic factor(s) responsible were just beginning to be investigated. In the years that followed, much has been learned about the molecules responsible for angiogenesis, particularly vascular endothelial growth factor (VEGF)-A, and about the steps and mechanisms by which tumors induce the new vascular supply that they require to grow beyond minimal size. Recent successes with blocking agents against VEGF-A suggest that antiangiogenesis may provide a valuable new approach to tumor therapy (2). This chapter reviews the properties of tumor blood vessels, their differences from normal vessels, and the steps and mechanisms by which they form.

### THE NORMAL MICROVASCULATURE AND STROMA

Before discussing tumors, it is important to review the structure of normal tissues to provide a standard of comparison. In general, normal tissues are comprised of two discrete but interdependent compartments, the parenchyma (generally epithelium) and stroma (vascular connective tissue). Stroma includes the microvasculature but is also comprised of extra-

cellular fluid, fibroblasts, and fibroblast products that include interstitial collagens, proteoglycans, hyaluronan, and other compounds. Stroma is required to maintain tissue structure and the microvascular component to provide gas exchange, nutrition, waste disposal, and other functions.

In most normal tissues, the microvasculature consists of three types of blood vessel: arterioles, capillaries, and venules, all linked in series (3). Arterial blood enters arterioles, then capillaries, which flow into postcapillary venules and, subsequently, into veins. In some tissues (e.g., skin), blood can bypass capillaries by way of arteriovenous shunts. Although part of a continuum with some degree of overlap, each of the three major types of normal microvessel has a characteristic structure and function. Arterioles are 10- to 20- $\mu\text{m}$  diameter vessels whose lining endothelium is covered with one or more layers of smooth muscle cells. Arteriolar tone is regulated by autonomic, generally sympathetic, nerves that modulate vascular smooth muscle cell contraction and, in this way, regulate blood pressure and flow. Smooth muscle relaxation is regulated in part by nitrogen oxide secreted by endothelium.

Capillaries are smaller vessels, 4 to 9  $\mu\text{m}$  in diameter, which are lined by a thin, flattened but continuous layer of endothelium and are enveloped by basement membrane and a variable coating of pericytes. In some tissues (e.g., kidneys, endocrine glands) the endothelium is fenestrated. Fenestrae are 50- to 150-nm diameter zones of extreme endothelial cell (EC) thinning that, in most cases, are closed by diaphragms. Capillaries are normally spaced at intervals of no greater than 100 to 200  $\mu\text{m}$  – distances that correspond to the diffusion range of oxygen ( $\text{O}_2$ ). This is important because capillaries are the principal “exchange vessels” and are engaged in tissue nutrition and waste disposal. Plasma solute and its low-molecular-weight constituents (i.e.,  $\text{O}_2$ , glucose, and salts) pass freely from proximal portions of capillaries, largely, it is thought, by processes of convection and diffusion. Distally, these same processes lead to reabsorption of interstitial fluid and solute, including metabolic waste products such as carbon

dioxide (CO<sub>2</sub>). Capillary endothelium is the principal barrier to molecular exchange between blood and underlying tissue, and two pathways have been implicated: paracellular (through inter-EC junctions) and transcellular (via caveolae and fenestrae). Small molecules below the size of plasma proteins can use the former pathway; however, plasma proteins are too large to pass through EC junctions in normal tissues and extravasate almost exclusively by caveolae (4). Caveolae are approximately 70-nm diameter membrane-bound vesicles that shuttle across EC cytoplasm from the vascular lumen to the ablumen where they discharge their cargo of plasma protein-rich solute into the tissues.

Venules are larger than capillaries, typically 20  $\mu$ m or greater, and are lined by a taller endothelium, basement membrane, and smooth muscle cells. They play a lesser role in metabolite transport but are the key segment of the microvasculature that is activated in both humoral and cellular inflammation. Majno demonstrated many years ago that venules are the primary site of the solute and plasma protein leakage induced by inflammatory mediators such as histamine and serotonin (5). He also proposed a mechanism for inflammatory venular hyperpermeability, namely, that inflammatory mediators caused venular ECs to pull apart, generating inter-EC gaps through which fluid and macromolecules could extravasate (6). However, more recent studies have provided strong evidence that many of the endothelial openings induced by inflammatory mediators in endothelium are transcellular, not intercellular (7). Also, a structure has been identified in venular endothelium, the vesiculo-vacuolar organelle or VVO, that likely accounts for much of the transendothelial plasma flux that occurs in response to VEGF-A and other mediators (8,9) (Chapters 71 and 74). VVOs are grape-like clusters of uncoated, largely parajunctional cytoplasmic vesicles and vacuoles that together form an entity that traverses endothelial cytoplasm from lumen to ablumen (10). The individual vesicles and vacuoles that comprise VVOs share many properties with caveolae and are linked to each other and to the luminal and abluminal plasma membranes by stomata that are normally closed by thin diaphragms resembling those that close fenestrae. VEGF-A, histamine, and other inflammatory mediators are thought to cause these diaphragms to open, providing a transcellular pathway for plasma and plasma protein extravasation.

Leukocytes also leave the vasculature by traversing venules. As with the passage of fluid, it was originally thought that leukocytes crossed venules through opened inter-EC junctions. However, more recent structural studies, making use of serial sections and three-dimensional reconstructions, have shown that granulocytes and monocytes can pass through ECs, possibly by way of VVOs, independent of intercellular junctions (11,12). More work is required to sort out the relative importance of paracellular versus transcellular pathways for both fluid and inflammatory cell extravasation. The problem is a difficult one because inter-EC junctions are complicated, irregular structures. Also, VVOs are concentrated parajunctionally, and individual VVO vesicles may open to the inter-

cellular cleft above and below specialized junctions, as well as to the luminal and abluminal surfaces (Chapter 71).

## THE TUMOR VASCULATURE AND STROMA

As in normal tissues, solid tumors are comprised of parenchyma (the malignant cells) and a vascularized stroma, which they induce and in which they are dispersed. All tumors, regardless of their site of origin, require stroma if they are to grow beyond minimal size, and for the same reasons that normal tissues require stroma – maintenance of structure, nourishment, gas exchange, and waste disposal. The numbers of new blood vessels and the amount of connective tissue stroma vary considerably among different tumors, and, in general, are not closely linked to the degree of tumor malignancy. Highly malignant tumors may have much or little vascular stroma, but all growing tumors require at least some. Even so-called “liquid” tumors have stroma. Thus, ascites tumors induce a vascularized connective tissue stroma resembling that of solid tumors in the tissues lining the peritoneal cavity, and the tumor cells themselves are suspended in ascites fluid, a plasma protein-rich exudate resulting from the increased permeability of peritoneal lining vessels (13–15). In the case of leukemias, the circulating blood itself serves as stroma but, in addition, vascularized stroma also may be induced in tumor-involved bone marrow (16–18).

Superficially, tumor stroma resembles normal connective tissue and includes, in addition to blood vessels, fibroblasts and their products such as collagen and proteoglycans. However, upon closer inspection, the composition of tumor stroma differs strikingly from that of normal tissues (19,20). Differences include a significantly higher content of plasma protein-rich interstitial fluid, deposits of extravascular fibrin and its breakdown products, matrix proteins such as alternatively spliced fibronectins and tenascin that are normally found only in fetal development, abnormal proteoglycans (21) and, the subject of this chapter, highly abnormal blood vessels (19,22).

### Organization of Tumor Blood Vessels

Tumors, like normal tissues, are supplied by what are believed to be normal arteries and are drained by apparently normal veins. The new blood vessels that tumors induce, therefore, correspond primarily to that portion of the vascular tree that is situated between arteries and veins – that portion that, in normal tissues, corresponds to the microvasculature. The types of new blood vessels induced by individual tumors, and the patterns they form, differ strikingly from one another. However, the vascular pattern of a given tumor remains relatively constant even after repeated transplantation and metastatic spread. Thus, as Warren observed, the vascular morphology of a specific tumor is characteristic for that tumor but may not be unique to that tumor (1).

Whereas normal microvessels are arranged in a hierarchy of evenly spaced, well-differentiated arterioles, capillaries,

and venules, tumor microvessels follow a chaotic pattern and are hierarchically disorganized (1). A characteristic feature is spatial heterogeneity (uneven distribution), and the frequency of localized zones of increased vascular density has been used as a predictor of clinical outcome (23). One thought is that these microvascular “hot spots” provide a point of entry of cancer cells into the blood to form metastases; by contrast, tumor cells only rarely invade muscle-coated arteries or arterioles.

Tumor vessels often exhibit a serpentine course, branch irregularly, and form arteriovenous shunts. In many cases, vessels are most abundant at the tumor–host interface, where they are often distributed circumferentially, forming a prominent mantle around nodules of tumor cells. Internal portions of tumors are typically less well vascularized. Blood flow through the tumor vasculature does not follow a consistent, unidirectional path. Rather, the tumor vasculature is organized as a maze of interconnected vessels through which blood flows haphazardly and irregularly. Not all open vessels are perfused continuously, and, over intervals of even a few minutes, blood flow may follow different paths and even proceed in alternating directions through the same vessel (24).

The tumor vasculature is also heterogeneous over longer periods of time (1). Morphometric studies have shown that vascular volume, length, and surface area all increase during early tumor growth. As a result, small tumors tend to be relatively well vascularized. Later, however, vascular growth slows and the tumor blood supply becomes progressively deficient, leading to central ischemia and necrosis. Thus, tumors are said to outgrow their blood supply or, put in other words, the developing vasculature and other stromal elements fail to keep pace with tumor cell growth.

### Structure of Tumor Blood Vessels

Tumor blood vessels are a caricature of their normal counterparts. They do not conform to the hierarchical pattern of normal vascular beds and are not easily classified. Writing in the late 1970s, Warren (1) described nine distinct types of tumor vessel (Table 158-1). Although this classification has been superseded, it is of historical interest because it represents the first serious attempt to classify tumor vessels. It is also worth presenting here because Warren’s classification was only published in monographs that are now long out of print. Not all the vessel types that Warren described were found in the same tumor; rather, his list represents a composite of vessel types found in a survey of a large number of different human and animal tumor types. Warren concluded that the main difference between the tumor and normal vasculature was that, in the former, capillaries and veins became tortuous and dilated. In fact, however, the commonly expressed idea that tumor vessels are “dilated” is a misconception. Correctly understood, dilatation results from relaxation of vascular smooth muscle cells, as occurs, for example, in normal arterioles in response to nitric oxide. Tumor vessels characteristically have a paucity of smooth muscle cells, and their

**Table 158-1: The Tumor Microcirculation According to Warren**

<i>Vessel Type</i>	<i>Vessel Properties</i>
Arteries, arterioles	Resemble those of normal tissues but may have reduced innervation and vasomotion
Capillaries	Resemble normal capillaries as far as is known, i.e., have intact and complete EC lining, intercellular junctions, basement membrane, etc.
Capillary sprouts	Blind-ended, growing branches of existing capillaries
Sinusoidal vessels	Large vessels with nonparallel EC lining, occasional pericytes
Blood channels with no or incomplete EC lining	Blood percolates in channels lined wholly or in part by tumor cells. Found in melanomas and some sarcomas
Giant capillaries	Large (up to 50 $\mu\text{m}$ diameter) vessels lined only by ECs with some fibrous supporting tissue; commonly tortuous and describe arcs around the expanding tumor
Capillaries with fenestrated endothelium	Common in endocrine tumors but also found in many other types of tumor
Arteriovenous anastomoses	Similar to those found in normal tissues where arterioles flow directly into venules or small veins

Adapted from Warren B. The vascular morphology of tumors. In Peterson H-I, ed. *Tumor Blood Circulation: Angiogenesis, Vascular morphology and Blood Flow of Experimental and Human Tumors*. Boca Raton: CRC Press; 1979:1–47.

average enlarged size reflects intrinsic properties of vascular development, not muscle relaxation.

### Tumor Blood Flow

For some years it was thought that tumors had a more extensive blood supply than that of normal tissues (25). However, in now classic studies, Gullino (20) demonstrated that blood perfusion rates in animal tumors were generally much lower than those of the normal tissues from which they arose. Moreover, as tumors grew in size, their average perfusion rate decreased further as an increasingly inadequate blood supply led to focal necrosis (25). Subsequent studies by many investigators have confirmed and generalized these observations, although, as with other properties of tumor vessels, extreme heterogeneity exists.

What accounts for the relatively reduced blood flow found in tumors? Although all the reasons responsible are not as yet fully understood, measurements by many investigators and particularly by the Jain laboratory have shown that all the variables affecting blood flow are altered in experimental tumors (26). Blood flow ( $Q$ ) in any vascular system is proportional to

microvascular pressure drop ( $\Delta P$ ) and inversely proportional to blood viscosity ( $\eta$ ), and to a factor referred to as extrinsic geometric resistance ( $z$ ) (Equation 1).

$$Q = \Delta P / \eta z \quad (\text{Equation 1})$$

Whereas pressures in the arteries supplying normal and tumor vessels are quite similar, microvascular pressures within tumors are elevated, and venous pressures are significantly reduced (27). Also, tumor blood vessels exhibit greater resistance to flow than do the vessels supplying normal tissues. Because of their serpentine course, thin walls, exposure to increased interstitial pressure, and other local factors, extrinsic geometric resistance is increased, frequently in experimental tumors by more than an order of magnitude. Finally, the viscosity of the blood within tumor vessels is increased for at least two reasons. First, the hematocrit is increased because tumor vessels are hyperpermeable and leak plasma, resulting in sluggish blood flow and rouleaux formation. Second, blood viscosity is increased as the result of the Fahraeus-Lindqvist effect (viscosity increases with increasing vessel size; tumor vessels are enlarged, on average, compared with their normal counterparts) (28).

Attempts have been made to increase or decrease tumor blood flow using a variety of vasoactive drugs but the response has been variable and inconsistent (25). In general, the vascular beds of most tumors behave as rigid tubes that are in a state of close to maximal diameter; little capacity is available to increase flow in response to higher vascular pressure, probably because of a paucity of muscularized blood vessels that can be induced to dilate. The net result is low maximum perfusion capacity (i.e., high vascular resistance) compared with most normal tissues.

### Tumor Vessel Function

Not unexpectedly, abnormal organization and structure and reduced blood flow lead to deficient tumor vessel function. The uneven distribution of vessels results in an unequal distribution of  $O_2$  and nutrients and uneven clearance of waste products, resulting in zones of metabolic deficiency, ischemia, and necrosis. Also, the increased average diameter of tumor vessels results in an altered surface area-to-volume ratio that further contributes to inefficient tissue nutrition. As a result, and also because of arteriovenous shunts, nutrients are not taken up efficiently by tumors, as is manifest by the increased oxygenation of the venous blood draining tumors. Poor clearance of  $CO_2$  and other metabolites, coupled with high tumor cell glycolytic activity, results in a tumor microenvironment that is acidic compared with that of normal tissues (pH  $\sim$ 7.2 versus pH  $\sim$ 7.4) (29).

### Tumor Vessel Hyperpermeability

Another general abnormality of the tumor vasculature is increased permeability to plasma – particularly to plasma pro-

teins, large molecules that escape only very slowly from normal blood vessels. As early as 1959, investigators from several different laboratories reported increased clearance of plasma proteins from tumor blood vessels (30). In parallel studies, Gullino (20) found that tumor interstitial fluid was increased both in quantity and in plasma protein content, as compared with normal tissues, resulting in an increase in interstitial colloid osmotic pressure. He and others suggested that vascular hyperpermeability, coupled with a lack of functional lymphatics, accounted for the edematous state of tumors.

Subsequent studies have demonstrated that hyperpermeability is indeed a general property of the blood vessels supplying malignant tumors. This finding has led to a parallel literature, summarized in the next sections, that describes tumor vessel hyperpermeability from structural and functional (physiological) perspectives.

### Structural Basis of Tumor Vessel Hyperpermeability

As noted above plasma components can extravasate across vascular endothelium by paracellular (through inter-EC junctions) and transcellular (caveolae, fenestrae, and VVOs) routes (see Chapter 71). Inter-EC junctions allow the passage of water and other small molecules but normally exclude plasma proteins and similarly sized molecules. Shuttling across capillary endothelium, caveolae can transport solutes of both large and small size; they also may join together to form continuous, transcapillary pores. Fenestrae are specialized structures confined to specialized endothelia; they normally restrict the passage of plasma proteins, while permitting the passage of peptide and steroid hormones. Finally, VVOs, like caveolae, provide a system for the passage of both small and large molecules such as plasma proteins.

Which of these pathways are responsible for the passage of plasma and plasma proteins in tumor vessels? There is as yet disagreement in the literature. Some investigators have observed gaps in tumor endothelium and have argued that these represent the opening of interendothelial junctions (6,31). We, however, are impressed with the sturdiness of inter-EC junctions, and are persuaded that the bulk of tumor vessel leakiness occurs through VVOs and the trans-EC pores that may result from VVOs activated by VEGF-A or other tumor-secreted vasoactive mediators (32).

### Physiological Measurements of Tumor Vessel Permeability

As usually understood in the cancer literature, the term *permeability* refers to the increased extravasation of solutes, particularly plasma proteins or other macromolecules, from tumor blood vessels. Physiologists, however, have a stricter definition of permeability, confining the use of this term to changes in the intrinsic properties of the vascular wall. Because endothelium is the limiting barrier to the extravasation of plasma solutes from blood vessels, any changes in permeability must take place at the level of the vascular endothelium. Physiologists

regard the endothelium as a semipermeable membrane, permeated by pores of varying size, and they attribute the passage of molecules across that membrane to two driving forces: convection and diffusion. Based on these considerations, Starling, Renkin, Michel, Curry, Rippe, and others (33–35) have developed equations that describe in mathematical detail the passage of solutes across blood vessels (Equations 2–4):

$$J_{s\text{-convection}} = J_{v\text{-convection}}[1 - \sigma]C_p \quad (\text{Equation 2})$$

where  $J_{s\text{-convection}}$  is the rate of flux of a solute such as plasma albumin;  $J_{v\text{-convection}}$  is the rate of flux of the solvent (plasma water);  $\sigma$  is the reflection coefficient of the vascular wall to the solute as compared to that of water; and  $C_p$  is the concentration of solute in plasma.

$$J_{v\text{-convection}} = L_p A [p_v - p_i] - \sigma [\pi_v - \pi_i] \quad (\text{Equation 3})$$

where  $J_{v\text{-convection}}$  is the rate of flux of solvent;  $L_p$  is the hydraulic conductivity of the vessel wall;  $A$  is the surface area of the vascular endothelium across which flux takes place;  $P_c$  and  $P_i$  represent hydrostatic pressures within the circulation and interstitium;  $\sigma$  is the osmotic reflection coefficient and  $\pi_v$  and  $\pi_i$  are the osmotic pressures within the vessel and interstitium, respectively.

$$J_{s\text{-diffusion}} = PA[C_v - C_i] \quad (\text{Equation 4})$$

where  $J_{s\text{-diffusion}}$  is the diffusive flux of the solute across the vessel wall under conditions of zero flow;  $P$  is the diffusive permeability of the vessel wall;  $A$  is the surface area available for exchange; and  $C_v$  and  $C_i$  are the concentrations of the solute in plasma and the interstitium, respectively.

From these equations, it is clear that the intrinsic properties of the vascular endothelium and the particular solute under investigation have central roles in regulating transvascular passage; these intrinsic properties are reflected in the variables  $L_p$ ,  $\sigma$ , and  $P$  (33–35). In addition, however, a number of other factors also can have important effects in regulating the passage of solutes across the EC barrier. These include the surface area available for plasma exchange, hydrostatic and osmotic pressures within the blood and interstitial tissues, solute concentrations within and outside the vasculature, and the ratio of convective to diffusive flux. It also must be said that these equations explain solute extravasation in terms of convection and diffusion and therefore apply if solutes are passing through trans-EC pores or interendothelial gaps. However, the endothelium is more than a semipermeable membrane, and solutes may cross ECs not only through open pores but also by shuttling caveolae and through VVOs, where passage from vesicle to vesicle is regulated by the opening and closing of diaphragms.

So, which of these factors account for the hyperpermeability of tumor blood vessels? The increased interstitial pressure, both hydrostatic and osmotic, that results from the increased

volume and protein content of tumor interstitial fluid would be expected to retard extravasation of molecules of all sizes, including proteins. Similarly, tumors have reduced overall vascular surface area for solute flux. Nonetheless, plasma and plasma proteins extravasate from tumor blood vessels to a much greater extent than from normal vessels, and this results, in large part, from changes in the intrinsic properties of the vascular endothelium lining tumor blood vessels. These changes are all the more impressive in that they involve only a subset of tumor blood vessels, particularly mother vessels localized at the tumor–host interface.

### Other Properties of Tumor Vascular Endothelial Cells

Another property shared almost universally by tumor vascular endothelium is an increased rate of proliferation. In a comprehensive study and literature review, Denekamp and Hobson (36) reported that the vascular endothelium labeling index (LI) for tumors was significantly higher than that of the vasculature of normal tissues (0.22%). However, as with other properties of tumor vessels, great variability was noted; studies of 131 individual tumors demonstrated an EC LI that varied from 3.6% to 32.3%. EC LI did not correlate closely with tumor growth rate, but was generally significantly lower than that of the tumor cells themselves (range of tumor cell LI: 7.1–60.5%). Thus, the rate of tumor cell proliferation in individual tumors is not directly related to the rate of EC proliferation in the tumor vessels responsible for supplying them with nutrients.

Although increased permeability and proliferation are properties shared by the vascular endothelium supplying nearly all tumors, other EC properties, although irregularly expressed, often differentiate tumor vessels from those of normal tissues. Thus, in different tumors, tumor vascular ECs are reported to express on their surfaces increased anionic phospholipids, the  $\alpha v\beta 3$  integrin, fibronectins, H/T cadherin, platelet-derived growth factor receptor (PDGFR)- $\beta$ , NG2/human melanoma proteoglycan (HMP), Tie, and other molecules, and increased or decreased leukocyte adhesion receptors (37–46). Recently, Hida and colleagues (47) have reported that blood vessels in several animal and human tumors express cytogenetic abnormalities.

### TUMOR ANGIOGENESIS

Very early in their growth, and, interestingly, also at very late stages of malignant progression, tumors may satisfy their nutritional and waste removal needs by coopting the normal vasculature (48). In some cases, this is dramatically manifest as tumor cells grow in cuffs around pre-existing normal blood vessels (49,50). However, for the most part, growing tumors must induce the formation of new blood vessels and do so even before they invade the surrounding tissues (19,51,52). Tumor angiogenesis was recognized early in the 20th century by Goldman (53), Algire (54), and others. In elegant experiments

that made use of filters permeable to large and small molecules but not to cells, Greenblatt and Shubi (55) and Ehrman and Knoth (56) demonstrated that tumors induced angiogenesis by producing a diffusible substance that could pass through filters into the surrounding tissues where angiogenesis actually took place. Folkman greatly extended this work during the early 1970s (57), proposing that tumor growth and metastasis depended on the induction of new blood vessels (angiogenesis), and that interfering with angiogenesis could provide a novel therapeutic approach. There followed a spirited search to identify the tumor factor(s) responsible for inducing angiogenesis, and a large number of candidate molecules have now been identified that can induce new blood vessel formation both *in vitro* and *in vivo* (58–62). These include proteins such as VEGF-A, other members of the vascular permeability factor (VPF)/VEGF family such as placenta growth factor (PlGF), cytokines such as fibroblast growth factor (FGF), transforming growth factor (TGF)- $\beta$ , PDGF, interleukin (IL)-8, ephrins, and angiopoietins, as well as a variety of small molecules. VEGF-A is thought to be the most important of these angiogenic factors for several reasons: (a) it is expressed by nearly all malignant tumors; (b) its receptors are selectively (although not exclusively) expressed on vascular endothelium and are consistently upregulated on tumor vascular endothelium; (c) many other angiogenic factors act by upregulating VEGF-A expression; (d) blocking VEGF-A or its receptors can inhibit the growth of animal tumors and, more recently, human tumors; and, finally, (e) because as is shown later, it can induce many of the types of blood vessels found in tumors (61,62).

### Vascular Endothelial Growth Factor-A

VEGF-A was discovered as the result of microscopic studies that followed the growth pattern of tumor cells at early stages after their transplantation into syngeneic animal tissues. The critical observation was that such tumors grew as clumps of neoplastic cells dispersed in an edematous fibrin gel (63,64). The Irish pathologist O'Meara (65) had described what he thought to be fibrin strands on tumor cells during the late 1950s, but the methodologies available at that time were not sufficient to provide a definitive answer. Only rare tumors have the capacity to produce fibrinogen, the fibrin precursor. Rather, the fibrin found in tumors results from plasma fibrinogen. Therefore, two essential requirements exist for fibrin deposition in tumors (or indeed in any tissue outside of the vasculature): (a) permeability of tumor blood vessels to fibrinogen and other necessary plasma clotting proteins, and (b) extravascular activation of the clotting system to transform extravasated fibrinogen to fibrin. The second step is not unique to tumors in that vascular leakage in normal tissues also results in activation of the clotting system because tissue factor is expressed by many tissue cells (66). Thus, the hyperpermeability of the tumor vasculature distinguishes it from normal, and led us to search for a tumor product that could induce vascular permeability. Initial studies revealed that a vascular permeability factor was indeed present in the culture

supernatants of a wide variety of tumors and also *in vivo* in tumor ascites fluid, and that it was a secreted protein that acted directly on vascular endothelium (64). Using the Miles assay to screen column fractions for their ability to induce vascular permeability, Donald Senger purified VPF to homogeneity (67). Sometime later, our colleagues at the Monsanto Company made use of Senger's N-terminal amino acid sequencing data to clone VPF, and they showed that it induced angiogenesis *in vivo* and promoted the proliferation of cultured ECs (68). Independently and in a back-to-back publication, Napoleone Ferrara and his colleagues at Genentech cloned the same protein as an EC mitogen and called it vascular endothelial growth factor (69). More recently, because other related growth factors have been found, VPF/VEGF is best referred to as VEGF-A.

VEGF-A is an alternatively spliced protein that exists in several different isoforms, each with a similar although not identical range of activities (70,71). VEGF-A<sub>165</sub> (the mouse equivalent, VEGF-A<sub>164</sub>, is one amino acid shorter), the most widely expressed and best studied isoform, is a multifunctional cytokine with a vascular permeabilizing activity some 50,000 times that of histamine. It also stimulates EC migration and is mitogenic for ECs, although only under low serum conditions that are unlikely to occur *in vivo*. VEGF-A is also an EC survival factor, able to avert both EC apoptosis and senescence (72,73). Aside from its vascular permeabilizing activities, VEGF-A's activities in angiogenesis depend to a large extent on its ability to reprogram the pattern of EC gene expression. All of VEGF-A's activities are thought to be mediated through two receptor tyrosine kinases, VEGFR1 (also known as FLT-1) and VEGFR2 (also known as KDR), and through a more recently described nontyrosine kinase receptor, neuropilin (74–76). Although expressed on normal endothelium, these receptors typically are overexpressed by tumor blood vessel ECs (61,62).

### Normal versus Tumor Angiogenesis

The microvasculature of normal tissues arises in the embryo by the twin processes of vasculogenesis (formation of vessels from primitive stem cell precursors) and angiogenesis (formation of vessels from pre-existing vessels). Although incompletely understood, these processes are highly regulated and result from the balanced secretion, in appropriate amounts and sequence, of many different cytokines and inhibitors, including VEGF-A (60,77,78). The result is a hierarchy of the intricate and highly ordered and differentiated microvascular channels of normal tissues described earlier, each with well-defined anatomic and physiologic properties.

In contrast, the pathological angiogenesis found in tumors (and also in wound healing and inflammation) is a much cruder process that involves the unbalanced secretion of a smaller subset of cytokines and particularly VEGF-A (61,62). If this general hypothesis is correct, then it should be possible to produce surrogate tumor blood vessels by expressing VEGF-A

(or other cytokines) in normal tissues – that is, it should be possible to generate tumor-like vessels in the absence of tumor cells. In fact, this approach has been successful. Nonreplicating adenoviral vectors engineered to express VEGF-A can be injected into normal mouse tissues where they infect host cells that serve for a time as factories producing VEGF-A. The result is an angiogenic response that mimics that of many tumors (62,79). Also, as in tumors (80), there is debate as to whether, and to what extent, the ECs that line the newly formed vessels induced by VEGF-A develop from pre-existing vascular endothelium or from bone marrow–derived circulating endothelial progenitor cells.

Adenoviral vectors offer several advantages for generating tumor-like blood vessels. They allow angiogenesis to be induced in any tissue accessible to vector injection; cytokine expression levels can be readily varied by adjusting viral dose; different cytokines can be combined, together or in sequence; and no foreign matrix need be introduced. A further advantage of this approach is that it allows insight into the steps and mechanisms by which tumor vessels of different types form. Finally, adenoviral vectors are not integrated into the genome, and therefore they are expressed for only a limited period of time (several weeks); as a result, it is possible to determine the effects of exogenous cytokine expression on the new blood vessels that have been induced. One disadvantage exists: namely, that experiments must be performed in immunodeficient mice to avoid an immune response directed against the vector.

#### TUMOR-SURROGATE VESSELS INDUCED BY AD-VEGF-A<sub>164</sub>

Using an adenoviral vector engineered to express VEGF-A<sub>164</sub>, it is possible to induce the formation of at least six different types of blood vessels (Table 158-2), all of which are found in human and animal tumors. These include mother vessels, bridged mother vessels, capillaries, glomeruloid vascular proliferations (glomeruloid bodies), and arteriovenous malformations (stabilized mother vessels). In addition, Ad-VEGF-A<sub>164</sub> induces arteriogenesis and a highly abnormal form of lymphangiogenesis (Figure 158.1; for color reproduction, see Color Plate 158.1) (81,82). The extent to which lymphatics are induced in tumors remains to be determined.

#### Mother Vessels

The term *mother* vessels was coined by Paku and Paweletz (83) to refer to the first type of new blood vessel to form in experimental tumors. These are also the first vessel type to appear in response to VEGF-A; hence, the other types of vessels that evolve from mother vessels may be regarded as *daughter* vessels (62,79,81). Mother vessels would seem to correspond to several of the types of blood vessel categorized by Warren (see Table 158-2) as *giant capillaries* and *sinusoidal vessels*; in addition, although not capillaries, they are lightly fenestrated. We have defined mother vessels as enlarged, thin-walled, hyper-

**Table 158-2: Proposed Classification of Tumor Blood Vessels**

<i>Vessel Type</i>	<i>Vessel Properties</i>
Feeder vessels	Large, often tortuous arteries and veins whose properties have not been well studied
Mother vessels	Large, thin-walled, hyperpermeable, lightly fenestrated pericyte-poor sinusoids that are engorged with red blood cells
Bridged mother vessels	Mother vessels in which EC processes extend into and across the lumen
Capillaries	Resemble normal capillaries as far as is known
Glomeruloid microvascular proliferations	Poorly organized vascular structures that macroscopically resemble renal glomeruli; they are comprised of ECs and pericytes with minimal vascular lumens and reduplicated basement membranes
Vascular malformations (stabilized mother vessels)	Mother vessels that have acquired an asymmetric coat of smooth muscle cells or, alternatively, fibrous connective tissue; resemble arteriovenous malformations found in other settings
Vascular mimicry	Blood-filled spaces lined by tumor cells that may contribute to tumor circulation

All these vessel types except for vascular mimicry can be induced by VEGF-A<sub>164</sub>.

permeable, pericyte-poor sinusoids (79). They arise from pre-existing venules and capillaries through a three-step process of basement membrane degradation, pericyte detachment, and extensive increase in cross-sectional area. This process begins within hours of Ad-VEGF-A<sub>164</sub> injection and is similar in all normal tissues studied, including brain (84). Initially (at least for the first 48 hours) mother vessel formation proceeds without significant EC division. Basement membrane degradation is an essential step because basement membranes are noncompliant (nonelastic) structures that do not allow microvessels to increase by more than approximately 30% in cross-sectional area (85), far less than the fivefold expansion characteristic of many mother vessels. The specific proteases responsible for basement membrane degradation have not as yet been identified. Whether pericytes detach from mother vessels by an active process or simply fall off as the result of basement membrane degradation is not known. Vascular expansion of capillaries and venules is accommodated by membrane stored in VVOs and caveolae. VVOs provide a particularly abundant source of stored intracellular membrane, corresponding to more than

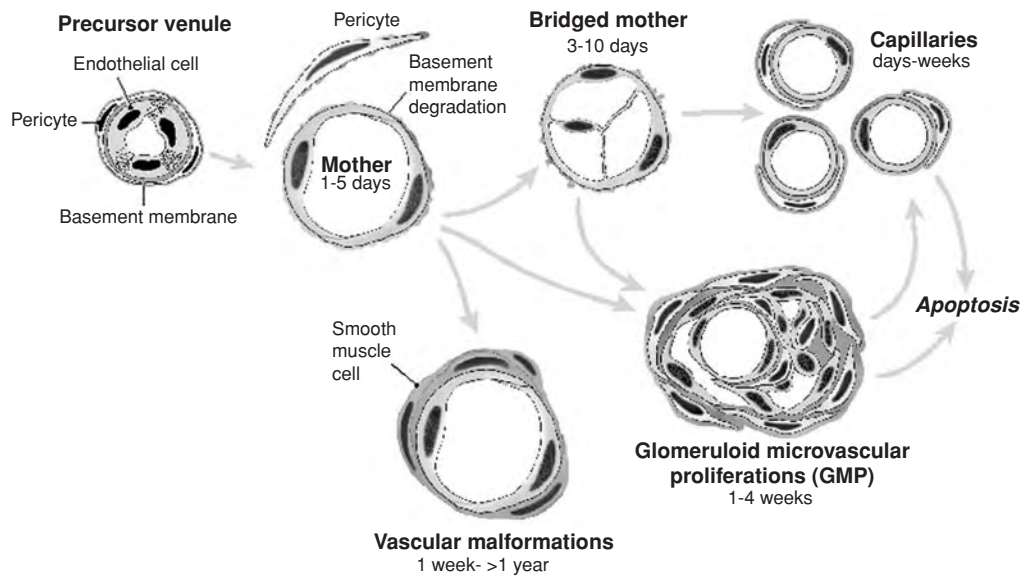

Figure 158.1. Schematic diagram depicting the types and sequence of new vessel formation in response to Ad-VEGF-A<sub>164</sub>. Heterogeneity of the angiogenic response induced in different normal adult tissues by vascular permeability factor/vascular endothelial growth factor. *Lab Invest.* 2000;80:99–115.) For color reproduction, see Color Plate 158.1.

twice that of the plasma membrane of pre-existing venular ECs (10,30). As mother vessels develop, the EC cytoplasm becomes greatly thinned and VVOs decrease in both number and complexity as they contribute their membranes to the greatly expanded plasma membrane. Vessels of this description are common in both animal and human tumors, and a similar process likely occurs in the formation of mother vessels in healing wounds (e.g., skin wounds, myocardial infarcts) (86,87).

Mother vessels are highly permeable to circulating macromolecules, such as plasma proteins and fluoresceinated macromolecular dextrans, and account to a large extent for the overall hyperpermeability of the vasculature in animal tumors. As in normal venules exposed to VEGF-A or other permeabilizing mediators, circulating macromolecules such as ferritin extravasate through VVOs. This may seem surprising in that, as noted earlier, mother vessel ECs have many fewer VVOs than are found in normal venular endothelium. The answer likely lies in the fact that, although fewer in number, the VVOs remaining are less complex (have fewer vesicles and vacuoles), and the vascular endothelium is greatly thinned; as a result, the transcellular pathway is greatly shortened.

Macromolecules also extravasate from mother vessels by way of fenestrations, although these cover less than 1% of the endothelial surface; this is of interest because the fenestrae of normal vessels are not thought to be permeable to large molecules such as plasma proteins.

Mother vessels are transitional forms, dependent on exogenous VEGF-A, and we postulate that they are the vessel type most susceptible to anti-VEGF-A therapy. However, mother

vessels evolve into several different types of daughter vessels, as listed in Table 158-2. Although the steps involved are understood in part, the molecular mechanisms have not been elucidated nor is it known why different mother vessels evolve into different types of daughter vessel.

### Bridged Mother Vessels and Capillaries

One process by which mother vessels evolve into capillaries was originally discovered in tumor vessels (15) and involves intraluminal bridging by vascular ECs. These endothelial bridges divide mother vessels into several smaller channels that are then thought to separate from each other to form independent capillaries (Figure 158.2; for color reproduction, see Color Plate 158.2) (79). A similar bridging process has been found in the new blood vessels that supply healing wounds (e.g., myocardial infarcts) (87) and in skeletal muscle exposed to chronic vascular dilatation (88). ECs extend cytoplasmic processes into and across mother vessel lumens, forming transluminal bridges that divide blood flow into multiple smaller-sized channels. This is unexpected, because mammalian cells normally migrate on surface matrices and would not be expected to extend processes into a flowing stream of blood. In fact, they may not be doing so. Because they are highly permeable to plasma, mother vessel lumens are packed with red blood cells and have little retained plasma; this results in increased viscosity and diminished blood flow, both of which favor intravascular clotting. Clotting is further favored in that VEGF-A upregulates EC expression of tissue factor (89), the procoagulant that initiates the

Figure 158.2. Illustration of the various types of new, tumor-surrogate blood vessels induced by Ad-VEGF-A<sub>164</sub> in Giemsa-stained, 1-micron Epon sections (A–F, H) and following immunohistochemical staining for CD31 (G). (A–C) Typical mother vessels, enlarged, thin-walled sinusoids with high hematocrit (as the result of vascular permeability to plasma) and few pericytes. In C, arrow indicates a detached pericyte. (D, E) Bridging of mother vessels by extension of EC processes that divide the lumen into multiple smaller channels. (F, G) Typical glomeruloid microvascular proliferations. (H) Vascular malformations; mother vessels that have become stabilized by acquiring an asymmetric coating of smooth muscle cells. Magnification bars: A, H, 50  $\mu\text{m}$ ; B–F, 15  $\mu\text{m}$ ; G, 25  $\mu\text{m}$ . (F reproduced with modification, with permission from Pettersson A, Nagy JA, Brown LF, et al. Heterogeneity of the angiogenic response induced in different normal adult tissues by vascular permeability factor/vascular endothelial growth factor. *Lab Invest.* 2000;80:99–115; H reproduced with modification, with permission from *Cold Spring Harbor Symp Quant Biol.* 2002;67:227–237.) For color reproduction, see Color Plate 158.2.

extrinsic clotting pathway. In fact, mother vessels in tumors and those induced by Ad-VEGF-A<sub>164</sub> commonly develop intravascular clots and may thrombose. Thus, although not proven, it is possible that the EC processes that project into mother vessel lumens are attached to a fibrin matrix. Whatever the mechanism, the smaller channels separate from each other to form individual, smaller-caliber capillaries that are, as far as is known, normal in structure.

#### Glomeruloid Microvascular Proliferations (Glomeruloid Bodies)

Glomeruloid microvascular proliferations (GMPs) are poorly organized vascular structures that resemble renal glomeruli (hence the name). They are commonly found in a num-

ber of different human tumors including glioblastoma multiforme and cancers of the stomach, breast, and other locations (79,90,91). GMPs are hyperpermeable to plasma and plasma proteins but, because they are poorly perfused, likely account for much less plasma extravasation than mother vessels. Nascent GMPs first appear as focal accumulations of large, poorly differentiated, CD31- and VEGFR2-positive cells in the endothelial lining of mother vessels (79,90). The source of these cells, whether locally from mother vessel endothelium or systemically from circulating endothelial progenitor cells, is not known. Whatever their source, these cells proliferate rapidly, extending into mother vessel lumens, and also outward into the surrounding extravascular matrix. In this manner, they encroach on and compress the mother vessels from which they had arisen, eventually dividing single large

mother vessel lumens into much smaller channels that are often too small to admit the passage of red blood cells. The great majority of cells comprising GMPs continue to express EC markers. However, as GMPs grow, cells expressing pericyte markers (NG2, PDGFR- $\beta$ ) and ultrastructural characteristics also appeared. Electron microscopy showed that pericytes were situated peripherally to small clusters of ECs that formed small or no evident vascular lumens. At least in this experimental setting, macrophages, identified by markers (F4/80, HLA DR2) and characteristic ultrastructure, also accumulated peripherally. An additional prominent feature is deposition of abnormal multilayered basal lamina.

The GMPs so generated were found to be dependent on the continued presence of exogenous VEGF-A<sub>164</sub> for their maintenance as well as for their generation. As adenoviral vector-derived VEGF-A<sub>164</sub> expression declined, GMPs underwent apoptosis and progressively devolved into smaller, normal-appearing capillaries (90). Similarly, all the human tumors known to form GMP also express VEGF-A, and tumors such as glioblastoma multiforme, which makes unusually large amounts of VEGF-A, are among those that most commonly have GMPs. Recent evidence suggests that the presence of GMPs in human tumors is a negative prognostic sign (91,92).

Fidler (93) has proposed a minor variation of this model of GMP induction, postulating that ECs lining large tumor vessels (presumably mother vessels) project inwardly to form transcellular bridges, as originally described by Nagy and colleagues (15). On the other hand, Dome and colleagues (94) have proposed a third, very different model in which tumor cells form GMPs by attaching to the basement membranes of

pre-existing cerebral microvessels and pulling entire capillaries (ECs and pericytes) into loops and coils. In this model, the vessels play only a passive role and exhibit very little in the way of cell proliferation. This model obviously cannot explain the formation of GMPs induced by Ad-VEGF-A<sub>164</sub> in the absence of tumor cells (90).

### Vascular Malformations (Stabilized Mother Vessels)

Thin-walled mother vessels lacking adequate pericyte and basement membrane support are subject to thrombosis or collapse. Although some mother vessels avoid these fates by evolving into capillaries or GMPs, others maintain their large size by acquiring a coat of smooth muscle cells and/or a rim of collagen-expressing fibroblasts. Such vessels are readily distinguished from normal arteries and veins by their inappropriately large size (for their tissue location), by their thinner and often asymmetric muscular coat, and by the presence of perivascular fibrosis. Vessels of this description closely resemble the vascular malformations found independent of malignant tumors – for example in skin and brain – thus suggesting a mechanism by which such malformations may form (95). As their structure would suggest, these vessels are not thought to be hyperpermeable; also, unlike mother vessels and glomeruloid bodies, they persist indefinitely, long after adenoviral vector-induced VEGF-A<sub>164</sub> expression has ceased (Figure 158.3; for color reproduction, see Color Plate 158.3). Thus, stabilized mother vessels have acquired independence from exogenous VEGF-A, although it is possible that they are maintained by VEGF-A secreted by the smooth muscle cells

Figure 158.3. Illustration of mother vessels (*M*), vascular malformations (*VM*) in human ovarian carcinomas (**A**, **B**, hematoxylin and eosin-stained, paraffin-embedded sections) and vascular mimicry in a mouse B16 melanoma (**C**, Giemsa stained 1-micron plastic section). Magnification bars: 50  $\mu$ m. For color reproduction, see Color Plate 158.3.

that closely envelop them. This finding has important implications, because these vessels would not be expected to be susceptible to anti-VEGF-A therapy.

### Vascular Mimicry and Mosaic Vessels

In some tumors, particularly melanomas, red blood cell-filled spaces have been found that are apparently lined by tumor cells instead of ECs. Such vessels have been referred to as examples of vascular mimicry – tumor cells that have acquired some of the structural and molecular properties of ECs and form channels that mimic those of blood vessels (96). That such spaces exist is not in question, but their significance is much debated (97). The issue hangs on whether these spaces are a part of a functional vascular system or whether they simply reflect hemorrhage into tumors from leaky but otherwise conventional vessels. Very recent studies have investigated this question further and report the finding of “mosaic” vessels in some experimental tumors; that is, vessels that are lined by an attenuated endothelium with sites that do not immunostain for EC markers, gaps marked by an apparently incomplete basement membrane (98).

### TUMOR VASCULAR ENDOTHELIUM AS A THERAPEUTIC TARGET

Because tumors, like normal tissues, depend on their vascular supply for survival and growth, attempts have been made to prevent angiogenesis as a strategy for inhibiting tumor growth. A variety of agents that block VEGF-A or its receptors have proved efficacious in animal studies and, recently, an antibody to VEGF-A has been effective in inhibiting the progression of certain types of cancer in patients (2). As noted earlier, certain tumor vessels require exogenous VEGF-A for their survival; therefore, inhibition of VEGF-A activity also may serve to destroy pre-existing vessels as well as preventing angiogenesis (72). These findings, coupled with the structural and functional differences that distinguish tumor from normal endothelium, have suggested that tumor vessels might express unique markers that could serve as therapeutic targets. A number of investigators are pursuing this line of investigation, using a variety of approaches that include brute-force biochemistry (99,100), selective isolation of the luminal plasma membranes of tumor vessel endothelium (101), and phage-display technology (102–105). Some promising targets have been identified, but it is as yet too soon to determine whether any will be useful in cancer therapy.

A final related point worth mentioning is that of tumor vessel normalization. Recent reports have called attention to an improvement in the quality of tumor blood vessels following antiangiogenic and other types of therapy (106). Vascular normalization could improve tumor access to standard chemotherapy and, by providing better oxygenation, render tumors more susceptible to radiation therapy.

### KEY POINTS

- Tumor blood vessels are heterogeneous and highly abnormal with respect to organization, structure, and function.
- Physiological angiogenesis, although as yet incompletely understood, results from the balanced secretion, in appropriate amounts and sequence, of many different cytokines and inhibitors, including VEGF-A.
- Tumor angiogenesis results from the unbalanced secretion of a small number of mediators and growth factors, particularly VEGF-A.
- The hyperpermeability of tumor blood vessels results in extravascular deposition of a fibrin provisional stroma analogous to that occurring in wound healing. Thus, tumors and healing wounds generate vascularized stroma by similar mechanisms.

### Future Goals

- To define the molecular mechanisms by which mother and the various types of daughter vessel form
- To determine which types of tumor vessels are affected by anti-VEGF-A therapy and whether additional types must be targeted to make antiangiogenesis therapy more effective

## Kaposi's Sarcoma

Kimberly E. Foreman

*Loyola University Medical Center, Maywood, Illinois*

In 1872, Moritz Kaposi (1837–1902), a Hungarian dermatologist, described five male patients presenting with deep red to brown-violet plaques or nodules on the skin of the lower extremities (Figure 159.1; for color reproduction, see Color Plate 159.1) (1). This disease, later designated Kaposi's Sarcoma (KS), was uniformly fatal for his patients. Kaposi stated: "The disease must, from our present experience, be considered from the onset not only as incurable, but also as deadly."

Today, KS is recognized as the most common tumor in human immunodeficiency virus (HIV)-1 infected individuals. The tumors are multifocal, highly vascularized neoplasms characterized histologically by spindle-shaped tumor cells that form slit-like vascular spaces often filled with erythrocytes (see Figure 159.1). The lesions also contain fibroblasts, endothelial cells (ECs, indicating angiogenesis), and an inflammatory infiltrate consisting of lymphocytes, eosinophils, and plasma cells. Early lesions resemble granulation tissue and, as the disease progresses, the tumor cells coalesce to form large masses. In these late-stage lesions, a vast majority of the tumor cells, as well as some surrounding ECs, are infected with the KS-associated herpesvirus (KSHV, also known as human herpesvirus [HHV]-8). This virus, which is believed to be the etiologic agent responsible for KS, is discussed in this chapter. As noted by Kaposi, the extremities are initially involved in most cases; however, the disease can progress to involve virtually any internal organ, particularly the lungs and gastrointestinal tract. Curative therapy has not been developed for KS, and current treatments are only able to temporarily relieve its symptoms (2).

### THE KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS

Research in KS changed dramatically in 1994, when Chang, Moore, and colleagues identified novel herpesvirus-like DNA sequences in over 90% of KS lesions (3). Subsequent work has confirmed these findings, and KSHV has since been consistently associated with KS and two lymphoproliferative disorders: primary effusion lymphoma and a subset of multi-

centric Castleman disease (4,5). KSHV is a lymphotropic virus (i.e., it persistently infects B-lymphocytes) that shares several features with other herpesviruses including a large, double-stranded DNA genome, replication within the nucleus, and the ability to establish a latent infection. Latency permits the life-long persistent infection of an individual, because only a small subset of viral proteins are produced, and the virus can effectively hide from the immune system. When appropriately stimulated, the virus can switch from the latent state to lytic reactivation. During the lytic cycle, viral replication occurs. A majority of the viral genes are expressed, progeny virions are produced, and the host cell is ultimately destroyed. In KS, the majority of tumor cells are latently infected, with only 1% to 3% of the cells undergoing reactivation (6).

Strong evidence indicates KSHV is the etiologic agent of KS. KSHV DNA has been detected in all four forms of KS and in virtually all tested KS lesions, seroepidemiologic studies found KSHV antibodies in most KS patients, and KSHV infection can predict the future development of KS (7–9). It is, however, currently unknown how KSHV causes KS. Clues can be gained from analysis of the KSHV genome, which has been sequenced. In addition to viral structural proteins and those necessary for viral replication, the KSHV genome contains a large number of unique genes encoding for homologues of human cellular proteins. Recent studies have identified many of these viral homologues as biologically active proteins that can induce proliferation, alter cell cycle regulation, and inhibit apoptosis, indicating they may play an important role in KS pathogenesis. In addition, KSHV alters expression of a variety of host cellular proteins to evade attack by the immune system.

### EPIDEMIOLOGICAL FORMS OF KAPOSI'S SARCOMA

Four clinical-epidemiological forms of KS are currently recognized: (a) classical, (b) endemic (African), (c) iatrogenic (transplant-associated), and (d) acquired immunodeficiency syndrome (AIDS)-related (epidemic). Although these forms are histologically indistinguishable, each possesses unique

Figure 159.1. (A) Kaposi's sarcoma lesion. (B) Hematoxylin and eosin (H&E) stain of a Kaposi's sarcoma lesion. Note the fascicles of spindle-shaped tumor cells in the center of the picture, which are characteristic of these lesions. For color reproduction, see Color Plate 159.1.

characteristics with respect to anatomic involvement, prognosis/aggressive nature of the tumors, age, sex, and geographical origin of the patient.

Classical KS occurs sporadically in older men (over 50 years) of Mediterranean, Eastern European, or Jewish descent. Men are preferentially afflicted at a 15:1 male:female ratio. Interestingly, individuals born in these regions (or whose families originate from these regions) are at an increased risk for developing classic KS long after their emigration to Europe or North America (10). The tumors in classic KS generally are confined to the skin, progress slowly, and are frequently thought of as a relatively benign, cosmetic nuisance. Visceral or mucosal involvement occurs in up to 10% of patients, and arises only after a period of years (11).

Endemic KS (also known as African KS) occurs in children and young adults in sub-Saharan Africa. Prior to the AIDS epidemic, KS accounted for 9% of all reported cancers in Uganda; now, in combination with the AIDS-related form, KS accounts for almost half of all cancers in Ugandan men (12,13). Endemic KS in young adults tends to have extensive involvement of the skin. Frequently, these patients suffer from painful edema, and their tumors can ulcerate and infiltrate the surrounding tissue. Endemic KS in children is surprisingly different from that found in young adults. The neoplasm generally begins as a lymphadenopathy rather than a cutaneous lesion and rapidly progresses to the visceral organs. The prognosis is poor, with virtually 100% fatality within 3 years (14).

Iatrogenic KS occurs in approximately 0.4% of transplant patients in the United States, but in countries where endemic or classical KS occurs, it can be the most common post-transplant tumor, affecting up to 5% of transplant patients. The tumors tend to occur 2 to 5 years post-transplantation, and are most commonly found in patients with renal transplants, although it is unclear if this is related to the large number of

renal transplants that are performed, or if it is due to some other unidentified factor. Iatrogenic KS can be aggressive, yet the lesions tend to regress if immunosuppressive therapy is reduced or discontinued. Several studies have attempted to determine if KSHV infection in these patients is the result of reactivation of pre-existing KSHV infection or if the recipient acquired KSHV from the organ donor, presumably through free virus or KSHV-infected B cells within the organ. Early reports indicated that both mechanisms were likely involved; however, an elegant study by Luppi and colleagues demonstrated that the KS tumor cells in five of eight (63%) renal transplant patients harbored either genetic or antigenic markers of the donor (15–17). The most striking finding in this report was the identification of the Y chromosome in KS tumor cells from female transplant patients who received an organ from a male donor (17). The simplest explanation for these findings is that individuals with no history of KS can harbor precursor tumor cells that are suppressed or killed in an immunocompetent host but, when introduced into the immunosuppressed transplant patient, the cells can circumvent normal growth control and result in tumor formation.

AIDS-related KS was initially identified in 1981, by dermatologists in San Francisco and New York, who noted the unusual diagnosis of clinically aggressive KS in otherwise healthy homosexual males (18). This observation, together with an increase in *Pneumocystis carinii* pneumonia, heralded the beginning of the AIDS epidemic in the United States. In this population, KS can be extremely aggressive. Patients can suffer from local progression as well as rapid dissemination to visceral organs, leading to death. At the beginning of the AIDS epidemic, approximately 20% of HIV-1 infected individuals were afflicted with this disease. With the introduction of highly active antiretroviral therapy (HAART) to treat HIV infection, the incidence of AIDS-KS has dramatically decreased, although it continues to be the most common tumor in HIV-1 positive individuals. This is particularly true in developing countries where state-of-the-art antiretroviral therapies are not readily available. Although it is a common misconception that KS tumor cells are infected with HIV-1, there is no evidence that HIV-1 can infect these cells. It is thought that HIV-1 contributes to KS pathogenesis through a dysregulation of the immune system that allows KSHV to escape normal immune surveillance and promotes the growth and proliferation of the tumor cells.

#### THE ORIGIN OF THE KAPOSI'S SARCOMA TUMOR CELL

The origin of the KS tumor cell has been debated since the time of Kaposi. Today, most experts favor the EC (or an EC precursor) as the likely progenitor of the spindle-shaped tumor cell, although compelling arguments still can be made for other cell types, including the dermal dendrocyte and pluripotent mesenchymal precursors. Most data supporting the endothelial origin of KS come from immunohistochemical

staining studies identifying specific EC markers on the tumor cells. Using factor VIII-related antigen (von Willebrand factor [vWF]) and binding of *Ulex europaeus* lectin I as markers for vascular endothelium, several early studies concluded that the proliferating spindle cells as well as the cells lining the vascular channels within the tumor were of endothelial origin (19,20). Many of these studies went further to try to identify the type of endothelium (vascular or lymphatic) based on the staining pattern. Not all studies, however, confirmed these early results. Some investigators failed to detect endothelial-specific markers on the tumor cells although the proliferating ECs in the vasculature were positive (21,22). Additional studies attempted to confirm or refute the immunostaining-based results using alternative techniques, such as the identification of Weibel-Palade bodies (endothelial-specific storage vesicles for vWF) by electron microscopy; yet contradictory results continued to plague these investigations (23–25).

As additional endothelial-specific antigens have been identified over the years, studies aimed at proving or disproving the endothelial origin of KS have been regularly published (summarized in Table 159-1). Data demonstrating the combined expression of phenotypic markers such as CD31, CD34, E-selectin, and vascular endothelial growth factor receptor 2 (VEGFR2) (also known as KDR/FLK-1) have strengthened support for an EC origin and, more recently, the detection of markers restricted to lymphatic endothelium (VEGFR3 [FLT-4] and podoplanin) have led many investigators to identify lymphatic ECs as the precursor of KS. Perhaps the most compelling evidence for an endothelial origin comes from recent studies demonstrating that ECs (derived from either the umbilical vein or dermal microvasculature) can be infected with KSHV *in vitro* resulting in conversion of the cells from their traditional cobblestone morphology to spindle cells and, in some cases, resulting in transformation (26). This infection induced the expression of several lymphatic-specific proteins such as Prox1 and lymphatic vessel endothelial receptor (LYVE)-1, effectively “re-programming” these blood vessel-derived cells to express a lymphatic phenotype (27).

Although the data linking KS cells with ECs (either vascular or lymphatic) are abundant, these findings cannot reconcile the coexpression of EC markers with macrophage-, smooth muscle-, and dendritic cell-specific markers that are also found on KS tumor cells (see Table 159-1). As mentioned earlier, investigators have argued that infection of normal ECs results in cellular reprogramming that promotes the expression of an unusual combination of antigenic markers. Other investigators have interpreted these findings to mean the spindle cells are actually a mixture of different cell types and, as the lesions progress, a single cell type may become more prominent (28). Still others have suggested that the KS tumor cell is derived from a pluripotent progenitor cell. Infection of the cell with KSHV and/or stimulation from the cytokine-rich microenvironment (discussed later) may promote differentiation of the cell down a unique pathway. Clearly, additional studies are needed to definitively identify the precursor of the KS tumor cell.

## CYTOKINES AND KAPOSI'S SARCOMA PATHOGENESIS

It has been hypothesized that KS begins as a polyclonal hyperplasia triggered by immune activation/dysregulation that may develop into a true monoclonal malignancy as the disease progresses (29). In early lesions, only 10% of the tumor cells are infected with KSHV, and this increases to virtually all of the tumor cells in late-stage lesions. These infected cells are believed to produce and release viral proteins as well as a unique combination of cytokines, chemokines, and angiogenic factors that act through autocrine and paracrine mechanisms to promote the growth, proliferation, and survival of KSHV-infected cells and uninfected cells. The importance of cytokines in KS was originally identified in studies using cultured KS tumor cells that showed the cells were highly dependent on cytokines and growth factors for growth and proliferation (30). These cells produce a large number of biologically active cytokines including interleukin (IL)-1 $\beta$ , IL-6, IL-8, platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), granulocyte macrophage colony stimulating factor (GM-CSF), transforming growth factor (TGF)- $\beta$ , oncostatin M (OSM), basic fibroblast growth factor (bFGF), and vascular endothelial growth factor (VEGF). Subsequent studies confirmed the expression of these factors in KS lesions using *in situ* hybridization and immunohistochemical staining.

The role of KSHV in producing these factors is currently unclear, because cultured KS tumor cells do not appear to be infected with KSHV (except during the earliest passages) (31). This loss of KSHV is not understood, and may be due to inappropriate culture conditions that are unable to support KSHV maintenance in the tumor cells or, perhaps, noninfected cells within the culture have a growth advantage. In either case, studies of ECs infected with KSHV or expressing individual KSHV proteins have begun to provide insight into the link between cytokines and KSHV. Hayward and colleagues showed that KSHV infection of microvascular ECs induced IL-8 and TGF- $\beta$  production, whereas expression of the constitutively active KSHV-encoded G-protein-coupled receptor (vGPCR; a homologue of the IL-8 receptor, CXCR2) or viral IL-6 induced VEGF expression (32–34). In addition, mediators produced by KS tumor cells may work in concert with other factors associated with immune dysfunction to create the cytokine-rich microenvironment characteristic of KS. For example, HIV-1 infected cells (including T cells, monocytes/macrophages, and dendritic cells) have been shown to secrete inflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$  and IL-1 $\beta$ , as well as induce the expression of cytokines by neighboring cells. HIV-1-infected patients are known to have higher circulating levels of IL-1, IL-3, interferon (IFN)- $\gamma$ , TNF- $\alpha$ , TNF- $\beta$ , TGF- $\beta$ , OSM, and bFGF, which is probably a result of chronic viral infection and stimulation of the immune system. Taken together, the complex “cytokine storm” within AIDS-KS lesions may be partly responsible for the aggressive nature of AIDS-related KS.

**Table 159-1: Antigen Expression by Kaposi's Sarcoma Tumor Cells in Vivo**

<i>Antigen or Respective Antibody</i>	<i>Normal Distribution</i>	<i>KS Tumor Cell Expression</i>	<i>References</i>
<b>Endothelial cells</b>

\*Binding of *Ulex europaeus* lectin I to lymphatic ECs appears controversial.

## ANGIOGENESIS

Angiogenesis is a complex process that is regulated by the precise balance of proangiogenic and antiangiogenic modulators. Not only are growth factors (such as VEGF and bFGF) necessary to stimulate EC proliferation and migration, but angiogenesis also requires the breakdown of the extracellular matrix by matrix metalloproteinases (MMPs), attraction of pericytes and macrophages, stimulation of smooth muscle cell proliferation and migration, and deposition of a new extracellular matrix. Establishment of adequate vascularization is essential for the development and growth of all tumors, and KS is no exception. In fact, KS is characterized by prominent vascularization, and key histologic features of the lesions include extravasated erythrocytes around new vessels and slit-like vascular spaces running alongside normal dermal vessels. These slit-like spaces are abortive vascular structures formed by the KS tumor cells. Interestingly, because the tumor cells may be of endothelial origin, mediators of angiogenesis also may function as growth factors for these cells. Indeed, many of the cytokines known to induce KS cell proliferation (including HGF, VEGF, bFGF, IL-8) are also key mediators of angiogenesis. KS cells also express the necessary receptors for these proteins including the HGF receptor *c-Met*, VEGFR2, and VEGFR3. Expression of VEGFR1 (FLT-1) has been reported by some groups, but was not confirmed by others (35,36).

VEGF and bFGF have been the focus of many studies in KS, because they appear to be particularly important in KS initiation and progression. High levels of both VEGF and bFGF are found in KS lesions, although circulating levels of only bFGF, not VEGF, are increased in AIDS-KS patients. Elevated levels of these angiogenic factors within the lesions may be related to the presence of inflammatory cytokines in the KS microenvironment that are known to induce both bFGF and VEGF expression (including TNF- $\alpha$ , IL-1 $\beta$ , PDGF, and IFN- $\gamma$ ). Elegant studies by Ensoli and colleagues found that simple overexpression of VEGF and bFGF synergistically induced angiogenic KS-like lesions in nude mice and vascular permeability/edema in guinea pigs (37). Interestingly, VEGF not only induces EC proliferation, but also induces expression of Bcl-2, an important antiapoptotic protein, which may enhance survival of the cells forming the growing vasculature (38). VEGF also stimulates production of MMPs, urokinase-type plasminogen activator, and collagenases by ECs, which are all involved in the breakdown of extracellular matrix. More recently, studies have implicated VEGF in promoting the entry of KSHV into target cells. The Raf oncoprotein, a member of the mitogen-activated protein kinase (MAPK) signaling cascade, induces VEGF expression, which subsequently enhances KSHV infection (39). It is currently unclear how VEGF promotes KSHV infection, although use of pharmacologic agents to block VEGFR1 and VEGFR2 signaling effectively blocked this enhancement.

As already mentioned, AIDS-associated KS is a particularly aggressive form of the disease. Although the immunosuppression caused by HIV-1 infection is clearly involved, studies

implicate a role for factors other than immune dysregulation. One potentially important factor is the HIV-1 encoded Tat protein. Extracellular Tat has been implicated in promoting angiogenesis, and it functions as a growth factor for KS tumor cells. Tat synergizes with bFGF, but not VEGF, to induce angiogenic KS-like lesions characterized by EC proliferation and migration in vivo (40). Studies indicate this interaction involves engagement of the integrin receptors  $\alpha 5\beta 1$  and  $\alpha v\beta 3$  by Tat, as the blockade of the RGD (arginine-glycine-aspartic acid)-binding site in  $\alpha v\beta 3$  inhibits lesion formation in mice in response to bFGF and Tat (41).

Recent studies have focused on the role of KSHV and KSHV-encoded proteins in promoting angiogenesis. KSHV-infected ECs express higher levels of VEGF, VEGFR1, VEGFR2, and VEGFR3 than do uninfected controls. Blockade of VEGF or VEGFR with antibodies or antisense oligonucleotides inhibited proliferation of KSHV-infected ECs (42). As already mentioned, KSHV-vGPCR has been shown to activate the MAPK signaling cascade resulting in VEGF expression. KSHV-vGPCR also induces constitutive activation of nuclear factor (NF)- $\kappa$ B and signaling activator protein (AP)-1 transcription factors. This was associated with expression of NF- $\kappa$ B-dependent cytokines such as IL-1 $\beta$ , IL-6, TNF- $\alpha$ , IL-8, and the AP-1-dependent bFGF. Moreover, transgenic mice expressing vGPCR under control of the *CD2* promoter developed angioproliferative lesions in the ears, tail, nose, and paws (43). These lesions strongly resemble human KS on gross and microscopic examination. Despite these exciting findings, many questions remain. The human *CD2* promoter targets gene expression to hematopoietic cells, and these transgenic mice express vGPCR only in natural killer cells and T-lymphocytes. These cells are not infected with KSHV in human disease, which complicates interpretation of the results. Furthermore, vGPCR is expressed only during lytic reactivation of the KSHV lifecycle and, therefore, can only be detected in less than 5% of cells within the lesion. It is currently unknown if expression in this small subset of cells can have a significant paracrine effect on latently infected neighboring tumor cells; however, some studies indicate that vGPCR can promote the tumorigenic potential of viral latent genes.

Several other KSHV-encoded proteins also appear to induce VEGF. Expression of vIL-6 in NIH-3T3 cells resulted in tumor formation in mice that was more vascularized than in control tumors. Enhanced VEGF expression could also be detected in these animals (34). KSHV also encodes for three chemokine homologues vMIP-I, vMIP-II, and vMIP-III. All three proteins have been shown to stimulate angiogenesis (44).

## ANTIANGIOGENIC AGENTS AS A THERAPEUTIC OPTION FOR KAPOSI'S SARCOMA

Currently, no cure exists for KS. Radiation, cryotherapy, and chemotherapy are generally used for localized lesions, whereas systemic chemotherapy is necessary for disseminated disease. A need clearly exists for more effective, less toxic therapies,

and antiangiogenic agents represent an attractive therapeutic target for patients with KS (as well as other cancers).

Around the time HAART therapy (including protease inhibitors) became widely used in the treatment of HIV-1 disease, the incidence of KS decreased dramatically in the United States. Although protease inhibitors were designed to specifically block the HIV-1 lifecycle and prevent virion production, studies have shown that protease inhibitors also block bFGF- and VEGF-induced angiogenesis by inhibiting MMP-2 proteolytic activity (45). MMP-2 is critical in degrading the basement membrane, and inhibition of this enzyme appears to block endothelial and KS cell invasion and prevent angiogenesis. Given this effect on neovascularization as well as the overall improvement in immunocompetence, it is understandable why HAART therapy/protease inhibitors have become a first-line therapeutic option for AIDS-related KS.

Similarly, studies have been initiated or recently completed to identify other therapeutic agents that target various aspects of angiogenesis. Clinical trials are currently underway for thalidomide, an agent that likely inhibits angiogenesis through several different mechanisms. Studies have shown that thalidomide blocks bFGF and VEGF effects, inhibits TNF- $\alpha$  synthesis, blocks NF- $\kappa$ B activation, downregulates adhesion molecule expression, stimulates T cells, and inhibits IL-6 and IL-12 production. In a phase II clinical study, 35% of AIDS-KS patients had a partial response, with 60% of those patients showing significant reductions in KSHV viral load (46). In another phase II trial, eight of 17 of patients (47%) had a partial response, and an additional two patients had stable disease (47). Unfortunately, not all antiangiogenesis agents have shown such promising results. Despite exciting preclinical and phase I results, TNP-70 (fumagillin, an inhibitor of methionine aminopeptidase, which is critically important for EC proliferation and angiogenesis), SU5416 (a VEGFR2 inhibitor), and IM862 (a dipeptide with antiangiogenic properties) were determined ineffective in phase II and phase III trials. It has been suggested that the problem may be that VEGF is more important during early tumor growth, when vessels are developing, than in tumors with established vasculature. Additional agents continue to be tested in preclinical studies with KS tumor cells (the prominent angiogenesis in these models is ideal for initial tests), while other agents are in clinical trials for other cancers. The most promising of these agents is bevacizumab, a humanized monoclonal antibody against VEGF, which in combination with standard chemotherapy has recently been approved by the U.S. Food and Drug Administration for colorectal cancer (48).

#### KEY POINTS

- KS is a potentially life-threatening neoplasm characterized by spindle-shaped tumor cells and prominent angiogenesis. The tumor cells are believed to be

derived from either vascular or lymphatic endothelium.

- The tumor cells are somewhat unique in that the cytokine-rich microenvironment of KS provides growth factors that not only promote tumor cell proliferation, but also induce angiogenesis.
- KSHV, a human herpesvirus, is believed to be the etiologic agent responsible for KS. Virally encoded homologues of human proteins appear to play a key role in promoting expression of cytokines that function in an autocrine and paracrine fashion to promote tumor and EC growth and proliferation.
- Although angiogenesis is necessary for all tumors to grow and metastasize, KS is characterized by prominent vascularization, making antiangiogenic therapies particularly attractive targets for treating this neoplasm. Clinical trials are in progress to test this possibility.

#### ACKNOWLEDGMENT

Due to page limitations, the author was unable to cite all of the important primary literature that is discussed in this chapter. This work was supported in part by a grant from the National Institutes of Health/National Cancer Institute CA108450.

## Endothelial Mimicry of Placental Trophoblast Cells

Hartmut Weiler and Rashmi Sood

*Blood Center of Wisconsin, Blood Research Institute, Milwaukee*

The placenta has evolved as a specialized organ in a subgroup of mammals to enable the prolonged intrauterine development of the fetus. It is a gender-specific and transitory organ that is essential for the exchange of nutrients and metabolites between the circulatory systems of the mother and fetus. The vascular bed of the placenta is established *de novo* at the onset of pregnancy, and regresses after delivery. The tissue mass of the placenta comprises both maternal and fetal elements. As a result of the so-called *hemochorial* type of placentation observed in humans, the vascular space containing maternal blood in the placenta is lined by two different types of cells: endothelial cells (ECs) of maternal origin and trophoblast cells of fetal origin. On the other hand, fetal blood vessels emanating from the embryo/fetus into the placental tissue remain intact, and fetal and maternal blood therefore remains segregated. Thus, whereas in all other vascular beds the blood vessel endothelium is the principal gatekeeper between tissue and blood, in the placenta a different cell type, the trophoblast cell, occupies part of the interface between (maternal) blood and (fetal) tissue. By their particular anatomical position at the blood–tissue boundary, trophoblast cells are equivalent to ECs in other organs, and fulfill EC-like functions. The concept of *endothelial mimicry* by trophoblast cells was initially coined to describe a remarkable process of remodeling of the maternal arteries supplying blood to the placenta, during which so-called *endovascular* fetal trophoblast cells replace the maternal endothelium in these arteries and induce an erosion of smooth muscle cells regulating the vascular tone of these arteries. It is now evident that not only endovascular trophoblast cells, but other fetal trophoblast cells in the placenta, adopt EC-like properties that allow them to function in a similar fashion to ECs in other segments of the vascular tree. Thus, in the vascular bed of the placenta, one encounters cellular and genetic heterogeneity of the vascular lining that is (under normal physiological conditions) not found anywhere else in the body. This unique architecture may underlie highly vascular bed–specific pathologies that emerge only during pregnancy and are caused by the failure of trophoblast cells to fulfill EC-like functions.

### ENDOTHELIAL MIMICRY BY ANATOMICAL LOCATION

Successful implantation of the blastocyst-stage embryo into the uterine wall triggers proliferation and differentiation of maternal stromal cells in the wall of the uterus. This results in a thickening of the uterine wall, in which the embryo then becomes embedded. This process of decidualization is accompanied by the growth of new blood vessels that extend from existing uterine arteries toward the site of implantation to deliver maternal blood to the embryo. A characteristic feature of placentation in humans is that maternal blood vessels supplying the decidua lose or fail to maintain their integrity, resulting in an “open-ended” circulation exposing the outermost layer of the implanted blastocyst to direct contact with maternal blood. This type of placentation is termed *hemochorial*. The outermost fetal cell population is represented by trophoblast cells derived from the fetal trophoblastoderm (TE). This cell population emerges as the result of the very first developmental lineage allocation in embryogenesis. This allocation specifies three cell populations in the blastocyst around the time of implantation: TE, primitive endoderm (PE), and the epiblast (EPI). The latter two constitute the inner cell mass (ICM), which contains the pluripotent embryonic stem cell population that gives rise to the embryo itself; PE gives rise to extraembryonic membranes (amnion, chorion), and TE is the source of all the trophoblast derivatives that establish the fetal aspect of the future placenta. For reviews of early postimplantation development, see Refs. 1–4.

Around the second week of pregnancy, the conceptus is surrounded by an outer layer of trophoblast cells that have fused into a multinucleated syncytium to form the syncytiotrophoblast. The syncytiotrophoblast layer is the first to be in contact with maternal blood, and it remains the principal fetal cell type at the blood–tissue interface. Between the second and third week of gestation, cytotrophoblast cells underlying the syncytium organize into columns (villi) that expand

Figure 160.1. Schematic representation of the vascular bed in the placenta. Maternal blood reaches the intervillous space through spiral arteries (*arrows* indicating the principal flow of blood). These vessels are remodeled through interaction with trophoblast cells (endovascular trophoblasts) that migrate out from the tip of anchoring villi and eventually line the terminal segments of the arteries. The surface of the fetal villi exposed to maternal blood is covered by trophoblast cells. Fetal blood vessels are always lined by an intact fetal endothelium. Blood exits through maternal veins into the cavernous sinus within the decidua. As a result, the lining of the intervillous space filled with maternal blood is made up almost exclusively of fetal trophoblast cells.

into the decidua. Initially, the columns consist entirely of cytotrophoblast (primary villi). Extraembryonic mesenchyme penetrates the primary villi and forms the core of the cytotrophoblast columns (secondary villi). By the third week, the villi expand into the spaces filled with maternal blood (lacunae), and the mesenchymal core of the columns is vascularized by fetal blood capillaries (tertiary villi), which are contiguous with the umbilical vessels. Villi that make direct contact with decidual tissue of the mother are termed *anchoring villi* (Figure 160.1).

As a consequence, the peculiar anatomy of hemochorial placentation creates a vascular bed in which the lining of the maternal blood space is comprised of ECs lining the maternal blood vessels leading into the placenta and of fetal trophoblast cells covering the surface of the placental villi. This heterogeneity with respect to cellular and genetic composition is unique to the vascular bed of the placenta.

#### ENDOVASCULAR TROPHOBLAST AND REMODELING OF MATERNAL ARTERIES

Maternal blood is supplied to the placenta through radial arteries that emanate from the arcuate blood vessels of the uterine

wall. As they enter the decidua, the former become coiled spiral arteries from which blood flows into blood lacunae into which the trophoblastic villi protrude. During the course of pregnancy, the morphology and functional properties of these supplying arteries change dramatically. These alterations are brought about in part by the interaction of spiral arteries with a specialized subpopulation of trophoblast cells, the invasive extravillous trophoblast. These trophoblast cells invade the maternal decidua from the tip of anchoring villi. Some of the extravillous trophoblast cells remain in the interstitium of the decidua, while others invade the distal portions of the spiral arterioles closest to the site of implantation. Initially, the latter form clusters of “endovascular” trophoblasts, which plug the outlets of the spiral arteries and, in this way, suppress flow through these arteries. It is thought that this “clogging” of maternal blood vessels sustains a state of relative hypoxia within the deep placental bed, which could in theory support or sustain an initial, hypoxia-driven burst of vascularization of the villi by fetal capillaries. Gradual resolution of endovascular trophoblast clusters, which may involve apoptosis, coincides with the onset of measurable blood flow in the placental bed at around 3 months into gestation.

After the onset of flow, spiral arteries undergo a remodeling process that results in the dilation of these vessels, loss of

elasticity and vasomotor control, loss of vascular wall smooth muscle cells, and invasive replacement of maternal ECs by fetal trophoblasts. The dilation and erosion of smooth muscle cells does not appear to depend on direct trophoblast–vessel interactions, but could be triggered by nitric oxide (NO) and/or other mediators released from remote trophoblast cells or by uterine lymphocytes, in particular a specific subset of so-called uterine natural killer cells. The mechanisms governing the evident tropism of endovascular trophoblasts toward arteries, as opposed to the venous segment of the maternal vessels, are largely unknown, and might involve chemokine signals released from platelets adhering to the terminal segments of the arteries (5), and/or cell–cell interactions mediated by the ephrin/ephrin-receptor system expressed by trophoblast cells and the vascular endothelium (6,7). The population of the spiral artery lumen and wall with endovascular trophoblasts is accompanied by a switch in the expression of adhesion receptors. Cytotrophoblast cells giving rise to endovascular trophoblast cells produce typical epithelial adhesion markers, such as E-cadherin and  $\alpha 6\beta 4$  integrin. In contrast, the trophoblast cells replacing the endothelium of spiral arteries downregulate these receptors, and switch to expressing typical EC adhesion molecules, such as vascular endothelial (VE)-cadherin, platelet-endothelial cell adhesion molecule (PECAM)-1, and  $\alpha V\beta 3$  integrin, as well as sialyl Lewis X (sLe<sup>x</sup>) (NeuAc $\alpha 2$ –3Gal $\beta 1$ –4[Fuc $\alpha 1$ –3]GlcNAc $\beta 1$ –) carbohydrate moieties, which might engage E- and P-selectins present on resident endothelium (8). The adoption of an EC-like adhesion receptor phenotype has been termed *endothelial mimicry*, or *epithelial–endothelial transformation* (9,10). It is thought that the sum of these alterations in the structure of the spiral arteries enhances maternal blood flow to the placenta, and – more importantly – uncouples the regulation of blood flow into the placental vascular bed from maternal vasomotor control.

Much of the interest in the molecular basis of the remodeling of uterine arteries and the consequences for placental perfusion has been fueled by the single most devastating disease of pregnancy, preeclampsia. In general, it is thought that the disease is the result of defective fetomaternal interactions regulating the perfusion of the placenta, including those summarized here. Abnormally low perfusion may trigger the release of trophoblast-derived signals into the systemic vasculature, which then cause the various pathologies characteristic of preeclampsia. The current knowledge about this disease is summarized in Chapter 161.

#### TROPHOBLAST CELLS REGULATE HEMOSTASIS AT THE FETO-MATERNAL INTERFACE IN AN ENDOTHELIAL-LIKE MANNER

The anatomical location of trophoblast cells places them in direct contact with maternal blood. In virtually all nonplacental organ systems, a major function of the blood vessel endothelium is to maintain a noncoagulant surface. Nor-

mal endothelium expresses a wide spectrum of molecules that proactively suppress the activity of the coagulation system and various aspects of platelet function. A survey of the literature provides ample evidence that trophoblast cells maintain an anticoagulant expression profile similar to that of ECs (Table 160-1). This comprises gene products that mediate intravascular hemostasis, including regulators of blood coagulation thrombomodulin (TM); endothelial protein C receptor (EPCR), the inhibitor of coagulation initiation tissue factor pathway inhibitor (TFPI)-1; the ectoenzyme ecto-ADPase/CD39, which suppresses ADP-dependent platelet activation; the thrombin inhibitor protease nexin (PN)-1; and the anticoagulant annexin V; fibrinolytic regulators such as urokinase-type plasminogen activator (u-PA), tissue-type plasminogen activator (t-PA), and plasminogen activator inhibitor (PAI)-1; and regulators of vascular tone and leukocyte interactions (including inducible NO synthase [iNOS], prostacyclin synthase, cyclooxygenase [COX]-2, and E-selectin).

A systematic analysis of the gene expression program of differentiating mouse trophoblast cells shows that this endothelial-like phenotype is conserved between mice and humans, and that trophoblast cells can acquire the EC-like anticoagulant phenotype in a differentiation-dependent manner in vitro. The differentiation-associated expression of a subgroup of these hemostatic regulators occurs in a concerted fashion, suggestive of a common regulatory mechanism that coordinates their expression during trophoblast differentiation (Figure 160.2; for color reproduction, see Color Plate 160.2).

Trophoblast cells are able not only to regulate the initiation and extent of the blood coagulation reaction, but also sense the presence of activated coagulation factors. Several reports describe the expression of the thrombin receptor protease-activated receptor (PAR)-1 in trophoblast cells of the human and mouse placenta, and demonstrate that – at least in vitro – the principal coagulation protease thrombin can modulate the invasiveness and proliferation of human and mouse trophoblast cells (11–14). Likewise, activation of the platelet arm of hemostasis is known to modulate placental function, and soluble mediators released by activated platelets stimulate trophoblast migration and invasion, and induce expression of  $\alpha 1$  integrin (5).

In summary, these observations suggest that the ability to control and sense the activation state of coagulation in the maternal blood space of the placenta is a defining and intrinsic feature of trophoblast cells, akin to that of the endothelium in other vascular compartments.

#### TROPHOBLAST CELLS AND ACTIVATED ENDOTHELIUM

As outlined earlier, the anatomical location of trophoblast cells places them in direct contact with maternal blood. Akin to blood vessel endothelium in other organs, the trophoblastic

**Table 160-1: Hemostasis-Related Genes Expressed by Mouse and Human Trophoblasts**

Gene	Increased during <i>In Vitro</i> Differentiation of Mouse Trophoblast <sup>auo</sup>	<i>In Situ</i> Expression (Refs.)

<i>COX-2</i>	8-fold		

Fold increases in expression are averages of four independent expression profiling experiments, each on trophoblast stem cells and their *in vitro* differentiated derivatives (AUO; authors' unpublished observations). Sites of *in situ* gene expression in developing mouse and human placenta are indicated: TGC, trophoblast giant cells; Lab, labyrinth; ST, spongiotrophoblasts; CT, cytotrophoblasts; SYN, syncytiotrophoblasts; Tr Memb, trophoblast membranes; I tr, invading trophoblasts; endo tr, endovascular trophoblasts; peri tr, perivascular trophoblasts.

lining of the maternal blood space in the placenta produces a battery of gene products that suppress the activation of coagulation and platelets. On the other hand, the placenta is also a rich source of the initiator of coagulation, tissue factor. Surprisingly, tissue factor antigen and, more importantly, procoagulant activity is also detected in syncytiotrophoblast membranes contacting maternal blood (15). Such an expression of tissue factor on cells at the blood–tissue interface is in striking contrast to all other vascular beds, in which tissue factor expression is strictly excluded from ECs. The sequestration of tissue factor from inadvertent contact with blood in a normal, unperturbed blood vessel is essential to prevent initiation of the blood coagulation pathways. However, tissue factor expression in ECs may be induced in response to a variety of stimuli usually associated with the presence of inflammatory challenges. Proinflammatory cytokines, ligands for Toll-like receptors, and the principal coagulation protease, thrombin, not only induce tissue factor expression, but also evoke increased production of adhesion receptors that regulate endothelial–leukocyte interactions. Moreover, these mediators simultaneously suppress the transcription of anticoagulant gene prod-

ucts, most notably endothelial thrombomodulin. This transition of the endothelial phenotype from a noncoagulant and antiadhesive phenotype to a state of enhanced coagulation and leukocyte interactions has been termed *endothelial activation*, and appears to reflect a principal switch in a concerted gene expression program that is under the control of defined transcription factors (16,17). Thus, trophoblast cells exhibit, even under normal conditions, at least one hallmark of activated endothelium – expression of tissue factor. This procoagulant feature of trophoblast cells has functional implications in the manifestation of organ-specific pathologies of dysregulated hemostasis in the placenta (see following sections).

The paradigm of trophoblast cells resembling “activated” endothelium extends to a critical regulator of endothelial–leukocyte interactions, E-selectin. This selectin is found on a subpopulation of trophoblast cells that line, or are in close apposition to, vascular channels of the maternal blood compartment in the decidua, and therefore are likely identical to endovascular trophoblast cells (18–20). E-selectin is an EC-specific lectin whose expression is – akin to tissue factor – induced by proinflammatory cytokines and

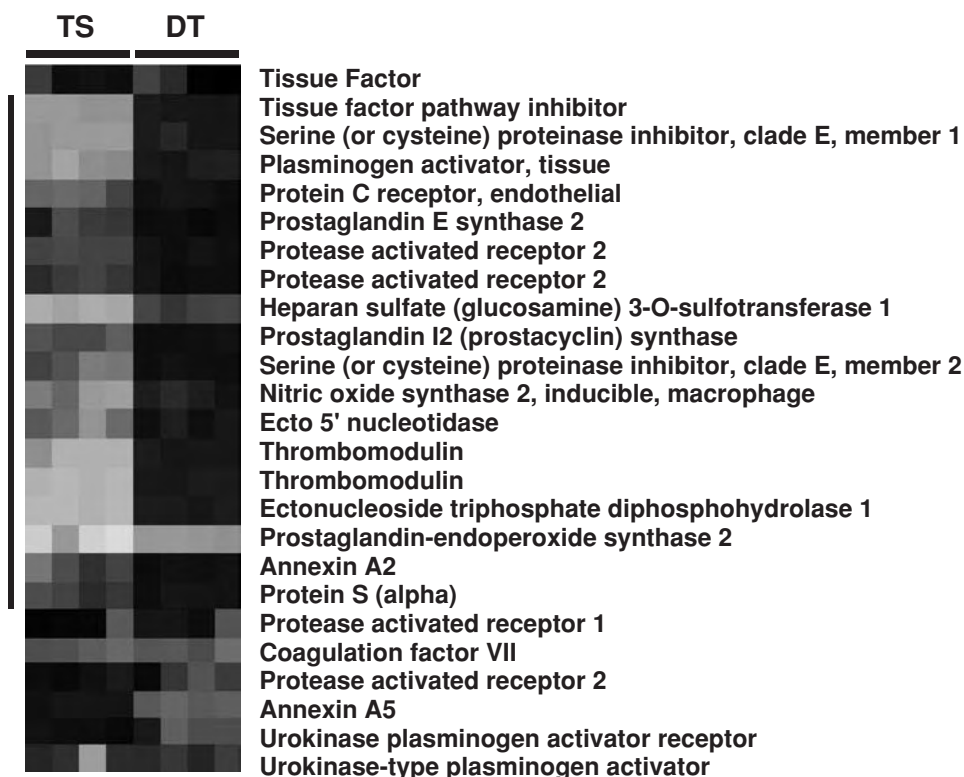

Figure 160.2. Expression of hemostasis-related genes during the in vitro differentiation of mouse trophoblast stem cells. The fetal trophoblast component of the placenta originates from a pool of trophoblast stem (TS) cells that proliferate and give rise to differentiated trophoblast derivatives (DT). This differentiation process of TS cells is recapitulated in vitro. The figure shows the result of a gene chip-based analysis of the changes in mRNA expression of hemostasis-related genes that occur during in vitro differentiation of TS cells. Each gene is represented by a single row of colored boxes; each experiment by a single column. The color of the box represents expression levels in comparison to median expression for that gene in all experiments. Gray represents downregulated (lower than median) expression; dark gray represents upregulated (higher than median) expression; genes unchanged in expression level during differentiation are colored black. Sixteen of the 22 hemostasis-related genes expressed in mouse trophoblasts are upregulated during differentiation, essentially following an “off-on” pattern. For color reproduction, see Color Plate 160.2.

lipopolysaccharide (LPS); E-selectin binds counter-receptors on neutrophils and monocytes and regulates leukocyte recruitment to, and rolling on, activated endothelium. The maternal endothelium lining vascular channels also displays a highly unusual profile of adhesion receptor expression. These maternal vessels display a combination of P-selectin and mucosal addressin cell adhesion molecule (MAdCAM)-1 that appears unique to the placenta (21). E-selectin expression on trophoblast cells, and the peculiar distribution of other leukocyte interaction receptors, may play an important role in allowing the antigenically “foreign” embryo to escape immune rejection by the mother. Theoretically, these adhesion receptors could mediate site-specific homing of leukocyte populations to defined anatomical regions in the placenta. Such an anatomical sequestration, recruitment of specific leukocyte subpopulations, or exclusion of populations with a high potential for allogeneic rejection may, in concert with other well-characterized mechanisms, help to maintain an immunologically permissive environment for the fetal allograft.

**“ENDOTHELIAL DYSFUNCTION” OF TROPHOBLAST CELLS: A CAUSE OF THROMBOPHILIA-ASSOCIATED PREGNANCY COMPLICATIONS?**

Pregnancy is an independent risk factor for the occurrence of venous thrombosis in the mother. Possibly as a response to the unique physiological challenges to the mother during pregnancy and childbirth, the production of coagulation factors is augmented and the activity of the protein C system declines over gestation. These changes lead to heightened hemostatic system activity and produce a physiological procoagulant state in pregnant females (22). Increased activation of the blood coagulation system also may have adverse effects on the health of the fetus: A body of evidence suggests that inherited and acquired thrombophilia of the mother, including defects in the function of the natural protein C anticoagulant pathway, contribute to the pathogenesis of fetal loss at various stages of gestation. A meta-analysis of 31 quality-controlled

epidemiological studies shows that the factor V (fV) Leiden mutation is associated with early and late recurrent fetal loss, and late, nonrecurrent fetal loss; protein S deficiency is associated with recurrent fetal loss; and activated protein C (APC) resistance unrelated to the fV Leiden mutation increases the odds of early recurrent fetal loss by more than threefold (23–25). Thrombophilia also has been associated with obstetric complications other than fetal loss – preeclampsia, intrauterine growth restriction (IUGR), placental abruption, and stillbirth (22).

It is noteworthy that none of these studies assessed the genotype of the fetus. Yet, one would expect that the incidence of fetal loss is increased if the mother's fV Leiden carrier status (rendering the maternal blood resistant to the anticoagulant of APC) coincided with reduced expression or function of thrombomodulin or the protein C receptor EPCR by fetal trophoblast cells (resulting in diminished activation of the mother's protein C at the villus surface). Such a failure of fetal trophoblast cells to sustain the natural protein C anticoagulant mechanism would lead to a vascular bed-specific epistasis of maternal and fetal risk factors that could result in localized coagulation activation in the placenta. Conversely, because of the aforementioned segregation of fetal and maternal circulatory systems, the fV Leiden status of the fetus would only affect the fetal intravascular compartment, but remain without consequence for hemostasis in the maternal blood contacting the placental villi. This concept may be an important issue to consider when evaluating epidemiological data on the association of maternal thrombophilia and fetal loss, because fetal defects in trophoblast function may be a critical modifying risk factor for pregnancy complications in mothers with pre-existing coagulation defects.

Dysfunction of trophoblast cells may also be the mechanism underlying fetal loss associated with the antiphospholipid antibody syndrome (APS). APS is an acquired autoimmune disorder that occurs in patients having elevated levels of antibodies against anionic phospholipid–protein complexes. It is characterized by clinical episodes of venous, arterial, or small-vessel thrombosis. In pregnant women, this syndrome is associated with recurrent spontaneous abortions, premature birth, intrauterine fetal death, preeclampsia, and intrauterine growth retardation (26,27). Up to 20% of women with recurrent miscarriage have laboratory evidence of antiphospholipid (aPL) antibodies (28). Of women with APS, approximately 15% to 20% have obstetric complications, and up to 50% to 75% of their pregnancies have a poor outcome (29,30). Antiphospholipid antibodies are a heterogeneous family of immunoglobulins that recognize a rather wide range of plasma proteins bound to anionic surfaces.  $\beta_2$ -glycoprotein I ( $\beta_2$ GPI), a phospholipid-binding protein, is the major antigenic target for aPL antibodies. Several proteins of the coagulation pathway, including prothrombin, protein C, protein S, EPCR, and annexin V are also targets of aPL antibodies (31–33). Thus, more than one biochemical mechanism may be involved in this syndrome, and both maternal systemic and local fetal components of the placenta are equally likely

targets of the dysregulation and fetal loss induced by aPL antibodies. aPL antibodies inhibit the inactivation of activated factor V (fVa) by aPC on a phospholipid surface (34,35). The term *acquired resistance to APC* has been coined to identify this condition, which is phenotypically very similar to the resistance to aPC seen in fV Leiden patients. aPL antibodies also have been proposed to disrupt the annexin V anticoagulant shield on placental trophoblasts. IgG fraction from APS patient serum reduces annexin V on cultured trophoblasts in vitro, whereas a marked reduction occurs in annexin V expression on syncytiotrophoblasts lining the placental villi in APS patients in vivo (36–38). In vitro studies show that removal of annexin V from the surface of mouse trophoblasts by treatment with ethylene glycol tetraacetic acid (EGTA) accelerates the coagulation of plasma exposed to these cells (39). Infusion of pregnant mice with polyclonal antiannexin V antibodies results in placental infarction and pregnancy wastage (40). The binding of aPL antibodies to  $\beta_2$ GPI leads to activation of cultured ECs, manifested by upregulation of cell surface adhesion molecules and increased secretion of interleukin-6 and prostaglandins. Annexin II, the molecule mediating high-affinity binding of  $\beta_2$ GPI to the endothelial surface, is highly expressed on mouse trophoblast cells and upregulated in differentiated cells characteristic of the chorioallantoic placenta (41). Although the contributions of thrombosis and trophoblast abnormalities in the pathogenesis of APS-associated fetal loss still need experimental demonstration, it is clear that complement activation is an absolute requirement in this process (42). The latter finding was based on the surprising observation that the beneficial effect of heparin treatment in an animal model of aPL-induced fetal loss was not due to heparin's anticoagulant effect, but rather to the intrinsic ability of heparin to inhibit complement activation (43).

Like humans, mice exhibit the hemochorial type of placentation. Despite anatomical differences, the basic architecture of the placental vascular bed and the relation of trophoblast cells to the maternal blood space are identical in both species (2). Analysis of mice with greatly reduced tissue factor activity, and of mice lacking the membrane receptor components of the protein C pathway (e.g., thrombomodulin and EPCR), has provided insight into the role of these coagulation regulators in placental development and function.

First, it was shown that constitutive expression of tissue factor by placental trophoblast cells is essential for normal placental function (44). In mice with greatly diminished tissue factor function, the placenta of tissue factor-deficient mothers carrying embryos with normal tissue factor function contains numerous blood pools in the maternal vascular compartment. If the maternal tissue factor defect coincides with reduced tissue factor function on the fetal aspects of the placenta (as occurs in tissue factor-deficient mothers carrying tissue factor-deficient embryos), pregnancy fails due to fatal hemorrhage of the mother. This clearly shows that normal placental function requires normal maternal *and* fetal tissue factor function.

Second, the analysis of mice lacking thrombomodulin or EPCR showed that the absence of either one protein C pathway component from trophoblast cells resulted in fetal loss at a time point roughly equivalent to the end of the first trimester in human gestation (14,45–47). These observations document that the ability of trophoblast cells to suppress the coagulation reaction in the maternal blood space are critical for placental function.

Third, in a mouse model of maternal thrombophilia secondary to the fV Leiden mutation, fetal loss occurs only if maternal thrombophilia coincides with a fetal defect in the trophoblasts' anticoagulant capacity (H. Weiler, unpublished observations). Mice that are homozygous for the fV Leiden polymorphism only rarely develop spontaneous thrombosis, and they appear able to sustain multiple pregnancies without complications. Likewise, in contrast to mice completely lacking thrombomodulin, mice with reduced thrombomodulin function are viable and show no reproductive abnormalities. However, a fetus that is homozygous for the thrombomodulin defect (which results in reduced ability of trophoblast cells to control coagulation) cannot survive in a mother that is a homozygous fV Leiden carrier (but has nearly normal thrombomodulin function). On the other hand, a fetus that is homozygous for both the fV Leiden mutation and the thrombomodulin defect can develop normally when carried by a mother who is only heterozygous for the Leiden allele. Moreover, the resulting mice are viable and do not appear to develop spontaneous thrombosis. Thus, in the placenta, the epistasis of a maternal fV Leiden defect and reduced fetal thrombomodulin function results in fetal loss, whereas the same gene–gene interaction does not disrupt vascular function in vascular beds other than the placenta. In part, the particular sensitivity of the placental vascular bed may be secondary to the constitutive presence of the blood clotting initiator tissue factor in trophoblast cells.

**KEY POINTS**

- The vascular bed of the placenta exhibits a unique cellular and genetic heterogeneity, in which the blood–tissue interface is comprised of both maternal endothelium and fetal trophoblast cells. These trophoblasts resemble ECs by anatomical localization, and by an endothelial-like ability to regulate hemostasis.
- Maternal arteries supplying blood to the placenta undergo a unique remodeling process that involves loss of smooth muscle cells from the arterial wall and replacement of maternal ECs by invasive “endovascular trophoblast” cells. This remodeling process is essential for the adequate perfusion of the placental vascular bed.

- The hemostatic balance in the placenta is regulated by coagulation factors and platelets in maternal blood, by maternal ECs, and by fetal trophoblast cells. Defects in the trophoblast cells' ability to regulate hemostasis in an EC-like manner are associated with placental pathology and reproductive failure.

**Future Goals**

- To determine the role of trophoblast cells in severe pregnancy complications such as preeclampsia and APS-associated pregnancy loss
- To undertake epidemiological studies required to determine the contribution of fetal trophoblast cell defects in determining the odds for the occurrence of pregnancy complications in pregnant women, especially in women with thrombophilic risk factors

## Placental Vasculature in Health and Disease

S. Ananth Karumanchi and Hai-Tao Yuan

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Vascular development occurs through the processes of angiogenesis and vasculogenesis (1,2). Angiogenesis is the process of neovascularization from pre-existing blood vessels, whereas vasculogenesis is the process of blood vessel generation from angioblast precursor cells. The human placenta undergoes high levels of both angiogenesis and vasculogenesis during fetal development (3). Additionally, the placenta undergoes a process of vascular mimicry (also referred to as *pseudovasculogenesis*), in which the placental cytotrophoblasts convert from an epithelial to an endothelial phenotype during normal placental development (4). When placental vascular development is deranged, serious complications such as intrauterine growth restriction (IUGR) and preeclampsia can occur. This chapter discusses placental vascular development during health and in disease, with an emphasis on the role of placental angiogenic factors in these processes.

### PLACENTAL VASCULAR DEVELOPMENT IN HEALTH

#### Implantation

Placentation, which is characteristic of and specific to mammals, allows for the development of the fetus within a protective maternal environment (5). The placenta provides oxygen ( $O_2$ ) and nutrients to, and transfers wastes from, the developing fetus. The placenta is a highly vascular organ, containing both embryonic and maternal blood vessels (Figure 161.1; for color reproduction, see Color Plate 161.1).

During embryonic development, the blastocyst separates into two cell populations: an outer polarized cell layer (the trophoectoderm) and the nonpolarized inner cell mass. The trophoectoderm gives rise to extraembryonic trophoblasts, whereas the inner cell mass is destined to form the embryo proper.

Implantation of the blastocyst into the uterine wall, which occurs approximately 1 week after fertilization, involves a complex interplay between the trophoblasts and maternal cells. The process involves initial adhesion of the blastocyst to the uterine wall, stable adhesion between blastocyst and uterine epithelium, and invasion of trophoblasts through the epithelial wall.

In some ways, these steps are analogous to those associated with leukocyte transmigration in the postcapillary venules. For example, both processes are dependent on the selectin receptor-counter-receptor interactions (6). The highly proliferative trophoblasts ultimately invade the entire endometrium, the outer one-third of the myometrium, and the maternal circulation. Hypoxia is an important driving force for trophoblast proliferation (7). As trophoblasts invade the uterus, they are exposed to increasing concentrations of  $O_2$ , at which time they exit cell cycle and differentiate.

Successful implantation requires a receptive uterus. Maternal receptivity is orchestrated by a combination of pituitary and ovarian hormones. During this process, the endometrium becomes more vascular. Implantation is associated with increased permeability of these blood vessels. Much of our understanding of these early events during implantation has been inferred from studies in nonhuman primates and rodents (8).

Invading trophoblasts form placental cords or villi. The villi contain an inner (relative to embryo) layer of mononuclear cytotrophoblasts and an outer layer of continuous multinucleated cytoplasm, the syncytiotrophoblast. An important function of trophoblast tissue is to establish a functional circulation as a means of promoting maternal–fetal exchange. The fundamental steps necessary for successful placentation include: (a) trophoblast invasion, (b) vascularization of the trophoblast tissue to establish and maintain a fetoplacental vasculature, and (c) subsequent maternal vascular remodeling to gain uteroplacental circulation. Both vasculogenesis and angiogenesis are involved in placental vascular formation.

#### Placental Vasculogenesis

Syncytiotrophoblasts invade maternal tissue, with the depth of invasion depending on the species, the deepest being in humans. Further development leads to the penetration of cytotrophoblastic cones into the syncytiotrophoblastic mass and the development of lacunae, which eventually becomes the intervillous space. Continuing growth and differentiation

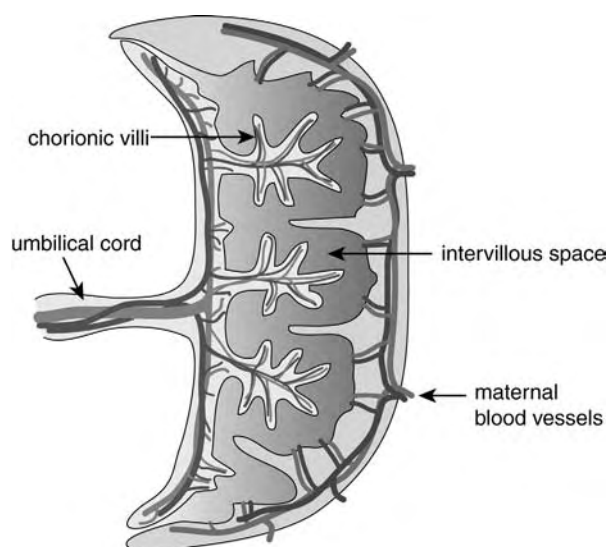

Figure 161.1. A schematic of a normal human placenta depicting the fetal and maternal circulations. For color reproduction, see Color Plate 161.1.

of the trophoblasts leads to branching of the trophoblast villi and the shaping of a placental labyrinth. Extraembryonic mesenchyme gives rise to mesenchymal cores that differentiate and grow into the center of the cytotrophoblast cores. These mesenchymal cells differentiate into endothelial cells (ECs), forming the first capillaries of the fetal placental vasculature. In humans, placental vasculogenesis is evident by approximately embryonic day (E)21 to 22 (3). At this stage, cords of hemangiogenic cells are present, and some demonstrate primitive lumen formation. These cords further develop, so that by approximately E32, most villi show the presence of capillary structures (3).

### Maternal Vascular Remodeling and Placental Pseudovasculogenesis

The formation of the maternal–placental circulation requires remodeling of maternal blood vessels (namely, the spiral arteries). In humans, during the mid to late first trimester, the trophoblasts invade deep into the endometrium and part of the myometrium of the uterus, causing complete remodeling of the upper parts of maternal spiral arterioles. Through the open endings of maternal vessels that are created by trophoblast invasion, maternal blood is released into the placental labyrinth, flows around the trophoblast villi, and is drained by spiral veins (Figure 161.2; for color reproduction, see Color Plate 161.2). When cytotrophoblasts invade maternal spiral arteries, they replace ECs of the maternal spiral arterioles, a process common in all hemochorial placentation. During this process, the endovascular cytotrophoblasts convert from an epithelial to endothelial phenotype, a process termed *pseudovasculogenesis* or *vascular mimicry* (Figure 161.2) (see Chapter 160) (4). This process involves cytotrophoblast stem cells losing epithelial markers, such as E-cadherin and  $\alpha6\beta3$  inte-

grin, and gaining expression of endothelial markers, including vascular endothelial (VE)-cadherin and  $\alpha v\beta 3$  integrin (4,9).

In addition to replacing maternal ECs, cytotrophoblasts also remodel the highly muscular tunica media of spiral arterioles, a process that requires matrix metalloproteinase (MMP)-9 (10,11), which then transforms the highly resistant maternal vessels into larger capacitance vessels with low resistance (see Figure 161.2) (12). Uterine blood flow during pregnancy increases more than 20-fold; the functional consequence of spiral arteriole remodeling is to maximize the capacity of the materno-placental circulation and to provide sufficient blood supply for placenta and fetus at low blood pressure (13). During intrauterine pregnancies, spiral arteries from both the implantation and nonimplantation regions display these physiological changes, although the mechanisms for these changes remain unknown (14). Placental  $O_2$  tension has been suggested to be one of the major regulators of cytotrophoblast migration and differentiation (7). It also has been hypothesized that decidual natural killer (NK) cells and/or activated macrophages may play a role in the vascular remodeling noted during pregnancy, but definitive evidence for this theory is lacking.

### Fetal Circulation and Placental Villous Angiogenesis

The fetal circulation enters the placenta via the umbilical vessels embedded within the umbilical cord. Inside the placenta, fetal circulation branches successively into units within the cotyledons and then into capillary loops within the chorionic villi. From E32 until the end of the first trimester, the endothelial tube segments formed by vasculogenesis in the placental villi are transformed into primitive capillary networks by the balanced interaction of two parallel mechanisms: (a) elongation of pre-existing tubes by nonbranching angiogenesis, and (b) ramification of these tubes by lateral sprouting (sprouting angiogenesis). A third process, termed *intussusceptive microvascular growth*, rarely contributes. In the third month of pregnancy, some of the centrally located endothelial tubes of immature intermediate villi achieve larger diameters of 100  $\mu\text{m}$  and more. Within a few weeks, they establish thin media- and adventitia-like structures by concentric fibrosis in the surrounding stroma and by differentiation of precursor smooth muscle cells expressing  $\alpha$ - and  $\gamma$ -smooth muscle actins in addition to vimentin and desmin. This is followed soon after by the expression of smooth muscle myosin (3,15). These vessels are forerunners of villous arteries and veins.

From week 25 postconception until term, patterns of villous vascular growth switch from prevailing branching angiogenesis to a prevalence of nonbranching angiogenesis. Analysis of proliferation markers at this stage reveals a relative reduction of trophoblast proliferation and an increase in endothelial proliferation along the entire length of these structures, resulting in nonsprouting angiogenesis by proliferative elongation. The final length of these peripheral capillary loops exceeds 4,000  $\mu\text{m}$  (16,17). They grow at a rate that exceeds that of

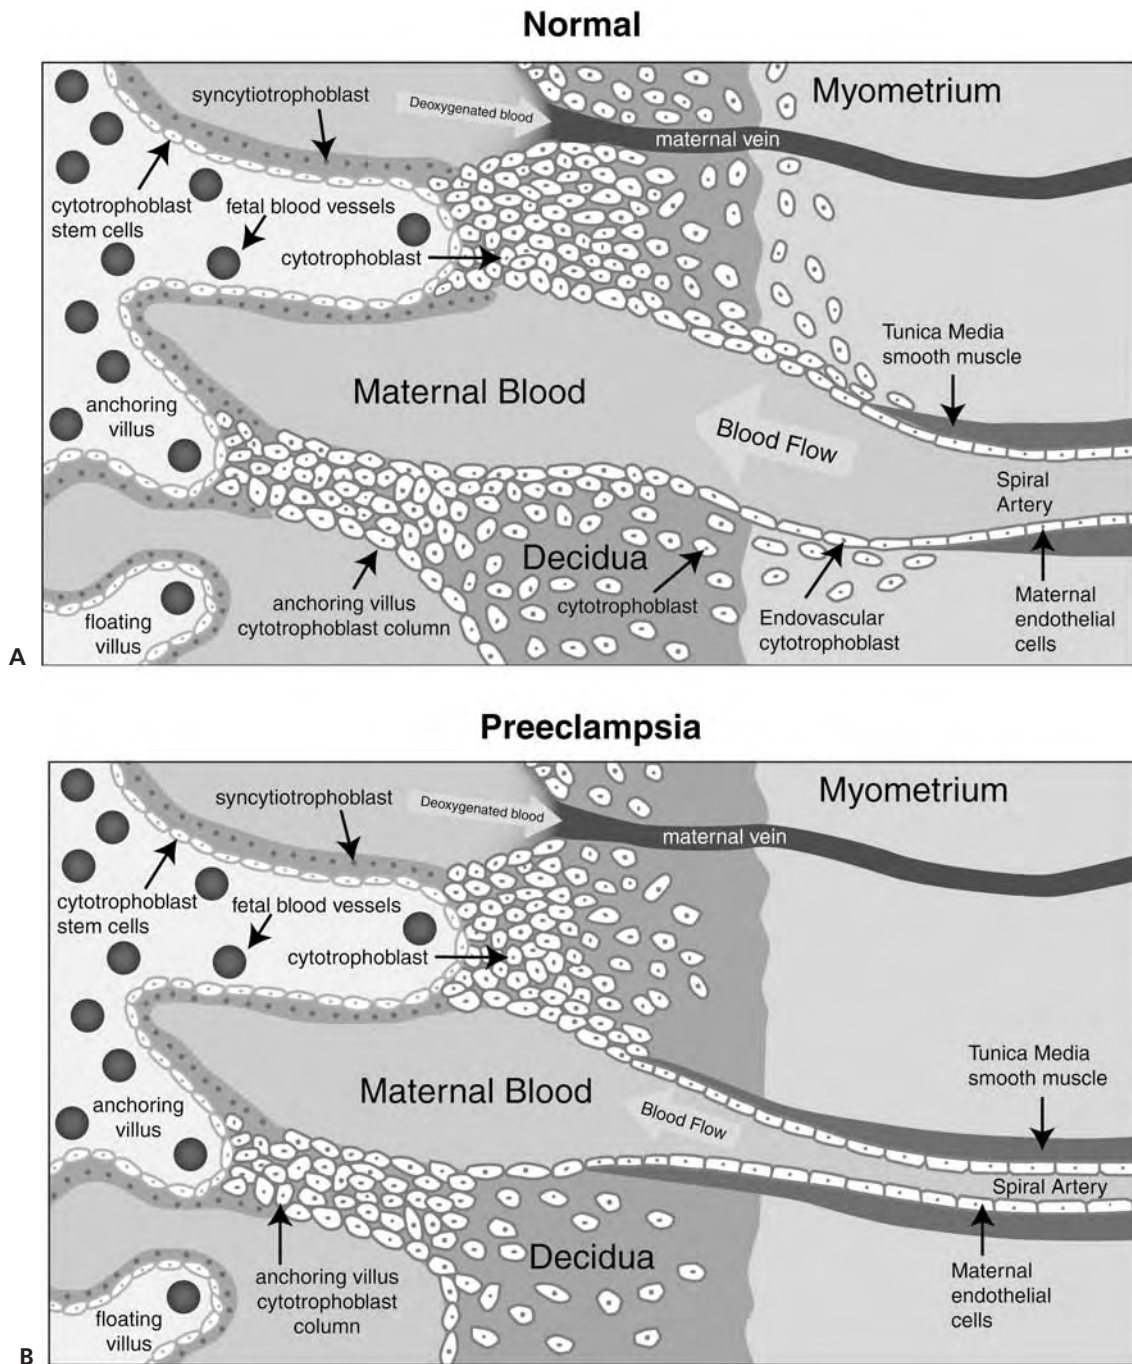

Figure 161.2. A schematic of placental vascular remodeling in health (*upper panel*) and in disease, preeclampsia (*lower panel*). Exchange of  $O_2$ , nutrients, and waste products between the fetus and the mother depends on adequate placental perfusion by maternal vessels. In normal placental development, invasive cytotrophoblasts of fetal origin invade the maternal spiral arteries, transforming them from small-caliber resistance vessels to high-caliber capacitance vessels capable of providing placental perfusion adequate to sustain the growing fetus. During the process of vascular invasion, the cytotrophoblasts differentiate from an epithelial phenotype to an endothelial phenotype, a process referred to as *pseudovasculogenesis* (*upper panel*). In preeclampsia, cytotrophoblasts fail to adopt an invasive endothelial phenotype. Instead, invasion of the spiral arteries is shallow, and they remain small-caliber, resistance vessels (*lower panel*). This is thought to lead to placental ischemia and secretion of antiangiogenic factors. (Reproduced with permission from Lam C, Lim KH, Karumanchi SA. Circulating angiogenic factors in the pathogenesis and prediction of preeclampsia. *Hypertension*. 2005;46:1077–1085.) For color reproduction, see Color Plate 161.2.

the villi themselves, resulting in coiling of the capillaries. The looping capillaries bulge toward, and protrude into, the trophoblastic surface and thereby contribute to formation of the terminal villi. Each of the latter is supplied by one or two capillary coils and is covered by an extremely thin ( $<2 \mu\text{m}$ ) layer of trophoblast that contributes to the so-called *vasculosyncytial membranes*. These are the principal sites of diffusional exchange of gases between mother and fetus. Normally, the capillary loops of five to ten such terminal villi are connected to each other in series by the slender, elongated capillaries of the central mature intermediate villus.

The fetal vessels (chorionic vessels) from the individual cotyledons of the placenta unite at the placental surface to form the umbilical vessels that then traverse in the umbilical cord. The umbilical cord consists of one vein and two arteries (see Figure 161.1). The connective tissue surrounding these vessels in the umbilical cord is referred to as *Wharton jelly*. Most umbilical cords are twisted at birth, probably related to fetal activity in utero. The umbilical vein carries the oxygenated blood from the placenta to the fetus and the umbilical arteries carry the deoxygenated blood back to the placenta. The umbilical vein was the first tissue used to derive ECs for cell culture studies (18), and these cells continue to date as the most common primary ECs used in vascular biology research. The ECs of the umbilical veins and arteries are unusually rich in organelles, which are not usually noted in vessels elsewhere in the body. Furthermore, the umbilical veins lack vasa vasorum, a finding probably related to the oxygenated blood that it carries.

### Vascular Growth Factors and Inhibitors During Normal Placental Development

Placental vascularization involves a complex interaction of several regulatory factors. The list of pro- and antiangiogenic molecules thought to play a role in placental vascular development is expanding exponentially (Table 161-1) and has been reviewed in detail elsewhere (19), but the families of vascular endothelial growth factor (VEGF) and angiopoietins (Angs) gene products have been most extensively studied.

As discussed in Chapter 32, VEGF-A was initially defined, characterized, and purified for its ability to induce vascular leak and permeability, as well as for its ability to promote vascular EC proliferation (20,21). The members of this family include VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). VEGF-A is an endothelial-specific mitogen and a survival factor that exists in four isoforms: VEGF-A<sub>121</sub>, VEGF-A<sub>165</sub>, VEGF-A<sub>189</sub>, and VEGF-A<sub>206</sub>. Inactivation of a single *VEGF* gene resulted in embryonic lethality in heterozygous embryos at E11 to 12, and significant defects in placental vasculature were observed, implicating VEGF in placental vascular development (22). The high-affinity receptor tyrosine kinases for VEGF-A include FLT-1 (also referred to as VEGFR1) and kinase-insert domain-containing receptor (KDR, human/FLK1, murine), also known as VEGFR2 (23). KDR mediates the major growth and permeability actions of

VEGF, whereas FLT-1 may have a negative role, either by acting as a decoy receptor or by suppressing signaling through KDR. PlGF was the first VEGF relative identified that was found to be abundantly expressed in the placenta, and it acts by binding to FLT-1 but not KDR (24). Although PlGF can potentiate the angiogenic activity of VEGF, reproduction was not affected in mice with an isolated *PlGF*<sup>-/-</sup> genotype, and no placental or embryonic angiogenesis defects were reported (25,26). VEGF-C and VEGF-D, based on their ability to bind the lymphatic-specific FLT-3 receptor (also known as VEGFR3), seem to be important for lymphatic development (27,28). Alternative splicing of *FLT-1* results in the production of an endogenously secreted antiangiogenic protein referred to as soluble FLT-1 (sFLT-1), which lacks the cytoplasmic and transmembrane domain but retains the ligand-binding domain (Figure 161.3) (29). Thus, sFLT-1 can antagonize VEGF and PlGF by binding to them and preventing interaction with their endogenous full-length receptors (29,30). Increased production of sFLT-1 has been shown to play a pathogenic role in the severe endothelial dysfunction in preeclampsia (discussed later).

The Tie2 receptor binds a family of ligands termed *angiopoietins*, of which there are four members (Ang1 to Ang4). Ang1-mediated activation of Tie2 promotes endothelial survival and capillary sprouting (31–33). The effects of

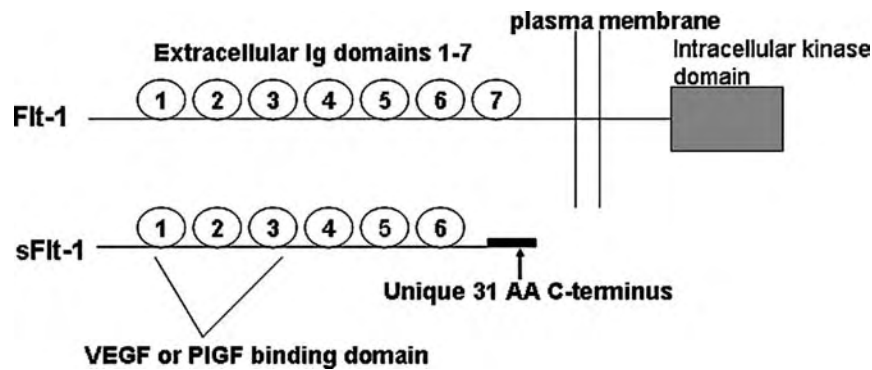

Figure 161.3. The protein structures of FLT-1 and sFLT-1 are illustrated. FLT-1 has seven immunoglobulin domains (IgG), which are thought to mediate ligand binding to VEGF and PlGF. sFLT-1 protein has a unique 31-AA C-terminus region derived from alternative splicing, and lacks the transmembrane and cytoplasmic domains. (Reproduced with permission from Karumanchi SA, Lim KH, Sukhatme VP, August P, eds. *Pathogenesis of preeclampsia*. Wellesley, MA: UpToDate; 2005.)

Ang1 and VEGF on sprouting are synergistic (31). In addition to its direct effects on ECs, Tie2 activation has been reported to induce maturation of adjacent smooth muscle and pericyte precursors via paracrine action of endothelial-derived factors such as platelet-derived growth factor (PDGF)-B (34). Ang1 also has been shown to inhibit capillary permeability (35,36), preventing plasma leakage in response to VEGF. In the presence of abundant VEGF, Ang2 is thought to destabilize vascular networks and facilitate sprouting, as during tumor growth (37,38). Conversely, with low ambient VEGF levels, Ang2 may cause vessel regression, as in corpus luteum involution (39).

Although few *in vivo* functional studies in humans demonstrate how placentation is regulated on a molecular basis by vascular growth factors, current knowledge about the expression patterns of angiogenic factors provides insights into potential molecular regulatory processes. In all primates studied to date, including humans, VEGF and its receptors have been localized in the placenta during early pregnancy, at the time when the syncytiotrophoblast penetrates maternal tissue, before vascular development and remodeling takes place. VEGF is expressed in maternal decidual cells (40–42) and in invading cytotrophoblasts (41,43). Early in gestation, of the two VEGF receptors, only FLT-1 expression is localized in the invading extravillous trophoblast (40,41,44). These observations raise the possibility that VEGF–FLT-1 interactions contribute to early trophoblast invasion. Later in gestation, within the trophoblast tree or columns (see Figure 161.2), VEGF is localized to cytotrophoblast cells (40,43,45), and FLT-1 to extravillous trophoblasts (40,43,45,46). This pattern suggests that, in addition to regulating trophoblast invasion, the VEGF–FLT-1 axis may play an important role in the coordination of trophoblast differentiation and migration. VEGF-A has been demonstrated to induce cytotrophoblast invasion *in vitro*, an effect that is blocked by exogenous sFLT-1 (45). Although homozygous knockout mice for both FLT1 and KDR have been shown to have defective fetal and placental vasculogenesis and angiogenesis (47,48), definitive *in vivo* evidence of impaired trophoblast invasion is still lacking, because the normal inva-

sion of trophoblasts is relatively shallow even at baseline in rodents (49), in contrast to human placentas, in which robust invasion occurs. Recent studies using *in vitro* trophoblast cultures suggest that PlGF and VEGF-C (two related growth factors) also are expressed by the invading cytotrophoblasts and may contribute to cytotrophoblast invasion and differentiation via FLT1 and FLT3 signaling, respectively (50).

The development of the trophoblast tree occurs simultaneously with formation of the fetoplacental vascular system. This latter process involves differentiation and proliferation of fetal ECs, tubule formation, and vessel stabilization. In the majority of studies, the KDR receptor was found to be exclusively expressed on ECs or mesenchymal cells from which ECs differentiate (40,43,44,46,51), whereas VEGF expression was localized in the trophoblast, indicating that EC differentiation, migration, and proliferation, as the essential steps for building the primary vascular network, are mediated by a VEGF/KDR ligand–receptor pair in a paracrine system.

The angiopoietins also are expressed during the very early placentation period in primates (52), indicating their involvement in the regulation of trophoblast growth. In primates, Ang1 is highly expressed in the syncytiotrophoblast, whereas its receptor, Tie2, is located in the cytotrophoblast (40,43). Similar observations have been made in the human placenta (43,53). Ang1 was shown to stimulate trophoblast growth and migration *in vitro* (53). *Ang1* gene expression has been found to increase with gestation (40). Thus, Ang1 expression may trigger the in-growth of the cytotrophoblast cones in the syncytiotrophoblast, whereas the relatively higher expression later during placentation may be required for branching of the villi and shaping the labyrinth.

Fetal capillaries within the placental villi are thin-walled, to allow O<sub>2</sub> diffusion, whereas the chorion vessels are stabilized by a thick wall of pericytes, smooth muscle cells, or both to fulfill their task of collecting and draining all fetal placental blood. Tie2 has been shown to be expressed at high levels in the endothelium of chorion vessels, and at low levels in the fetal capillaries of the villi (40). These results suggest that the

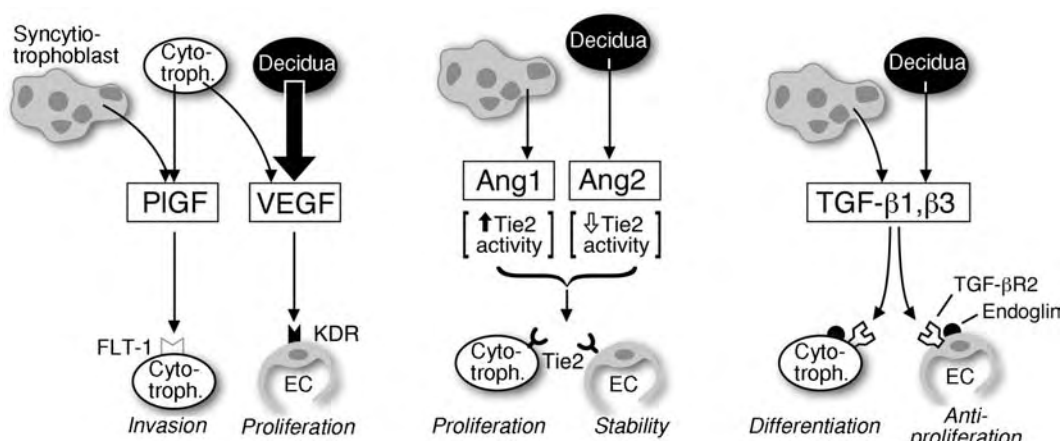

Figure 161.4. Summary of the role of angiogenic factors in placental trophoblast differentiation/invasion and angiogenesis. Cytotroph., cytotrophoblast.

Ang1/Tie2 ligand–receptor pair acts on the fetal vasculature, especially on chorion vessels, to induce stability. In humans, Ang1 expression was found in the media of stem villous vessels at term (53), which is also consistent with its reported role in vessel maturation and stabilization.

Maternal vessels must be remodeled to attain uteroplacental circulation. In humans, the invasion process of the trophoblast is so deep that upper parts of maternal spiral arterioles become completely digested, and the placental labyrinth is filled by the open endings of the spiral arterioles. In humans, Ang2 is localized in the syncytiotrophoblast, whereas Tie2 is expressed in the maternal endothelium (53,54), indicating a paracrine mechanism during maternal remodeling (55). In some mammals, such as rats, invasion is more superficial, and the integrity of maternal vessels is preserved throughout pregnancy. In these animals, maternal vessels form gaps through which maternal blood is released into the labyrinth.

In primates, high expression of *Ang2* mRNA is detected during early gestation, when maternal remodeling mainly takes place. Ang2 is a possible candidate for induction of maternal vascular transformation because it destabilizes the vasculature (39). This destabilization process is a local event, which may be driven by Ang2/Tie2. In humans, although the remodeling process of maternal vessels may be supported by Ang2/Tie2, it is mainly driven by the aggressive trophoblast invasion. Finally, transforming growth factor (TGF)- $\beta$ 1 and -3, two angiogenic proteins made by the maternal decidua and the syncytiotrophoblasts, have been shown more recently to also affect cytotrophoblast invasion and differentiation through endoglin signaling (56,57).

In summary, abundant evidence supports a role for angiogenic growth factors in hemochorial placentation in human and nonhuman primates. The most comprehensive study investigating both growth factor families, VEGF and angiopoietins, and their receptors during early, mid, and late pregnancy has been undertaken in marmoset monkeys, and the study indicates a tight spatial and temporal regulation of diverse developmental processes during placentation by angiogenic

inducers (40,52). In accordance with these reports, it has been specifically hypothesized that VEGF/FLT-1 and Ang1/Tie2 may be involved in trophoblast differentiation and invasion; VEGF/KDR and Ang1/Tie2 may trigger fetoplacental vascular development, whereas Ang2/Tie2 may support the remodeling processes of the maternal vasculature (Figure 161.4) (40).

In contrast to proangiogenic proteins, little attention has been paid to the characterization of antiangiogenic proteins in the placenta. The first major endogenous inhibitor of angiogenesis that has been known to be made in abundant quantities in the placenta is sFLT-1, a potent circulating antiangiogenic molecule (58). This potent antiangiogenic molecule is abundantly expressed by the cytotrophoblasts, and goes up in expression with increasing gestation (29,30) (see Figure 161.3). Other antiangiogenic proteins that have been found to be expressed in the placenta include thrombospondin-1, endostatin, and prolactin. However, the precise role of these proteins during normal placentation is unclear. In general, early on in pregnancy, the proangiogenic proteins are overexpressed and probably account for placental angiogenesis and the increase in placental mass that accompanies fetal development (59). Toward the end of pregnancy, antiangiogenic factors increase in expression, possibly in preparation for delivery (59). In addition to the gestational age-dependent distribution of these proteins, spatial differences also occur in the expression of the angiogenic proteins in the human placenta. For example, at term, placental extracts derived from the decidual side have been found to have stronger antiangiogenic activity, as compared with chorionic villus extracts (60).

## PLACENTAL VASCULAR DEVELOPMENT IN DISEASE

As discussed earlier, during the first two trimesters of pregnancy, the spiral arteries undergo extensive remodeling. This is thought to reduce maternal blood flow resistance and increase uteroplacental perfusion. Abnormal spiral arterial remodeling

is a key pathological feature seen in preeclampsia and in IUGR. In addition, impaired villous angiogenesis is noted in IUGR placentas. Other pregnancy complications, such as placental abruption and intrauterine fetal death (IUFD), also have been hypothesized to be due to defective placental vascular development and coagulation abnormalities; however, the mechanisms mediating these disorders are less well understood.

### Preeclampsia

Preeclampsia occurs in 5% of all human pregnancies (61), and is the leading cause of maternal death in the industrialized world. This condition is characterized by the new onset of hypertension and proteinuria, developing after 20 weeks of gestational age. Variant forms of preeclampsia include eclampsia, which is characterized by grand mal seizure; and HELLP syndrome, which is manifested by hemolysis, elevated liver enzymes and low platelet count. These latter conditions are associated with life-threatening complications, including cerebral hemorrhage, lung edema, liver hemorrhage, and disseminated intravascular coagulation. Preeclampsia is associated with IUGR and iatrogenic preterm birth of the fetus, resulting in a high risk of early neonatal death and infant mortality or morbidity (61). Current treatment consists of symptom relief and, ultimately, delivery.

A pathophysiological role for the placenta in preeclampsia is supported by the observation that this syndrome occurs solely in the presence of a placenta or a hydatidiform mole, and remits dramatically in the postpartum period after delivery of the placenta (62). The major pathological abnormality in the preeclamptic placenta is insufficient maternal spiral artery remodeling. The decrease in remodeling of the uterine spiral arterioles is thought to be due to defective endovascular invasion by cytotrophoblasts and impaired pseudovasculogenesis (see Figure 161.2) (63,64). The hypothesis that defective trophoblastic invasion with accompanying uteroplacental hypoperfusion may lead to preeclampsia is supported by both animal and human studies. Pathologic examination of placentas from pregnancies with advanced preeclampsia often reveals numerous placental infarctions and sclerotic narrowing of arterioles (65). In one-third to one-half of preeclamptic women however, these changes are not pronounced. Using ultrasound estimation, the uteroplacental blood flow usually is diminished, and uterine vascular resistance usually is increased in preeclamptic women (66). Placental ischemia induced by mechanical constriction of the uterine arteries or the aorta produces hypertension, proteinuria and, variably, glomerular endotheliosis in several animal species (66). However, placental ischemia alone, as seen in many cases of IUGR, does not appear to be sufficient to produce preeclampsia. Thus, although uteroplacental ischemia is an important trigger of preeclampsia, it may be absent in some cases, and the maternal response to placental ischemia is variable.

Studies during the 1980s implicated maternal endothelial dysfunction as a key contributor to the clinical symptoms in preeclamptic patients (67,68). Roberts and colleagues pro-

posed that EC injury caused increased sensitivity to pressor agents, vasoconstriction, and activation of the coagulation cascade as the basis of preeclampsia (69). Evidence of EC injury was provided by the classic renal lesion of preeclampsia – glomerular endotheliosis – in which glomerular capillary ECs are engorged with intracellular inclusions (70). Blood from preeclamptic patients demonstrates markers of endothelial injury, including von Willebrand Factor (71–73), cellular fibronectin (74–76), and thrombomodulin (77,78). Levels of circulating prostacyclins (normally made by healthy ECs) also are decreased in preeclamptic patients (79). Blood vessels from preeclamptic patients reveal decreased endothelial-mediated vasodilator function (80). Data from many studies support the notion that the maternal serum in preeclampsia has soluble factors that mediate endothelial dysfunction. For example, serum or plasma from preeclampsia patients has been shown to alter endothelial phenotype in vitro, including altered expression of vascular cell adhesion molecules and nitric oxide (NO), and changes in prostaglandin balance (81,82). Interestingly, preeclamptic patients also have been noted to have lower skin capillary density compared with healthy pregnant patients, a finding that suggests that defective angiogenesis may be implicated in the pathogenesis of preeclampsia (83). Finally, women with a prior history of preeclampsia have an increased incidence of ischemic heart disease, stroke, and hypertension (84). The association between preeclampsia and subsequent development of cardiovascular disease points to the existence of systemic endothelial dysfunction in these individuals.

To identify the soluble factors that mediate maternal endothelial dysfunction, we performed gene expression profiling of placental tissue from women with and without preeclampsia by using microarray chips. We found messenger RNA for *sFLT-1* to be upregulated dramatically in preeclamptic placentas (85). We also showed that increased systemic levels of sFLT-1 were present in patients with preeclampsia that decreased to baseline 48 hours after delivery. Hence, we hypothesized that excess circulating sFLT-1 levels may lead to an antiangiogenic state and cause endothelial dysfunction and the clinical syndrome of preeclampsia. Increased circulating sFLT-1 concentrations in patients with preeclampsia were associated with decreased circulating levels of free VEGF and free PlGF, a finding that also has been reported by a number of groups (85–88). Furthermore, in a recent study, uterine vein sFLT-1 concentrations were almost four- to five-fold higher than the peripheral venous concentrations, suggesting that the predominant source of maternal sFLT-1 was the placenta (89). By using endothelial tube formation assay, an established in vitro model of angiogenesis, we found that serum from patients with preeclampsia inhibited endothelial tube formation. Notably, 48 hours postpartum, this antiangiogenic effect had disappeared from the serum, suggesting that the inhibition of tubes noted with serum from preeclamptic patients was caused by a circulating factor released by the placenta. When sFLT-1 was added to normotensive serum at concentrations noted in patients with preeclampsia, tube

formation did not occur, mimicking the effects seen with serum from preeclamptic patients. This antiangiogenic effect could be restored by adding exogenous VEGF and PlGF (85). These results suggest that the antiangiogenic properties of serum from preeclamptic patients were caused by blockade of VEGF and PlGF by excess circulating sFLT-1. Finally, exogenous gene transfer of sFLT-1 using an adenoviral vector into pregnant rats produced hypertension, proteinuria, and glomerular endotheliosis, the classic pathologic renal lesion of preeclampsia (85). This effect also was seen in nonpregnant animals, suggesting that the effects of sFLT-1 on the maternal vasculature were direct and not dependent on the placenta. Furthermore, a soluble form of VEGF receptor-2 antagonist (sFLK-1; which does not antagonize PlGF), when given exogenously, did not induce a preeclamptic phenotype in pregnant rats, suggesting that antagonism of both VEGF and PlGF is necessary to induce the maternal syndrome. Hence, we concluded that excess sFLT-1 made by preeclamptic placentas may be responsible for the hypertension and proteinuria of preeclampsia by inducing a deficiency of VEGF and PlGF. It is still unknown whether the excess sFLT-1 made in preeclampsia is a primary phenomenon or secondary to placental ischemia.

Alterations in both circulating angiogenic proteins have been shown to antedate clinical preeclampsia, suggesting important diagnostic and predictive implications for this syndrome (86,87,90,91). Alterations in sFLT-1 were useful to predict proximity to the clinical disease, whereas alterations in PlGF were found to be very useful to predict preterm preeclampsia (86). Alterations in the levels of sFLT-1 and free PlGF were greater in women with an earlier onset of preeclampsia and in women in whom preeclampsia was associated with a small-for-gestational-age infant (86,92). The free (unbound) PlGF also is filtered freely into the urine and therefore may also serve to predict the subsequent development of preeclampsia (93). More recently, circulating levels of yet another placental antiangiogenic protein, soluble endoglin, have been reported to be elevated in patients with preeclampsia. Soluble endoglin amplifies the vascular damage mediated by sFLT-1 in pregnant rats, inducing a severe preeclampsia-like syndrome with features of the HELLP syndrome (94). The precise role of soluble endoglin and its relationship with sFLT-1 currently is being explored.

Circumstantial evidence suggests that antagonism of VEGF and PlGF may have a role in hypertension and proteinuria. VEGF induces NO and vasodilatory prostacyclins in ECs, suggesting a role in decreasing vascular tone and blood pressure (95,96). Exogenous VEGF has been found to accelerate renal recovery in rat models of glomerulonephritis and experimental thrombotic microangiopathy (97,98). More recently, exogenous VEGF was shown to ameliorate post-cyclosporine-mediated hypertension, endothelial dysfunction, and nephropathy (99). Additionally, in recent antiangiogenic clinical trials, VEGF signaling inhibitors have resulted in hypertension and proteinuria (100). The organs targeted in preeclampsia (such as the glomerulus or the hepatic sinusoids) have fenestrated endothelia. It has been shown that

VEGF induces endothelial fenestrae *in vitro* (101), and the loss of 50% of VEGF production in the mouse glomerulus leads not only to glomerular endotheliosis but also to loss of glomerular endothelial fenestrae (102). Collectively, these data suggest that VEGF is important not only in blood pressure regulation, but also in maintaining the integrity of the glomerular filtration barrier, and that antagonism of VEGF signaling, as occurs with excess sFLT-1, might lead to endothelial dysfunction, proteinuria, and hypertension. Finally, the excess sFLT-1 theory in preeclampsia is consistent with the evolutionary explanation for preeclampsia discussed by Haig and colleagues (Chapter 17). However, there are limitations and several unanswered questions to the sFLT-1 story. Although placental hypoxia has been suggested as the cause of excess sFLT-1, the precise mechanisms of excess sFLT-1 production by the placenta are not known. The exact role of sFLT-1 in normal placental development and in placental pseudovasculogenesis also is not clear. No brain abnormalities (eclampsia) were reported in sFLT-1-treated animals. Although sFLT-1 was increased in most patients with preeclampsia, it was not increased in some patients with mild preeclampsia (103). Moreover, the relationship of sFLT-1 with known risk factors for preeclampsia (such as obesity, pre-existing hypertension) is unclear; one hypothesis is that a threshold for sFLT-1 to cause disease exists, below which a normal pregnancy proceeds and above which preeclampsia results, and that women with risk factors may represent a group whose threshold has been effectively lowered, rendering them more susceptible to sFLT-1 and resulting in the maternal syndrome at levels that match those of normal pregnancy. Additional synergistic factors that are elaborated by the placenta, such as circulating soluble endoglin, may play a role in the pathogenesis of the generalized endothelial dysfunction noted in preeclampsia.

More recently, endostatin (a circulating fragment of collagen XVIII and an endogenous inhibitor of angiogenesis) also was reported to be increased modestly in patients with preeclampsia (104). However, it is unclear at present if these alterations are functionally relevant in the pathogenesis of preeclampsia or whether this reflects an increase of endothelial basement membrane turnover.

It also has been hypothesized by Wallukat and colleagues that agonistic angiotensin 1 (AT1) receptor autoantibodies noted in women with preeclampsia may play a pathogenic role (105). They hypothesized that these antibodies, which activate the AT1 receptor, may account for the increased angiotensin (Ang)-II sensitivity of preeclampsia. The same investigators later showed that these AT1 autoantibodies, like Ang-II itself, stimulate ECs to produce tissue factor, an early marker of endothelial dysfunction (106). Xia and coworkers found AT1 autoantibodies decreased the invasiveness of immortalized human trophoblasts in an *in vitro* invasion assay, suggesting that these autoantibodies might contribute to defective placental pseudovasculogenesis as well (107). AT1 autoantibodies are not limited to pregnancy; they also appear to be increased in malignant renovascular hypertension and vascular rejection

in nonpregnancy (108,109). In addition, these antibodies have been identified in women with abnormal second-trimester uterine artery Doppler studies who did not develop preeclampsia, suggesting this antibody may be a nonspecific response to placental hypoperfusion (110).

### Intrauterine Growth Restriction

Normal fetal growth is a complex interplay of fetal, maternal, and placental health. An abnormality in any of these three systems leads to small-for-gestational age babies. Such babies who arise as a result of placental vascular insufficiency are referred to as IUGR. Although IUGR frequently is associated with severe premature preeclampsia, IUGR also can occur in the absence of any evidence of preeclampsia. Low birth weight in IUGR babies also has been suggested as a predisposing factor for increased hypertension and cardiovascular diseases later in life (111). Normal pregnancy results in a significant increase in diastolic blood flow velocity as a result of physiological maternal vascular remodeling. In pregnancies complicated by IUGR, severe placental vascular insufficiency occurs, and the Doppler waveforms are similar to the nonpregnant state (66). This can be demonstrated by several methods, including Doppler ultrasound and magnetic resonance imaging of the uterine vessels. Similar to preeclampsia, placental bed biopsies in human IUGR show impaired migration of the extravillous trophoblasts and remodeling of the maternal spiral arterioles (12). It is still unclear why some patients with IUGR have the full-blown maternal syndrome of preeclampsia, while others do not. Human IUGR placentas, but not preeclamptic placentas, also have been found to have defective villous capillarization (112). The morphology of the trophoblast covering these diseased villi are also abnormal, with reduced amounts of proliferating villous cytotrophoblasts and an apoptotic syncytiotrophoblast. Recent work suggests that decreased syncytial fusion may lead to the increased syncytial apoptosis noted. Placental hypoxia is thought to preserve the syncytiotrophoblast integrity, and higher levels of O<sub>2</sub> are thought to inhibit cytotrophoblast proliferation and accelerate syncytial apoptosis. There is less O<sub>2</sub> extraction and consumption by the IUGR fetus, and the resulting higher levels of Po<sub>2</sub> have been hypothesized to inhibit the fetoplacental angiogenesis (113). However, studies documenting lack of relative hypoxia in IUGR placentas (without preeclampsia) are still lacking.

Impairment of insulin-like growth factor (IGF)-1 and -2 signaling pathways in experimental animals leads to IUGR (114–116). Recently, two babies with IUGR were reported to have mutations of the *IGF-1R* gene (117). Although abnormalities in IGF signaling are a relatively uncommon cause of IUGR, impaired IGF-2 signaling through IGF1R is the first molecular abnormality reported in this complex disease. IGFs are potent proangiogenic molecules both in vitro and in vivo (118–120). Decreased levels of pregnancy-associated plasma protein (PAPP)-A also have been associated with IUGR; however, its role in the pathogenesis is not well under-

stood (121,122). Abnormalities in other angiogenic proteins have been shown in small clinical studies, but definitive pathogenic role for these factors have not been demonstrated so far. Serum concentrations of sFLT-1 have been found to be increased modestly in patients with IUGR without preeclampsia (88), a finding that has not been confirmed by others (123). More recently, endostatin concentrations in the fetus and neonate were reported to be lower in pregnancies complicated by IUGR (124). Leptin and asymmetric dimethylarginine also have been reported to be elevated during placental insufficiency (125,126), but the cause-and-effect relationship of these molecules has not yet been established.

### KEY POINTS

- Normal placental development is characterized by angiogenesis, vasculogenesis, and vascular mimicry, and abnormality in these physiological processes may lead to disorders such as preeclampsia and IUGR.
- A normal pregnancy requires a balance between pro- and antiangiogenic factors that are expressed in the placenta.
- Abnormalities in the signaling of these angiogenic factors may lead to defective trophoblast differentiation, spiral arterial vascular remodeling, and villous angiogenesis of the placenta.
- Increased placental production of circulating sFLT-1, with accompanying defective VEGF signaling in the placenta and in the maternal vasculature, leads to preeclampsia.
- As our understanding continues to advance based on molecular and genetic techniques, we are hopeful that new interventions may improve our management of placental vascular disorders in the near future.

### Future Goals

- To undertake studies, especially in animals (nonhuman primates that resemble human placentation) lacking angiogenic factor signaling components specifically in the placenta, to better define the role of angiogenic proteins and vascularization during placental development and maternal health
- To identify and characterize novel angiogenic factors that control trophoblast differentiation and vascular remodeling, to help not only in understanding the pathogenesis of these placental vascular disorders, but also to suggest novel clinical diagnostic and therapeutic options for patients with these disorders

- To continue large-scale multicenter trials (such as the Genetics of Preeclampsia [GOPEC]) trial to shed light on the susceptibility genes for the various placental vascular diseases (127)

## GLOSSARY

**Chorionic villus** is a finger-like projection of the placenta that contains fetal blood vessels and that grows into the intervillous space.

**Decidua** is hormonally altered endometrium of the uterus, present during pregnancy or during the end of the luteal phase of menstruation.

**Extravillous trophoblasts** are a type of cytotrophoblast that invades into the maternal decidua and the myometrium. When they invade into the maternal vessels present in the decidua, they are referred to as *endovascular trophoblasts*. The counterpart of these cells in rodents is referred to as *trophoblast giant cells*.

**Glomerular endotheliosis** is the signature lesion noted in the kidneys of patients with preeclampsia. It is characterized by glomerular endothelial swelling with loss of endothelial fenestrae and relatively preserved epithelial foot processes.

**Hemochorial placentation** is a type of placenta (as in humans) in which the placental tissue is in direct contact with maternal blood supply. This makes it easy for placentally derived molecules to enter the maternal bloodstream.

**Placental labyrinth** represents that part of the placenta in which the fetal/maternal exchange of oxygen (O<sub>2</sub>) and nutrients occur. It is a system of channels, half of which contain maternal blood lacunae (intervillous spaces) lined by syncytiotrophoblasts; the remaining half contains fetal capillaries, lined by fetal endothelium.

**Spiral artery** is a branch of the uterine artery that traverses the myometrium and the decidua to deliver blood to the placenta.

**Trophoblasts** are the epithelial cells that constitute the bulk of the placenta. The outer layer of trophoblasts form a shell that is in contact with the decidua; it fuses to form multinucleated cells referred to as *syncytiotrophoblasts*. The inner layer of cells remain unfused and are referred to as *cytotrophoblasts*. The cytotrophoblasts can perform specialized functions, such as invasion and differentiation.

**Vascular mimicry** or **pseudovasculogenesis** occurs when the cytotrophoblasts invade and line the maternal blood vessels; they convert from an epithelial to endothelial phenotype. This process is analogous to the vascular mimicry noted in metastatic cancers, in which epithelial cells line the vascular spaces.

## Endothelialization of Prosthetic Vascular Grafts

Thomas S. Monahan and Frank W. LoGerfo

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

Each year in the United States, over 100,000 patients will undergo lower-extremity arterial reconstruction for peripheral vascular disease, and an additional 400,000 patients will have a coronary artery bypass graft (CABG) (1). Conduits for arterial reconstruction or bypass may be separated into two broad categories: autologous and prosthetic. Autologous conduits are derived from the patient's own tissue and include saphenous vein grafts, arm vein grafts, and arterial grafts such as radial artery or hypogastric artery grafts. Prosthetic conduits include fabric or plastic grafts such as expanded polytetrafluoroethylene (ePTFE or Gore-Tex) and polyester or Dacron. Other prosthetic grafts are fabricated from denatured, cross-linked tissue such as human umbilical cord vein grafts.

Regardless of the prosthetic graft used, the clinical experience with small diameter (<6 mm) prosthetic arterial grafts has been poor. The surface of all prosthetic grafts is thrombogenic, and rapidly becomes covered with a fibrin coating or pseudointima (Figure 162.1). In humans, this surface remains thrombogenic and acellular for the lifetime of the conduit. These grafts are unable to tolerate low-flow conditions. In contrast, autologous conduits retain a viable endothelium that actively inhibits thrombosis, making such grafts suitable for the low-flow conditions associated with CABG procedures or long bypass grafts to small arteries. One solution to the prosthetic graft problem is to try to create and maintain a healthy autologous endothelial surface on prosthetic arterial grafts.

For the same reason, it is desirable to minimize injury to the existing endothelium when implanting autologous bypass grafts. If the endothelium is injured, highly thrombogenic subendothelial collagen is exposed to circulating blood, leading to platelet adhesion (2). Platelets release factors that cause direct thrombosis or clot formation and cause adjacent endothelium to release growth factors that stimulate hyperplasia of the underlying vascular smooth muscle cells (VSMCs); this is known as intimal hyperplasia (IH). IH is initiated by the pathologic migration and proliferation of VSMCs from the media to the intima and a subsequent change in phenotype from a native contractile phenotype to a pathologic secretory phenotype (3). The resulting lesion consists of these secretory VSMCs and extracellular matrix. The absence of an

intact endothelium, and the resulting specific genetic signaling events that occur, trigger the changes associated with the pathogenesis of IH (3–5). Evidence also suggests that adventitial fibroblasts contribute to the pathogenesis of IH (6). Irrespective of the origin of the offending cells, preservation of an intact, uninjured endothelium at the time of surgical bypass is important in preventing the formation of IH in autologous bypass grafts. The end result of IH is a narrowing in the bypass graft, which increases the incidence of graft thrombosis.

Because the body of a prosthetic conduit is acellular, IH cannot occur except at the junction of the graft and the host artery (the anastomosis), where it is referred to as neointimal anastomotic hyperplasia (NIH). NIH tends to be greater at the outflow end of prosthetic grafts, where it can lead to a gradual compromise in flow through the graft. Because the surface of the graft remains thrombogenic, delayed thrombosis of the graft occurs as flow rate decreases. A natural approach to limiting the consequences of anastomotic IH is to provide a conduit with either an endothelium or endothelial-like structure to maintain an actively antithrombogenic surface (7,8).

### HISTORY OF BIOENGINEERED PROSTHETIC GRAFTS

It is well established that autogenous grafts (especially small-caliber grafts  $\leq 6$  mm) have superior long-term patency compared to prosthetic grafts. However, up to 30% of patients requiring a small-caliber vascular graft do not have autogenous tissue of sufficient length or quality to use for arterial reconstruction (9). Unacceptable patency rates for small-caliber expanded polytetrafluoroethylene (ePTFE) and polyester grafts have driven researchers to attempt to develop a synthetic graft that confers similar long-term patency rates to those achieved with autologous tissue.

The Holy Grail of prosthetic vascular grafts would embody several essential characteristics. The most important characteristic of a prosthetic graft is mechanical strength. It must be capable of withstanding the constant strain of arterial

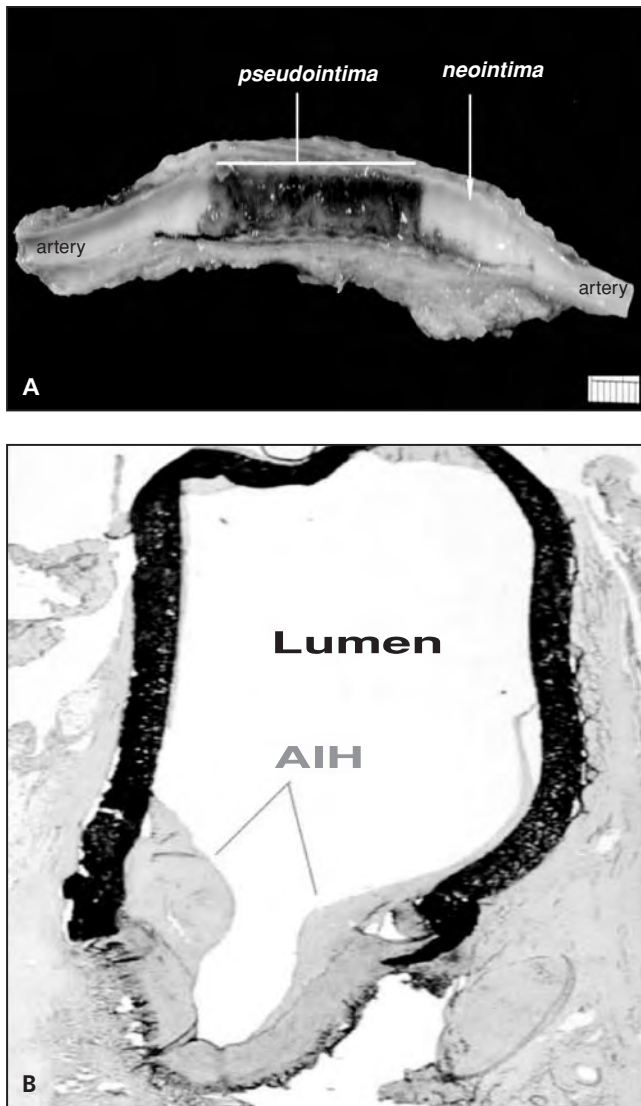

Figure 162.1. Neointima formation on a 6-mm Dacron vascular interposition graft implanted in an experimental canine model. A glistening neointima (A) is readily observed as early as 30 days after grafting into the arterial circulation. At this relatively early time point, there is already a readily identifiable neointima (B) that has formed at the anastomosis.

pressures for the life of the graft without fatigue; failure to do so would result in disruption of the graft and hemorrhage. In addition to mechanical strength, the graft must have favorable suturability and handling characteristics, comparable to those of presently available conduits. Finally, the ideal prosthetic graft would be resistant to both thrombosis and infection (10). An additional desirable characteristic of a synthetic graft is the ability to grow over time, as would be required in the special case of pediatric cardiovascular surgery (11).

Since the first clinical demonstration that synthetic materials could be employed as conduits in the arterial circulation over 50 years ago (12), surgeons have been attempting to improve on available prosthetics to embody the characteristics

of the ideal vascular graft. Over the years, polyester and ePTFE have demonstrated the desired mechanical durability, ease of handling, and availability required for a successful prosthetic, but lack the antithrombogenic properties essential for long-term patency in narrow-caliber grafts.

Histological analysis of implanted vascular grafts has revealed a cellular ingrowth that occurs with time. Experimental studies have demonstrated that in nonhuman primates, endothelial cells (ECs) have the capability of populating the mid-portion of ePTFE grafts (13); this suggests that the same events are possible in humans and could lead to a fully endothelialized surface. However, significant endothelial ingrowth has not been observed in humans. Despite speculation that the endothelial ingrowth observed in nonhuman primates is attributed to differences in porosity of the prosthetic grafts, there is no evidence of *in vivo* endothelialization of prosthetic grafts in the clinical setting, regardless of porosity. In polyester, ePTFE, and all other prosthetic grafts in humans, the graft develops a fibrin clot pseudointima that lacks the antithrombogenic qualities of a true endothelium-lined intima (see Figure 162.1). At the junction or anastomosis with the host artery, multiple factors come into play that lead to the development of localized IH. In this case the ECs grow from the host artery into the graft for a distance of only 5 to 10 mm. At this location, IH occurs with prosthetic arterial grafts, and the lesion can become flow limiting. It appears that those ECs that grow into the prosthetic at these locations are activated, and release cytokines that initiate hyperplasia.

The creation of bioengineered vascular prosthetics was fostered by the demonstration that human ECs could be grown successfully in tissue culture (14). With the technology to isolate and grow ECs, the logical extension was to use these cells to coat the lumen of a prosthetic graft with autologous ECs *ex vivo* and then to use the endothelial-seeded graft for conduit. The first attempts to seed the lumen of grafts involved incubating the graft with cell suspensions in culture medium, a “one-step” procedure. However, incubating the cells on the surface of the graft resulted in fewer than 10% of cells attaching and remaining on the graft under flow conditions (15). In addition to poor retention rates, the ECs failed to demonstrate the flattened phenotype of native endothelium. On electron microscopic examination of the luminal surface of both ePTFE and Dacron grafts, it was evident that these prosthetics represent a hostile environment that largely precludes cellular adhesion and the growth of a confluent endothelium.

After consideration of the failures of the early prosthetic grafts, second-generation or “two-step” grafts were created. These ePTFE prosthetic grafts were first precoated with fibrin glue, then lined with cultured autogenous ECs. This approach demonstrated improved retention of cells; however, a large number of the autogenous cells were still lost under flow conditions. Nonetheless, with the improved substrate for cellular attachment, the remaining ECs survived and, after 4 weeks in an experimental animal model, demonstrated high cellular density and a mature, well-differentiated appearance. In contrast, the control, untreated grafts were lined by a fibrin

pseudointima rich in adherent platelets, similar to our own experience with these grafts (16).

Other investigators attempted to create an endothelialized vascular graft using alternative scaffoldings that more closely resembled the surface of a native vessel. One of the first reports described using a collagen matrix to first culture bovine VSMCs, then apply ECs and finally fibroblasts. This graft was not strong enough to tolerate even very low (<10 mm Hg) intraluminal pressures. When the graft was bolstered with a Dacron mesh, the intraluminal burst pressure was only raised to the physiological level (17).

Variou subsequent attempts were made to strengthen the structural component of synthetic grafts to accommodate higher intraluminal burst pressures. Biodegradable polymers such as polyglycolic acid (PGA) exhibit porosity and the ease of handling desired of a synthetic graft. However, this polymer degrades in just 2 months, preventing the newly forming cellular graft from acquiring the strength necessary to tolerate arterial pressures. When PGA is combined with other copolymers, such as polyhydroxyalkanoate (PHA), the mechanical strength of the graft is increased to levels that would allow implantation in the arterial circulation. PGA-PHA grafts have been successfully implanted in the infrarenal aortic position in lambs with excellent results. These cellular grafts demonstrated superior patency to acellular, control grafts and, on retrieval after 5 months, demonstrated stress-strain curves similar to native vessels.

PGA-PHA grafts begin to take on the appearance of native vessels after 5 months of maturation in the arterial circulation. In addition to exhibiting the strength and thrombosis-resistance of native vessels, histologically they have a distinct intima and media confirmed by immunohistochemical analysis (18). To date, this represents one of the most promising approaches to the creation of a prosthetic vascular graft. The time required to create such a graft, the cost associated with the graft, and the inability to size a graft appropriate for the required reconstruction all limit clinical utility.

#### CLINICAL EXPERIENCE WITH ENDOTHELIALIZED VASCULAR GRAFTS

These improvements in the endothelialization of prosthetic arterial grafts have led to several clinical trials. In a phase I trial, 49 patients with no available autogenous conduit requiring femoropopliteal bypass grafting were randomized into two treatment groups. The first included 16 patients with either critical limb ischemia or disabling claudication who received a standard bypass graft with an untreated 6-mm ePTFE graft. The second treatment group was composed of 33 patients with similar indications for operations who received the previously described 6-mm ePTFE graft treated with the "two-stage" autogenous endothelial seeding. The patients receiving the treated graft enjoyed significantly improved graft patency compared with the untreated group at almost 3 years follow-up (19).

With promising phase I data, this procedure was adopted for routine operations in 153 patients lacking adequate autogenous conduit. In this series, both 6-mm and 7-mm ePTFE grafts were used as conduit to both the above-knee and below-knee popliteal arteries, with a preponderance of grafts to the above-knee popliteal artery. These grafts had a 7-year patency rate of 62% by Kaplan-Meier analysis (20), a rate that compares favorably to other published series evaluating patency of ePTFE grafts (21). This did not, however, represent an improvement over well-established outcomes with standard nonendothelialized grafts.

One obvious disadvantage to evaluating the long-term morphologic changes in prosthetic grafts in humans as opposed to animals is the inability to have access to grafts for study. In the large study published by Meinhart and colleagues (20), failures occurred in the endothelialized grafts that allowed both radiographic and histologic assessment of the "two-stage" graft after long-term implantation in the human arterial system. One patient who received bilateral engineered grafts experienced a unilateral graft failure. Interestingly, the regions of stenosis were in the mid-portion of the graft, in sharp contrast to the typical stenosis of anastomotic IH (Figure 162.2). This finding suggests a significantly different pathologic mechanism of graft failure in these engineered grafts (22). In a "bare" graft, the acellular pseudointima cannot develop a hyperplastic cellular lesion. Apparently, however, the endothelialized surface is capable of forming the typical lesion of IH seen in autogenous grafts. Thus, the antithrombogenic advantages of an endothelialized surface may be offset by the development of flow-limiting stenosis in the body of the graft.

Scanning electron microscopy demonstrated an intact EC layer over the entire length of the graft, consistent with the animal data for the "two-stage" graft. Immunohistochemical analysis confirmed that the endothelium lining the graft was functional and displayed all the expected markers of healthy endothelium, including the EC marker CD34, von Willebrand factor, and Weibel-Palade bodies. The endothelium also rested on a basement membrane consisting of type IV collagen (22).

The development of a small-caliber prosthetic graft with acceptable long-term patency is of particular interest for surgery of the coronary arteries. The small caliber of coronary arteries necessitates conduit much smaller than the smallest clinically approved 6-mm ePTFE graft. The previously described studies all employed endothelial-coated grafts with diameters of at least 6 mm. Using a similar approach, cardiac surgeons have begun to engineer endothelialized vascular grafts for patients with no other available conduit. In place of ePTFE, Lamm and colleagues used cryopreserved allograft veins (CAV) as the scaffolding for their endothelium. The CAVs were mechanically de-endothelialized, precoated with autogenous serum (analogous to the previously described pretreatment with fibrin glue), and then treated with autogenous ECs from unusable conduits supplied from the bypass graft recipient. In their series, they used 15 autologous endothelialized vein allografts in 12 patients requiring CABG surgery and who lacked adequate autogenous conduit. Only two grafts

Figure 162.2. Angiogram of failing endothelialized ePTFE graft. Note that the graft on the patient's right is patent and smooth from its origin from the femoral artery to its insertion on the popliteal artery. In contrast there is a 75% stenosis (arrow) of the graft with similar construction on the contralateral side. This pattern of occlusion is dramatically different from that more commonly observed, which is caused by anastomotic IH and follows the pattern observed in vein bypass grafting. (Adapted with permission from Deutsch M, et al. In vitro endothelialization of expanded polytetrafluoroethylene grafts: a clinical case report after 41 months of implantation. *J Vasc Surg*. 1997;25:757-763.)

occluded on angiographic follow-up, and one patient expired due to causes unrelated to the graft, which was patent on post-mortem exam (23). These studies are very encouraging, showing that, over the last 20 years, significant strides have been made to create an artificial graft with a functional endothelium. In at least 12 patients, these grafts have proved life-saving.

Lamm and colleagues used cryopreserved veins for their scaffolding to grow a cellular prosthetic arterial graft. Other matrices have been used clinically in the creation of a prosthetic graft. The first reported case of using an entirely synthetic biodegradable scaffold was presented in 2001. Peripherally harvested cells seeded onto a PGA copolymer scaffold were used to create a prosthetic graft to bypass a completely occluded pulmonary artery in a 4-year-old girl. At 7 months'

follow-up, the patient was doing well, and there was no evidence of aneurysm formation or graft occlusion (11,24). A larger series of synthetic vascular grafts used to treat over 40 children with congenital heart disease from the same group of investigators reports a patency of over 95% for the first year (25). These findings suggest that grafts created in this manner might potentially grow with the child, thus obviating the need for later surgical procedures.

## FUTURE DIRECTIONS AND INSIGHTS

Although much progress has been made in the creation of an endothelial-lined prosthetic graft, much work needs to be done for this technology to reach mainstream cardiovascular surgery practice. As noted, few trials demonstrate adequate patency of grafts of less than 6 mm in diameter. Additionally, because it takes a significant amount of time to produce these grafts, it is not feasible to prepare them at the time of surgery. The present technology is not available for patients needing emergent bypass grafting, and no selection of graft sizes is available to the surgeon at the time of operation. Thus, today's grafts fail to meet the Holy Grail criteria.

Alternative strategies for achieving the thrombosis-resistant surface required for small-caliber grafts are being investigated. One strategy is to bind an antithrombogenic molecule such as heparin to the luminal surface of the graft, thus preventing thrombosis. Early studies suggest that this treatment increases patency rates in an animal model (26). In that study, significant activity of the bound heparin occurred after 12 weeks of implantation in the arterial system. Our own group has developed the technology to bind both the anticoagulant hirudin and vascular endothelial growth factor (VEGF) to the luminal surface of Dacron. The purpose of this model is to both prevent early thrombosis and to promote the ingrowth of native vascular ECs. Early in vivo data in animals are encouraging.

Investigators also are modifying the surfaces of polymers used as structural scaffolding for prosthetic vascular grafts. Various peptides can be applied to the surface of the graft to induce VSMC ingrowth and attachment, in the same manner that VEGF might induce EC ingrowth in Dacron grafts. Growth factors such as transforming growth factor (TGF)- $\beta$ 1 have been attached to the surface of PGA to stimulate matrix production and increase the strength of the graft (27). Ultimately, the strength provided by a robust vascular smooth muscle ingrowth will need to be balanced against a narrowed graft lumen, as observed in IH.

An obvious need exists for a thrombosis- and infection-resistant synthetic conduit. The previously described studies highlight some of the many advances that have been made over the past 20 years in the bioengineering of prosthetic arterial grafts. These studies should serve to provide future engineers with direction in the construction of vascular grafts, but also to draw attention to the limitations and requirements dictated by vascular biology.

**KEY POINTS**

- An intact, functional endothelium is essential for vein-graft patency; without a functional endothelium, prosthetic grafts less than 6 mm in diameter have unacceptable patency rates.
- The “Holy Grail” of prosthetic grafts would combine strength, suturability, ready availability, and resistance to thrombosis.
- Prosthetic vascular grafts are available, but lack a thrombosis-resistant lining, thus requiring a diameter of at least 6 mm.
- Synthetic vascular grafts composed of cultured ECs on artificial scaffolding have been used successfully in small trials, but are not practical for widespread use in patients.

*Future Goals*

- To create a quiescent endothelium: At this time, prosthetic grafts seeded with autogenous endothelium are of limited utility due to cost, availability, time needed to fabricate the graft, and IH. Perhaps this can be accomplished using different substrates, subendothelium, or through genetic manipulation. Promising future directions in the development of prosthetic arterial grafts include binding of antithrombogenic proteins to create an actively antithrombotic surface.

## The Endothelium's Diverse Roles Following Acute Burn Injury

Rob Cartotto

*Sunnybrook and Women's College Health Sciences Centre, University of Toronto, Canada*

It is estimated that each year in the United States, 1.25 million burn injuries occur, and it is known that between 60,000 and 80,000 people require in-hospital care for their burns, and that 1.4 people per 100,000 of the population will die as a result of a burn (1). Morbidity from a burn also may be considerable and includes disfigurement as well as the possibility of permanent impairment of functional abilities. The cost of hospital care for a patient with flame burns and/or smoke inhalation injury ranges from \$29,560 to \$117,506 (USD) per patient, whereas the cost of a single fire-related death, including loss of future earning potential, is estimated at between \$250,000 and \$1 million (1). It should be readily apparent then, that burn injuries are a major source of morbidity, mortality, and financial loss.

The endothelium, which at the outset might seem to be a relatively minor player in the complex overall picture of a burn injury, in fact has a major role in the pathophysiology that follows a burn. The thesis of this chapter is that the burn wound should be conceptualized as a dynamic "organ," and that the endothelium within this organ, in concert with the coagulation, fibrinolytic, and inflammatory pathways, is responsible for many of the local as well as systemic derangements that follow a burn.

Thermal injury to the skin and soft tissues acutely produces local damage at the site of the injury and systemic derangements distant from the injury. Although heat itself is the initial insult at the injury site, the host response to the heat-induced injury is responsible for both ongoing local tissue damage, as well as numerous remote pathophysiological alterations. The effect of heat on a cell depends on an inverse relationship between the temperature to which the cell is heated and the duration of exposure to that temperature (2). For example, exposure of pig skin to 60°C for 3 seconds produces irreversible epidermal necrosis, whereas exposure of the same skin to 43°C for several hours will result only in mild cellular protein denaturation, and exposure below 40°C to 42°C indefinitely does not produce direct cellular injury (2).

Historically, the burn wound was considered as a relatively inert and passive source of fluid leak and infection. However, it is now recognized that the microvascular endothelium of the burn wound, through its interactions with the coagulation and fibrinolysis pathways, and the acute inflammatory cascade, plays a critical role in integrating and mediating the host response – both locally and systemically (Figure 163.1). Viewed from this perspective, the burn wound may be considered a specialized "organ" (3), complete with its own endothelial-lined blood supply and characterized by discrete physiological and pathophysiological properties. The notion that the burn wound contains blood vessels with an active endothelium suggests that this cell layer may be not only central in mediating the host response, but also may be leveraged for therapeutic gain.

### CONCEPTUALIZATION OF THE BURN WOUND

When heat is applied to the skin, the local vasculature responds with immediate vasodilatation in an effort to dissipate heat. If the amount of heat energy delivered to the skin, which is, as noted, based on an inverse relationship between temperature and duration of exposure (2), is greater than the capacity of the local circulation to dissipate heat, then direct heat injury ensues. Heat-induced injury includes malfunction of intracellular enzymes, cell swelling, progressive protein denaturation, and ultimately coagulation necrosis of tissue (2,4). (In this sense, "coagulation" refers both to the complete denaturation of cellular proteins and structure such that normal cellular architecture is completely obliterated, as well as to total occlusion of the microcirculation, with coagulated blood and cells including erythrocytes, neutrophils, and platelets.) This process leads to a three-dimensional zone of injury (termed the *zone of coagulation*) at the site of maximal heat energy (5) (see Figure 163.1). This region is characterized by complete cell death, obliteration of the micro- and macrocirculation,

Figure 163.1. Schematic view of the concentric zones of the burn wound demonstrating the dynamic zone of stasis, in which deregulation of the normal homeostatic balance between the endothelium, coagulation, fibrinolysis, and inflammation results in local burn wound progression and systemic manifestations such as the systemic inflammatory response syndrome (SIRS), multiple organ dysfunction syndrome (MODS), and burn shock.

and loss of blood flow (5,6). The protective potential of heat shock proteins (HSPs), which are proteins generated by cells upon heating, is not entirely understood. Some experimental models suggest that induction of the heat shock response with subsequent production of HSPs improves outcome following experimental burns (7).

Concentrically surrounding the zone of coagulation is a much larger three-dimensional zone of injury, termed the *zone of stasis*, in which the microcirculation is packed with red blood cells, neutrophils, and platelet microthrombi and microemboli. Cells in this zone have sustained a partial heat injury and have been rendered ischemic by the impaired blood flow. The net result is an intense inflammatory response, characterized by a complex interplay between resident and infiltrating cells (endothelial cells [ECs], platelets, leukocytes), and soluble mediators. Locally, these reactions lead to the accumulation of interstitial fluid and further tissue ischemia. Systemically, they may produce distant effects including the systemic inflammatory response syndrome (SIRS), the acute respiratory distress syndrome (ARDS), burn shock, and multiple organ dysfunction syndrome (MODS) (8). The zone of stasis is dynamically unstable. Normally, it “falls victim” to its own intensity, and undergoes coagulation necrosis, creating the appearance of concentric expansion of the zone of coagulation (6). Clinically, this is appreciated as an apparent “extension” or “deepening” of the burn wound, which is observed over the first 72 hours following a burn. In exceptional circumstances, for example with experimental delivery of anti-inflammatory agents to

the burn wound, the zone of stasis may partially recover (4). Indeed this zone represents a vital target for future therapies in burn patients.

Finally, in a third concentric zone peripheral and deep to the zone of stasis, is the *zone of hyperemia*, in which heat dissipation was sufficient to avoid cellular injury and in which temporary vasodilatation will be followed by complete recovery.

Burns are classified based on the depth of injury into the skin. First-degree burns involve only an epidermal injury. Second-degree (or partial-thickness) burns have sustained injury to the epidermis and some part of the upper dermis, while leaving some amount of the deeper dermis and the underlying subdermal vascular plexus unscathed, the exception being a deep second-degree burn in which injury extends well down into the dermis, with potential compromise of the subdermal vascular plexus. A third-degree (or full-thickness) burn includes injury to the epidermis and the entire dermal thickness, and typically features injury to or complete obliteration of the subdermal vascular plexus.

#### THE ENDOTHELIUM AND ACUTE BURN WOUND INTERSTITIAL EDEMA FORMATION

Rapid and profound edema formation is a fundamental characteristic of the acute burn wound and is directly related to activation and dysfunction of ECs within the zone of stasis. The immediate effect of heat is the disruption of numerous cellular enzyme systems. One important enzyme system that becomes impaired is the Na,K-ATPase pump (3,9). ECs with dysfunctional Na,K-ATPase pumps become “flooded” with sodium and water, and their transmembrane potential diminishes from  $-90$  mv to  $-60$  mv. Electron microscopic studies have directly demonstrated that ECs, particularly those lining postcapillary venules, swell and begin to pull away from each other, creating large gaps that allow the efflux of fluid and proteins from the circulation into the interstitial space (3,10–12) (Figure 163.2). Compounding the effects of swelling-induced endothelial gap formation are the effects of numerous acute inflammatory mediators, such as histamine, bradykinin, complement, prostaglandins, thrombin, and leukotrienes, which have inundated the zone of stasis in response to heat-induced tissue damage and which act to increase EC permeability (Figure 163.2). The resulting loss of barrier function leads to burn wound edema and, if the wound is large enough, intravascular volume depletion. Although other forces contribute to loss of intravascular volume (e.g., changes in oncotic pressure and hydrostatic pressures within the capillary) (13), the breakdown of normal EC–EC contacts and loss of barrier function is largely responsible for the generation of the edema and fluid shifts that are so characteristic of a major burn injury. As ECs swell, and as fluid accumulates in the interstitium, the vessel lumen diameter narrows and blood flow within the zone of stasis is further impeded, promoting tissue ischemia and wound progression.

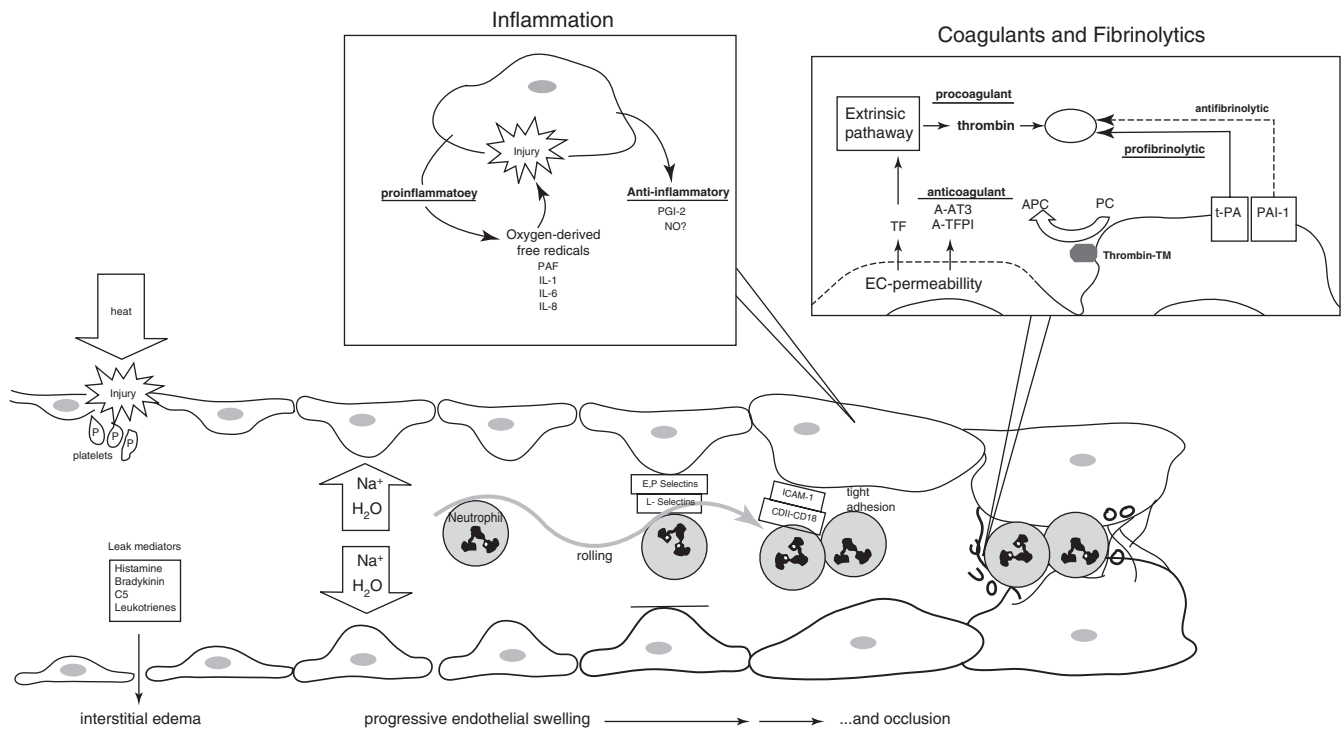

Figure 163.2. Schematic diagram demonstrating multiple roles of the endothelium in the pathophysiology of the burn wound. Progressive EC swelling and microvascular lumen occlusion are shown from left to right. P, platelets; TF, tissue factor; A-AT3, activated antithrombin 3; A-TFPI, activated tissue factor pathway inhibitor; PC, protein C; APC, activated protein C; TM, thrombomodulin; t-PA, tissue plasminogen activator; PAI-1, plasminogen activator inhibitor; OFR, oxygen-derived free radicals.

### ENDOTHELIUM IS A TARGET FOR AND A SOURCE OF ACUTE INFLAMMATORY MEDIATORS IN THE ZONE OF STASIS

Numerous inflammatory mediators are liberated within the zone of stasis following thermal tissue injury. These mediators may act upon the endothelium and, in many cases are produced by the endothelium itself. They may exert both local and systemic effects.

#### Histamine

Within the zone of stasis, resident mast cells, stimulated by burn injury and activation of the complement cascade, release histamine, which causes vasodilatation and acts on the endothelium to increase microvascular permeability. Histamine's ability to induce endothelial microvascular leakage appears to be responsible for the early rapid phase of edema formation in the burn wound (3,8,14). Experimentally, this response can be greatly inhibited by pretreatment with  $H_1$ -histamine receptor antagonists (15). Furthermore, within the burn zone of stasis histamine appears to stimulate xanthine oxidase activity within ECs, resulting in oxidization of hypoxanthine and liberation of the oxygen free radical superoxide ( $O_2^{\cdot -}$ ) (4,16,17), which in turn mediates ongoing microvascular injury. In an experimental burn model in rats, allopurinol, a xanthine oxidase inhibitor, was found to reduce edema formation in the

zone of stasis (16). Thus, within the zone of stasis, the endothelium itself may become a source of oxygen free radicals (see Figure 163.2).

#### Kinins

The kinin system is activated following thermal injury by both activated Hageman factor (XIIa) and by damaged tissue cells to produce bradykinin and lysyl bradykinin (18,19). Bradykinin, in particular, causes an increase in permeability across the microvascular endothelium within the zone of stasis (8).

#### Complement

The complement system becomes activated mainly through the alternative pathway following burn injury (8,20,21). Although complement plays a particularly important role in chemoattraction, phagocyte activation, bacterial opsonization, and target cell lysis, certain complement components (e.g., C5a) act on the microvascular endothelium to increase permeability (8).

#### Platelet-Activating Factor

ECs (along with platelets, neutrophils, and monocytes) are an important source of platelet-activating factor (PAF) following thermal injury. A major effect of PAF is to cause increased

microvascular permeability across the endothelium within the zone of stasis, resulting in prolonged ongoing edema formation in the burn wound (8).

### Cytokines

Cytokines are intercellular messenger proteins that are produced not only by cells of the immune system such as lymphocytes, monocytes, and macrophages, but also by the endothelium. Within the zone of stasis, ECs are both a source of, and target for, cytokines. For example, ECs express interleukin (IL)-1, IL-6, and IL-8 (see Figure 163.2). Following burn injury, increased levels of IL-1, IL-6, and IL-8 have been observed both systemically (8,22) as well as in burn blister fluid (the exudative fluid contained within the epidermal-domed blisters and bullae that are the classic clinical finding in second degree [partial thickness] burns of the skin) (8,23). These interleukins have a variety of effects including generation of fever, promotion of clot formation through activation of the extrinsic coagulation pathway, and stimulation of the cascade of neutrophil chemotaxis, neutrophil adhesion to the endothelial surface, and release of injurious reactive oxygen metabolites and hydrolytic enzymes by activated, adherent neutrophils (8,24).

### The Arachidonic Acid Cascade

Activation of the arachidonic acid cascade, resulting in increased production of the end-products (prostaglandins, thromboxanes, lipoxins, and leukotrienes) in burned tissue, was recognized almost 30 years ago (3,8,25). ECs, leukocytes, platelets, and mast cells all generate leukotrienes (C4, D4, and E4), which probably all act on the microvascular endothelium within the zone of stasis to increase permeability and cause edema formation (3,8,26) (see Figure 163.2). During the acute inflammatory phase of burn injury, burn-injured endothelium fails to secrete normal amounts of prostacyclin (PGI<sub>2</sub>), favoring platelet and leukocyte aggregation and adhesion to the endothelium (3). However, in the latter, prolonged post-traumatic phase, increased endothelial production of PGI<sub>2</sub> appears to play a role in mediating prolonged vasodilatation and inhibiting platelet aggregation within and around the burn wound.

### PLATELETS ARE ACTIVATED AND ADHERE TO THE ENDOTHELIUM IN THE BURN WOUND

In vivo models of burn injury in the mouse ear demonstrate that, within the zone of stasis, platelets rapidly adhere to endothelial surfaces that have been injured by heat (6,27). Upon adhesion, the platelets become activated and release thromboxane A<sub>2</sub>, which promotes vasoconstriction and platelet aggregation within the already compromised microcirculation. Surface membrane phospholipids of the activated platelets (e.g., formerly platelet factor [PF-3]) become exposed in order

to bind coagulation factors during thrombin formation (21). The activated platelets also secrete numerous cytokines (transforming growth factor- $\beta$ , insulin-like growth factor, platelet-derived growth factor, and epidermal growth factor), which collectively serve to activate and attract macrophages and fibroblasts, cells that are necessary in the later phases of wound repair and regeneration (8).

### ENHANCED LEUKOCYTE-ENDOTHELIAL ADHESION FOLLOWING BURN INJURY

It is recognized that activated neutrophils, attracted to the zone of stasis by numerous chemotactic factors, adhere to the microvascular endothelium and in so doing release reactive oxygen metabolites and hydrolytic enzymes that cause ongoing tissue injury as well as further microvascular leakage (8). The toxic inflammatory "soup" within the zone of stasis consists of many chemotactic agents for neutrophils, including complement component C5a, leukotriene B<sub>4</sub>, thrombin, PAF, IL-1, IL-8, and tumor necrosis factor (TNF). Chemoattractant activity, along with sluggish blood flow in the congested microcirculation, helps to bring neutrophils into proximity with the endothelium (28,29). In the next step, leukocytes "roll" along the endothelial surface, a process that is mediated by an interaction between L-selectin, a glycoprotein on the neutrophil surface, and E-selectin and P-selectin, which are molecules expressed on the EC surface in response to various stimuli such as cytokines, thrombin, complement, histamine, and leukotrienes (28). Rolling is followed by tight adhesion between leukocyte and endothelium. This latter process is mediated by CD11/CD18 and intercellular adhesion molecule (ICAM)-1. CD11/CD18, a member of the integrin family of glycoproteins, is expressed both constitutively and in response to inflammatory stimuli on the surface of leukocytes. ICAM-1 is a member of immunoglobulin supergene family, which is largely restricted to ECs. ICAM-1 is normally expressed at low levels, but is significantly upregulated on the surface of activated ECs (28). Following experimental burn injury in a rabbit model, administration of anti-ICAM antibodies improved blood flow in the zone of stasis, suggesting an important role for this adhesion molecule there (30). The CD11/CD18-ICAM-1 interaction results in a tight adhesion of the now stationary leukocyte to the EC surface (28) (see Figure 163.2). The adherent neutrophils then begin the process of transendothelial migration and, ultimately, take on a phagocytic role as they enter the wound. During adhesion/transmigration and in the process of phagocytosis, neutrophils release oxygen-derived free radicals and proteolytic enzymes into the local microenvironment (Figure 163.2). Neutrophils are considered an important source of oxygen free radicals after burn injury (17). These oxygen free radicals participate in cell membrane damage through lipid peroxidation, and are believed to be key elements in progression of the burn wound as well as in the development of burn shock and remote organ injury following burns (17,31).

Following burn injury, CD11/CD18 expression is increased on the surface of circulating leukocytes (28,32). Administration of antibodies to either CD18 or ICAM-1 both prior to and 30 minutes following burn injury in a rabbit model resulted in improved microvascular perfusion as measured by laser Doppler and reduced wound progression in the burn wound zone of stasis. These findings support an important role for neutrophil–endothelium adhesion in mediating burn wound progression (30). Importantly, they raise the possibility that this process may be amenable to therapeutic targeting.

### ENDOTHELIUM AND NITRIC OXIDE PRODUCTION FOLLOWING BURN INJURY

The endothelium is a major source of nitric oxide (NO). The endothelium produces NO from the oxidation of L-arginine, catalyzed by the constitutively expressed enzyme endothelial NO synthase (eNOS), as well as by inducible NO synthase (iNOS), which is induced by pathological stimuli (33). NO regulates vasomotor tone, inhibits platelet aggregation, and has both proinflammatory as well as anti-inflammatory effects. Within the burn wound zone of stasis, upregulation of both eNOS and iNOS activity results in increased NO production (33,34), which may in turn contribute to the development of local edema through potentiation of substance P release, the recruitment and adhesion of neutrophils, and the dilatation of blood vessels (33,35,36). On the other hand, NO also may act locally to attenuate inflammation by inhibiting platelet aggregation and by downregulating endothelial expression of certain adhesion molecules, including selectins and ICAM-1 (33,37). Human and animal studies showing elevated levels of the stable NO metabolite  $\text{NO}_3^-$  in both plasma and urine post-burn support the notion that increased systemic production of NO occurs following a burn injury (33,34,38). In one study, administration of the nonspecific NOS inhibitor  $\text{N}^G$ -monomethyl-L-arginine, (L-NNMA), attenuated this effect (39). This increased systemic production of NO is believed to contribute to increased gastrointestinal bacterial translocation, pulmonary microvascular leakage and leukocyte infiltration, and myocardial dysfunction following major burn injury (33,40,41). However, these effects are highly variable and largely depend on the time point post injury at which NO is acting.

### ENDOTHELIUM AND ALTERATIONS IN COAGULATION AND FIBRINOLYSIS FOLLOWING BURN INJURY

The endothelium plays a central role in regulating hemostasis. Through a finely tuned balance of procoagulant activity, anticoagulant forces, and fibrinolytic components, the endothelium normally presents a nonthrombogenic surface to circulating blood (21,24). On the procoagulant side, ECs express von Willebrand factor (vWF), tissue factor, as well as

inflammation-related proadhesive molecules such as selectins and ICAM-1. On the anticoagulant side, ECs produce heparan, which serves as a cofactor for antithrombin III (ATIII); tissue factor pathway inhibitor (TFPI), which inhibits factor VIIa-TF; and thrombomodulin (TM), which catalyses conversion of protein C to activated protein C (APC), a powerful anticoagulant, profibrinolytic, and anti-inflammatory agent (42,43). In addition, ECs also produce NO and  $\text{PGI}_2$ , which inhibit platelet adhesion and aggregation. The endothelium is intimately involved in the regulation of fibrinolysis through the production of tissue-type plasminogen activator (t-PA) and plasminogen activator inhibitor (PAI)-1. t-PA converts plasminogen to plasmin. Plasmin in turn lyses fibrin (and fibrinogen), producing D-dimers. Increased circulating levels of D-dimers are diagnostic of ongoing coagulation and fibrinolysis (21). PAI-1 is a natural inhibitor of t-PA (21) (see Figure 163.2). Thrombin represents an important link between coagulation and inflammation. In addition to its role in cleaving fibrinogen to generate fibrin, thrombin has proinflammatory effects that include neutrophil chemotaxis, endothelial adhesion molecule expression (selectins), barrier dysfunction, and promotion of PAF expression (44).

When thrombin binds to TM on the surface of ECs, it acquires anticoagulant and anti-inflammatory properties. TM-bound thrombin activates protein C. APC is a central modulator of coagulation, fibrinolysis, and inflammation (43). The anticoagulant effects of APC include inhibition of thrombin generation by inactivation of clotting factors Va and VIIIa, and inhibition of tissue factor release from monocytes and endothelium. Profibrinolytic effects of APC include inactivation of PAI-1 and thrombin-activated fibrinolysis inhibitor (TAFI). Finally, APC's anti-inflammatory effects include the suppression of inflammatory cytokines production, such as IL-1 and TNF, and inhibition of selectin-mediated neutrophil adhesion to the endothelium (43).

It is widely believed that the endothelium plays a pathophysiological role in severe sepsis. Under these conditions, the endothelium acquires a procoagulant surface, attenuates fibrinolysis, expresses proadhesion molecules and inflammatory mediators, and undergoes apoptosis (24,43,44). The end result is progressive occlusion of the microcirculation and cell death, which may contribute to organ failure and mortality. Although less well characterized than in sepsis, a similar cascade of events appears to occur following burn injury. Two studies involving a total of 103 burn patients with moderate to severe burns (45–47) demonstrated that, in the initial days following burn injury, intense burn-size-dependent activation of coagulation occurs. The hypercoagulable state was characterized by increased levels of clotting factor VIIa and thrombin-antithrombin (TAT) levels, combined with depression of the anticoagulants ATIII and protein C. Presumably, burns result in rapid activation of the extrinsic pathway through upregulation of tissue factor on the surface of monocytes (and possibly ECs). Theoretically, collagen exposure in the burn wound can activate the intrinsic limb of coagulation, although there is little evidence for the existence of this pathway *in vivo* (47).

Simultaneously, there also appears to be burn-size–dependent activation of fibrinolysis, characterized by increased levels of t-PA, D-dimers, and reduced levels of plasminogen (46,47). However, the activation of fibrinolysis appears to yield over time to a general inhibition of fibrinolysis, as characterized by progressive elevation of the antifibrinolytic PAI-1 over the first 7 days post burn (47). This is a particularly interesting finding because it was recognized nearly 30 years ago that inhibition of fibrinolysis existed in the plasma of thermal injury patients (48), and 10 years ago that burn blister fluid was antifibrinolytic (49).

This state of hypercoagulation with relatively ineffective fibrinolysis could well play a role in the progressive occlusion of the microcirculation within the burn wound zone of stasis, and be partly responsible for the phenomenon of wound progression. Furthermore, these derangements in coagulation and fibrinolysis are associated with development of organ dysfunction remote from the burn seen after burn injury. In the study by Garcia, organ failure scores were significantly correlated with ATIII, plasminogen, and protein C levels (47). Thus, based on the limited data available from burn patients, there appear to be some important similarities between the procoagulant/antifibrinolytic/inflammatory state recognized during sepsis, and the local burn wound and systemic state following a major burn injury.

#### KEY POINTS

- The burn wound is best conceptualized as a dynamic, specialized organ, complete with its own endothelium-lined blood supply. In concert with the coagulation, fibrinolysis, and inflammatory pathways, the endothelium plays a central and multifaceted role in directing local progression of the burn wound, as well as many of the systemic derangements seen following a major thermal injury.
- Endothelial gap formation and increased microvascular endothelial permeability are the basis of the profound edema that characterizes the burn wound, as well as the intravascular volume depletion that follows a major burn injury.
- Recognition of the role of enhanced endothelium–leukocyte adhesion following burn injury is a relatively new and unexplored area. Inhibition of this adhesion process by antiadhesion molecule antibodies appears to improve perfusion of the burn wound. However, the effects of this approach in clinical burn care, and the possible infectious risks of this approach, remain unknown.
- The development of a hypercoagulable state and an activated endothelium with relative suppression of fibrinolysis at the microcirculatory level following

an acute burn injury has been recognized, but is not as well characterized as it is during sepsis. However, there appear to be similarities between the two processes, and this hypercoagulable/hypofibrinolytic state could well be the basis of burn wound progression and distant organ dysfunction following a major burn injury.

#### Future Goals

- To further characterize the coagulation and fibrinolysis state at a microvascular level following acute burn injury is necessary; the role of agents such as recombinant APC, which appears to have a profound effect during sepsis, offer theoretically ideal benefits with respect to control of burn wound progression and the systemic alterations following major burns.

## Trauma-Hemorrhage and Its Effects on the Endothelium

---

Yukihiro Yokoyama and Irshad H. Chaudry

*Center for Surgical Research and Department of Surgery, University of Alabama at Birmingham*

Despite improvements in critical care medicine, trauma continues to be one of the leading causes of death in developed countries. Severe trauma induces an elevation of circulating inflammatory cytokines (1), upregulation of vasoconstrictors (2), and alteration in coagulation cascade (3). It also leads to an impairment of endothelial function and circulatory alterations in major organs, which can lead to multiple organ dysfunction syndrome (MODS) (4) and eventually to multiple organ failure (MOF). In this regard, numerous studies have focused on examining the mechanisms of endothelial dysfunction following trauma so that effective treatment strategies may be developed.

In the literature, a tendency exists to group trauma and massive hemorrhage under the same heading. Indeed, massive hemorrhage rarely occurs (with the exception of aortic aneurysm) in the absence of trauma (experimental models notwithstanding), and severe trauma usually is accompanied by hemorrhage. However, it is important to recognize that simple hemorrhage per se or tissue trauma without massive blood loss may trigger distinct pathways and lead to differences in host response. Severe hemorrhage (with and without tissue trauma) or severe tissue trauma (with or without massive blood loss) eventually leads to the activation of the same final pathways that lead to organ dysfunction and eventual failure, if the process is not controlled and corrected in due course. Furthermore, the site of injury (e.g., brain, thoracic, abdominal, and extremity) and the modality of resuscitation (e.g., massive blood transfusion versus resuscitation by Ringer's lactate) also may result in different host response. In this regard, allogeneic blood transfusion clearly will elicit immunosuppression and produce an entirely different response than resuscitation with Ringer's lactate. Furthermore, additional complicating issues include whether the injury is internal or external, penetrating or blunt. Although these confounding factors can influence the initial responses, many similarities have been observed with respect to the process of organ dysfunction and failure including endothelial dysfunction among these insults.

Not only is endothelium vulnerable to the effects of trauma, it also plays a key pathophysiological role in mediating the trauma phenotype. Trauma induces inflammatory and coagulation responses, which in turn result in endothelial activation. Even with trauma on an extremity, endothelial dysfunction is affected in the remote major organs (5,6). Once activated, endothelial cells (ECs) may contribute to organ injury (Figure 164.1). Data from extensive basic and clinical research in trauma support four potentially important mechanisms of EC dysfunction and/or endothelial-mediated organ dysfunction: (a) enhanced inflammatory processes, (b) cellular damage by excessively produced oxygen-derived free radicals, (c) impaired tissue circulation due to an imbalance between vasodilators and vasoconstrictors, and (d) the damaging effect of gut-derived mesenteric lymph. Finally, there is increasing evidence for the role of gender dimorphism in dictating clinical outcomes in trauma.

### MECHANISMS OF ENDOTHELIAL DYSFUNCTION AND ENDOTHELIAL- MEDIATED ORGAN INJURY FOLLOWING TRAUMA-HEMORRHAGE

#### **Enhanced Inflammatory Processes**

Hemorrhagic shock is associated with increased leukocyte adhesion and extravasation (7). Leukocyte trafficking is mediated, in large part, by the inducible expression of adhesion molecules (e.g., selectins, integrins, and members of the immunoglobulin superfamily) on the surface of the endothelium. The various rodent models of simple hemorrhage, soft-tissue trauma with or without hemorrhage, and soft-tissue trauma plus bone fracture and hemorrhage are listed in Table 164-1 (8–28). Although various species of animals such as dogs, pigs, monkeys, and horses have been utilized to study trauma-hemorrhage, we will restrict discussion to trauma-hemorrhage models in rodents.

**Table 164-1: Rat and Mouse Models of Hemorrhage and Trauma-Hemorrhage**

<i>Models</i>	<i>References</i>
Anesthetized fixed-volume bleed-out model of hemorrhage	9–14
Anesthetized fixed-pressure model of hemorrhagic shock	15–18
Unanesthetized fixed-volume hemorrhage model	19, 20
Unanesthetized fixed-pressure model of hemorrhage	21–26
Unanesthetized nonheparinized model of trauma-hemorrhagic shock	27, 28

In a mouse model of hemorrhagic shock, P-selectin was shown to increase in the lungs, liver, heart, kidney, intestinal mesentery, stomach, small bowel, and colon (29). In another study, hemorrhagic shock resulted in early induction of intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 in the pulmonary microvessels and in the marginal and trabecular areas of the spleen (30), as evidenced by immunostaining. Furthermore, it remains unclear whether these organ-specific patterns of expression/induction correlate with the degree of leukocyte extravasation. Although the precise mechanism(s) by which hemorrhage leads to upregulation of adhesion molecules is unclear, it likely involves activation of ECs by some combina-

tion of proinflammatory cytokines, chemokines, hypoxia, low flow, and/or reactive oxygen species (ROS) (31).

These and other similar observations suggest that therapeutic targeting of leukocyte–endothelial interactions may attenuate hemorrhagic shock–induced organ damage (Table 164-2). For example, monoclonal antibodies targeted against CD18 (human leukocyte adherence glycoprotein) substantially decreased injury to the lung, liver, and gastrointestinal mucosa in hemorrhage models (32). A recombinant type I tumor necrosis factor (TNF)-binding protein also has been reported to reduce leukocyte adhesion in the liver sinusoids as well as mean adhesion time of leukocytes in the hepatic central vein (33). Resuscitation with 25% albumin after hemorrhagic shock significantly attenuated the increase in leukocyte CD11b, L-selectin, and endothelial ICAM-1 expression (34). Furthermore, high-density lipoproteins (HDLs) have been shown to inhibit the cytokine-induced expression of EC adhesion molecules both in vitro and in vivo, and to reduce inflammatory infiltration of neutrophils and development of MODS following hemorrhagic shock in rats (35). Other therapies that may prove useful in reducing leukocyte adhesion in hemorrhagic shock include adrenocorticotropin (36), hypertonic saline (37), pentoxifylline (38), low-molecular-weight heparin (39), and nonanticoagulant heparin (40). Any benefit of these agents is hypothetical and/or anecdotal and will require confirmation in clinical studies. Certainly none has become a gold standard for the treatment of hemorrhagic shock in patients.

**Table 164-2: Mechanisms of Complications in Trauma-Hemorrhage**

<i>Conditions</i>	<i>Complications</i>	<i>Mechanisms</i>	<i>Models</i>	<i>References</i>
Trauma	Hemorrhage; massive transfusion; hypotension; tissue lysis	Ischemia, I/R, activation of innate immunity (danger response via TLR); fat emboli, increased endothelin, cytokines, free radicals	H/R femur fracture	1, 3, 7 5, 6, 30
Hemorrhage	Massive transfusion; hypotension	Hypoxia/reoxygenation, ischemia, I/R, oxygen-derived free radicals, increased proinflammatory cytokines, clotting cascades, P-selectin	I/R, H/R	1, 7, 29, 30–33, 35, 36, 38, 39, 42, 43, 58, 60–62, 64
Massive transfusion	TRALI	Proinflammatory activation	Two-hit model (sepsis and transfusion)	29, 30 (see also Chapter 166)

I/R, ischemia/reperfusion; H/R, hemorrhagic shock/resuscitation; TRALI, transfusion-related acute lung injury; TLR, Toll-like receptor.

### Increased Oxygen-Derived Free Radical Formation

Severe hypoxic stress induced by hemorrhagic shock and subsequent resuscitation results in the formation of oxygen-derived free radicals. These products interact directly with ECs, resulting in lipid peroxidation and cellular damage, increased adhesion of leukocytes to endothelium, and cytokine release (41). In a mouse model of hemorrhage, ROS, derived from either endothelial xanthine oxidase or neutrophil nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, have been shown to mediate increased expression of P-selectin in the vascular beds of the lung, heart, liver, kidney, stomach, small bowel, and colon (42). Furthermore, the production of prostacyclin (PGI<sub>2</sub>), a vasodilator and inhibitor of platelet aggregation, was inhibited by oxygen radicals in the splanchnic circulation, thus leading to impaired vascular relaxation and decreased mesenteric perfusion (43). Oxygen radicals also may be associated with impaired acetylcholine-induced relaxation of blood vessels after hemorrhagic shock (44).

### Impaired Endothelium-Dependent Vasodilator Response

Marked hemodynamic alterations due to severe hemorrhage markedly affect EC function. Furthermore, shock without blood loss, such as septic shock, also showed similar EC dysfunction as observed after hemorrhagic shock (45,46). Studies have also shown that hypoxemia per se without any blood loss produces immunosuppression (47,48). In view of this, it might be expected that EC functions would also be depressed following hypoxemia. Studies in fact indicate this to be the case (49). In one study, the response to the endothelium-dependent vasodilator, acetylcholine, was significantly depressed in the thoracic aorta of rats subjected to hemorrhagic shock (50). A similar defect was observed in renal (51), cerebral (52),

pulmonary (53), and coronary arteries. (54) In contrast, endothelium-independent vasodilation induced by adenosine remained unchanged in the shock state. These results suggest that hemorrhagic stress selectively depresses endothelial function in the arterial system. This hypothesis is further supported by studies showing decreased endothelial nitric oxide synthase (*eNOS*) mRNA expression in the cerebral arterial endothelium after subarachnoid hemorrhage (55). Moreover, administration of L-arginine, the precursor for the endothelium-derived relaxing factor, nitric oxide (NO), was shown to restore vascular reactivity in a feline model of hemorrhage (56).

One potentially negative effect of NO is the formation of peroxynitrite, which is formed when excessive NO is produced, and acts as a highly toxic oxygen radical. A moderate amount of NO is useful in maintaining tissue perfusion and inhibiting leukocyte adhesion to endothelium. However, excessive amounts of NO are detrimental, because they form harmful oxygen radicals, which not only directly damage the endothelium, but also upregulate leukocyte adhesion molecules. This hypothesis is supported by several lines of investigation. First, in a rat model of hemorrhagic shock, the administration of exogenous NO in the liver resulted in significantly reduced adhesion of leukocytes to sinusoidal endothelium (57), indicating a suppressive effect of NO on the expression of adhesion molecules. Sodium nitroprusside, an NO donor, also significantly decreased neutrophil adhesion and migration in rat mesentery after hemorrhage (58). In contrast, inhibition of inducible NO synthase (iNOS), which is upregulated in the gut following hemorrhagic shock, leads to significant downregulation of gut ICAM-1 expression, indicating that excessive production of NO could serve as an inducer of intestinal ICAM-1 expression (59). NO scavenger reduces *ICAM-1* mRNA expression in the lung and causes a subsidence of inflammatory response after hemorrhagic shock (60). The amount of NO production may differentially affect the gut

function. Gut mucosa barrier function is impaired by hemorrhagic shock and leads to an enhanced bacterial translocation. Under such conditions, NO maintains intestinal integrity, thus preventing bacterial translocation by maintaining microcirculation through its vasodilating effects. On the other hand, excessive amounts of NO damage gut barrier function (61). These controversial issues need further clarification by additional studies.

### **Increased Vasoconstrictor Production and Increased Endothelial Sensitivity to Vasoconstrictors**

Endothelin, a potent vasoconstrictor, is primarily produced by vascular ECs. Increased production of endothelin, or increased vascular sensitivity to endothelin, induces persistent vasoconstriction and impairment in organ microcirculation. Plasma endothelin levels are increased during stress conditions, including hemorrhagic shock, and the elevation of plasma endothelin linearly correlates with the amount of blood loss (62). Vasoconstrictive response to exogenous endothelin also is enhanced after hemorrhage or trauma-hemorrhage, which is evident in the hepatic portal system (63). In this regard, blockade of endothelin receptor prevents systemic and portal hyperemia in the liver (64). Circulating levels of other vasoconstrictors, such as thromboxane A<sub>2</sub>, also are increased following hemorrhage, and these also could be potential therapeutic targets.

### **The Effect of Gut-Derived Mesenteric Lymph on Posthemorrhage Endothelial Dysfunction**

The splanchnic organs are subjected to severe hypoxia during hemorrhagic shock, and blood flow to the organs is persistently reduced even 24 hours after resuscitation. In response to hemorrhage, the gut produces a variety of inflammatory factors including TNF, interleukins (ILs), platelet activating factor, and oxygen radicals. Recent studies have indicated an important role of splanchnic lymph rather than portal venous blood as a causative factor in producing EC dysfunction and subsequent organ injury after hemorrhagic shock (65). Mesenteric lymph collected from posthemorrhage animals increases the permeability and even cell death of human umbilical vein ECs (HUVECs). It also activates neutrophil superoxide formation to a greater extent than does portal venous plasma (65). Given that mesenteric lymph drains into the subclavian vein via the thoracic duct, it is interesting to speculate that this fluid contributes to hemorrhagic shock-induced lung injury. In support of this notion, mesenteric lymph collected from rats subjected to trauma-hemorrhagic shock has been shown to increase permeability of cultured pulmonary microvascular ECs (66). Moreover, ligation of the mesenteric lymphatic ducts in rat model of hemorrhagic shock prevented upregulation of P-selectin and acute lung injury (67). At present, the identification of factor(s) in the mesenteric lymph responsible for producing tissue injury remains elusive, although size fractionation studies suggests that one putative mediator is larger

than 100 kDa (68). Elucidation of this factor could provide useful information in establishing a treatment strategy for the patients subjected to severe hemorrhage and/or trauma.

### **GENDER DIMORPHISM IN THE OUTCOME OF TRAUMA-HEMORRHAGE WITH SPECIAL FOCUS ON ENDOTHELIAL FUNCTIONS**

Extensive studies have shown gender dimorphism in cardiovascular and immune response to stressful conditions. In this regard, proestrus female rats are better able to tolerate the deleterious effects of trauma-hemorrhage on cardiovascular and immune functions, compared with males (69). Additionally, male rats subjected to hemorrhagic shock had increased gut injury and lung permeability compared with female rats (70). Furthermore, mesenteric lymph from male rats after hemorrhagic shock was more cytotoxic to HUVECs compared with that from female rats (70). Interestingly, the effects of trauma-hemorrhage in precastrated males were similar to female animals, whereas those of ovariectomized female animals were similar to intact males. These results indicate that the prevailing sex hormone milieu at the time of injury is an important determinant in maintaining or inhibiting organ and immune functions following trauma-hemorrhage.

Vascular endothelial function and associated organ perfusion also show gender dimorphism. Although cardiac and splanchnic perfusion was significantly decreased following trauma-hemorrhage in male rats, such alterations were attenuated in proestrus females (71). Moreover, males, but not females, demonstrated endothelial dysfunction in the intestinal vasculature, as evidenced by impaired response to acetylcholine (71). An understanding of these gender-specific responses may provide important insights into therapy. Indeed, as is discussed later, studies in animal models of trauma-hemorrhage have established a role for several sex hormones and hormone receptor inhibitors in improving EC function.

#### *Estrogen*

Estrogen (E<sub>2</sub>), the primary female sex hormone, acts not only as a gonadal hormone, but also as a vasomodulator. In a rat model of trauma-hemorrhage, administration of a single subcutaneous dose of E<sub>2</sub> to male animals restored the depressed cardiac, hepatic, and immune functions (72–74). Furthermore, E<sub>2</sub> administration improved splanchnic perfusion and oxygen consumption in the small intestine when trauma-hemorrhage was followed by a “second hit,” such as sepsis (75). These results suggest that E<sub>2</sub> increases organ perfusion, perhaps through its stimulation of vasodilatory factors (e.g., PGI<sub>2</sub> and NO synthesis) and inhibition of vasoconstricting mediators (e.g., angiotensin II and endothelin) (Figure 164.2). Indeed, E<sub>2</sub> induces the expression of eNOS in cultured ECs (76). This effect is independent of cytosolic calcium (Ca<sup>2+</sup>) mobilization, and may be associated with rapid activation of the phosphoinositide 3-kinase (PI3K)/Akt pathway (76,77). Moreover, E<sub>2</sub> inhibits endothelin release from

Figure 164.2. Estrogen-mediated regulation in the release of vasoactive agents from vascular ECs. Actions may be mediated either by the activation of ERE through genomic pathways or by direct activation of intracellular signal transductions through nongenomic pathways. ERE, estrogen-response element; ET, endothelin; O<sub>2</sub><sup>-</sup>, superoxide anion; ATII, angiotensin II; PGI<sub>2</sub>, prostacyclin; NO, nitric oxide.

cultured ECs by inhibiting mitogen-activated protein kinase (MAPK) activity (78). Finally, there is evidence that E<sub>2</sub> attenuates endothelin-mediated vasoconstriction of the hepatic portal system following trauma-hemorrhage (63).

Estrogens, like other steroid hormones, cross the cell membrane and form complexes with cytoplasmic receptors. These ligand–receptor complexes enter the nucleus and bind to specific DNA sequences called E<sub>2</sub>-responsive elements. This process, which occurs over hours, leads to increased expression of target genes and alteration in cellular function. In addition to the latter “genomic” effects of estrogen, E<sub>2</sub> exerts “nongenomic” effects through receptor-mediated or receptor-independent pathways (79). These activities do not require new transcription or translation, and occur very rapidly (on the order of minutes). The nongenomic pathway activates MAPK, cyclic guanosine monophosphate (cGMP) production, and rapid release of NO from ECs (see Figure 164.2) (80). A recent report indicates that the nongenomic pathway contributes to the vasodilatory effects of E<sub>2</sub> through the activation of endothelial E<sub>2</sub> receptors located on the cell surface (79).

Two different types of E<sub>2</sub> receptors (ERs) have been identified in mammalian tissues: ER- $\alpha$  and ER- $\beta$ . These receptors differ in their function, ligand affinity, and tissue distribution. ER- $\alpha$  is believed to play a more prominent role than ER- $\beta$  in regulating endothelial function. ER- $\alpha$  correlates functionally with E<sub>2</sub>-mediated rapid activation of eNOS, production

of cGMP, release of NO, and activation of MAPK in cultured ECs (79), and increased production of NO in the thoracic aorta (81).

Other mechanisms of E<sub>2</sub>-mediated salutary effects on endothelium may involve inhibition of leukocyte adhesion and reduced production of oxygen-derived free radicals. Inflammatory cytokine-induced expression of E-selectin is suppressed by E<sub>2</sub>, through a process that requires the DNA-binding domain of ER- $\alpha$  (82). Estrogen causes a time- and concentration-dependent decrease in oxygen radical formation in HUVECs (83). Estrogen also increases the activities of superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase in female bovine aortic ECs, which leads to decreased oxygen-derived free radical production, compared to those in male (84).

### Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is the most abundant steroid hormone in plasma and, depending on the hormonal milieu, serves as an intermediate in the synthesis of testosterone and E<sub>2</sub>. DHEA has both androgenic and estrogenic effects. The administration of a single dose of DHEA following trauma-hemorrhage restored the depressed splenocyte and macrophage functions under those conditions (85). When sepsis was induced by cecal ligation and puncture at 48 hours after trauma-hemorrhage, DHEA administration following trauma-hemorrhage significantly increased the survival rate of animals (80). The impaired cardiac output and hepatocellular function following trauma-hemorrhage were also restored by DHEA administration (86). These results indicate the presence of a mechanism similar to estrogen with regard to the regulation of vascular tone. However, since DHEA is a precursor for both androgen and E<sub>2</sub>, it remained unclear whether the administered DHEA acted through androgenic or estrogenic pathway in those animal models. This question was resolved by administering DHEA along with an ER antagonist (ICI 182,780), which abolished the salutary effects of DHEA (62). These findings indicate that the effects of DHEA on cardiac and hepatocellular functions after trauma-hemorrhage are mediated via the ER. Nonetheless, it is still unclear whether the ERs are activated by direct binding of DHEA, or by E<sub>2</sub> synthesized through the metabolism of DHEA (87).

### Androstenediol

Androstenediol is one of the metabolites of DHEA. Studies have shown that administration of androstenediol following trauma-hemorrhage and resuscitation attenuated the reduced portal blood flow, bile production, and serum albumin levels under those conditions (87). This was associated with upregulation of hepatic eNOS expression in the liver, which might produce appropriate amounts of NO in the liver and maintain hepatic microcirculation. As stated earlier, upregulation of iNOS and greater amounts of NO production are thought to be among the major contributors to hepatic injury after severe hemorrhagic shock. Additionally, endothelin is another mediator responsible for deteriorating liver circulation after

trauma-hemorrhage (63). Interestingly, *in vivo* administration of androstenediol significantly inhibited the upregulation of these factors at both mRNA and protein levels (87). This may at least partially explain the mechanism of androstenediol-mediated salutary effects in the hepatic circulation following trauma-hemorrhage. Moreover, androstenediol showed salutary effects on cardiac function and splanchnic circulation, both of which are also decreased following trauma-hemorrhage (88).

### *Flutamide*

Flutamide, a nonsteroidal androgen receptor antagonist, has protective effects on immune function in male mice following trauma-hemorrhage (89). Although IL-2 and IL-3 release by splenocytes, splenocyte proliferative capacity, as well as splenic and peritoneal macrophage IL-1 release were significantly reduced following trauma-hemorrhage, these alterations were minimized by administration of flutamide following trauma-hemorrhage. The survival rate following trauma-hemorrhage and induction of subsequent sepsis was also significantly increased in the flutamide-treated group (90). In addition, the decreased left ventricular performance, cardiac output, hepatic microvascular blood flow, and hepatocellular function following trauma-hemorrhage were significantly improved by flutamide treatment (91). Androgens also appear to play an inhibitory role in small intestinal endothelial function. In rats with low plasma androgen levels (castrated males, proestrus females, and estrogen-treated non-castrated males), a positive correlation was noted between plasma androgen levels and acetylcholine-induced perfusion pressure reduction in the small intestine (92). Intestinal tissue NO levels were also significantly higher in these animals, indicating an inhibitory role of androgens on endothelium-derived NO production. In this regard, flutamide administration following trauma-hemorrhage attenuated the depressed endothelium-dependent vascular relaxation (i.e., the production of vascular endothelium-derived NO) (93). Organ blood flow and O<sub>2</sub> consumption also were improved in the liver, small intestine, and kidneys in males. Interestingly, the expression of thromboxane A<sub>2</sub> receptor and the action of thromboxane A<sub>2</sub> on the artery have been shown to be enhanced by testosterone (94). In contrast, the synthesis of PGI<sub>2</sub> has been shown to be inhibited by testosterone (95). Although the precise mechanism responsible for the beneficial effects of flutamide on endothelial function remains unknown, the findings described here may indicate one of the possible mechanisms.

### **FUTURE DIRECTIONS OF ENDOTHELIUM RESEARCH FOLLOWING TRAUMA-HEMORRHAGIC SHOCK**

Extensive studies using animal models have helped to elucidate mechanisms of endothelial dysfunction following trauma-

hemorrhage. Collectively, these data have provided a strong foundation for therapeutic intervention. However, despite promising results in animals, clinical trials with these agents have yielded disappointing results. For example, leukocyte adhesion blockade with a recombinant human monoclonal antibody against CD18 failed to demonstrate efficacy in a phase II clinical study of trauma patients with hypotension from hemorrhagic shock (96). Although resuscitation with hypertonic saline plus dextran was reported to benefit animals with trauma (97), the effect was limited to hemodynamic improvement in human patients (98). Although ligation of the mesenteric lymphatic duct protects against lung injury in animal models of trauma-hemorrhage, this procedure is not practical in the clinical setting. Thus, effective treatment strategies for patients with major traumatic injuries still must be developed.

Based on the findings with estrogen, DHEA, androstenediol, and flutamide, these hormones/receptor antagonists may prove useful as a therapeutic adjunct in trauma-hemorrhage. These hormones/receptor antagonists may not only prevent organ dysfunction by preserving the integrity of endothelial function, but may also improve and restore immune and cardiovascular depression following trauma-hemorrhage. Another advantage of these agents is that, in contrast to anti-cytokine or antichemokine therapies, they target a broad spectrum of homeostatic functions, and thus restore integrity of the entire organism (including endothelial function). In addition, they are endogenous mediators and pose little risk to patients, even when used chronically. Nonetheless, further studies are required to elucidate the precise nature and mechanisms by which sex steroids influence the endothelium, particularly following trauma-hemorrhage and other low-flow conditions.

### **KEY POINTS**

- Endothelial dysfunction occurs following trauma-hemorrhage and contributes to the resulting organ damage.
- The major mechanisms involved in endothelium-mediated organ injury are: (a) enhanced inflammatory processes; (b) cellular damage by excessive production of oxygen-derived free radicals; and (c) impaired tissue circulation due to an imbalance between vasodilators and vasoconstrictors.
- Female sex hormones, especially estrogen, have been shown to inhibit these responses, thereby suggesting that the use of estrogen following trauma-hemorrhage could be a useful therapeutic adjunct for preventing multiple organ dysfunctions following trauma-hemorrhage.

- Although several mediators and agents have been shown to be useful in preventing endothelial dysfunction following trauma-hemorrhage in animal models, many of them have not been shown to be effective in the clinical arena following trauma.
- There appears to be a hormonal regulation of endothelial functions under stressful conditions such as trauma-hemorrhage. In this regard, sex hormones such as estrogen, DHEA, androstenediol, or the hormone receptor antagonist, flutamide, have been shown to be effective in restoring trauma-hemorrhage-induced endothelial function.

#### Future Goals

- To examine the use of sex hormones or their receptor antagonists in the clinical arena to determine whether such adjuncts improve the outcome following injury; the side effects of these agents may be minimal because most of the proposed agents are administered only once after injury, and all these agents are widely used clinically without major complications.

# Coagulopathy of Trauma

## Implications for Battlefield Hemostasis

---

Anthony E. Pusateri and John B. Holcomb

*U.S. Army Institute of Surgical Research, Fort Sam Houston, Texas*

There is increasing appreciation for the role of the endothelium in orchestrating the host response to infection and injury, as occurs in sepsis, trauma, or surgery. An urgent need exists to identify novel therapies that attenuate or modify the host response and thus improve patient outcome. This chapter focuses on the nature and mechanisms of coagulopathy associated with trauma, particularly that related to combat injury. Trauma-related coagulopathy is qualitatively different from that seen in sepsis and surgery. Trauma suffered in combat, as distinct from civilian life, introduces additional variables that may impact on the bleeding phenotype. Although at present we have little understanding of how the endothelium is influenced by and/or mediates the host response in trauma, it seems likely that this organ will ultimately serve as an important diagnostic tool and therapeutic target.

### NATURE OF COMBAT WOUNDS

#### Causes of Death

Approximately 50% of those who die from combat injury die from exsanguinating hemorrhage, which is the leading cause of death from combat trauma (1,2). Historically, a small percentage of these deaths have been from sites where the bleeding might be controlled by compression. This population of casualties will be reduced through the use of improved training for self care, medics, and other first-responder personnel, coupled with effective equipment like improved tourniquets or hemostatic dressings. The military has aggressively and successfully pursued these measures. The largest percentage of potentially preventable hemorrhagic combat deaths, however, is due to noncompressible (internal) hemorrhage (47%). The challenge is to develop means with which medics can initiate control of truncal hemorrhage through nonsurgical means. This represents a significant research hurdle. Many of these combat deaths occur from almost immediate exsanguination from wounds that are not amenable to surgical

repair. However, there exists a population of potentially preventable deaths, comprising approximately 6% of all combat deaths and 47% of the potentially preventable deaths, that may be salvageable with improved hemorrhage-control methods for internal bleeding (1,2). These casualties often die during transport, and also are represented in the deployed hospitals where hemorrhagic death early after admission is not uncommon. This discussion is primarily focused on this population.

#### Wounding Patterns

Combat trauma differs from civilian trauma in several important ways. In combat trauma, the distribution of mechanisms of injury is strongly dependent on the branch of service and the tactics of the enemy. For example, burns are extremely common among those wounded in armored fighting vehicles, but not so among dismounted infantry (1). Military personnel in downed aircraft suffer burns and massive blunt force injury with a lethality rate approaching 80%. Among dismounted troops or those in open vehicles, penetrating trauma dominates (>80%) and, in the current Global War on Terrorism, explosions account for 77% of all injuries, resulting in casualties with significant soft tissue injury and multiple penetrating wounds. Small-arms fire accounts for 17%, whereas significant burns account for 5% of all evacuated casualties (2). A common theme in military trauma, one that differentiates it from civilian trauma, is the predominance of multiple massive soft-tissue injuries, the number of penetrating wounds in each patient casualty, and the sheer number of those patients who arrive daily.

#### Evacuation Time

Due to tactical and environmental factors, the time required for evacuating combat casualties for surgical care is often prolonged far beyond civilian urban transport times. Under

combat conditions, medics and others often must stabilize and maintain a severely injured patient for several hours before handing them off to others, who must maintain the casualty patient during transport. Environmental factors, austere field conditions, and prolonged evacuation times make the combat casualty patient particularly prone to developing life-threatening, trauma-related coagulopathy.

## MECHANISMS OF TRAUMA COAGULOPATHY

### Incidence and Importance

In severe trauma, blood loss, tissue damage, inflammatory response, immobilization, and environmental factors can set the stage for the development of coagulopathy. The derangements in the blood coagulation system occur rapidly and have been observed within the first hour and even minutes following trauma. By the time of arrival at the emergency department, 28% (2,994 of 10,790) of trauma patients had a detectable coagulopathy that was associated with poor outcome (3,4), and the incidence of coagulopathy was increased with increasing injury severity scores (Figure 165.1). Patients who have sustained traumatic injuries and hemorrhage are at risk for coagulopathy due to factors such as hypothermia, acidosis, and hemodilution (5–9), as well as the actions of immune cells and inflammatory mediators (10–14). Consumptive processes also play a role (15). Patients with traumatic brain injury are prone to develop coagulopathy, which may be either hypercoagulable or hyperfibrinolytic, as rapidly as 1 to 4 hours after injury (16–24). Release of tissue factor from injured brain tissue has been proposed as a likely causative factor of the coagulopathy associated with head trauma (11,25); however, it does not appear that this fully explains the phe-

nomenon (16,24). The remainder of this discussion focuses on those trauma patients without head injury who are at risk of bleeding to death.

In the normal state, a balance exists among procoagulant, anticoagulant, fibrinolytic, and antifibrinolytic mechanisms, and platelet function also is regulated. The result is a system that allows circulating blood to remain in a fluid state yet respond within seconds to a vascular insult to provide a compartmentalized procoagulant response. This system allows hemostasis to occur without appreciably altering the systemic anticoagulant balance. Hypothermic, acidotic, hemodilutional, and inflammatory changes occur rapidly following severe trauma, and often are present and compounded by standard treatment by the time of admission to the emergency department. Trauma-related coagulopathy is multifactorial and characterized by dysregulation of balanced mechanisms. Given the compressed time span during which the conditions associated with coagulopathy develop, it is apparent that multiple factors contribute to coagulopathy simultaneously, especially in the most severely injured patients. At a given point during the posttrauma time course of a casualty, some coagulopathic processes may dominate, while others are masked by dominant processes or are not yet fully developed. It becomes apparent that resuscitation interventions can contribute either favorably or unfavorably to this process. The following discussion addresses in some detail hypothermia, acidosis, hemodilution, systemic inflammatory response, and consumptive processes as they pertain to trauma coagulopathy during the first 12 hours after trauma. This is the critical period following severe trauma, largely determining if the patient will live or die (26,27). It is also a period when the care of a combat casualty patient may significantly differ from that of a civilian casualty patient.

Figure 165.1. Coagulopathy in acute trauma. (Reproduced with permission from Brohi K, Singh J, Heron M, Coats T. Acute traumatic coagulopathy. *J Trauma*. 2003;5:1127–1130.)

## Hypothermia

Combat casualty patients are at particular risk for developing hypothermia due to such factors as the field environment, use of cold prehospital fluid resuscitation, wounding mechanisms that result in loss of clothing and tissue, and extended evacuation times. It is well known that hypothermia slows the coagulation process. Extended plasma clotting times are detectable below 35°C (28,29). Enzymatic rates for the tissue factor/factor VIIa and the prothrombinase complexes decrease with temperature, consistent with the expected twofold increase in enzymatic rate for each 10°C increase in reaction temperature for most enzymes (30). The inhibitory activity of antithrombin III (ATIII) declines with temperature to a lesser degree than do coagulation enzyme rates (31), suggesting that changes in both pro- and anticoagulant components of the balance may contribute to the effects of hypothermia on coagulation. The rate of whole-blood clot formation is slowed, but final clot strength is not reduced by hypothermia (28,32,33). Hypothermia reversibly impairs platelet function, resulting in defects in primary hemostasis and possibly other functions. Template bleeding times are extended by hypothermia (34,35). Platelet aggregation in response to thrombin is greatly reduced, as is shear-induced platelet surface adhesion when the temperature declines to 33°C (31). Platelet aggregation in response to shear increases during hypothermia, but this is not associated with functional activation, and may represent a mechanism that reduces the number of platelets available to respond physiologically to vascular insult (36). Platelet thromboxane production is decreased during hypothermia (34,35). In whole blood, hypothermia slows thromboxane production, serotonin release, and thrombin generation (37). Taken together, alterations in pro- and anticoagulant processes, and changes in platelet function, combine to impair hemostasis during hypothermia.

## Acidosis

Plasma clotting times are prolonged as pH is reduced (38). The activity of the tissue factor/factor VIIa complex decreases by 55%, and activity of the prothrombinase complex declines by 70% as pH levels decline from 7.4 to 7.0 (30). There also appears to be a platelet defect resulting from acidosis that involves both platelet depletion and altered function. Following induced acidosis at pH 7.1, capillary bleeding time was prolonged in swine (32). This was accompanied by a reduced whole blood clotting response to collagen, a platelet agonist. Acidosis reduces the ability of platelets to aggregate in response to the physiological agonists epinephrine, adenosine diphosphate (ADP), and particularly collagen (39,40). Reduced responsiveness of platelets to physiological agonists under acidotic conditions may involve inhibition of extracellular calcium influx (41,42). In apparent contrast with reduced platelet responsiveness in acidosis, a number of early studies demonstrated that prolonged acidosis resulted in platelet depletion. In a recent study, acidosis increased platelet acti-

vation status and the number of circulating aggregates, while decreasing platelet counts (43). It is not clear how this phenomenon occurs. This *in vivo* activation may be a shear-related phenomenon or the result of a nonfunctional partial activation of platelets in response to acidosis. The end result appears to be that a population of platelets aggregate in response to acidosis and are rapidly removed from the circulation, whereas remaining platelets may be less able to form an initial platelet plug in response to physiological agonists at the site of a vascular injury. The impairments in coagulation enzyme and platelet function induced by acidosis can be significant in terms of hemostasis. The combined effects of hypothermia and acidosis on certain hemostatic parameters appears to be greater than the effects of either condition alone (Figure 165.2) (32,45).

## Hemodilution

Hypovolemic shock resulting from hemorrhage leads to a hemodilution due to the altered balance between blood pressure and tissue oncotic pressures. The remaining coagulation factors and platelets are diluted as the body shifts fluid from the extravascular to intravascular compartment to restore circulating volume (46). Further dilution occurs with the standard crystalloid resuscitation practices. This dilution of coagulation proteins and functional platelets is compounded by massive transfusion of standard blood products that have a lower functionality than native blood (46). Mild hemodilution (up to 20% to 30%) with saline or lactated Ringer's solution results in a slightly hypercoagulable state, as measured by some, but not all, laboratory tests (47), but this hypercoagulability is reversed at higher levels of dilution (48). Low platelet counts are associated with poor hemostasis and reduced clot strength. Red cells contribute to hemostasis by concentrating platelets near the endothelial surface, metabolically enhancing platelet responsiveness, and possibly by contributing procoagulant surfaces at the site of thrombus formation. Therefore, reduced red cell count from hemodilution can also contribute to coagulopathy (49). Colloidal solutions can impair blood clotting to a degree beyond that explained by simple dilutional effects, depending on the nature of the colloid molecule. As an example, we have observed that fluids containing high-molecular-weight hetastarch reduced the velocity of clot formation by 48% and final clot strength by 24% compared to normal saline or lactated Ringer's solution, over a range of hemodilutions *in vitro* (A.E. Pusateri, J.B. Holcomb, unpublished observations). Hetastarches, dextrans, and gelatin induce a von Willebrand disease-like condition that impairs hemostasis by effectively reducing factor VIII and von Willebrand factor (vWF) concentrations. Among hetastarch formulations, those that employ molecules with higher molecular weights and higher degrees of hydroxyethyl substitution have the greater effect. Albumin appears to have little, if any, negative effect on coagulation (50). A degree of hemodilution occurs naturally as part of the body's attempt to restore circulating blood volume. This by itself may induce changes in hemostatic function. Much more

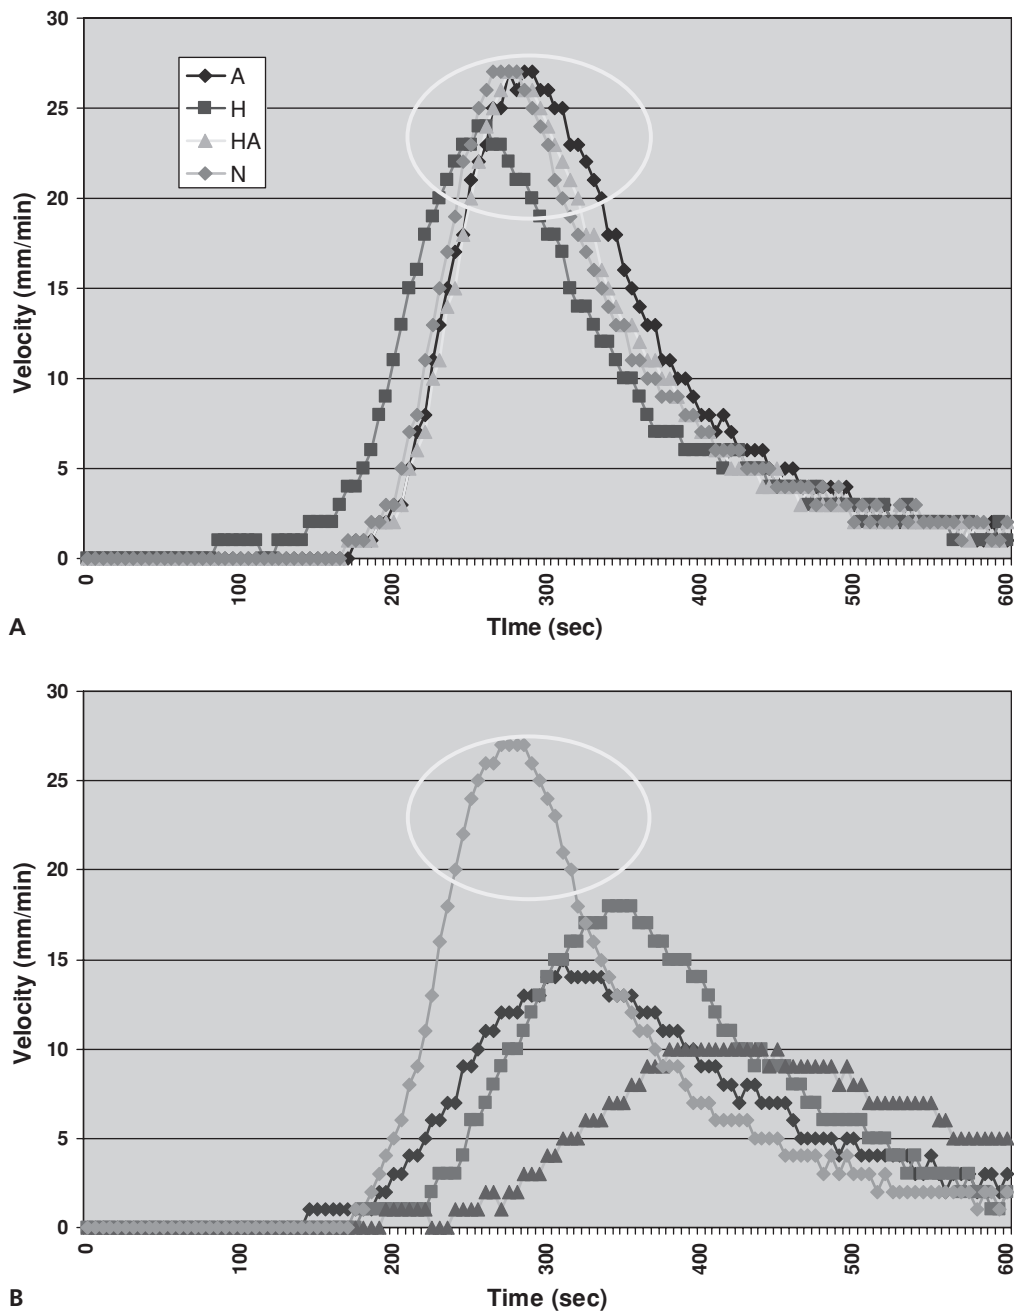

Figure 165.2. Velocity of clot formation before (A) and after (B) induction of in vivo hypothermia (*H*; core temperature 32°C), acidosis (*A*; pH 7.1), or hypothermia and acidosis (*HA*; core temperature 32°C and pH 7.1). Velocity of clot formation measured using thromboelastography, as previously described (44). Coagulopathic conditions decrease the peak velocity of clot formation and prolong the time required to reach peak velocity (32).

significant are the dilutional effects of common fluid resuscitation regimens.

### Inflammatory Response and Consumptive Processes

Historically, the term disseminate intravascular coagulation (DIC) has been used to describe the consumptive processes that may occur following trauma. It is now understood (ISTH

DIC subcommittee), and we agree that the consumptive process with regard to trauma occurs along a continuum and is not limited to “classical” DIC, as occurs in classical sepsis. This is especially true during the early posttrauma period (15). This is an important distinction, in terms of pathophysiology, nomenclature, and treatment. Nonetheless, the term DIC will be used here for continuity with the majority of the literature. A combination of mechanisms, including release into the

circulation of phospholipids and tissue factor from damaged tissues, mechanical damage to the endothelium, and hemolysis may contribute to DIC (11). Additionally, it is clear that immune cells and inflammatory mediators play a major role in the development of DIC (10–13). It appears that inflammation and DIC synergistically contribute to poor outcome in trauma patients (51,52). The severity of the systemic inflammatory response syndrome (SIRS) following trauma corresponds with the development of organ failure (53,54) and is an independent predictor of length of stay and mortality (55,56). In patients with trauma, the duration of SIRS is a key determinant for the development of multiple-organ dysfunction syndrome (MODS) (56). Further, persistent systemic thrombin activity associated with DIC is closely linked to SIRS (14,57). Following severe trauma, immune cells and inflammatory mediators impinge upon hemostatic regulatory mechanisms at multiple levels, including effects on the procoagulant, anticoagulant, and fibrinolytic mechanisms, as well as on platelet function.

#### *Procoagulant Response*

Tissue factor is elevated within hours of severe trauma, both as plasma tissue factor (15,57–60) and as tissue factor expressed on circulating monocytes (23). In a series of trauma patients with a mean injury severity score of 24, monocyte tissue factor expression was elevated to 25% to 30% of monocytes at the time of presentation to the emergency department (compared to an average of 2% expression for healthy controls). These patients also had more platelet–monocyte aggregates (23). Rapid elevations in plasma free tissue factor have been observed in patients with severe trauma without DIC (58), but tissue factor levels have been most highly elevated in trauma patients who developed SIRS (57), DIC (60), and adult respiratory distress syndrome (ARDS) (58,61). The source of this early rise in plasma tissue factor is not clear. It may be the result of cleavage/shedding from tissue factor–bearing monocytes (23). It also may be due to release of tissue factor from endothelial cells (ECs) in response to cytokines (62).

#### *Suppression of Physiological Anticoagulant Mechanism*

The impaired function of natural regulatory pathways of coagulation activation also contributes to the procoagulant state and intravascular fibrin deposition. Plasma levels of ATIII, the most important inhibitor of thrombin, are reduced in trauma patients with DIC (20,53,59), and the degree of reduction has been linked to the severity of DIC as well as morbidity and mortality in trauma patients. In 1996, Owings and colleagues demonstrated that reduced ATIII levels in trauma patients were associated with DIC, ARDS, and deep vein thrombosis (DVT) (20). Lower ATIII levels were associated with organ failure in another study (53). This reduction in ATIII levels appears to be the result of a combination of consumption due to continued thrombin generation, degradation by neutrophil elastase, and impaired ATIII synthesis (11). Other anticoagulant systems also appear to be involved. Low protein C (59), an imbalance between the levels of tissue

factor and tissue factor pathway inhibitor (58,63), and loss of thrombomodulin from ECs (64) also have been associated with coagulopathy after trauma.

#### *Changes in Fibrinolysis*

A consistent finding in trauma-related DIC is that the fibrinolytic system is impaired. An increased level of plasminogen activator inhibitor (PAI)-1 has been a consistent finding in posttraumatic DIC (51,59,65), and this elevation is observed very early in the posttrauma period. In another study, tissue-type plasminogen activator (t-PA) and PAI-1 were elevated in trauma patients with DIC (66). This may reflect an initial fibrinolytic activity due to endothelial release of t-PA that is offset by a sustained large increase in PAI-1, as has been observed in response to experimental ischemia–reperfusion injury (67,68). Gando and colleagues reported reduced  $\alpha$ 2-antiplasmin concentrations in trauma patients, perhaps reflecting reduced requirements resulting from suppression of plasminogen activation by PAI-1 (15).

#### *Platelet–Leukocyte Interaction*

Shortly following trauma, platelet activation can be detected in the circulation. In trauma patients, the percentage of circulating activated platelets (as indicated by P-selectin and GPIIb–IIIa expression) was increased approximately 10-fold over the levels in normal controls at the time of arrival at the emergency department (69). In addition to exposing circulating procoagulant phospholipid surfaces, this activation results in enhanced platelet–leukocyte interactions, which can promote leukocyte adhesion to endothelium (70).

#### *Role of Cytokines*

Inflammatory cytokines and other products released by immune cells play a significant role in the derangement of coagulation and fibrinolysis. Elevations in interleukin (IL)-1 (65), IL-6 (53,66), IL-8 (53), and tumor necrosis factor (TNF)- $\alpha$  (65) have been documented within 12 hours after trauma in patients who developed DIC. These cytokines are related to posttraumatic inflammatory response and organ failure, as well as DIC (53,65,66).

IL-1 increases endothelial procoagulant activity (71,72). Additionally, IL-1 decreases endothelial t-PA and increases PAI-1 (73), leading to reduced fibrinolysis. IL-6 is procoagulant (74), through actions on monocytes (75) and endothelium (62), but does not appear to affect the fibrinolytic system (74). IL-8 may exert procoagulant activity by increasing monocyte tissue factor expression (75). TNF- $\alpha$  is procoagulant (76,77), enhancing tissue factor expression by ECs (62,76) while suppressing the protein C pathway (76,78–80). TNF- $\alpha$  also stimulates plasminogen activation and PAI-1 activity, yielding a net antifibrinolysis (73,77,81). The actions of cytokines during the early posttrauma period are consistent with the overall procoagulant and antifibrinolytic state that favors the deposition of fibrin within the microvasculature and the systemic consumption of coagulation proteins and platelets.

### *Elastase*

Neutrophil-derived elastase is elevated systemically within hours of trauma (51,53), and has been related to poor outcome. Neutrophil activation is associated with endothelial injury, which is important in the development of MODS in posttrauma DIC patients (52,53,64). Elastase cleaves thrombomodulin, impairing the protein C system of anticoagulation (82–84), and may act synergistically with oxygen-free radicals in damaging the endothelium (85).

### *Oxidation and Nitration*

Peroxynitrite ( $\text{ONOO}^-$ ) is a potent and a relatively long-lived cytotoxic oxidant formed *in vivo* in the reaction between superoxide anion ( $\text{O}_2^-$ ) and nitric oxide (NO). Neutrophils and activated macrophages that produce significant quantities of  $\text{O}_2^-$  and NO during inflammatory responses may be the major sources of  $\text{ONOO}^-$ . When  $\text{ONOO}^-$  is generated in excess, it may damage cells and functional proteins by oxidation and nitration, potentially resulting in altered function of platelets and proteins of the coagulofibrinolytic system. Under these conditions, NO is scavenged in the production of  $\text{ONOO}^-$ , diminishing the normal regulatory influence of NO and potentially leading to further dysregulation of the local hemostatic balance. At low concentrations of  $\text{ONOO}^-$ , platelet response to physiological agonists is inhibited in a reversible manner (86,87). However, at higher concentrations,  $\text{ONOO}^-$  results in partial activation of platelets and damages platelets such that their ability to respond to normal physiological agonists, such as collagen (86) and thrombin (88–90), is reduced.  $\text{ONOO}^-$  also reduced cyclooxygenase activity (91). Incubation of normal plasma with peroxynitrite resulted in dose-dependent increases in prothrombin time (PT) and activated partial thromboplastin time (aPTT), and in prolonged clot formation time and reduced clot strength as determined by thromboelastography (92). Components of the procoagulant, anticoagulant, and fibrinolytic mechanisms can be impaired by  $\text{ONOO}^-$ . Exposure of fibrinogen to  $\text{ONOO}^-$  results in oxidation of fibrinogen and a resultant dose-dependent decrease in the ability of fibrinogen to form a fibrin clot (93). Peroxynitrite incubation decreases the activities of tissue factor (94–96), factor VII, factor VIII complex, and factor X (92). ATIII and protein C activity also are impaired by peroxynitrite (92), as is t-PA (97). Oxidants other than  $\text{ONOO}^-$  may have similar effects (98). Oxidation and nitration of a number of cellular- and plasma-phase molecules can result in the dysregulation of the hemostatic mechanism at multiple levels.

### **Summary of Coagulopathy Mechanisms**

Within the first hours following severe trauma, blood loss, tissue damage, immobilization, and environmental factors can set the stage for the development of coagulopathy. Multiple factors, including hypothermia, acidosis, hemodilution (including both “natural” and that due to resuscitation measures), inflammatory response, and consumptive processes impair hemostasis and potentially predispose to later com-

plications by deranging the normal hemostatic mechanism. The system is affected at multiple levels of regulation, including pro- and anticoagulant mechanisms, pro- and antifibrinolytic mechanisms, and platelet function. Involved components include the plasma, platelets, red cells, immune cells, and endothelium.

### **NEED AND OPPORTUNITY FOR INITIAL HEMOSTATIC RESUSCITATION AND INFLAMMATORY MODULATION**

Present initial resuscitation regimens provide intravascular volume to enhance stroke volume and cellular perfusion but do nothing hemostatically, other than contribute to hemodilution. For the majority of trauma patients, this is adequate, because they are minimally injured and in reality do not require resuscitation. In the urban trauma environment, this is probably adequate for 75% of the patients who arrive at a trauma center, but even in an arena of very rapid evacuation, fully 25% (who are the most seriously injured) arrive already coagulopathic. In this environment, advanced care, including blood products and other resources, will be rapidly available after a relatively short evacuation. In contrast, the military casualty patient and many rural transport patients often must be stabilized for several hours prior to receiving surgical care or blood products. Conventional strategies for these casualties serve to promote the coagulopathy in the severely injured patient. A new hemostatic resuscitation approach offers the opportunity to deliver drugs or other compounds that could enhance survival by mitigating factors associated with coagulopathy. This could result in a decrease or cessation of bleeding, which could reduce overall blood loss, the period or severity of shock, lessen acidosis and hypothermia, and improve survival. Delivery of an immunomodulatory drug might dampen the initial inflammatory response to trauma which, by extension, could reduce the consumptive processes and related longer-term sequelae, such as SIRS, MODS, and multiple-organ failure (MOF).

Although currently no approved hemostatic resuscitation regimen exists, some promising drugs may prove useful. Recombinant activated factor VII has been used to improve hemostasis in hemophilia patients for years, and use in other coagulopathies, including those resulting from trauma, is gaining attention around the world. The theoretic risk for this drug is that it might induce DIC or thrombosis in trauma patients who have systemic exposure of tissue factor and procoagulant phospholipids. However, data from a recent prospective, randomized, blinded, multicenter trial suggest that the safety fears related to this theoretic risk are unfounded in this population (99). As the safety and efficacy of this drug for trauma becomes more certain, it may be possible to employ this drug in the prehospital setting as part of a resuscitation regimen. Resuscitation solutions that contain hypertonic saline inhibit immune cell function. Evidence suggests that early resuscitation with hypertonic solutions may

minimize the initial inflammatory response, mitigating the drastic shifts in hemostatic regulatory mechanisms due to the activation of immune cells and release of inflammatory mediators. Freeze-dried platelets, plasma, and fibrinogen also are becoming available (100). Combination therapy using these and other products could form the basis for a hemostatic resuscitation strategy, which may then be incorporated into a global damage control resuscitation paradigm that would address more than just intravascular volume and tissue oxygenation. Focused research examining these and other approaches is needed to develop a hemostatic resuscitation regimen for the treatment of combat casualty patients and potentially other trauma patients.

### KEY POINTS

- Trauma-related coagulopathy is multifactorial, involving the nearly simultaneous effects of hypothermia, acidosis, hemodilution, inflammatory responses, and consumptive processes in various combinations that result in dysregulation at multiple levels of the hemostatic mechanism.
- Combat casualty patients differ from civilian trauma patients in both the severity and pattern of wounds, as well as in the expected time required for evacuation to surgical care. Further advances in prehospital stabilization and treatment are essential to improve battlefield hemostasis.
- Current prehospital and hospital resuscitation strategies using crystalloids, colloids, and blood products can worsen trauma-induced coagulopathy in severely injured casualties

### Future Goals

- To undertake research aimed at furthering our understanding of the interaction between the coagulation and inflammatory processes, thus allowing us to define the optimal hemostatic resuscitation strategy

## The Effects of Blood Transfusion on Vascular Endothelium

---

Christopher C. Silliman

*Bonfils Blood Center and the Departments of Pediatrics and Surgery, University of Colorado  
School of Medicine, Denver*

Blood transfusions reduce the mortality associated with such conditions as major trauma, major surgery, and myelotoxic chemotherapy and, as such, have revolutionized medical care. With the exception of acute hemolytic transfusion reactions, the practice of blood transfusion was once considered to be relatively risk-free. It is now clear that blood transfusions are associated with short- and long-term side effects, including the transmission of infectious agents, transfusion-related immunomodulation (TRIM), and proinflammatory stimulation of the innate immune system (Table 166-1) (1–3). As an interface between circulating blood and underlying tissue, the endothelium is preferentially exposed to cellular and noncellular mediators contained within blood products. Thus, transfusion may result in phenotypic alteration of the endothelium.

### INFECTIOUS AGENTS

Owing to marked improvements in screening assays (particularly nucleic acid amplification–based protocols), transfusion-transmitted viral infections rarely occur today. However, it is important to recognize that pathogenic viruses from other parts of the world may undergo a change in their natural range of distribution, and thus become introduced into the United States, as illustrated by the recent reports of West Nile Virus (4). Many viruses and viral proteins, most notably cytomegalovirus (CMV) and the Tat proteins from human immunodeficiency virus (HIV)-1, have been shown to interact directly with the endothelial cell (EC) membrane, resulting in increased surface expression of adhesion molecules and the synthesis and release of chemokines (5,6). The resulting proinflammatory phenotype may lead to the firm adhesion of granulocytes, polymorphonuclear neutrophil (PMN)-mediated acute lung injury (ALI), or other tissue damage (5,6). Some viruses, such as HIV-1 or Bunyaviridae, efficiently enter and replicate in the vascular endothelium and cause massive endothelial damage, whereas other viruses, including Hanta

virus or Arenaviridae, do not actually infect the cell (7). The ultimate impact of viral infection on the endothelium depends on many factors, including the type and titer of virus, mode of cellular entry, nature of the host response, and vascular bed involved (7).

In contrast to advances in eliminating viral pathogen transmission, bacterial contamination remains a leading cause of transfusion-related morbidity and mortality. Indeed, continued efforts to prolong the storage time of platelets will likely result in even higher rates of bacterial infection (8). The skin flora of the donor is the usual source of bacterial contamination. However, there are exceptions. For example, donors with reptile pets are at risk for transmitting more virulent organisms, including *Salmonella* species (8). Once infused into the recipient, bacteria may directly infect ECs. More commonly, components of the bacterial wall (e.g., lipopolysaccharide) activate pattern recognition receptors (e.g., Toll-like receptors) on the surface of monocytes and ECs, resulting in a proinflammatory and procoagulant phenotype (9). Bacteria also may damage the endothelium through the release of exotoxins, which induce pores in the endothelium and result in vascular leak (7,10). Finally, parasites also may be transmitted by transfusion and may have similar effects on endothelium. Malaria infection is the most recognized parasitic complication of blood transfusion and, although rare in the United States (0.3/1,000,000), represents the most common transfusion-related parasitic infection worldwide (11). *Trypanosoma cruzi*, the etiologic agent in Chagas disease and endemic to Central and South America, has been transmitted by transfusion to four immunocompromised recipients in the past 50 years (11).

Transmission of prion disease (e.g., variant Creutzfeldt-Jakob disease [vCJD]) is a rare complication (12). Prions may infect the vascular endothelium. Infected ECs are highly efficient at replicating these proteins, and thus may serve as a primary and sustained reservoir of blood-borne prions (13). Although prions have been implicated in relatively few cases

**Table 166-1: Complications of Transfusion**

<i>Complication</i>	<i>Most Common Product Associated with Complication</i>	<i>Incidence</i>	<i>Mechanism</i>	<i>Mechanism(s) of EC Dysfunction</i>	<i>Reduced with Leukoreduction</i>	<i>Reduced with Washing</i>	<i>Reduced with Fresher Blood</i>
<b>Infection</b>							
HIV	Plasma-containing or plasma-derived components	1/2,400,000–1/1,400,000	Presence in plasma or plasma-derived products	Direct interaction with EC membrane; direct entry	No	No	No
CMV	Cellular components with leukocytes	Rarely due to transfusion	Infected blood donor leukocytes	Direct interaction with EC membrane; direct entry	Yes	No	No
Hepatitis C	Plasma-containing or plasma-derived components	1/1,700,000–1/872,000	Presence in plasma or plasma-derived products	Direct interaction with EC membrane; direct entry	No	No	No
Bacteria	PCs, rarely PRBCs		Contamination of donor blood	Activation of TLR	No	Not known	No
Prion: Variant Creutzfeldt-Jakob disease (vCJD)	???	Rare (2 cases)	Long incubation periods	Direct infection	In experimental models only	No	No
<b>TRIM</b>	PRBCs, WB, and PCs	Not known	Passenger leukocytes and/or soluble biologic response modifiers (BRMs)	Not known	Variable results; Two randomized, controlled trials (RCTs) demonstrate efficacy	Limited data, one RCT shows efficacy	Not known
<b>Massive Transfusion (MODS/MOF)</b>	PRBCs	Not known	Presence of soluble proinflammatory BRMs	Proinflammatory action of BRMs in stored blood	No	Not Known	Yes
<b>TRALI</b>	Platelets, FFP, PRBCs, IVIG	1/5,000–1/3,23 USA 1/769, 230–1/7,900 EU	Antibody-mediated (single insult) vs. two insults (clinical status 1st; antibodies or BRMs 2nd)	???	No	Likely, but no RCTs	Possibly if due to BRMs, no RCTs

WB, whole blood; TLR, Toll-like receptors; IVIG, intravenous immunoglobulin; MODS, multiorgan dysfunction syndrome.

of spongiform encephalopathy, the potential for transfusion-related infection may be enormous due to our inability to detect these agents, the long incubation period between exposure and the clinical signs of infection, and our relative inexperience with these pathogens that may lead to a delayed diagnosis (12).

### TRANSFUSION-RELATED IMMUNOMODULATION

TRIM was first recognized in 1978 by Opelz and colleagues, who demonstrated enhanced survival of renal allografts in multiply transfused hosts as compared with nontransfused organ recipients (14). Other manifestations of TRIM include increased postoperative infections, death from multiple organ failure, and increased mortality related to the age of the transfused product (2). Hypothetical concerns include the accelerated growth or spread of malignancies, and reactivation of latent viruses (2). The mechanisms of TRIM are poorly defined, but presumably involve soluble mediators and/or donor cells in the transfusion product. Prestorage leukoreduction has been shown to decrease the incidence of TRIM, supporting a pathophysiological role for donor leukocytes (2,15). Interestingly, transfusion of fresher, compared with stored, blood components leads to a decreased incidence of postoperative pneumonia, suggesting that biologic response modifiers either of leukocyte or noncellular origin may be the causative agents (16). Randomized, controlled clinical trials are needed before recommending the routine use of fresher blood products. Washing of cellular components removes biologic response modifiers that accumulate in the plasma during routine storage (3,17). However, such a procedure has not been shown to prevent TRIM, is expensive and time consuming, and is thus reserved for patients with severe allergic reactions to blood components.

Little information is available on whether or how TRIM alters the phenotype of the endothelium or to what extent the endothelium contributes to the TRIM phenotype. Extrapolating from the observed immunomodulatory effects of viruses (especially HIV-1), drugs, and ethanol on the endothelium, TRIM may be predicted to result in endothelial damage and/or barrier dysfunction and an increased risk for secondary invasion by viral pathogens or toxic substances into discrete organs, particularly the liver (18).

### TRANSFUSION AND INFLAMMATION

#### Massive Transfusion

Massive transfusion, defined as the replacement of one blood volume per day or the transfusion of 10 units of packed red blood cells (PRBCs), has long been recognized as a predisposing factor for ALI and the acute respiratory distress syndrome (ARDS) (19–22). Many investigators have assumed that trans-

fusions are not pathogenic per se, but rather represent a surrogate marker for shock and its effects on organ dysfunction. However, PRBC transfusion has been shown to be an independent risk factor for the development of multiple organ failure (MOF) in traumatically injured patients (23). In that study, transfusion of more than six units of PRBCs within the first 12 hours increased the risk for MOF in patients with intermediate injury severity scores (23). Furthermore, the risk for MOF directly correlated with the storage age of the PRBCs transfused, such that patients who received PRBC units of greater than 21 days of storage developed MOF, whereas those transfused with units that were banked for shorter periods did not (24).

Recent studies have shown that the plasma fraction of stored, but not fresh, PRBCs causes proinflammatory activation of cultured pulmonary human microvascular ECs (HMVECs) (25,26). In these experiments, the plasma fraction from PRBCs on day 42 (the upper limit of storage time for this blood product) resulted in increased surface expression of intercellular cellular adhesion molecule (ICAM)-1; increased synthesis and release of chemokines, namely interleukin (IL)-8, growth-related oncogene (GRO)- $\alpha$ , and epithelial neutrophil activating peptide (ENA)-78; and increased adherence of PMNs (25,26). In contrast to these results, plasma fractions taken from the identical PRBC unit on day 1 failed to elicit a proinflammatory phenotype. The day-42 plasma activity was localized to the chloroform-soluble fraction, implicating a role for lipids that accumulate during routine PRBC storage (25,26).

To rule out a confounding effect of leukocytes during PRBC storage, we recently collected units of blood from healthy donors. The samples were divided into two fractions: One was leukoreduced by filtration; the other was left unmodified (control). Plasma derived from the PRBCs (stored for 1 or 42 days) was then added to pulmonary HMVECs. Plasma from day-42 PRBCs, whether prestorage leukoreduced or not, caused increased surface expression of ICAM-1, whereas day-1 plasma from the identical units had no such effect (C. Silliman, unpublished observations). Consistent with the results of previous studies, the lipid fraction was shown to contain the responsible activity (C. Silliman, unpublished observations). Together, these data suggest that, during routine storage of PRBCs, a leukocyte-independent, biologically active lipid accumulates in the plasma fraction that causes proinflammatory activation of HMVECs and may predispose massively transfused patients to ALI or MOF. Further work is required to identify the nature and source of the biologically active lipid.

Similar to these findings, plasma from whole blood-derived platelet concentrates demonstrate storage-dependent activation of HMVECs (27). In contrast, platelet concentrates collected by apheresis techniques did not activate HMVECs, irrespective of their storage age (27). Because whole blood-derived platelet concentrates are not widely used in the developed world, these effects may be of little concern. However, in developing countries, in remote areas, or on the battlefield

in which apheresis platelet concentrates are not available, one must account for such potential untoward effects from transfusions of whole blood-derived platelets.

### **Transfusion-Related Acute Lung Injury**

Transfusion-related acute lung injury (TRALI) is the leading cause of transfusion-related mortality over the past 2 reporting years (28). TRALI was first reported in 1951, but was not recognized as a distinct clinical entity until 1985 (29,30). TRALI remains underdiagnosed and under-reported (31–34). The syndrome is clinically indistinguishable from ALI, and is manifested by tachypnea, cyanosis, dyspnea, fever, hypoxia, and pulmonary edema (21,30,32). The differential diagnosis of patients who have pulmonary insufficiency following transfusion includes transfusion-related circulatory overload, anaphylactic transfusion reactions, and transfusions contaminated with bacteria (33). Treatment consists of aggressive respiratory support. The mortality rate from TRALI ranges from 5% to 25% (33).

#### ***Antigranulocyte Antibodies Directed against Human Leukocyte Antigen Class I or Granulocyte-Specific Antigens***

The pathophysiology of TRALI is complex, and a number of different models have been proposed. The first postulates that TRALI is due solely to the infusion of antigranulocyte antibodies directed against human leukocyte antigen (HLA) class I or granulocyte-specific antigens. Infusion of these antibodies into a patient with the cognate antigen present on their granulocytes results in activation of complement, pulmonary sequestration of PMNs, and PMN-mediated damage (30). In addition, infusion of viable granulocytes into a patient with antileukocyte antibodies also may cause TRALI. Although this mechanism is thought to account for less than 5% of all cases, it has particular importance for patients requiring granulocyte transfusions (30,35). An animal model was developed that reinforced this hypothesis using infused human neutrophil antigen (HNA)-3a antibodies, HNA-3a<sup>+</sup> human PMNs, and human plasma as a complement source that were infused into isolated, perfused rabbit lungs (36). If any of these components were deleted, including substitution of nonspecific immunoglobulins, lung injury did not occur. However, one must take into account the effect of the tubing, because such surfaces may act to promote PMN priming and the transition from a nonadhesive to an adhesive phenotype (33). This model has been updated and appears to require at least two events to precipitate ALI (37).

#### ***Antibodies Directed Against Human Leukocyte Antigen Class II Antigens***

A second antibody-mediated pathogenesis involves the infusion of HLA class II antibodies directed against specific HLA class II antigens in the recipient (38). Upon engagement of these antibodies to their cognate antigens on monocytes, cytokines are produced that may cause or exacerbate TRALI;

moreover, following prolonged incubation with cytokines *in vitro*, PMNs may express HLA class II antigens, and such antibodies may have the capacity to directly affect the microbicidal arsenal of the PMN (39–41). The exact details of PMN-mediated ALI secondary to HLA class II antibodies requires further elucidation (33,42).

#### ***Two-Event Model***

A two-event model also has been proposed for TRALI: The first event involves proinflammatory activation of the pulmonary endothelium, and the second event is the transfusion itself (22,43). Many different clinical conditions result in activation of pulmonary endothelium (the first event), including sepsis, trauma, and surgery (21,32,33). Transfusion (the second event) results in the delivery of donor antibodies directed against antigens on the surface of PMNs adhering to activated lung endothelium, or against other biological response modifiers that accumulate during routine storage of the cellular product, resulting in accentuated PMN-induced endothelial damage and capillary leak (33). Although the plasma component of blood products is believed to mediate the second event, whole blood-derived platelets are most frequently implicated in this syndrome, followed by fresh frozen plasma (FFP) and PRBCs (33).

TRALI may be studied using *in vitro* and/or *in vivo* models. Under *in vitro* conditions, pulmonary microvascular ECs treated with endotoxin demonstrate increased expression of ICAM-1 and chemokines, as well as firm adhesion and priming of PMNs (first event) (44). Subsequent addition of lysophosphatidylcholine (lyso-PC), the lipid product that accumulates during storage of cellular blood products, promoted nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity in the adherent/primed PMNs (second event) (44). The resulting burst of reactive oxygen species resulted in cytokine-dependent EC damage (44). These findings mimic the proposed two-event model of TRALI and suggest that the cell culture system may prove useful for dissecting the molecular basis for this phenomenon.

To generate an *in vivo* model of TRALI, endotoxin was systemically administered to Sprague Dawley rats via intraperitoneal injection and resulted in active adhesion (as distinct from physical sequestration) of PMNs to pulmonary endothelium for up to 12 hours (first event) (45). The second event involved the transfusion of stored autologous blood components. In this two-event model, plasma and lipids from stored but not fresh PRBCs and platelet concentrates resulted in TRALI (45,46). The histology of the rat lungs demonstrated the presence of firmly adherent PMNs in the pulmonary vasculature, PMN-mediated damage of the endothelium, and infiltration of alveoli with PMNs and fluid (45,46). These findings are identical to those reported in a recent autopsy of fatal TRALI (45,47).

Among the transfusion-transmitted mediators that have been implicated in TRALI are antibodies directed against specific antigens on the surface of granulocytes, for example, antibodies to HNA-3a (5b), including those against HLA class I,

HLA class II, and granulocyte-specific antigens; soluble CD40 ligand (sCD40L), which accumulates during the storage of platelet concentrates; complement, which may be caused by the interaction of cells with tubing employed for collection; and biologically active lipids that accumulate during routine storage of all cellular components (44,45,48). Recent *in vitro* data have determined that both granulocyte-specific antibodies and sCD40L have the capacity to prime the PMN NADPH oxidase and cause PMN-mediated HMVEC damage in this *in vitro* model of TRALI (48,49).

TRALI also occurs in neutropenic hosts, albeit rarely (21,22). These cases appear to defy both the two-event and antibody-mediated models, because fewer leukocytes are present to cause pulmonary injury. In these patients, platelet-mediated release of vascular endothelial growth factor (VEGF) may cause fenestration of the pulmonary endothelium and result in mild capillary leak identical to the mild pulmonary leak caused by VEGF in isolated, perfused rat lungs (50). Although preliminary results have implicated VEGF in a case of TRALI in a neutropenic patient, more data are required to confirm the role of this permeability and growth factor in TRALI (50).

#### OTHER EFFECTS OF TRANSFUSION ON ENDOTHELIUM

Storage of PRBCs for longer than 15 days yields many red cells that are stiff and unable to navigate the tortuous capillary beds in various organs (51,52). Investigators have postulated that these stored PRBCs may cause vaso-occlusion by adhering to the vascular endothelium. Consistent with this hypothesis, older (hence stiffer) RBCs demonstrate increased adherence to human umbilical vein ECs (HUVECs) or bovine ECs (51,53). In addition, older RBCs have reduced intracellular levels of 2,3-DPG and increased oxygen (O<sub>2</sub>) affinity, which renders them less efficient in O<sub>2</sub> delivery. Transfusion of older RBCs may lead to increased mortality in cardiac bypass patients, microcirculatory hypoperfusion in the critically ill, acute chest syndrome in sickle cell anemia, and certain clinical manifestations in patients with hereditary stomatocytosis postsplenectomy, including dyspnea, chest pain, and abdominal pain (15,51,53–55). Recent *in vitro* data suggest that prestorage leukoreduction of PRBCs and treatment of ECs with nitric oxide (NO) may restore membrane fluidity and attenuate the widespread adherence of older RBCs to endothelium (56). However, further studies are required before advocating widespread administration of younger RBCs, prestorage leukoreduction, and/or NO treatment in these patient populations (56,57).

The effects of FFP on PMN–endothelial interactions have been investigated because FFP is commonly employed in the injured or surgical patient for the treatment of severe bleeding. Despite the potential for FFP to contain bioactive substances derived from leukocytes that may cause proinflammatory activation of the vascular endothelium, *in vitro* FFP “treatment” of

HUVECs in cocultures with human PMNs actually decreased the interactions between PMNs and HUVECs (58). In contrast, albumin, which has been employed for decades for colloid resuscitation of patients, causes proinflammatory activation of endothelial monolayers and vascular endothelium in animal models, that results in increased surface expression of cellular adhesion molecules and PMN adhesion (59). These proinflammatory effects of albumin may be due to its role as a carrier of bioactive lipids and other proinflammatory agents, especially if the source is outdated human blood.

The development of hemoglobin substitutes as O<sub>2</sub> carriers has been hampered by their effects on the vascular endothelium, particularly their interference with NO- and endothelin-1-mediated vascular tone (60–63). In fact, the vasoconstrictive properties of one hemoglobin-based O<sub>2</sub> carrier has been cited as the reason for the unexpected mortality in a recent randomized control trial (64–67). Polymerized hemoglobin solutions appear not to cause significant vasoconstriction and, as opposed to other hemoglobin substitutes that cause a proinflammatory activation of ECs, appear to have an anti-inflammatory capacity (64,67). Further work is required to discern the effects of all of these compounds on human vascular endothelium *in vivo*.

Finally, although improved renal allograft survival was initially attributed to transfusions, it has become increasingly clear that the multiple transfusion of an allograft recipient may lead to rejection of the allograft (68,69). This transfusion-related rejection is not relegated to any one type of transplant and, in the case of corneal allograft rejection, has been related to endothelial rejection (68).

#### AVOIDANCE

Many of the effects of transfusion may be avoided by washing and resuspending the cells in saline (3,17). The proinflammatory potential of stored blood on PMNs and ECs is abrogated by this procedure (3) (C. Silliman, unpublished observations). Clinical data in cancer patients suggest that washing of all ABO-matched components imparts better survival, possibly due to eradication of soluble mediators or plasma proteins that may be etiologic in immunomodulation of the host (70). Plasma itself may potentially impart detrimental effects on the transfused host, especially if collection is through some of the newer machinery that causes extensive cellular exposure to plastic tubing, identical to cardiopulmonary bypass or dialysis equipment, resulting in complement activation and subsequent transfusion of activated complement into an ill patient (71). Further work is required to identify the real risk of adverse events due to FFP infusion in such patients. In addition, more restrictive transfusion practices have decreased the number of adverse events and improved survival in injured patients, despite increases in both patient age and injury severity score, two indicators of worse outcome (D. Ciesla, unpublished observations). Thus, if a transfusion is not clinically indicated, it should be avoided.

## KEY POINTS

- Transfusion of cellular components and plasma is vital to restore O<sub>2</sub>-carrying capacity and maintain hemostasis, but it is important to recognize that transfusions may have a number of deleterious effects, including the transmission of infectious agents, host immunomodulation, and proinflammatory activation of the innate immune system. The vascular endothelium plays an important role in all these processes, and strategies to decrease the effects of transfusion on host endothelium must be implemented as therapeutic options become available.
- More restrictive transfusion policies, the use of fresher or washed components, and transfusion of prestorage leukoreduced PRBCs are strategies that may decrease the effects of transfusion on the vascular endothelium, but experimentation in vitro and in vivo as well as multicenter clinical trials must be completed to possibly decrease the adverse events associated with transfusion.
- For example, the role of stored platelet transfusions, which may contain large amounts of VEGF, in the metastatic or recurrent potential of solid tumors has never been explored and may provide a key element in the supportive care of patients with malignancies.

## Future Goals

- To emphasize that the clinician must be wary of using in vitro or animal data to make clinical decisions, because many of these experiments may have little to do with the clinical condition of human patients, despite the best attempts of the investigators to approximate human disease

## The Role of Endothelium in Erectile Function and Dysfunction

Muammer Kendirci and Wayne J.G. Hellstrom

*Tulane University Health Sciences Center, New Orleans, Louisiana*

Penile erection is a neurovascular event that depends on neural integrity, a functional vascular system, and healthy cavernosal tissues (1). Physiological erectile function involves three synergistic and simultaneous processes: (a) a neurogenically mediated increase in penile arterial inflow, (b) relaxation of cavernosal smooth muscle, and (c) restriction of venous outflow from the corpora cavernosa. The corpus cavernosum of the penis is composed of a meshwork of interconnected smooth muscle cells lined by vascular endothelium. In addition, endothelial cells (ECs) and underlying smooth muscle line the small-resistance helicine arteries that supply blood to the corpora cavernosa during penile tumescence. Structural and functional alterations in the vascular tree of the corpus cavernosum or impairment of any combination of neurovascular processes can result in erectile dysfunction (ED). ED has traditionally been classified as psychogenic, organic, or a combination of these two entities. More recent data show that more than 80% of ED cases have an organic basis, with vascular disease being the most common etiology (2). Although ED is a natural consequence of aging, its severity is directly related to the number and degree of vascular risk factors, such as hypertension, cigarette smoking, atherosclerosis, hypercholesterolemia, and diabetes mellitus (3) (Table 167-1). Hence, endothelial dysfunction in the penile vascular bed can lead to ED (4).

ED is defined as the consistent inability to attain or maintain an erection sufficient for satisfactory sexual intercourse (5). The Massachusetts Male Aging Study (MMAS), a substantial epidemiological survey that quantified the prevalence of ED in a noninstitutionalized population of men in the Boston suburbs (3), revealed that 52% of 1,290 men aged 40 to 70 years had some degree of ED; with almost 10% exhibiting a total absence of erectile function. It has been estimated that 25 to 30 million men in the United States have partial to complete ED (5). Extrapolation of this data estimates that the worldwide incidence of ED will increase from 152 million men in 1995 to 322 million men by the year 2025 (6). Ongoing calculations from the participants in the MMAS reveal the overall inci-

dence of ED after an average follow-up of 8.8 years to increase to 26 cases per 1,000 man-years (7).

### VASCULAR ENDOTHELIUM AND PENILE ERECTION

The vascular endothelium of the penis plays a pivotal role in modulating vascular tone and blood flow into the penis in response to humoral, neural, and mechanical stimuli. The endothelium releases various factors that affect the contractile and relaxatory activity of the underlying vascular smooth muscle. In addition, physical hemodynamic changes caused by alterations in penile blood flow and shear stress release various mediators that modulate the underlying smooth muscle tone. In endothelial dysfunction, the regulatory role of the endothelium is hindered, resulting in decreased responsiveness to vasodilatory mediators and/or increased sensitivity to various vasoconstricting agents. The term *endothelial dysfunction* implies a decrease in endothelium-dependent corpora cavernosal smooth muscle relaxation, for the most part secondary to increased destruction or total loss of nitric oxide (NO) bioactivity in the vascular tree.

NO serves many vital physiological functions, including regulation of vascular tone, immunomodulation, neurotransmission and, for our purposes, penile erection (8). Furthermore, NO inhibits smooth muscle cell proliferation and collagen synthesis, and can have a direct toxic effect on these tissues. The main or constitutive NO synthase (NOS) isoforms (endothelial NOS [eNOS] and neuronal NOS [nNOS]) are involved in the initiation and maintenance of penile erection and are coupled to calcium ( $\text{Ca}^{2+}$ ) and calmodulin (9). NO involved in signaling events that regulate neurotransmission and penile vascular tone is produced by (a) eNOS from ECs lining the cavernosal smooth muscle cells; (b) agonist-induced activation via acetylcholine released from cholinergic nerves, and (c) nNOS activity initiated by nonadrenergic noncholinergic (NANC) neurons. NO diffuses

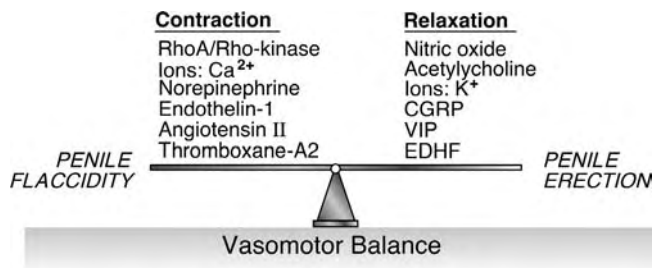

Figure 167.1. Endothelial, neural, and humoral factors mediating vasoconstriction and vasodilation in penile erection and flaccidity.

into the adjacent smooth muscle cells and stimulates the enzyme guanylate cyclase (GC). GC increases the synthesis of cyclic guanosine monophosphate (cGMP), which in turn, through a cascade of events, decreases intracellular  $\text{Ca}^{2+}$  concentrations and causes smooth muscle relaxation and penile erection.

### PHYSIOLOGY AND PHARMACOLOGY OF PENILE ERECTION

The balance between the contractile ( $\alpha$ -adrenergic, endothelin (ET), angiotensin (Ang), RhoA/Rho-kinase, thromboxane  $\text{A}_2$ ) and vasodilatory second-messenger systems (GC/cGMP and adenylate cyclase/cyclic guanosine monophosphate [AC/cAMP]) determines the overall tone of the corpora cavernosal smooth muscle of the penis (10) (Figures 167.1 and 167.2). This balance is controlled by both central and peripheral mechanisms and involves a plethora of neurotransmitters acting through various signal transduction pathways. In the corpora cavernosa, the vascular endothelium and cavernosal arteries are a source of both vasorelaxing (NO, prostacyclin [ $\text{PGI}_2$ ], endothelium-derived hyperpolarizing factor [EDHF]) and vasoconstricting (Ang-II, ET-1, and Rho-kinase) factors.

The vasodilators prostaglandin E (PGE) and  $\text{PGI}_2$  are produced by ECs in the vasculature. Prostaglandin synthesis is activated by NO through shear stress from blood flow in the penis. Activation of specific PGE receptors in the penis increases intracellular concentrations of cAMP via activation of AC, causing a reduction in intracellular  $\text{Ca}^{2+}$  and cavernosal smooth muscle relaxation (11). Both  $\text{PGE}_2$  and its derivative  $\text{PGE}_1$  are potent vasorelaxing agents in human corpora cavernosa smooth muscle.  $\text{PGE}_1$  has been employed clinically because of its highly efficacious local activity in the medical treatment of ED.

EDHF is released by endothelium-dependent agonists (acetylcholine or bradykinin) or by shear stress that triggers the synthesis of a cytochrome P450 metabolite and acts by hyperpolarizing the underlying cavernosal smooth muscle (12,13). Recent studies have shown that EDHF mediates relaxation of human penile resistance arteries, which are normally resistant to NOS and cyclooxygenase (COX) inhibition

(14). The authors postulate that EDHF plays more of a precise role in the endothelium-dependent relaxation of the penile vascular bed. Studies from our laboratory have determined that the pharmacological inhibitor of cytochrome P450 2C, sulfaphenazole, can attenuate the cavernosal nerve-mediated erectile responses in the rat, suggesting that the cytochrome P450 metabolite may mediate an EDHF-dependent smooth muscle effect in the penis (15).

ET-1, a member of the ET family, is generated by the vascular endothelium and is a very potent vasoconstrictor of the penile vasculature (16). Two ET receptors modulate the effects of ET-1, namely  $\text{ET}_A$ , located on the underlying smooth muscle, and  $\text{ET}_B$ , located on both the smooth muscle and vascular endothelium.  $\text{ET}_A$  receptors mediate contraction and promote smooth muscle growth, whereas  $\text{ET}_B$  receptors

Figure 167.2. Rho-kinase pathway. The detumescent state of the corpus cavernosum smooth muscle (CCSM) is considered to be mediated by release of contractile neurotransmitters or modulators including noradrenaline and ET-1. GTP-RhoA activates Rho-kinase and inhibits MLC phosphatase, increasing MLC20 phosphorylation by basal level activity of MLC kinase. The resulting myosin phosphorylation and subsequent CCSM contraction occur without a change in sarcoplasmic  $\text{Ca}^{2+}$  concentration. (Adapted with permission from Andersson KE. Erectile physiological and pathophysiological pathways involved in erectile dysfunction. *J Urol.* 2003;170:S6–13.)

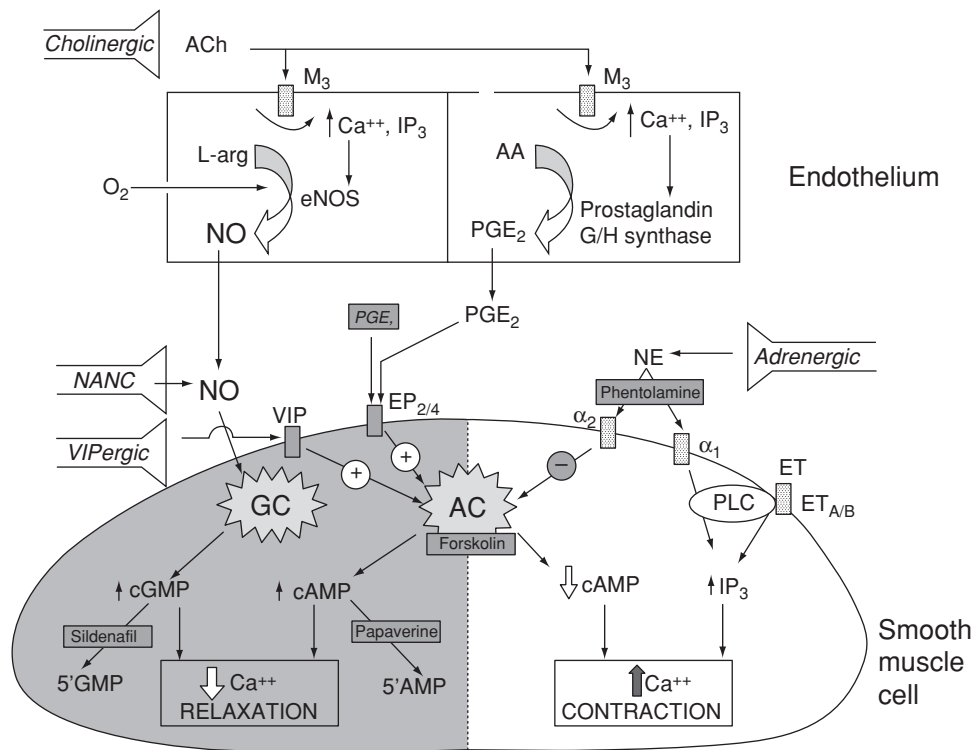

Figure 167.3. The interaction between vascular endothelium and cavernosal smooth muscle cells. (Adapted with permission from Moreland RB, Hsieh G, Nakane M, Brioni JD. The biochemical and neurologic basis for the treatment of male erectile dysfunction. *J Pharmacol Exp Ther.* 2001;296:225–234.)

on the endothelium promote NO- and prostacyclin-mediated vasorelaxation and contractions of the smooth muscle. In vitro cavernosal tissue strip experiments reveal that ET-1 functions as a vasodilator at low doses via  $ET_B$  receptor activation and as a vasoconstrictor via  $ET_A$  receptor activation at high doses (16). Despite the presence of ET receptors in the corpora cavernosa, current animal and clinical data do not support a central role for ET-1 in regulating the erectile response (17,18). However, studies in diabetic animal and human corpus cavernosal strips have demonstrated upregulation of  $ET_A$  receptors and downregulation of  $ET_B$  receptors, suggesting that ET-1 may be more involved in the pathophysiology of diabetic ED (19,20).

Ang-II, another potent vasoconstrictor, has been hypothesized to have a local functional role in the regulation of the vascular tissue in the penis (21). ECs in the corpora cavernosa appear to contain a local Ang-II paracrine system that modulates vascular tone and sustains cavernosal smooth muscle cell contraction (22). In vitro studies have confirmed that Ang-II causes a dose-dependent contraction of cavernosal tissues (23). In human studies, men with organic ED have been observed to have elevated Ang-II levels, supporting a role for Ang-II in the pathogenesis of organic ED (24).

Contraction of cavernosal smooth muscle is primarily mediated by  $Ca^{2+}$ -sensitization (Figure 167.3). This mechanism involves either  $Ca^{2+}$ -independent promotion of myosin light chain kinase (MLCK) or attenuation of myosin light chain

phosphatase (MLCP) activity (25). A principal regulator of MLCP is the serine/threonine kinase, Rho-kinase. RhoA, a member of the Ras low-molecular-weight GTP-binding proteins, mediates agonist-induced activation of Rho kinase and contraction of smooth muscle cells (26). Norepinephrine (NE) and ET-1 both stimulate the GTPase RhoA in vascular smooth muscle cells via a RhoA/Rho-kinase-dependent pathway (Figure 167.2). The role of the RhoA/Rho-kinase pathway in the regulation of cavernous smooth muscle tone in both human ECs and human corpora cavernosa smooth muscle cells grown in culture has recently been described (27,28).

As a corollary, direct administration of the Rho-kinase inhibitor Y-27632 into the corpora cavernosa causes a dose-dependent increase in intracavernosal pressure and erection in rats (29). Treatment with Y-27632 also potentiates NO-mediated increase in erectile function (30). Moreover, adeno-associated viral gene transfer of the RhoA mutant to the rat corpora cavernosa enhanced erectile function, suggesting that inhibition of RhoA/Rho-kinase expression in the penis can augment cavernosal smooth muscle relaxation and erectile function (31). Given that NO partly mediates the erectile response via inhibition of RhoA/Rho-kinase  $Ca^{2+}$ -sensitizing pathway, it has recently been postulated that endogenous NO-mediated vasodilation may occur through the inhibition of Rho-kinase vasoconstrictor activity. Recent evidence suggests that the RhoA/Rho-kinase signal transduction pathway is an important signal mediator of penile vascular EC function

(32). Further exploration of this exciting area of study is anticipated.

### DIABETES AND PENILE ENDOTHELIAL DYSFUNCTION

Diabetes mellitus is associated with a high prevalence of ED, because at least 50% of diabetic men are afflicted (33). The major underlying factors contributing to diabetic ED in cavernosal tissues are a decrease in the number of nitrergic NOS-containing nerve fibers, reduction in nNOS and eNOS activity, and impaired endothelial- and neurogenic-mediated smooth muscle relaxation (34,35). Diabetic animal studies have documented significant reductions in cavernosal eNOS and nNOS protein and gene expression, and decreased cavernosal cGMP levels in the penile tissues (36–38). Furthermore, endothelium-independent cavernosal smooth muscle relaxation is impaired in diabetic ED (39). These and other observations reveal that diabetes attenuates endothelial- and neurogenic-NO neurotransmission and decreases soluble GC, cGMP, and protein kinase G (PKG) (39). Diabetic ED is the result of a dysfunctional NO/cGMP system and reduced NO production, most likely because of decreased eNOS and nNOS in the penile vasculature.

In diabetic vascular dysfunction, the RhoA/Rho-kinase pathway plays an important role in suppressing eNOS gene expression and enzyme activity in ECs by inhibiting Akt (40). In alloxan-induced diabetic rabbits, researchers have demonstrated that Rho-kinase levels are increased in corpora cavernosal smooth muscle, showing that cavernosal smooth muscle tone is modulated in part via Rho-kinase sensitization of the endothelin-mediated contractile pathway. Hence, Rho-kinase may be a key component of the molecular mechanism in the origin of diabetes-induced ED (20).

In streptozotocin-induced diabetic rats, our laboratory also noted an increase in RhoA and Rho-kinase levels in the corpora cavernosa and a reduction in eNOS protein and enzyme activity (32). This increased expression of RhoA/Rho-kinase was countered by the Rho-kinase inhibitor, Y-27632, which caused an enhanced erectile response. Adeno-associated viral vector encoding for a dominant negative RhoA mutant was directly injected into the corpora cavernosa to reduce RhoA-Rho-kinase expression (32). After gene transfer, the RhoA/Rho-kinase expression was significantly reduced, eNOS protein and activity were increased, and erectile responses to cavernosal nerve stimulation were restored. These data reveal that there is an upregulation of cavernosal Rho-kinase expression when endothelial-derived NO production in the penis is reduced.

An interesting concept in deciphering the actions of these pathways is the study of arginase. Arginase competes with eNOS for the substrate L-arginine in ECs throughout the vascular system. Thus, increased expression of arginase in diabetic corpora cavernosa may diminish endothelial-derived NO biosynthesis by competing for the substrate L-arginine.

Studies have demonstrated an increase in arginase activity, arginase II protein, and gene expression in diabetic human corpora cavernosa compared with nondiabetic cavernosal tissue (41). Furthermore, diabetic cavernosal tissues exhibit a significantly lower conversion of L-arginine to L-citrulline, suggesting that the constitutive  $\text{Ca}^{2+}$ -dependent eNOS/NO pathway is impaired in diabetes (41). In vitro studies in diabetic rabbits treated with long-term oral L-arginine have reported increased endothelium-dependent cavernosal smooth muscle relaxation. In theory, L-arginine transport or availability to interact with eNOS in the endothelium of diabetics is reduced, thereby contributing to endothelial dysfunction (42). Preliminary clinical observations have not supported oral ingestion of L-arginine to ameliorate ED.

Another interesting observation is the presence of advanced glycation end-products (AGEs) in diabetes (43). A common consequence of AGE formation is the pathologic cross-linking of collagen, leading to vascular thickening with a loss of elasticity, endothelial dysfunction, and subsequently, atherosclerosis of the vascular tree. AGE accumulation in endothelial and cavernosal smooth muscle cells have been documented to reduce eNOS levels via intracellular glycation and alteration of eNOS activity (44). These data suggest that AGE formation may in some manner be another pathway that contributes to the pathogenesis of diabetic endothelial dysfunction and ED. Our laboratory has demonstrated that aminoguanidine, an AGE inhibitor, halts the time-dependent progression of impaired erectile responses in the streptozotocin-induced diabetic rat (45,46). Aminoguanidine may prevent the diabetes-induced changes in the connective tissue composition of the microvascular wall of the arterioles supplying the penis. Another interesting observation is that delayed administration of ALT-711, an AGE cross-link breaker, improved erectile function and decreased AGE levels, suggesting that AGE cross-link breakers may have a significant therapeutic potential for reversing the consequences of established diabetic ED (47).

### AGING AND PENILE ENDOTHELIAL DYSFUNCTION

Aging is known to be associated with diminished vascular endothelial function and reduced erectile function. Various pathophysiological mechanisms have been postulated for age-related ED, including decreased NANC fibers in the corpora cavernosa, reduction in constitutive NOS activity, altered NO bioavailability, impaired endothelium-dependent smooth muscle relaxation, and increased degradation or scavenging of NO (48–51). Although normal or elevated levels of eNOS protein have been reported in the corpora cavernosa of aged rats by some researchers, eNOS activity and endothelial-derived NO biosynthesis generally are reduced with aging (48). This may, in part, be explained by increased production of reactive oxygen species (ROS) and reduced enzyme activity of eNOS in the aged penile vasculature.

Researchers have demonstrated a significant increase of eNOS protein and mRNA, constitutive NOS activity, endothelial-derived NO, and cavernosal cGMP levels in the penis of aged rats after transfection with adenovirus encoded with the eNOS isoform (48,52). There was a corresponding increase in erectile function as measured by cavernosal nerve stimulation and after intracavernous acetylcholine administration. Hence, age-related diminished endothelial function (reduced NO biosynthesis) can be reversed in the penile vascular endothelium using gene-based therapy (50).

As mentioned, arginase has a theoretical role in regulating eNOS activity in the penile vascular endothelium and is considered a possible contributing factor in age-related endothelial dysfunction and ED (53). Decreased constitutive NOS activity and NO bioavailability in the aged penis in animals may be due to a lack of L-arginine substrate available to produce eNOS. Studies have shown that there is an increase in arginase activity and arginase I mRNA and protein expression in the corpora cavernosa of aged mice (15). Recent experiments have shown that a combination of an arginase inhibitor and adeno-associated virus encoding an antisense sequence to arginase I has restored eNOS activity and improved endothelium-dependent erectile responses to acetylcholine and cavernosal nerve stimulation (15).

#### **HYPERCHOLESTEROLEMIA AND PENILE ENDOTHELIAL DYSFUNCTION**

Impaired endothelium-dependent relaxation in the vascular beds of men with hypercholesterolemia has been well established (54,55). The association between hypercholesterolemia and ED was originally attributed to atherosclerosis in the hypogastric-cavernosal arterial vascular bed, thereby causing a reduction in penile blood flow (56). Experimental studies in rabbits revealed that hypercholesterolemia produces a marked reduction in cavernosal smooth muscle cells, ECs, and elastic fibers, and increases in collagen III and IV in the cavernosal tissues (57). Histological evaluation of rabbits placed on high-cholesterol diets demonstrated significant cavernosal smooth muscle cell degeneration with a loss of intercellular contacts (58).

Gholami and colleagues revealed that penises of hypercholesterolemic rats had lower nerve content, fewer ECs, and higher smooth muscle content than those of rats with normal cholesterol levels (59). In this study, rats placed on high-cholesterol diets demonstrated hypermyelination, severe atrophy of axons, a decrease in the number and size of nonmyelinated axons, disarray of the smooth muscle cells with scant myofilaments and foamy cytoplasm, and denuded endothelial lining of the sinusoids covered by numerous platelets, suggesting that a high-fat diet caused ED via both neurogenic and vascular alterations. Vascular endothelial growth factor (VEGF) has been used to upregulate eNOS in the corpus cavernosum and increase the production of NO (60). Intravenous and intracavernosal administration of VEGF in

hypercholesterolemic rats increases EC content and function, and improves endothelium-dependent smooth muscle relaxation in the corpus cavernosum. These findings have led researchers to postulate that VEGF may in some manner protect the corporal endothelium from hypercholesterolemia-induced injury, thus preserving endothelium-dependent corporal smooth muscle relaxation (59,61,62).

#### **OXIDATIVE STRESS AND PENILE ENDOTHELIAL DYSFUNCTION**

ECs produce ROS in response to shear stress, endothelium-derived agonists, including acetylcholine and bradykinin, and also in various vascular disease states. Potential sources of ROS in ECs include nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (generates superoxide anion), lipooxygenase, cyclooxygenase, peroxidases, cytochrome P450s, xanthine oxidase, and eNOS (63). The reaction of superoxide anions and NO in the vascular endothelium or smooth muscle cells triggers the formation of the highly toxic molecule, peroxynitrite (64). Due to its toxic effects, peroxynitrite can cause direct tissue injury, alterations in vascular tone, oxidation of vascular proteins and lipids, and overall organ dysfunction (65). The antioxidants superoxide dismutase (SOD), catalase, glutathione peroxidase and reductase play a pivotal role at the cellular level in protecting against ROS (66). Among the three types of SOD isoforms in the human body, copper- and zinc-containing SOD (CuZn-SOD) and extracellular-SOD (EC-SOD) have been identified in the penis, predominantly in the endothelial and cavernosal smooth muscle cells (67). Increased levels of superoxide anions in the endothelium and cavernosal smooth muscle cells contribute to ED by causing endothelial dysfunction and reducing cavernosal NO biosynthesis. Apart from reducing NO biosynthesis, superoxide anions cause  $Ca^{2+}$  mobilization, which results in reduced  $Ca^{2+}$  levels in the cavernosal ECs. Overall, increased oxidative stress and superoxide anion production alter the penile vasculature and impairs endothelial-derived NO in the erectile tissues, resulting in ED (15,68).

Oxidative stress is quite prominent in certain chronic disease states, including diabetes, hypercholesterolemia, and aging, and is associated with significant changes in the endothelium and smooth muscle cells in the penis (69,70). As noted, superoxide anions react with NO and form peroxynitrite. In aging, increased production of peroxynitrite accelerates the degeneration of nerves and ECs involved in the erectile process (67). An imbalance in superoxide anion generation and inactivation in the penile vasculature causes impaired endothelium-dependent smooth muscle relaxation and ED (67). In aged rats experimentally transfected with adeno cytomegalovirus (CMV)-EC-SOD, there was a significant increase in EC-SOD mRNA and protein expression and a significant reduction of superoxide anions. Moreover, EC-SOD gene therapy increased cGMP levels in the corpus cavernosum and was found to enhance the *in vivo* erectile response to cavernosal nerve

stimulation. These observations implicate EC-SOD as beneficial in limiting superoxide anion production and preventing some of the outcomes of age-related ED (67).

The effects of diabetes on endothelium-dependent and NANC-mediated cavernosal smooth muscle relaxation are well established in diabetic animal models and in vitro studies (34,37,71,72). Oxidative stress has been suggested to also play an important role in diabetic endothelial dysfunction. An in vitro study by Khan and colleagues demonstrated that SOD treatment restored endothelial- and NANC-mediated cavernosal smooth muscle relaxation, inferring the significance of the production of superoxide anions in diabetic endothelial dysfunction (73). Another related study in streptozotocin-induced diabetic rats, malondialdehyde, an oxidative stress marker, and superoxide anions were increased in the corpus cavernosum (74). Adenoviral gene transfer of EC-SOD to the diabetic rat penis reduced cavernosal malondialdehyde and superoxide anion levels and restored cavernosal nerve-mediated erectile function in vivo (75).

Oxidative stress is similarly involved in the endothelial dysfunction observed in hypercholesterolemia. In hypercholesterolemic rabbits, endothelium-dependent corpus cavernosal smooth muscle relaxation is impaired and superoxide levels are correspondingly elevated (76). In response to this oxidative insult, a significant increase in cavernosal CuZn-SOD and manganese SOD (MnSOD) levels occurs in order to scavenge the increased superoxide anions. Despite the elevated SOD levels and increased scavenging activities, there remain significant impairments in endothelium-dependent smooth muscle relaxation. Other studies have documented elevated low-density lipoprotein (LDL) peroxidation and the early development of atherosclerosis (77). An oxidative stress-derived pathogen, ox-LDL, formed by superoxide anions and peroxynitrite, also has been shown to impair endothelium-dependent relaxation in the penis in hypercholesterolemia (78).

A recent study assessed the effect of sildenafil on SOD formation and p47<sup>phox</sup> (the active subunit of NADPH oxidase) expression in cultured corpus cavernosal smooth muscle cells (79). Cavernosal smooth muscle cells derived from rabbit penis were incubated with U46619 (thromboxane A<sub>2</sub> analogue) with and without sildenafil. This study demonstrated that sildenafil inhibited the SOD formation effect of U46619. The investigators concluded that sildenafil is a potent inhibitor of SOD formation in cavernosal smooth muscle cells, suggesting the inhibitory role of sildenafil in therapy of ED related to intrapenile oxidative stress.

## CONCLUSION

Endothelial and erectile dysfunctions have many origins, yet share similar vascular risk factors and pathophysiological mechanisms. A healthy vascular endothelium plays an important role in normal erectile function. Vascular disease states, such as diabetes, hypertension, atherosclerosis, advanced age,

hypercholesterolemia, and coronary artery disease, are associated with impaired endothelial function. Alterations in the vascular endothelium of the penis decrease the responsiveness to vasodilatory mediators and increase the sensitivity to vasoconstrictors, resulting in ED. Vascular risk factors in these disease states also cause decreased NO bioavailability and impaired eNOS enzyme activity, which is crucial for cavernosal smooth muscle relaxation and penile erection. Because normal penile erection necessitates coordinated arterial endothelium-dependent vasorelaxation and cavernosal endothelium-dependent smooth muscle relaxation, insights into the pathophysiological mechanisms involved in endothelial dysfunction and their relation to various vascular comorbidities will lead researchers and clinicians to innovations in prevention and EC-based strategies to cure ED.

## KEY POINTS

- Approximately 52% of men aged 40 to 70 years have some degree of ED. Normal penile erection requires a coordinated arterial endothelium-dependent vasorelaxation and cavernosal endothelium-dependent smooth muscle relaxation. Endothelial and erectile dysfunctions have a multifactorial origin and share similar risk factors and pathophysiologies. Vascular risk factors, such as diabetes, hypertension, atherosclerosis, advanced age, hypercholesterolemia, and coronary artery disease, are associated with impaired vascular endothelial and erectile function. As a corollary, the onset of ED should direct clinicians to search for underlying vascular risk factors. Erectile function mirrors endothelial and vascular health.
- Penile erection is a neurovascular event that relies on neural integrity, a functional vascular endothelial system, and healthy cavernosal smooth muscle.
- A healthy vascular endothelium plays an important role in erectile function. Any alteration in the vascular endothelium of the penis may result in a decreased responsiveness to vasodilator mediators or an increased sensitivity to vasoconstrictors, with the net effect being ED.
- Common consequences of vascular risk factors on the endothelium are impairment in NO bioavailability and decreased eNOS enzyme activity.

## Future Goals

- To advance our understanding of the pathophysiology of endothelial dysfunction, thus leading to novel prevention strategies and EC-based pharmacological and gene-related therapies to correct ED

- To promulgate to the public those lifestyle changes that will preserve and/or improve vascular endothelial and erectile function

## Avascular Necrosis

### Vascular Bed/Organ Structure and Function in Health and Disease

---

Chantal Séguin

*Montreal General Hospital, McGill University, Canada*

Avascular necrosis (AVN) of the femoral head is a clinical entity in which bone death occurs as a result of interruption of blood at the level of the microcirculation. The etiology and pathogenesis of nontraumatic AVN have not been fully elucidated. The understanding of this disease progression is important for several reasons. First, AVN is a devastating musculoskeletal condition that strongly impacts those affected. Second, it tends to occur in young people. Third, current treatments are suboptimal since they are, for the most part, palliative rather than curative. Finally, we are currently unable to identify individuals who will develop AVN, even in the group considered at high risk; consequently, practitioners are not able to stop the progression of the disease or reverse the process once AVN has developed.

Although the actual prevalence of the disease is unknown, an estimated 10,000 to 20,000 new patients with AVN are diagnosed each year in the United States (1). AVN is the underlying diagnosis in 5% to 18% of the more than 500,000 total hip arthroplasties performed yearly in the United States and Western Europe (1).

AVN has been associated with a variety of risk factors, and classified as either secondary or idiopathic. Environmental risk factors include hyperlipidemia, steroid use, alcohol, various blood dyscrasias (e.g., hemoglobinopathies, coagulopathies), pregnancy, hyperbaric exposure, use of chemotherapeutic agents, systemic lupus erythematosus, inflammatory bowel disease, lipid storage diseases (Gaucher disease), and familial thrombophilias (1).

The condition may occur in up to 30% of patients with lupus erythematosus. In a large U.S. study of 2,590 patients with sickle cell disease, Milner and associates reported a prevalence of 9.8% (1). There is also a high incidence of AVN among organ transplant recipients. Allogenic bone marrow transplantation carries the highest incidence of AVN, reported to be 10% in the United States. Likewise, a 42.8% incidence of AVN of the femoral head has been found in a review reported

by Arlet and colleagues of 138 patients with lower extremity vascular occlusive disease demonstrated by arteriography (2). Many recent studies also have described AVN in association with human immunodeficiency virus (HIV) infections (3). More recently, some studies have shown an association of AVN of the mandible with the chronic use of bisphosphonates, although no cases were seen in hip AVN (4). AVN also has been described after septic shock associated with multiorgan failure and after renal transplantation (5).

Several studies suggest that alcohol and steroid use may account for 90% to 100% of all nontraumatic "secondary" cases of AVN (6). The effects of both alcohol and corticosteroids have been related to alterations in lipid metabolism through intravascular coagulation and fat embolism phenomena. However, of those people fulfilling the risk criteria for AVN development, most never develop the disease. This finding suggests that a second event is necessary to initiate the development of AVN in a subset of patients with an acquired or inherited predisposition for this disorder (6).

#### **HISTOLOGY OF THE FEMORAL HEAD IN AVASCULAR NECROSIS**

The immunochemistry of 14 femoral heads with late-stage nontraumatic AVN in a study conducted in Denmark in 1995 by Starklint and colleagues (7) identified five histologically distinct zones in most of the affected heads. In the transitional zone, several areas with intravascular aggregations of newly formed and older fibrin clots were noticed, mainly on the venous side of the vascular system. Small vessels were collapsed, with a few endothelial cells (ECs) clumped together in the center of a concentric fibrous tissue. These and other findings suggest that obstruction of the venous outflow due to intravascular thrombosis is important in the pathogenesis of nontraumatic AVN of the femoral head.

**ROLE OF ENDOTHELIUM  
IN AVASCULAR NECROSIS**

Accumulating evidence suggests that the endothelium is involved in the development of AVN. Glucocorticoids have been shown to alter EC phenotypes (see Chapter 180). Nishimura and colleagues, in their histopathologic study of veins in steroid-treated rabbits, were able to show damage to ECs and smooth muscle cells via electron microscopy (8). Borcsok and colleagues reported that glucocorticoids induced the expression of endothelin-1 in ECs via an endothelin-A receptor-dependent mechanism (9). EC dysfunction under glucocorticoid influence also was demonstrated by Kitajima (10). We have shown that the addition of dexamethasone 1,000 nM to human umbilical vein ECs (HUVECs) results in increased expression of vascular cell adhesion molecule (VCAM)-1. We are currently studying the effect of plasma from a cohort of AVN patients versus healthy controls on the induction of activation markers in HUVECs (C. Séguin et al., unpublished observations).

Other studies have demonstrated endothelial dysfunction and subsequent platelet thrombosis following intravascular bubble formation in dysbaric osteonecrosis (11) and a possible role for lipid peroxide on ECs by suppressing their proliferation (12).

AVN is a frequent bone complication seen in patients with sickle cell disease. Bone infarcts can occur at multiple sites.

The endothelium plays a critical role in the pathophysiology of sickle cell anemia. In sickle cell anemia, the endothelium acquires an activation phenotype, promoting increased leukocyte adhesion and displaying a procoagulant surface. These changes contribute to reduced blood flow and ischemia. Indirect evidence that the vascular endothelium is abnormally activated in sickle cell disease comes from the study of circulating ECs (CECs). CECs from sickle cell patients have abnormally increased expression of VCAM-1, intercellular adhesion molecule (ICAM)-1, E-selectin, and tissue factor, reflecting a proadhesive and procoagulant state (13). Sickle cell anemia also has been associated with reduced nitric oxide (NO) bioactivity in resistance vessels, with resultant impaired vasodilation (14). EC dysfunction has been implicated in such complications as stroke and pulmonary hypertension. It is interesting to speculate that phenotypic changes in the bone endothelium contributes to the initiation and/or progression of AVN.

The identification of vascular bed-specific markers that are associated with an increased risk for AVN and/or contribute to the pathogenesis of this disease might provide a foundation for molecular diagnostic tests aimed at detecting individuals at high risk before the disease occurs or progresses to irreversible stages. Also, such information might lead to the development of novel therapies, with the goal of reducing repeated surgical treatments, the resultant morbidity, and consequently the associated costs to our health system.

Figure 168.1. Matrigel assay. HBDECs forming tubular structures in Matrigel after 8 hours. Cells started to migrate to the inside of the lumens after 48 hours (arrows).

## ISOLATION OF HUMAN BONE-DERIVED ENDOTHELIAL CELLS

The first successful isolation of bone-derived ECs was reported by Zhang in a mouse study model using a 0.5% collagenase (15). We have successfully isolated human bone-derived ECs (HBDECs) from unaffected (control) and affected (AVN) femoral heads from human subjects undergoing surgery (C. Séguin, unpublished observations). These studies demonstrate the presence of a population of cells that are positive for the EC surface markers, platelet-endothelial cell adhesion molecule (PECAM)-1/CD31, CD105 (endoglin), and von Willebrand factor. Furthermore, when assayed in Matrigel, these cells formed tubular structures, suggesting their capability to undergo angiogenesis (Figure 168.1). These preliminary results hold great promise. Although the cells were isolated from the cancellous bone of the femoral head, this technique can be expanded to isolate ECs from other human bone tissues. The cells isolated could provide a primary population of ECs for the biological analysis of human vascular bone diseases.

### KEY POINTS

- AVN is a devastating musculoskeletal disorder affecting mainly young people; it is associated with significant morbidity in those affected, and it impacts highly on the health care system.
- Intravascular thrombosis is manifested on histopathological bone studies, implying the contribution of the vascular system in the pathogenesis of AVN.
- Evidence suggests that EC dysfunction or activation is a key mechanism underlying the development of microvascular thrombus and as such, supports the hypothesis of bone-derived endothelium in the development of vascular bone diseases.

### Future Goals

- To develop a suitable animal model based on clinical disease state, to appreciate better the contribution of bone-derived endothelium in the pathogenesis of vascular bone diseases

## Molecular Control of Lymphatic System Development

Darren Kafka and Young-Kwon Hong

*Keck School of Medicine, University of Southern California, Los Angeles*

The human body has two major circulatory systems: the blood and lymphatic vascular systems. Both systems share functional and anatomical similarities and play complementary roles in tissue perfusion and fluid circulation. Nonetheless, the two systems have attracted different levels of scientific and clinical attention. Although the blood vascular system has been extensively studied, in contrast, the lymphatic system has been neglected, despite the essential roles it plays in tissue fluid homeostasis, immune response, and lipid absorption. This is largely due to the lack of lymphatic-specific molecular tools to visualize and characterize lymphatic vessels. However, a number of recent discoveries involving the characterization of lymphatic-specific molecules and lymphatic endothelial cells (ECs) have begun to unravel the mystery of the lymphatic system and have opened a new era of lymphatic research. Moreover, studies of genetic mouse models have provided important insights into the molecular mechanisms underlying lymphatic development, as well as the genetic basis of human diseases associated with the lymphatic system. In this chapter, we review some of the landmark findings that have significantly advanced our current understanding of the lymphatic system.

### STRUCTURE AND FUNCTION OF THE LYMPHATIC VASCULAR SYSTEM

The blood vascular system is a closed circular network in which blood leaves and returns to the heart after flowing through the arteries, tissue capillaries, and veins. In comparison, the lymphatic system is a blunt-ended linear system: The initial lymphatic vessels begin at the interstitial spaces of peripheral tissues and organs, and they are connected to the thicker collecting lymphatic vessels, which are eventually connected to the inferior vena cava through the thoracic duct (Figure 169.1, Table 169-1). From peripheral tissues and organs, lymphatic capillaries drain protein-rich interstitial fluid, extravasated cells, and large extracellular molecules (collectively called

lymph), eventually transporting it back to the blood vascular system for recirculation. When this draining function of the lymphatic system is compromised by surgery, radiation, or infections, the lymph fluid accumulates and cause swellings (lymphedema) in the affected tissues or organs. In fact, surgical lymph node removal for the purpose of tumor staging is one of the most common causes of tissue swelling. Therefore, the major function of the lymphatic system is to control tissue-fluid homeostasis. In addition, the lymphatic system serves as a conduit for the absorption of large molecules and lipids in the digestive systems. Lymphatics also play a critical role in the trafficking of lymphocytes and antigen-presenting cells to regional lymph nodes. Unfortunately, many malignant tumors take advantage of the lymphatic system for their dissemination.

Despite their overlapping functional and anatomical features, the blood vascular and lymphatic systems display distinct phenotypes. Blood capillaries possess a compact, three-layered structure in which the blood vascular ECs (BECs) are surrounded by a continuous basement membrane (the liver sinusoids are an exception), which in turn is covered to a variable degree by smooth muscle cells/pericytes. ECs of the blood capillaries tend to be tightly connected to each other through adherens, gap junctions, and tight junctions. By comparison, the lymphatic capillaries consist of a single layer of lymphatic ECs (LECs) that partially overlap one another. They tend to have large, irregularly shaped lumens. In contrast to BECs, LECs lack tight junctions. With the exception of the larger collecting lymphatic vessels that have luminal valves, LECs in lymphatic capillaries are rarely surrounded by a continuous basement membrane or smooth muscle cells/pericytes. Instead, they are directly connected to the surrounding extracellular matrix through anchoring filaments (Figure 169.2). Under normal conditions, most lymphatic capillaries remain collapsed. When interstitial pressure increases, the anchoring filaments exert tension on the LECs, pulling open the intercellular junctions, and allowing interstitial fluid to enter the lumen of lymphatic capillaries.

Figure 169.1. Schematic illustration of the blood vascular and lymphatic systems. The blood vascular system is a circular and closed system, whereas the lymphatic system is a blunt-ended and linear system. Fluid, macromolecules, and cells extravasated from blood capillaries flow into lymphatic capillaries in peripheral tissues and are then transported back to the blood vascular system for recirculation.

In addition to lymphatic vessels, the lymphatic system includes lymphatic organs such as the lymph nodes, tonsils, Peyer patches, spleen, and thymus. These so-called secondary lymphoid organs control the quality of immune responses by serving as a fluid filter in which pathogens and other foreign agents encounter immune cells. Most vascularized tissues and organs have lymphatic vessels, with the exception of the brain, spinal cord, and retina. Although lymphatic vessels do not exist in the brain and spinal cord, studies found that tracers injected into the cerebrospinal fluid (CSF) or brain parenchyma were cleared into lymphatic vessels external to the cranium and into lymph nodes in the head and neck (1). This finding established a physiological relationship between the CSF and extracranial lymph compartments. Although the normal cornea lacks both blood and lymphatic vessels, various corneal diseases and surgical manipulation can induce lymphangiogenesis as well as angiogenesis (1).

#### DEVELOPMENT OF THE LYMPHATIC SYSTEM: HISTORICAL AND PHYLOGENETIC PERSPECTIVES

Lymphatics were initially described as “white blood vessels” by Hippocrates. After that first description, the lymphatic system was virtually ignored until 1627, when the Italian anatomist

Gasper Asellius rediscovered lymphatic vessels as “milky veins” in the mesentery of a dog (2). These cursory observations contrasted with William Harvey’s seminal and thorough description of the closed blood vascular system in the following year (1628) in his book, *An Anatomical Study of the Motion of the Heart and Blood in Animals* (3). Following Asellius’s finding of the mesenteric lymphatic vessels, the collecting lymphatic vessels and the thoracic duct were identified and their fluid-draining function was further characterized. At the beginning of the 20th century, two competing hypotheses were proposed regarding the genesis of the lymphatic system. One hypothesis (centrifugal model) claimed that lymphatic endothelium derives from blood vascular endothelium and that lymphatic vessels are formed through the sprouting of preexisting blood vessels. The other hypothesis (centripetal model), which was more widely held then, posited that LECs are independently differentiated from mesenchymal cell-derived lymphangioblasts, and that the lymphatic connection to the blood vascular system is acquired only later. Using ink-injection experiments in pig embryos, Florence Sabin showed, in 1902, that the initial lymphatic sacs were derived from embryonic veins, and that these primitive lymphatic plexuses gradually spread throughout the body to form the lymphatic network (4,5). Although Sabin’s experiment strongly supported the centrifugal model, it would take another 100 years to resolve this debate.

About four decades ago, Leak and Burke pioneered a comparative morphological study of blood and lymphatic vessels and – for the first time – attempted to establish a defined culture of LECs (6). However, these efforts were hampered by the absence of available lymphatic-specific markers. During the past decade, new lymphatic-specific molecular markers, such as vascular endothelial growth factor receptor 3 (VEGFR3), lymphatic vessel endothelial receptor (LYVE)-1, and podoplanin have been identified and characterized. One of the landmark (and unexpected) discoveries in lymphatic research was made in 1999, when *Prox1*-knockout mice were shown to lack a lymphatic system (7). This and subsequent studies showed that a subset of embryonic cardinal vein ECs express *Prox1* during early embryogenesis, and that the *Prox1*<sup>+</sup> cells bud off and migrate out to form the initial lymphatic vessels (7,8). This finding was consistent with Sabin’s data and largely confirmed the blood vascular origin of mammalian lymphatic system. In contrast to mammals, lymphatic vessels in *Xenopus* tadpoles have been reported to develop from lymphangioblasts or, through transdifferentiation, from venous ECs (9). Moreover, several studies of avian development revealed that independent lymphangioblasts contributed to the formation of the lymphatic system in early wing buds, limb buds, and the chorioallantoic membrane (10–12). Whether lymphangioblasts exist in mammals and contribute to mammalian lymphangiogenesis remains unclear.

From an evolutionary standpoint, the lymphatic system first appeared in vertebrates (13). Although zebrafish (*Danio*

**Table 169-1: Schematic Comparisons between the Blood Vascular and Lymphatic Systems**

	<i>Blood Vessels/BEC</i>	<i>Lymphatics/LEC</i>
Structure	Closed, circular	Open, linear
Division	Arteries, arterioles, capillaries, venules, veins	Capillaries, collecting vessels, lymph nodes, thoracic duct
Constituents	Blood	Lymph (protein-rich interstitial fluid, extravasated cells and large extracellular molecules)
Functions	Hemostasis, inflammation, leukocyte trafficking, barrier function	Tissue fluid homeostasis; absorption of large molecules and lipids in the digestive systems; trafficking of lymphocytes and antigen-presenting cells to regional lymph nodes
Vessel wall	Depending on vessel type, vascular bed: adherens and tight junctions, continuous basement membrane (except in liver sinusoids), pericytes or vascular smooth muscle cells	Overlapping ECs, no tight junctions, discontinuous basement membrane; few pericytes (except large collecting vessels); collecting vessels contain interluminal valves to prevent reverse flow
Development	Vasculogenesis and angiogenesis	Lymphangiogenesis (budding from cardinal vein)
Origin	Mesoderm	Mesoderm
Examples of cell-type specific markers	CD34, PAL-E	LYVE-1, VEGFR3, Prox1, and podoplanin
Absence	Cartilage, cornea	Cartilage, brain, spinal cord, and the retina, cornea
Activation	Response to inflammatory mediators, usually consists of combination of procoagulant and proadhesive properties and increased permeability	Response to inflammatory mediators; HGFR is expressed in inflammation or wound-associated lymphatic vessels
Heterogeneity	Phenotypic heterogeneity is well established. EC phenotypes vary between tissues, within a given organ and even between neighboring ECs	The extent of EC heterogeneity in lymphatics remains to be established

*erio*) provide a valuable experimental model system for the study of angiogenesis, they do not have a lymphatic system.<sup>1</sup> Later, amphibians and reptiles developed specialized lymph hearts that drain and transport the interstitial fluid to the blood vascular system for recirculation. The primitive lymphatic system further evolved in birds and mammals to include lymph nodes, which play important roles in immune functions. The lymphatic system of *Xenopus* (frogs) has been used as a simple experimental tool for studies of the development and function of the lymphatic system (15–20).

1 It has since been reported that zebrafish have a functional lymphatic system (14).

## MOLECULAR PLAYERS IN LYMPHATIC DEVELOPMENT

One of the landmark advances in lymphatic research was the establishment of defined cultures of LECs (21–24). Cultured ECs isolated from dermal microvascular lymphatic and blood vessels have been shown to retain many, but not all, of their lineage-specific phenotypes. Furthermore, cell morphology and growth characteristics of these two different types of ECs are largely indistinguishable. Several microarray analyses revealed that approximately 96% to 98% of transcripts were comparably expressed between the two cell types, with only 2% to 3% of genes (corresponding to approximately

Figure 169.2. Schematic representation of the structure and function of lymphatic vessels in the skin. Lymphatic capillaries have irregular lumens and consist of a single layer of overlapping ECs without basement membrane and pericyte coverage. Lymphatic ECs are connected to the surrounding extracellular matrix through anchoring filaments. When interstitial pressure increases, these filaments exert tension on ECs and pull open the intercellular gaps, through which fluid and cells enter the vessels for recirculation.

300–400 genes) being differentially expressed (21,25), thus corroborating their close histogenetic relationship. In this section, we review several genes that are specifically or predominantly expressed in LECs and that play important roles in the development and function of the lymphatic system (Table 169-2).

### Prox1

Prox1 is a homeodomain transcription factor that was originally isolated based on its amino acid homology to the *Drosophila* protein, Prospero (26–28). Prospero was first identified based on its mutational phenotype of a defective neuronal lineage establishment in the *Drosophila* central nervous system. During *Drosophila* neuroblast cell division, only one of two daughter cells receives the Prospero protein due to its asymmetrical segregation. A daughter cell that received the Prospero protein enters a differentiation program to become a neuron or glial cell, whereas the other cell remains as a neuroblast. Therefore, Prospero specifies the neuronal fate of the cell (29,30). Prospero is also essential for glial cell differentiation (31) and for eye development (32). Based on sequence homology to Prospero, Prox1 proteins have been identified in human, mouse, chicken, newt, frog, and zebrafish, and their amino acid sequences are highly conserved across these species (26,27,33). In particular, their C-terminal ends (the homeodomain and the prospero domain) share over 60% amino-acid identity with the Prospero protein (26,27). During development, Prox1 is expressed in the liver, lens, retina, nervous system, pancreas, and heart (26), where it plays an important role as a master regulator in cell fate decisions that lead to the establishment of many different cell lineages.

Both heterozygous and homozygous *Prox1*-knockout mice develop severe tissue edema during development. Homozygous mutant embryos die at embryonic day (E) 14.5 to 15.5 due to a combination of several phenotypic alterations, including arrested hepatocyte migration and failure of lymphatic system. Studies of heterozygous mouse whose *Prox1* gene was replaced with the *LacZ* gene have significantly advanced our understanding of lymphatic vascular development (7,8). At E8.5 in mice, all cardinal vein ECs display lymphatic competence by expressing the lymphatic markers VEGFR3 and LYVE-1 (Figure 169.3). Around E9.5 to E10.5, a yet-unknown inductive signal from the surrounding mesenchyme stimulates a subset of the venous ECs to express Prox1. These Prox1<sup>+</sup> cells gradually bud off the vein and migrate out to form the rudimentary lymph sacs. The budding lymphatic endothelial precursor cells modulate their gene expression profiles to adopt a lymphatic phenotype by expressing additional lymphatic markers, such as secondary lymphoid chemokine (SLC; also named CCL21) and neuropilin 2 (NRP2), and by progressively downregulating blood vascular EC markers including CD34, laminin, and collagen type IV (Figure 169.3). While the Prox1<sup>+</sup>, lymphatically specified ECs further differentiate and sprout throughout the embryo from E12.5 on, the remaining Prox1<sup>-</sup> ECs in the cardinal vein gradually lose VEGFR3 and LYVE-1 expression to further differentiate into BECs.

Importantly, the initial budding of immature LECs was still detected in *Prox1*<sup>-/-</sup> mice. However, lymphatic specification of these cells did not occur in the absence of Prox1 (7,8), suggesting that Prox1 functions as a master regulator that determines lymphatic cell fate by reprogramming the

**Table 169-2: Molecular Markers Specifically or Predominantly Expressed in Either Blood or Lymphatic Capillaries**

Markers	Blood Vessels	Lymphatic Vessels	Also Expressed in
Prox1	-	+	Non-ECs in lens, retina, CNS, heart, liver, pancreas
LYVE-1	-	+	Macrophages, blood sinusoidal endothelium in liver and spleen, placental syncytiotrophoblasts
Podoplanin	-	+	Osteoblasts, lung alveolar type 1 cells, kidney podocytes, epidermal keratinocytes
VEGFR3	-	+	Tumor blood vessels, macrophages, dendritic cells
SLC/CCL21	-	+	Liver, spleen, lymph nodes, neuronal cells
NPR2	-	+	Neuronal cells
CCL20/MIP-3 $\alpha$	-	+	Intestinal epithelium, keratinocytes, monocytes
Desmoplakin	-	+	Epithelial cells, cardiac muscle
Laminin	+	-/+	Extracellular matrix, basal lamina
Collagen IV	+	-/+	Epidermal basal lamina
NPR1	+	-	Neuronal cells
CD34	+	-	Hematopoietic progenitor cells
VEGFR1	+	-	Monocytes/macrophages

### Embryonic Vein

Figure 169.3. Current model of the stepwise embryonic development of the mammalian lymphatic system. At mouse embryonic day (E) 8.5, all ECs of the cardinal vein express the lymphatic markers LYVE-1 and VEGFR3 and display lymphatic competency. Upon stimulation by a yet-unidentified inductive signal, a subset of venous ECs becomes lymphatically biased and upregulates Prox1 at around E10.5. At E11.5 and thereafter, these Prox1<sup>+</sup> cells bud off and migrate out to form initial lymphatics. They also upregulate additional lymphatic-specific molecules such as podoplanin, SLC, and NRP2.

Figure 169.4. Schematic illustration of specific growth factors and their receptors expressed by blood vascular and lymphatic ECs. Blood vascular ECs express VEGFR1, VEGFR2, and NPR1, whereas lymphatic ECs express VEGFR2, VEGFR3, and NPR2. VEGF-A, -C, and -D can promote angiogenesis and lymphangiogenesis.

transcriptional profiles of embryonic venous ECs. Indeed, we and others have shown that ectopic expression of Prox1 in differentiated primary BECs isolated from human foreskin was sufficient to reprogram BECs to adopt an LEC phenotype (25,34). When expressed in BECs, Prox1 downregulated several BEC-specific genes such as E-selectin, interleukin (IL)-8, laminin, collagens, NRP1, and vascular endothelial growth factor (VEGF)-C, and upregulated certain lymphatic-specific genes including VEGFR3, podoplanin, and desmoplakin I and II (25,34). Furthermore, knockout and overexpression studies have shown that Prox1 directs the progenitor cells of the mammalian retina and the eye lens to exit from the cell-cycle and to induce postmitotic differentiation programs (35–37). However, Prox1 does not appear to regulate the cell cycle during lymphatic development, suggesting that the mechanism of cellular differentiation induced by Prox1 may be cell-type specific (7,8). A recent study of *Prox1* mutant mice provided new insights into the role of lymphatics in fat accumulation (38). The latter study showed that the leakage of the lymph from structurally compromised lymphatic vessels in *Prox1*-deficient mice causes adult-onset obesity. Indeed, lymphedema resulting from lymphatic dysfunction due to the surgical removal of lymph nodes often is associated with fat accumulation and tissue fibrosis. Therefore, this study provided a long-suspected, yet hitherto unproven, link between adipogenesis and the lymphatic system.

Prox1 has been also implicated in Kaposi's sarcoma (KS), the most common neoplasm in human immunodeficiency virus (HIV)-infected patients (39–41). The causative agent in KS is KS-associated herpes virus (KSHV, also known as HHV-8). When KSHV infects BECs in vitro, the virus reprograms the cell type to resemble LECs by upregulating Prox1. KSHV is also capable of infecting cultured LECs and, interestingly, the virus downregulates Prox1 expression to re-specify the cell type toward that of BECs (39). The pathological

significance of this Prox1-mediated cell type reprogramming remains to be further studied.

### Vascular Endothelial Growth Factor Receptor 3

VEGFR3, also known as FLT-4, is a member of the FMS-like tyrosine kinase family that comprises seven extracellular immunoglobulin (Ig) homology domains, a single transmembrane domain, and a split intracellular tyrosine kinase domain. It is structurally related to VEGFR1/FLT-1 and VEGFR2/KDR/FLK-1, the principle receptors for VEGF-A (42,43). VEGFR3 serves as a major receptor for VEGF-C and VEGF-D, two important lymphangiogenesis factors and, unlike VEGFR1 and VEGFR2, does not bind to VEGF-A (Figure 169.4). After biosynthesis, the fifth Ig domain is proteolytically processed, and the resulting polypeptide chains remain linked by a disulfide bond. Binding of VEGFR3 to its ligands induces dimerization of the receptor and transphosphorylation of the intracellular domains. This creates docking sites for the adaptor proteins Shc and Grb-2, and leads to the activation of Akt, extracellular-signal-regulated protein kinase (ERK)-1/2, related adhesion focal tyrosine kinase (RAFTK), and nuclear factor (NF)- $\kappa$ B, resulting in altered gene expression, cell survival, and proliferation (44).

*VEGFR3* was the first gene whose expression was found to be specific for LECs in adults (43). Although VEGFR3 is also expressed in ECs of the cardinal vein and in angioblasts of the head mesenchyme during early development, its expression becomes restricted to lymphatic endothelium at a later developmental stage and in adults (43). In contrast, VEGFR3 expression in arterial ECs is tightly repressed by Notch signaling, an essential signaling pathway that determines arterial versus venous cell fates (45,46). *VEGFR3*-knockout mice die at E9.5 and display abnormal blood vascular organization, defective lumens in large blood vessels, and fluid accumulation in

the pericardial cavity (47). However, initial vasculogenesis and angiogenesis appear to occur normally.

Because *VEGFR3*<sup>-/-</sup> embryos die prior to formation of the lymphatic system, the knockout model could not be used to ascertain the role of VEGFR3 in lymphatic development. Overexpression of soluble VEGFR3 (a competitive inhibitor of membrane-bound VEGFR3) in transgenic mice inhibited fetal lymphangiogenesis and induced regression of preformed lymphatic vessels without affecting blood vessels, resulting in tissue lymphedema and fibrosis (48). Moreover, separate studies showed that neutralizing VEGF-C/VEGFR3 signaling suppresses tubular morphogenesis of lymphatic vessels and inhibits tumor cell entry and spread through lymphatic vessels (49–51). Notably, some tumor- or wound-associated blood vessels are reported to express VEGFR3 (52). Studies of transgenic mice expressing a mutant form of VEGF-C (VEGF-C156S) that selectively binds and activates VEGFR3, but not VEGFR2, revealed that activation of VEGFR3 alone is sufficient to promote lymphangiogenesis (53).

### Vascular Endothelial Growth Factor-C and -D

VEGF-C and VEGF-D, originally cloned by virtue of their affinity to VEGFR3, bind to both VEGFR2 and VEGFR3. Their interaction with VEGFR3 strongly promotes lymphangiogenesis (54–58). VEGF-C is widely expressed by a various cell types such as mesenchymal cells around embryonic veins, activated macrophages, skeletal muscle cells, and smooth muscle cells surrounding large arteries (54,59–61). Interestingly, VEGF-C is also expressed by BECs (21), implying that the blood vascular system may control growth and/or maintenance of lymphatic vessels. Both VEGF-C and -D are synthesized as precursor proteins with the N- and C-terminal propeptides and, when secreted, undergo proteolytic processing by secretory pro-protein convertases such as furin, PC5 and PC7, or plasmin. When fully processed, the isoforms acquire an increased affinity to VEGFR2 and therefore induce angiogenesis in vivo (53,62–65). A mutant form of VEGF-C that contains a cysteine to serine point mutation at residue 156 was shown to selectively activate VEGFR3, but not VEGFR2 (66). Activation of VEGFR3 by VEGF-C and/or VEGF-D promotes proliferation, survival, and migration of cultured human LECs and the VEGF-C/VEGFR3 pathway delivers a major lymphangiogenic signal in vivo (24,53,67). Importantly, tumor cells overexpressing VEGF-C and VEGF-D were shown to promote tumor lymphangiogenesis and metastasis in mice (68,69). These studies demonstrated – for the first time – that the expression of lymphangiogenic factors by tumor cells in a mouse model significantly promote tumor lymphangiogenesis and that the enhanced lymphangiogenic activity results in an increased incidence of tumor metastasis to regional lymph nodes and distant organs. A strong positive correlation between tumor metastasis and the density of tumor-associated lymphatic vessels has been consistently demonstrated in many different types of cancers, a list that continues to grow (70–75). Moreover, the tumor-associated lymphatic vessel density was

shown to be a novel prognostic factor for malignant melanoma in human (75).

VEGF-C-deficient mice display normal blood vessel development, but absent lymphatic vessel formation (61). These data indicate that VEGF-C is essential for embryonic lymphangiogenesis, but dispensable for vasculogenesis and angiogenesis (61). Although the mutant mice exhibited Prox1 expression, Prox1<sup>+</sup> venous ECs failed to migrate out to form the initial lymph sacs. Notably, the sprouting defect was rescued by exogenous administration to embryos of VEGF-C or VEGF-D, but not VEGF-A (61). These results suggest that the lymphatic specification of Prox1<sup>+</sup> venous ECs and subsequent migration of committed LECs independently regulated processes.

Interestingly, heterozygous VEGF-C mutant mice demonstrated cutaneous lymphatic hypoplasia and lymphedema, showing a haploinsufficiency effect of VEGF-C for the normal development and function of the lymphatic system. Surprisingly, VEGF-D-deficient mice seem to develop a normal lymphatic system despite the putative role of this growth factor in physiological and pathological lymphangiogenesis (76). It will be interesting to investigate if *VEGF-C* and *VEGF-D*-double knockout mice display more severe lymphatic phenotypes than do the VEGF-C single mutant mice.

### Vascular Endothelial Growth Factor Receptor 2

VEGFR2, also known as KDR or FLK-1, is a receptor for VEGF-A, VEGF-C, and VEGF-D. VEGFR2 is expressed by both BECs and LECs in vitro and in situ (21,23,77). Although the role of VEGF-A/VEGFR2 signaling in angiogenesis has been well established (see Chapter 32), its contribution to lymphangiogenesis is currently a matter of controversy. VEGF-A can potently enhance proliferation and tube formation of cultured LECs (21,77). Also, a local injection of adenovirus expressing murine VEGF-A<sub>164</sub> into mouse ears resulted in pronounced and persistent in vivo lymphangiogenesis (78). Similarly, transgenic mice that specifically overexpress murine VEGF-A<sub>164</sub> in the skin showed enhanced lymphangiogenesis – in addition to angiogenesis – during tissue repair and in skin inflammation (77,79). Blockade of VEGFR2 signaling using a VEGFR2 blocking antibody inhibited both angiogenesis and lymphangiogenesis in healing wounds, indicating the importance of VEGFR2 for repair-associated lymphangiogenesis (78). In contrast, adenoviral-mediated overexpression of the human VEGF-A<sub>165</sub> isoform did not show distinct lymphangiogenic activity in mouse models (80,81). This discrepancy may be due to a possible species-specificity of VEGF-A. VEGF-A/VEGFR2 signaling also induces lymphangiogenesis in the sentinel lymph node as well as in tumors, and significantly promotes tumor metastasis (82).

### Lymphatic Vessel Endothelial Receptor-1

LYVE-1 is the lymph vessel endothelial hyaluronan (HA) receptor-1 and, along with VEGFR3 and podoplanin

(discussed in the next section), was the first to be identified as a lymphatic vessel marker. HA, a large mucopolysaccharide polymer ( $10^2$ – $10^4$  kDa), is a prolific component of the extracellular matrix in various tissues, and plays an important role in maintaining structural integrity of connective tissues by serving as a ubiquitous substratum for cell adhesion, migration, and differentiation (83,84). Extracellular HA undergoes a constant turnover under normal conditions and HA released from the tissue matrix is transported through lymphatic vessels to the lymph nodes, where it is partially degraded and subsequently transported to the liver for complete hydrolysis. LYVE-1 was originally identified by its high sequence homology to the inflammatory leukocyte homing receptor CD44 that is predominantly expressed by blood vascular endothelium (85). Although LYVE-1 is absent from BECs, it is expressed by activated tissue macrophages and sinusoidal endothelium of the liver and the spleen, where high-molecular-weight HA is absorbed and degraded (83,84). LYVE-1 also is implicated in the trafficking of cells within lymphatic vessels and lymph nodes. Despite the important role of LYVE-1 in HA homeostasis and its specific expression in lymphatic vessels, LYVE-1-deficient mice appear normal – no obvious lymphatic vascular malfunctions or morphological abnormalities have been detected thus far (86).

### Podoplanin

Podoplanin, a mucin-type transmembrane sialoglycoprotein, is expressed by LECs, but not BECs *in vivo* and *in vitro* (21,23,25,87,88). The expression of podoplanin is also detected in a wide range of other cell types, including lung type I alveolar cells, choroid plexus cells, ciliary epithelial cells of the eye, osteocytes, and kidney podocytes. It has been independently cloned by a number of groups, and variably named OTS8, E11 antigen, RTI40, murine gp38, canine gp40, human gp36, aggrus, and murine PA2.26 (87–92). During mouse development, podoplanin is expressed at around E9 in the central nervous system and the foregut, but not yet in the vascular system (88,89,93). Around E11.5 to E12.5, its expression becomes apparent in all ECs in the cardinal vein, including the budding Prox1<sup>+</sup> cells (88). Similar to VEGFR3 and LYVE-1, the expression of podoplanin is maintained in the budding cells that are committed to the lymphatic lineage, but is progressively downregulated in venous ECs (88). Podoplanin-deficient mice die at birth due to lung failure (88,89). Importantly, newborn mutant mice display lymphedema in the limbs due to impaired cutaneous lymphatic transport (88). The podoplanin mutant mice develop a normal blood vasculature, but the lymphatic networks of their intestine and skin are disorganized. *In vitro* functional analyses showed that podoplanin is essential for the migration, adhesion, and tube formation of LECs (89). Because *podoplanin*-null mice die at birth, the generation of tissue-specific knockout mice will be essential to further study the role of podoplanin in adult lymphatics.

### Angiopoietins

Angiopoietin 1 (Ang1) and Ang2 are competing ligands for the EC-specific tyrosine kinase receptor Tie2 (94,95). Whereas Ang1 recruits perivascular cells and stabilizes mature blood vessels, Ang2 interferes with this stabilizing signal, resulting in disturbed interactions between BECs and surrounding pericytes and dismantling of the EC–basement membrane–pericyte structure. Ang2 induces angiogenic sprouting when VEGF is present, but promotes vessel regression in the absence of VEGF (96,97). Ang2 is expressed by the smooth muscle cells of large arteries, large veins, and venules, and its expression is enhanced by VEGF-A and hypoxia in microvascular ECs at sites of vascular remodeling (97–99). A study of *Ang2*-knockout mice revealed that Ang2 is dispensable for embryonic vascular development but is required for subsequent angiogenic remodeling (100). *Ang2*-knockout mice also display major lymphatic vessel defects and develop chylous ascites and lymphedema due to lymphatic dysfunction (100). Their large lymphatic vessels are structurally irregular and leaky, and the smaller lymphatic vessels display abnormal patterning. Interestingly, overexpression of Ang1 rescued the defects of the lymphatic system, but not those of the blood vascular system in *Ang2*-deficient mice (100). This suggests that Ang2 acts as a Tie2 agonist for lymphatic vessels but as an antagonist for blood vessels, adding additional complexity to the exquisite interplays between Ang1/2 and other angiogenic factors (100). Although LECs express Tie2, the lymphatic phenotype of Tie2-deficient mice was not studied due to their embryonic lethality at E10.5, when the lymphatic system is about to appear (101,102). Recently, Ang1 was shown to promote lymphatic sprouting and hyperplasia in a mouse model (103).

### Syk and SLP-76

Spleen tyrosine kinase (Syk) and SH2 domain-containing leukocyte protein of 76 kDa (SLP-76), are two adaptor molecules involved in signaling in hematopoietic cells. The protein tyrosine kinase Syk is widely expressed in hematopoietic cells and transfers signals from activated immunoreceptors that result in diverse cellular responses such as cell proliferation, differentiation, and phagocytosis (104). SLP-76, also known as lymphocyte cytosolic protein 2 (LCP2), is a substrate of Syk and serves as an adaptor protein for the signal transduction (105). Syk- and SLP-76-mediated hematopoietic signaling was shown to be required for normal development of the lymphatic system because Syk- or SLP-76-deficient mutant mice displayed incomplete separation of developing lymphatic vessels from embryonic vein during embryogenesis (106). This failure of separation gave rise to an arterio-venous-lymphatic shunting and, as the result, the mutant mice exhibited cardiomegaly, elevated cardiac output, and admixture of blood with lymph (106). The Syk- or SLP-76-deficient mouse embryos develop extensive hemorrhage into the developing

cutaneous lymphatic vessels at around E12. Interestingly, chimeric vessels that are composed of both LYVE-1<sup>+</sup> lymphatic- and LYVE-1<sup>-</sup> BECs were found in the mutant mice (106). Because neither EC type expresses Syk or SLP-76, these findings suggest that hematopoietic cells might be involved in the separation of the two vascular systems (106). Consistent with this notion, transplantation of bone marrow cells from SLP-76-deficient mice into lethally irradiated wild-type mice reproduced the same lymph-vascular phenotype as that of SLP-76-deficient mice (106). Collectively, these findings raise the possibility that hematopoietic cells contribute to the development of the lymphatic system. However, it remains to be answered how Syk and SLP-76 influence lymphatic development.

### CC Chemokine Ligand 21

CC chemokine ligand 21 (CCL21) plays an important role in inflammatory responses. CCL21 is also known as secondary lymphoid-tissue chemokine (SLC), Exodus-2, or 6Ckine. CCL21 is predominantly expressed by lymphatic endothelium, high endothelial venules (HEVs), and the T-cell area cells in lymph nodes, and Peyer patches. CCL21 serves as a ligand of chemokine receptor 7 (CCR7) and promotes adhesion and stimulates migration of thymocytes, T lymphocytes, macrophages, and neutrophils via high-affinity binding to the receptor. It is the first chemokine identified that mediates homing of lymphocytes and migration of antigen-stimulated dendritic cells into secondary lymphoid organs (107,108).

### Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) was first isolated by its sequence homology to a viral oncogene, and was subsequently shown to promote the proliferation of mesenchymal cells. PDGF consists of two chains and five members (PDGF-AA, -BB, -AB, -CC, and -DD) constitute the PDGF family. PDGF receptors (PDGFRs) comprise two subunits ( $\alpha$  and  $\beta$ ), forming PDGFR- $\alpha\alpha$ ,  $\alpha\beta$ , and  $\beta\beta$ . Ligand binding to a receptor subunit induces homo- or heterodimerization of the receptors, resulting in their autophosphorylation. PDGF has been implicated in pathological angiogenesis. Recently, the PDGF family also was found to promote lymphangiogenesis (109). PDGF-BB stimulated mitogen-activated protein kinase (MAPK) activity and the cell motility of isolated LECs. PDGF-BB potently induced growth of lymphatic vessels *in vivo* and promoted tumor metastasis, independent of the VEGFR3 signaling pathway. Consistently, PDGFR- $\beta$  was shown to be expressed in LECs (109).

### Hepatocyte Growth Factor

Hepatocyte growth factor (HGF) was found to promote lymphangiogenesis both *in vitro* and *in vivo* (110). Activated LECs in wounds or inflamed skin display significantly higher levels

of HGF receptor (HGFR), whereas little or no HGFR expression was detected in lymphatic vessels from normal tissues. Notably, HGF-induced proliferation of LECs did not require activation of VEGFR3, and HGF-induced cell migration was partially mediated by integrin  $\alpha 9$  (110).

### Insulin-Like Growth Factors

Insulin-like growth factor (IGF)-1 and -2 were recently reported to promote lymphangiogenesis in a mouse cornea assay (111). IGF-1-induced lymphangiogenesis was not blocked by administration of soluble VEGFR3, suggesting that the VEGFR3 signaling pathway is not required for IGF-1-mediated lymphangiogenesis. IGF-1 and IGF-2 stimulate phosphorylation of intracellular signaling components, such as Akt, Src, and ERK in LECs.

### Neuropilin 2

NRP2 is a nonkinase type I transmembrane receptor and functions as a neuronal guidance molecule. NRP2 binds to the class III semaphorins and several VEGF family members including VEGF-A<sub>165</sub>, placental growth factor (PlGF)-2, and VEGF-C (112). Although NRP1 is predominantly expressed in arterial ECs, NRP2 is mainly expressed in veins. Whereas NRP2 is strongly expressed in visceral lymphatic vessels, its expression is weak in cutaneous lymphatic capillaries (34,113,114). Interestingly, NRP2 mutant mice display a severe reduction of small lymphatic vessels in all tissues including the skin, gut, heart, diaphragm, and lung, but develop normal arteries, veins, as well as larger, collecting lymphatic vessels (113). This mutant phenotype is consistent with the finding that NRP2 binds VEGF-C and that VEGF-C signaling through VEGFR3 may be enhanced by NRP2, resembling the NRP1-mediated promotion of VEGF-A signaling through VEGFR2 (61,114). Therefore, NRPs are essential not only for axon guidance, but also for angiogenesis and lymphangiogenesis by serving as multifunctional semaphorin and VEGF family receptors.

### Fibroblast Growth Factor 2

Fibroblast growth factor 2 (FGF2) potently stimulates angiogenesis. Similarly, FGF2 was also shown to strongly activate proliferation of cultured LECs and *in vivo* lymphatic vessel growth in the mouse cornea assay. However, it was proposed that the lymphangiogenic activity of FGF2 is indirectly mediated through the VEGF-C/VEGFR2 signal pathway based on a mouse cornea assay in which neutralizing VEGFR3 blocked FGF2-induced lymphangiogenesis. However, FGF receptors were shown to be expressed in LECs both *in vitro* and *in vivo* (115). Interestingly, a low dose of FGF2 induces lymphangiogenesis without accompanying angiogenesis, suggesting that lymphatic vessel growth does not require preceding growth of blood vessels.

## LYMPHEDEMA AND THE DEVELOPMENT OF MOLECULAR THERAPIES

Lymphedema refers to chronic tissue swelling (most commonly of the extremities) that is caused by the accumulation of interstitial fluid due to lymphatic dysfunction resulting from lymphatic hypoplasia, lymphatic vessel malformation, impaired lymphatic transport, and/or obstruction of lymph flow. Lymphedema can be divided into primary (genetic) and secondary (acquired) forms, based on underlying etiology (116–119). Primary lymphedema arises from a developmental abnormality of the lymphatic system caused by genetic defects. Depending on the age of onset, primary lymphedema is further subdivided into three groups: congenital lymphedema (at birth), lymphedema praecox (early onset), and lymphedema tarda (late onset).

Congenital lymphedema represents all forms of lymphedema that are clinically evident at birth, and accounts for 10% to 25% of all primary lymphedema. Females are more commonly affected than males (by a factor of 2), and lower extremity swelling is threefold more common than is upper extremity swelling. A subgroup of congenital lymphedema (Milroy disease) has been recently linked to the *VEGFR3* locus on distal chromosome 5q, and various missense mutations in the *VEGFR3* gene have been identified in patients with this disorder (120–122).

Lymphedema praecox (Meige disease) is the most common form (60%–80%) of primary lymphedema and becomes clinically apparent in childhood and around puberty. Females are affected four times more than males, and patients display hypoplastic lymphatic networks with reduced caliber and number of lymphatic vessels. Lymphedema-distichiasis, a subset of lymphedema praecox, is a rare autosomal dominant disease characterized by double rows of eyelashes in addition to swelling of the limbs. Lymphedema-distichiasis has been genetically linked to the *FOXC2* gene, which encodes a member of the forkhead/winged-helix family of transcription factors that are involved in diverse developmental pathways (123–125). *Foxc2*-deficient mice display lymphatic dysfunction, associated with defective valves of the collecting lymphatic vessels, irregular lymphatic patterning, and abnormal pericyte coverage on lymphatic capillaries (126). Hypotrichosis-lymphedema-telangiectasia, another subset of lymphedema praecox, has been recently described to be unusually associated with hypotrichosis and telangiectasia (127,128). Mutations of the SRY-related transcription factor *SOX18* were found to be responsible for both recessive and dominant forms of this disease.

The third form of primary lymphedema is called lymphedema tarda, which is defined as a late onset lymphedema (after age 35), and constitutes about 10% of all primary lymphedema. This form of lymphedema displays a tortuous, hyperplastic pattern of lymphatic vessels characterized by an increase in diameter and number. Notably, patients with this form of lymphedema often lack functional lymph valves.

Secondary (acquired) lymphedema is mainly caused by functionally compromised lymphatics due to surgery, radiation, infection (filariasis), or compression. Lymph dissection (lymphadenectomy) is a common procedure for staging tumors of breast, gynecological, head and neck, testicular, prostate, bladder, or colon cancers, rendering patients at an increased risk for lymphedema. To date, the highest incidence of secondary lymphedema is observed among breast cancer patients who undergo radiation therapy following auxiliary lymphadenectomy. Several studies show that 25% to 56% of breast cancer patients develop mild-to-severe lymphedema after cancer treatment (129–132). Worldwide, the most common cause of lymphedema is filariasis, the direct infestation of lymph nodes by the parasite *Wuchereria bancrofti*. Other causes of lymphedema include vein stripping, vascular surgery, lipectomy, and burns. Lymphedema presents considerable social, economic, and psychological hardship to patients and their families. Unfortunately, there is no currently available cure for this disfiguring disease.

Lymphedema also has been described in a number of genetic mouse models (Table 169-3). The *Chy* mouse, originally generated by ethylnitrosourea-induced mutagenesis, displays chronic lymphedema that is attributed to an amino acid substitution mutation in the highly conserved *VEGFR3* tyrosine kinase domain (similar to human Milroy disease) (114). Targeted overexpression of a soluble form of *VEGFR3* in the skin resulted in functional blockade of endogenous VEGF-C and VEGF-D signaling, and a lymphedema-like phenotype (48). Furthermore, similar to human lymphedema-distichiasis, the heterozygote *Foxc2* mutant mice developed generalized hypoplasia of lymphatic vessels and lymph nodes associated with occasional hindlimb swelling (133). Finally, mouse embryos with targeted deletion of the *Net* gene, an Ets ternary complex transcription factor, showed an accumulation of chyle in the thoracic cage (chylothorax) and dilated lymphatic vessels (lymphangiectasis) (134).

To date, a number of lymphangiogenic factors have been reported, including VEGF-A, VEGF-C, VEGF-D, FGF2, PDGF, IGF-1, IGF-2, Ang1, and HGF, and the list is rapidly growing. Among them, VEGF-C has been best characterized and provides a hope to treat lymphedema at least in animal models. Application of a VEGF-C-expressing adenovirus promoted generation of functional new lymphatic vessels in the *Chy* mutant mice (114). Likewise, adenovirus-mediated overexpression of VEGF-C in normal skin or at the edge of epigastric skin flaps in mice has been shown to induce lymphangiogenesis (80,115). Furthermore, when human recombinant VEGF-C was applied to rabbit ears, of which lymphatics were previously surgically ablated to induce lymphedema, a single dose of VEGF-C was sufficient to increase lymphangiogenesis and to reverse the tissue hypercellularity of the lymphedema (136). Similarly, VEGF-C gene therapy augmented postnatal lymphangiogenesis and ameliorated secondary lymphedema in the rabbit ear and mouse tail lymphedema models (137). Notably, however, lymphatic vessels induced by VEGF-C in a tumor model exhibit a retrograde draining pattern possibly

**Table 169-3: Mutant Mouse Models Showing Abnormalities of the Lymphatic Vascular System**

<i>Genes</i>	<i>Models</i>	<i>References</i>	<i>Phenotypes</i>
<i>Ang2</i>	KO	98	Chylous ascites, subcutaneous edema, and poor interstitial fluid uptake; abnormal lymphatic patterning
<i>FOXC2</i>	KO	103, 124	Abnormal lymphatic vascular patterning, increased pericyte investment of lymphatic vessels, agenesis of valves and lymphatic dysfunction
<i>HGF</i>	TG	108, 139	Increased lymphangiogenesis
<i>Integrin <math>\alpha 9</math></i>	KO	140	Chylothorax, excessive pleural fluid, edema
<i>NRP2</i>	KO	111	Reduction of small lymphatic vessels during development
<i>Podoplanin</i>	KO	86	Lymphedema, dilation of lymphatic vessels, and diminished lymphatic transport
<i>Prox1</i>	KO	7	No lymphatic vasculature developed
<i>SLP-79 and Syk</i>	KO	104	Failure of blood–lymphatic separation
<i>VEGF-C</i>	TG	66	Hyperplastic lymphatic vessels
<i>VEGFR3</i>	KO	46	Cardiovascular failure and defect remodeling of vascular networks
<i>VEGFR3</i>	<i>Chy mice</i>	112	Chylous ascites, hypoplastic cutaneous lymphatic vessels, swelling of limbs

KO, knockout; TG, transgenic

due to defective intraluminal valves of the vessels (138). Therefore, although VEGF-C provides promising data to be used as a new therapy against lymphedema, additional studies remain to be performed on the functionality of VEGF-C–induced lymphatic vessels and on the long-term toxicity and efficacy of VEGF-C.

## CONCLUSION

Since its early description by Hippocrates, the lymphatic system has received far less attention than the blood vascular system. This relative anonymity of the lymphatics is, at least in part, due to its elusive molecular, anatomical, and functional features. However, in recent years, the discovery of novel lymphatic-specific molecular markers and a defined LEC culture has significantly improved our understanding of the genesis and function of the system. Despite remarkable advances during the past decade, many unanswered questions remain. What are the ultimate signaling mechanisms that induce the differentiation program of LECs during embryogenesis? What are the molecular mechanisms underlying maturation and regeneration of lymphatic vessels in adults? To what extent is the lymphatic endothelium heterogeneous in structure and function in the adult, and how do the spatial and temporal dynamics of the system contribute to health and disease?

What are the molecular interactions between tumor cells and the LECs of tumor-associated lymphatic vessels, and how do these interactions mediate tumor metastases? The answer to these and related questions should provide a strong foundation for developing new therapies for patients with lymphedema and/or cancer.

## KEY POINTS

- The lymphatic system is derived from the blood vascular system during development.
- *Prox1*, *LYVE-1*, *podoplanin*, and *VEGFR3* are expressed in LECs but not in BECs.
- A number of molecular players are involved in development of the lymphatic system.
- An obstruction of the lymphatic system results in lymphedema.

## Future Goals

- To understand the inductive signal and molecular mechanism underlying lymphatic differentiation of venous BECs during development

- To identify and characterize additional BEC- or LEC-specific molecules essential for lineage-specific differentiation
- To identify and characterize lymphatic endothelial precursor cells that are essential for physiological and pathological lymphangiogenesis
- To develop novel therapies to treat primary and secondary lymphedema

## High Endothelial Venules

Jean-Marc Gauguet, Roberto Bonasio, and Ulrich H. von Andrian

*The CBR Institute for Biomedical Research and Department of Pathology,  
Harvard Medical School, Boston, Massachusetts*

Leukocytes, the cellular component of the immune system, are generated in primary lymphoid organs (bone marrow [BM] and thymus), but it is in the secondary lymphoid organs (SLOs) – which include peripheral lymph nodes (PLNs), mesenteric lymph nodes (MLNs), Peyer patches (PPs), spleen, appendix, and tonsils – that the immune response is orchestrated. These highly specialized organs collect antigen (Ag) and Ag-presenting cells (APCs) from distinct anatomical regions and serve as filters for Ag arriving from the periphery. Their extravascular environment is designed to optimize lymphocyte recognition of, and subsequent responses to, cognate Ag. A remarkable property of SLOs is their ability to recruit vast numbers of blood-borne B and T cells, which function as the backbone of the adaptive immune response. With the exception of the spleen, all SLOs contain specialized postcapillary and small collecting venules, called high endothelial venules (HEVs). These serve as the principal site of lymphocyte entry from the blood (1,2). HEVs express organ-specific patterns of traffic molecules, which define a unique vascular address that is not found in other microvascular beds. These molecules coordinate the recruitment of circulating lymphocytes by promoting multistep adhesion cascades involving selectins, chemokines, integrins, and their respective ligands or counter-receptors (3,4). Selectins recognize ligands with extensive post-translational carbohydrate modifications. Indeed, HEVs express abundantly glycosylated adhesion molecule ligands, which serve to recruit circulating lymphocytes (5). Although selectins and their ligands are constitutively active, integrins require activation to bind to their ligands (6), and activation typically comes via signals delivered when chemokines or other chemoattractants presented on endothelial cells (ECs) in HEVs (which will be referred to throughout the chapter as high ECs, or HECs) bind their G-protein-coupled receptors (7). In this chapter, we discuss our current knowledge about the functional, structural, and molecular characteristics of HEVs that allow them to serve as the portal to SLOs. We examine the development of HEVs in normal and pathological settings, and explore how these unique microvessels respond to environmental cues. In addition,

we discuss techniques to study these structures as well as emerging technologies that may pave the way for future discoveries.

### HISTORICAL AND COMPARATIVE PERSPECTIVES

HEVs have been the subject of scientific scrutiny since as early as the 19th century. Histological examination of SLO endothelium revealed at least three types of vascular beds: (a) prototypical flat-walled vessels that comprise arteries, most venules, and capillaries; (b) fenestrated ECs similar to those found in kidney, liver, spleen, and BM; and (c) a unique postcapillary vascular bed lined by cuboidal (or high) ECs – the HEVs. Another interesting feature of HEVs was that numerous lymphocytes could be found in close association with them, and some lymphocytes could be seen traversing them. These findings led to a great deal of controversy, for even after it was firmly established that HEVs are part of the circulatory system, the prevalent initial interpretation was that lymphocytes were generated in lymphoid organs and secreted via HEVs into the blood (8,9). A much clearer understanding emerged only during the early 1960s, when Gowans and Knight demonstrated that small (i.e., naïve) lymphocytes recirculate from the blood into lymph nodes (LNs) and via the thoracic duct back into the blood (10). These authors injected  $^3\text{H}$ -labeled lymphocytes intravenously into rats and recorded the recovery of labeled cells in thoracic duct lymph. The recirculating cells first appeared 2 to 4 hours after injection and peaked in the lymph after 24 hours. More than 90% of the injected cells were recovered from chronic thoracic duct fistulas within 4 days, indicating that virtually all lymphocytes migrate actively and continuously (10).

The critical link between lymphocyte recirculation and HEVs was revealed when Marchesi and Gowans used electron microscopy (EM) to demonstrate that these vessels serve as the entry site for circulating lymphocytes into SLOs (1). In this landmark study, intravenously injected lymphocytes could be

“seen penetrating the endothelium of the venules” in LNs; lymphocytes were found within the vessel lumen, between ECs, and in the region of the subendothelial basement membrane. Labeled cells in the LN parenchyma were in close proximity to HEVs, suggesting that the new arrivals had recently crossed the microvascular barrier.

In most mammals, the chief direction of lymphocyte migration is from the blood across HEVs into lymphoid tissues, although some cells also may migrate in the opposite direction. In sheep and rat PLNs (11,12), lymphocytes use HEVs predominantly to migrate into lymphoid organs, whereas in pig MLNs, lymphocytes migrate from the lymphoid tissue into the bloodstream (13). Despite these apparent species differences, HEVs remain essential vascular components of lymphocyte traffic in all mammals.

## STUDYING HEVS: IN VITRO AND IN VIVO MODELS

### In Vitro Microscopy

The light microscope first allowed investigators to visualize HEVs, and our understanding of these structures has deepened with advances in microscopy technology. EM allowed investigators to peer into HECs to examine their intracellular components and architecture (discussed in the next section) (14). The first description of how lymphocytes use HEVs to gain entry into lymphoid organs utilized EM (1). In the years since, there has been a multitude of EM studies of SLOs, most recently to examine the transport of soluble lymph-borne factors across HEVs into the vessel lumen (15).

The first in vitro tool to study lymphocyte interaction with HEVs was described by Stamper and Woodruff (16). In that assay, frozen sections of lymphoid organs were incubated with a lymphocyte suspension, gently washed, and fixed with glutaraldehyde. Using dark-field microscopy, it was then possible to visualize and enumerate lymphocytes that interacted with HEVs. A later modification of the Stamper-Woodruff assay reduced the number of lymphocytes needed (17). Because lymphoid organs rapidly recruit and transiently sequester circulating lymphocytes, an in vivo homing assay can be used to measure the number of transfused lymphocytes (labeled with radioisotopes, fluorescent dyes, or genetically encoded markers) that enter into a lymphoid organ within a certain period (typically 1–24 hours) (17). Investigators also used these assays to test the role of specific traffic molecules, for example, by treating lymphocytes, tissue sections, or animals with antibodies or with an enzyme such as neuraminidase (18–21).

### Immunohistochemistry

Immunohistochemistry and affinity chromatography with HEV-specific monoclonal antibodies (mAbs), and in situ hybridization have been among the key technologies used to identify and characterize molecules produced by HECs that are essential for lymphocyte trafficking. For example, the

mAb MECA-79 was critical for the identification of peripheral lymph node addressin (PNAd), a group of sulfated glycans that are expressed in both human and mouse PLN HEVs (20); Mel-14 permitted identification and characterization of L-selectin (18); and the mAb ER-TR7 has been instrumental in helping investigators visualize the fibroblastic reticular architecture of the LN (22). In situ hybridization was instrumental, for example, in identifying the chemokine, CCL21 (SLC/TCA-4/6CKine/exodus 2) (23).

### Culturing High Endothelial Cells

Several attempts have been made to grow and study primary HECs ex vivo (24,25). After in vitro culture, these cells preserve some of the properties of bona fide HECs, including a certain ability to bind lymphocytes (26), and the expression of some proteins and antigens characteristic of freshly isolated HECs (27,28). However, no culture conditions used so far have been able to produce HECs that fully recapitulate the phenotype observed in vivo (27,28). The major obstacle to maintaining these cells in vitro appears to be the difficulty in reproducing the unique microenvironment found in the PLN, for it has been shown that 48 hours after HECs are removed from their in vivo setting, they rapidly lose expression of several important HEC-specific genes (29). Likely, this loss of HEV gene expression is due to the absence of afferent lymph-derived factors, which are necessary for maintenance of the HEV phenotype.

### Genomics

The specialized phenotype of HEVs must originate from a unique repertoire of expressed genes. Because bona fide HECs cannot be grown long-term in vitro, mRNA for expression profiling requires the cumbersome purification of relatively few HECs from single-cell suspensions of mammalian lymphoid tissues. Quantitative 3'-cDNA libraries have been generated using this approach for both murine PLN (30) and PP (31) HEVs, leading to the identification of several known and unknown genes expressed in HEVs, but not in flat ECs. Human tonsil HEVs have been compared with other human ECs by subtractive hybridization and similar molecular techniques (32–34). These studies have identified several HEV-specific surface proteins, enzymes, molecules involved in sulfate metabolism, and a nuclear transcription factor, NF-HEV, which is much more abundantly expressed in HEVs compared with other vascular beds (35). It remains to be determined whether and to what extent NF-HEV is necessary and/or sufficient to induce or regulate HEV function or phenotype. Genomic analysis of HECs also has demonstrated that the PLN microenvironment exerts control on HEC gene expression. When Girard and colleagues compared mRNA extracted from freshly isolated human tonsil HECs with mRNA purified from HECs following 2 days in vitro culture, they observed a dramatic loss in mRNA expression of several important HEV genes, including *FT-VII*, Duffy antigen-related chemokine receptor (*DARC*) and newly

identified HEV-specific genes such as collagen XV (29). Using reverse transcription-polymerase chain reaction (RT-PCR), it was shown that HECs and medullary venular ECs in PLNs differentially express FucT-IV and FucT-VII, which leads to high levels of L-selectin ligand activity in HECs and lower levels in medullary venules (36). Data from these genomic analyses may allow researchers to determine with greater confidence whether attempts to culture HECs in vitro produce cells that recapitulate their in vivo origin.

### Intravital Microscopy

The ability to visualize and record leukocyte dynamics in the vessels of a living animal has revealed fascinating complexity. Advances in microscopic, fluorescence, and biological technology have dramatically aided in this endeavor (37). Successful recordings require a surgical preparation that sufficiently exposes the specimen (typically a vascular bed) of interest without disrupting blood supply or inducing excessive surgical trauma, achieves an adequate degree of immobilization to dampen motion resulting from normal respiration or peristalsis, and prevents sample desiccation by superfusion with physiological buffer. Animals also must be anesthetized during the procedure, which adds to the level of sophistication required compared to in vitro studies. Despite these challenges, the earliest studies date back to the 19th century, when scientists examined vascular beds in the translucent tissues of frogs (38,39). Recent intravital microscopy (IVM) experiments have continued to use bright-field, but increasingly epifluorescence, microscopy to examine leukocyte migration. During the early 1990s, studies of leukocyte migration initially examined the effect of inflammation on leukocyte adhesion to various non-LN vascular beds, including those of the cremaster and mesentery (40–42). More recent studies have investigated the interaction of lymphocytes with HEVs in a living animal, including the murine PP (43,44) and subiliac LN (also called inguinal LN) (45,46). IVM in solid organs such as the PPs and PLNs requires leukocyte visualization by epifluorescence. Leukocytes can be stained with intravital fluorophores through the intravenous injection of dyes such as rhodamine 6G, which labels nucleated cells (leaving red blood cells unstained). The drawback to this technique is that the observer cannot unambiguously determine what kind of leukocyte is being studied, although mononuclear cells can sometimes be distinguished from polymorphonuclear cells (46). This obstacle can be overcome by purifying and labeling a cell population of interest *ex vivo*, or by using cells from a transgenic mouse that expresses enhanced green fluorescent protein (EGFP) or another fluorescent protein in a specific leukocyte subset (37,47–49).

IVM has been a powerful tool to dissect the multistep adhesion cascades for lymphocyte homing via HEVs (50). However, traditional epifluorescence-based IVM cannot generate three-dimensional images, which negates its usefulness in studies of extravascular events, such as diapedesis or migration within the parenchyma. Multiphoton microscopy (MPM) (51) has

revolutionized this field by allowing investigators to generate optical sections deep within intact lymphoid and nonlymphoid tissues (52). Recent studies have analyzed the behavior of lymphocytes in intact, freshly excised LNs (53–55) and, more recently, in intravital settings using anesthetized mice (56–58). MP-IVM also has been used to evaluate the localization and interaction of dendritic cells (DCs) with the reticular fiber network of PLNs (59).

## MORPHOLOGY AND ANATOMY OF HIGH ENDOTHELIAL VENULES

### Functional Anatomy of Peripheral Lymph Nodes and Peyer Patches

PLNs are strategically located along lymphatics, which drain virtually all peripheral tissues. The prototypical PLN is a bean-shaped parenchymatous organ, composed of lymphoid and myeloid leukocytes and stromal cells, surrounded by a fibrous capsule that confers structural integrity. PLNs are subdivided into two main areas: cortex and medulla (Figure 170.1; for color reproduction, see Color Plate 170.1). The cortex comprises the superficial B-cell area that contains B follicles and germinal centers and the deeper T-cell area, or paracortex. The structural unit of the deep cortex is the paracortical cord, a column of T cells and antigen-presenting cells delimited by lymph-draining sinuses (60). At the center of each cord is a HEV, which merges with other HEVs into incrementally larger collecting venules while draining blood toward the medulla. The medulla contains a highly developed system of lymphatic sinuses that receive lymph fluid from the subcapsular and cortical sinuses and coalesce at the PLN's hilum into the efferent lymphatic vessel (61). The paracortical cords extend into the medulla, where they are referred to as *medullary cords*, and contain many plasma cells and macrophages (62).

PPs are organized lymphoid organs in the wall of the small intestine. In contrast to PLNs, PPs do not receive afferent lymph; instead, antigen influx into PPs occurs via M cells, a specialized type of epithelial cell that interfaces with the gut lumen and continuously transcytoses antigenic material from the intestinal cavity into the subepithelial dome, an area rich in DCs (63,64). The PP parenchyma is dominated by large B follicles, whereas T cells are confined to the smaller interfollicular area.

### Microvascular Organization of Peripheral Lymph Nodes and Peyer Patches

The microvascular organization varies considerably between different PLNs, but has a number of shared features. We distinguish a main feeding artery and a main collecting vein, both of which access the organ at the hilum (see Figure 170.1A). The arterial endothelium is not specialized to support interactions with circulating leukocytes; on the other hand, the degree of organization on the venular side is remarkable. In mouse inguinal LNs, starting from the main collecting venule,

Figure 170.1. Functional anatomy of lymph nodes. (A) A schematic representation of a mouse LN is provided. The venous microcirculation as well as the feeding artery are shown in black and gray, respectively. The collecting venule that drains blood from the medulla is marked as order I. For better clarity, only a segment of the intranodal venular tree is shown. Lymph-draining conduits are shown in light gray. Arrows indicate the direction of lymph flow. (B) Cross-section of an HEV with fibroblastic reticular cell conduits (FRC) that drain lymph fluid and lymph-borne small molecules such as chemokines (shown as small circles) from lymphatic sinuses toward the HEV. EM studies suggest that the FRC conduits drain lymph into a narrow perivenular channel (PVC) surrounding each HEV. Upon delivery to HEVs, chemokines are transcytosed for presentation in the lumen. An adherent lymphocyte is shown inside the HEV. Also shown is a resident DC in close association with the FRC. (C) Architecture of a venular tree showing the branching orders characteristic of mouse subiliac LNs. For color reproduction, see Color Plate 170.1.

a distinct hierarchy of branches can usually be identified (65) (Figure 170.1C). The endothelium of the first and second branching orders in the medulla has a flat appearance similar to endothelium in nonlymphoid tissues. In contrast, endothelium in higher-order venules in the paracortex and deep cortex has a cuboidal, cobblestone-like shape. Thus, only microvessels with a higher branching order are HEVs. Ultrastructural studies indicate that ECs in the transition region between HEVs and flat-walled venules often are arranged in an overlapping plate pattern (66).

Whereas HEVs in PLNs are restricted to the T-cell area, HEVs in PPs originate in B follicles. From here, they drain blood toward the interfollicular T-cell zone, where they merge into larger collecting venules. Although no apparent structural differences exist between HEVs in PLNs and PPs (67), biochemical, immunohistochemical, and functional studies have uncovered a number of tissue-specific differences, which manifest in the selective recruitment of distinct lymphocyte subsets.

### Lymph Flow in Peripheral Lymph Nodes and Fibroblastic Reticular Cells

Lymph is drained to PLNs by a system of blind-ending vessels lined by specialized lymphatic ECs. Afferent lymphatic vessels perforate the capsule of the PLN on its convex aspect, distal to the hilum, and drain into the subcapsular sinus (see Figure 170.1A). Lymph-borne cells, particulate material, and soluble

molecules have different fates after entering a PLN. DCs and effector memory lymphocytes invade the subcapsular sinus floor and migrate to their proper location in the cortex (68,69). Particulate material and large molecules are excluded from the parenchyma (70) and are phagocytosed by subcapsular phagocytes or drain to the efferent lymphatic vessel through the sinus system. Low-molecular-weight molecules with a radius of less than 4 nm are channeled into the parenchyma along a network of collagen fibers (71,72) that are ensleaved by fibroblastic reticular cells (FRCs). This sizing, column-like drainage system is called the *FRC conduit* (50,60). A monoclonal antibody, ER-TR7, has been used recently to visualize the FRC network within PLNs. FRCs also encircle HEVs, and EM studies have suggested the existence of a narrow perivascular gap between them, the perivenular channel (PVC), that is thought to receive lymph fluid via the FRC conduit (Figure 170.1B).

FRCs directly contact some of the hematopoietic components of the lymph node, and recent studies have demonstrated a significant functional consequence of these interactions. In vitro, FRCs recruit lymphocytes, and these interactions induce FRCs to generate a stromal network that supports cell migration and immune cell contacts (73). In addition to the paracortical cords surrounding HEVs, FRCs are particularly dense within the cortical ridge, which is the boundary between T- and B-cell follicles (74). Tissue-derived DCs are found near the cortical ridge (74), and also adjacent to HEVs (69), where they can interact with newly arrived naïve T cells. In fact, some DCs form intimate contacts with FRCs (see Figure 170.1B),

Figure 170.2. Characteristic ultrastructural features of HECs in PLN. Specialized subcellular and molecular features that distinguish HECs from other type of endothelium are indicated in the figure. Most importantly, the prominent Golgi apparatus supports the generation of L-selectin ligands and the MECA-79 antigen by post-translational modifications of sialomucins. For color reproduction, see Color Plate 170.2.

which allow them to sample and present to naïve T cells antigen drained through the FRC from the periphery (75). These *in vitro* and *in vivo* findings suggest that FRCs generate structures that can help organize and coordinate the various hematopoietic components of a PLN and optimize antigen sampling and T-cell activation.

### Ultrastructure of High Endothelial Cells

The ultrastructure of HECs is dominated by a prominent Golgi apparatus, which is often oriented toward the luminal aspect of the cell (14) (Figure 170.2; for color reproduction, see Color Plate 170.2). In addition, HECs have abundant mitochondria and ribosomes, sparse rough endoplasmic reticulum, and multivesicular bodies (14,76,77). These ultrastructural characteristics, and the ability of PLN HECs to incorporate substantial amounts of sulfate (78), are atypical for conventional ECs and were interpreted as indicative of a cellular machinery with high metabolic activity geared toward the biosynthesis of glycoproteins (14).

Shallow pits (12) and a glycocalyx that appears thicker than the glycocalyx on non-HEV endothelium (79) line the apical surface of HECs. In addition, microvillous-like protrusions project into the luminal space, possibly in order to facilitate tethering of circulating lymphocytes (34). Another important feature of HEVs is the existence of discontinuous

“spot-welded” junctions between HECs (79). These discontinuous junctions differ from the tight junctions that characterize capillary and arterial endothelium, but are similar to the “nonoccluding” junctions found in other postcapillary venules, and likely facilitate the passage of lymphocytes between adjacent HECs (2).

### Chemokine Presentation on High Endothelial Cells

Chemokines produced by HECs or surrounding stromal cells are presented on the endothelial surface, where they induce integrin activation and firm arrest of rolling leukocytes (47). The immobilization and display of chemokines is thought to be mediated by glycosylaminoglycans (GAGs) (see Figure 170.2). GAGs are proteoglycans that carry negatively charged sulfate and carboxyl groups, which permit electrostatic interactions with basic peptide motifs present in most chemokines (80,81). Heparan sulfate are highly expressed on ECs and are likely candidates to bind and present chemokines. Versican is a sulfated proteoglycan that has been demonstrated to block the functional activity of some chemokines, including CCL21, without affecting the interaction of CCL21 with its receptor, CCR7 (82). This function of versican has only been demonstrated *in vitro*; its expression pattern and function in SLO HECs remains to be investigated.

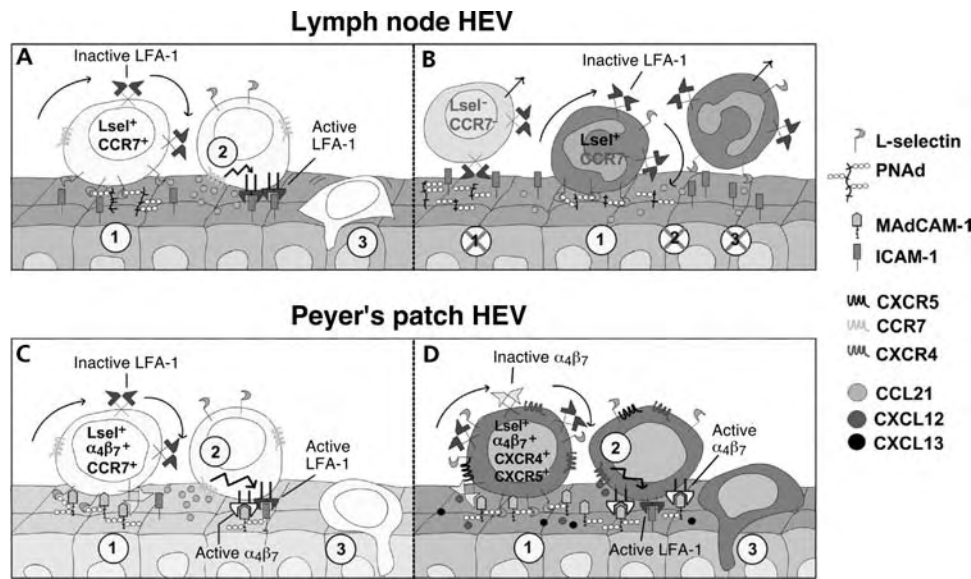

Figure 170.3. Adhesion cascades in HEVs. Examples of dedicated multistep cascade in PLNs (A–B) and in PPs (C–D). (A) Naïve T lymphocytes undergo tethering and rolling via L-selectin–PNAd (step 1); chemoattractant stimulation by CCR7–CCL21 (step 2); and sticking (firm adhesion) via high-affinity LFA-1–ICAM-1 interactions (step 3), followed by diapedesis. The selectivity of this recruitment cascade is illustrated in (B); L-selectin<sup>−</sup> cells (e.g., effector memory T cells) and CCR7<sup>−</sup> leukocytes (e.g., granulocytes) fail to establish one or more of the required interactions. PPs display different “ZIP codes” in HEV segments within the interfollicular T cell area (C) and in upstream B follicles (D). MAdCAM-1 is expressed in all PP HEVs, and mediates rolling interactions by binding to either L-selectin or integrin  $\alpha 4\beta 7$ . For step 2, HEVs in different areas of the PP present distinct chemokines to rolling leukocytes: T cells are activated by CCL21, while HEVs associated with B follicles present CXCL12 and CXCL13 to stimulate B cell–expressed CXCR4 and CXCR5, respectively. Firm arrest of both B and T cells in PPs are mediated by activated  $\alpha 4\beta 7$  and/or LFA-1 integrins. For color reproduction, see Color Plate 170.3.

DARC is a nonsignaling seven-transmembrane receptor that binds both inflammatory CC and CXC chemokines. DARC is highly expressed in HEVs (34), and has been suggested to play a role in chemokine transport, because it is found in endothelial caveolae (83), which, in flat endothelium, have been shown to function as conduits for chemokine translocation from the abluminal to the luminal surface (84). Studies in knockout mice suggest that DARC does not play a role in regulating constitutive lymphocyte trafficking to PLNs (85). However, DARC can scavenge inflammatory chemokines, including CCL2, which suggests a role for DARC in regulating inflammation, possibly during “remote control” of monocyte recruitment to PLNs (49).

### Leukocyte Recruitment via High Endothelial Venules

It is widely accepted that tissue- and subset-specific leukocyte migration is governed by a sequence of molecularly distinct adhesion and signaling events (3,4,86). Adhesion cascades are initiated by a tethering step that allows leukocytes to bind loosely to ECs (step 1A). Once attachment has occurred, margined cells are pushed forward by the bloodstream,

resulting in a slow rolling motion along the vascular wall (step 1B). Subsequently, rolling cells encounter chemotactic stimuli on or near the EC surface that can bind to specific leukocyte receptors (step 2). Chemoattractant binding, in turn, induces rapid intracellular signaling and triggers activation-dependent adhesion steps that allow leukocytes to stick firmly (step 3) and, eventually, to emigrate through the vessel wall.

Although microvessels in most nonlymphoid tissues can only support substantial leukocyte traffic upon exposure to inflammatory mediators, HEVs must recruit large numbers of lymphocytes in the absence of inflammation. Thus, HEVs constitutively express a unique pattern of traffic molecules that are fundamental for the normal function of the immune system.

### The Multistep Adhesion Cascade in Peripheral Lymph Nodes

Detailed IVM analyses have defined the specific adhesion cascades that mediate T- and B-cell homing to LNs (Figure 170.3A; for color reproduction, see Color Plate 170.3) (46,47,87–89). Tethering and rolling of both subsets is mediated by L-selectin (CD62L). The endothelial L-selectin ligand in PLNs is PNAd, an O-linked carbohydrate moiety, the major

components of which are recognized in humans and mice by the mAb MECA-79 (20,90). The structure of the MECA-79 antigen and HEV-expressed L-selectin ligands is discussed in the section "PLN Ligands and MECA-79."

Firm arrest of rolling T and B cells in LN HEVs is mediated by lymphocyte function-associated antigen (LFA)-1 (46,91,92). LFA-1-deficient lymphocytes home poorly to LNs, although the observed magnitude of the homing defect was somewhat variable between two independently generated knockout strains (92,93), possibly due to the different backgrounds of the animals used. In one strain, residual LFA-1-independent homing was mediated by the family of  $\alpha 4$  integrins,  $\alpha 4\beta 7$  and  $\alpha 4\beta 1$ , which interact with vascular cell adhesion molecule (VCAM)-1 in LN HEVs (93).

HEC ligands for LFA-1 include intercellular adhesion molecule (ICAM)-1 and -2. ICAM-2 contains two Ig-like domains, whereas ICAM-1 contains five; these Ig-like domains function as the binding site for LFA-1 (94,95). Although both ICAM-1 and -2 are expressed on HECs, deficiency in either ICAM-1 or -2 does not result in any defect in lymphocyte homing to SLOs (96–98). Rather, a defect in homing to PLNs is only observed in ICAM-1-deficient mice treated with ICAM-2 blocking antibodies or wild-type mice treated with both ICAM-1 and -2 blocking antibodies (99), suggesting a redundant function of ICAM-1 and -2.

CCL21 (also called SLC, TCA-4, 6-C-kine, or exodus 2) activates integrins on naïve and central memory T cells (47,87). CCL21 is constitutively expressed by HECs and binds to CCR7 (100–102). A second CCR7 agonist, CCL19 (also called ELC or MIP-3 $\beta$ ), is expressed by lymphatic endothelium and interstitial cells within LNs, but not by HEVs. However, lymph-borne CCL19 can be transported to the luminal surface of HEVs and induces integrin activation on rolling T cells (15). The physiological role of CCL19 in lymphocyte homing remains to be determined.

Mice carry two isoforms of CCL21: CCL21ser is expressed in HECs, whereas CCL21leu is generated in lymphatic endothelium (103). A spontaneous mutant strain called *plt/plt* (paucity in lymph node T cells) is deficient in CCL21ser and CCL19 (103,104). LNs of *plt/plt* mice and CCR7-deficient mice contain few naïve T cells, but the B-cell compartment is much less affected. LNs in these mutant animals also contain substantial numbers of central memory T cells (105,106). This indicates that B cells and central memory T cells may respond not only to CCR7 agonists, but also to another integrin-activating signal in HEVs. Indeed, CXCL12 (SDF-1 $\alpha$ ), the ligand for CXCR4, can trigger B-cell and central memory T-cell arrest in HEVs (88,107). CCR7 and CXCR4 can independently maintain B-cell homing (albeit at somewhat lower levels than in wild-type animals, where both function simultaneously). Interestingly, although CXCL12 potently induces integrin activation on rolling naïve T cells in vitro (101,108), it does so very poorly in vivo (109). Thus, despite low-level expression of CXCL12 in murine HEVs, naïve T cells require CCR7 signals, at least in the Balb/c and DDD/1 genetic background (47,88). On the other hand, CXCL12 and CXCR4 have

a modest role in T-cell homing in C57BL/6 mice, indicating that some chemokine pathways may be regulated in a strain-dependent manner (88). CXCL13 has been detected on the surface of PLN HECs (110); however, its contribution to B-cell homing is likely small because B-cell homing to PLNs is almost completely abrogated in the absence of signaling through CCR7 and CXCR4 (88).

Although B cells can respond to two (or more, depending upon the tissue) distinct integrin activation signals in HEV, B-cell homing to LNs is significantly less efficient than that of T cells. This is because the L-selectin levels on B cells are approximately 50% lower than on T cells (111). T cells from *L-selectin*<sup>+/-</sup> heterozygous mice express similar L-selectin levels as *L-selectin*<sup>+/+</sup> B cells; however, *L-selectin*<sup>+/-</sup> T cells still traffic to PLNs better than do wild-type B cells, suggesting that factors other than absolute expression of L-selectin regulate lymphocyte trafficking to PLNs (111). In experiments with pre-B-cell clones stably transfected with human L-selectin, we observed that at least 50,000 L-selectin molecules per cell were needed for efficient rolling in LN HEVs (45,112, and unpublished data). Thus, it is important to keep in mind that the mere presence of L-selectin on a leukocyte does not necessarily predict its potential to home to PLNs, even when this cell expresses all other prerequisite traffic molecules (i.e., CCR7 and LFA-1). A leukocyte may be deemed L-selectin<sup>+</sup> based on flow cytometric criteria, but this would be of little consequence if the expressed copy number is substantially lower than that on naïve T cells (~70,000–100,000 molecules/cell).

The fact that a sequence of three distinct molecular steps must be successfully engaged in HEVs explains why some leukocytes home to PLNs, whereas others do not. For example, granulocytes express L-selectin and LFA-1, but not CCR7 or CXCR4; mature myeloid DCs express CCR7 and LFA-1, but not L-selectin; and effector CTLs lose both L-selectin and CCR7. Consequently, granulocytes roll, but fail to arrest, whereas DCs and effector cells cannot tether or roll in LN HEVs (46,87,113) (see Figure 170.3B).

L-selectin-independent homing via HEVs can be induced through intravenous injections of activated platelets (114,115). Circulating activated platelets express P-selectin on their surface, which mediates platelet binding to PNAd on HEVs and, simultaneously, to P-selectin glycoprotein ligand (PSGL)-1 on circulating leukocytes (114). This platelet bridge can transiently restore lymphocyte homing in L-selectin-deficient mice. Indeed, L-selectin-deficient animals mount poor cutaneous hypersensitivity (CHS) responses when they are sensitized with a cutaneous hapten antigen, because naïve T cells do not migrate into skin-draining LNs (116). When the homing cascade is restored during the sensitization phase by infusing activated platelets for several hours, the CHS response is restored (115). Of note, a small fraction of leukocytes roll in a P-selectin-dependent manner in PLN HEVs of L-selectin-deficient mice, even when no platelets are being infused (115). However, it is not yet clear if this minor rolling pathway contributes to physiologic L-selectin-independent homing and

whether the relevant sources of P-selectin in this setting are circulating activated platelets or ECs or both.

### *The Multistep Adhesion Cascade in Peyer Patches and Mesenteric Lymph Nodes*

The homing cascade just discussed applies primarily to skin-draining LNs. HEVs in mucosa-associated SLOs, such as MLNs and PPs, express not only PNAd, but also the mucosal addressin cell adhesion molecule (MAdCAM)-1, a ligand for the  $\alpha 4\beta 7$  integrin (19,117). The  $\alpha 4\beta 7$ /MAdCAM-1 pathway can mediate selectin-independent lymphocyte tethering and rolling in HEVs (44). Thus, L-selectin deficiency compromises lymphocyte homing to PLNs more severely than to MLNs (118), whereas  $\beta 7$  integrin deficiency results in reduced homing to MLNs, but has no effect in PLNs (119). Deficiency for both L-selectin and  $\alpha 4\beta 7$  results in the profound inability of lymphocytes to adhere to PP HEVs or enter into PPs (120), although a nominal role for P-selectin was reported when surgically traumatized PPs were examined by IVM (121).

PP HEVs express MAdCAM-1, but not PNAd on their luminal surface (although MECA-79-reactive material is present at the abluminal side of PP HEVs [20]). MAdCAM-1 is a bifunctional adhesion molecule. The first Ig domain of MAdCAM-1 contains the binding site for  $\alpha 4\beta 7$  (122), whereas MAdCAM-1's mucin domain can be decorated with L-selectin ligands. Indeed, affinity-purified MAdCAM-1 from MLNs is recognized by the mAb MECA-79 (123). By contrast, MAdCAM-1 in PP HEVs is not detected by MECA-79, but nevertheless supports lymphocyte tethering and rolling via both L-selectin and  $\alpha 4\beta 7$  integrin (44). In its active conformation,  $\alpha 4\beta 7$  can mediate firm arrest (124); however, naïve lymphocytes express relatively little  $\alpha 4\beta 7$  (125) and require additional engagement of LFA-1 for firm arrest, whereas  $\alpha 4\beta 7$  is primarily critical to slow down the rolling cells (44) (see Figure 170.3C).

IVM experiments have shown that the integrin-activating chemokines in PP HEVs are segmentally presented (88,110,126). In B follicles, HEVs present CXCL12 and CXCL13, the ligands for CXCR4 and CXCR5, respectively (see Figure 170.3D). Signals through these two receptors induce integrin activation on rolling B cells, but not on T cells (88,110). Conversely, as soon as HEVs enter into the interfollicular T-cell area, they express CCL21 and stimulate preferential T-cell arrest (126). Thus, HEVs are not only distinct between different lymphoid tissues, but segmental specialization even occurs within individual microvessels. The factors that orchestrate this remarkable endothelial subspecialization remain to be identified.

### **Remote Control**

Unique mechanisms exist to modulate leukocyte recruitment to PLNs during inflammation (47,49). Chemokines, such as CCL2 (monocyte chemoattractant protein [MCP]-1), produced at a peripheral site of inflammation, can drain via the lymph to the subcapsular sinus where they enter the FRC con-

duit and are channeled toward HEVs in the cortex (72) (see Figure 170.2B). Chemokines reaching the abluminal surface of HEVs are then transcytosed within vesicles to the luminal side and presented to rolling leukocytes (15,49). The mechanism of chemokine transport across HEVs has not been determined, but might involve caveolae, which have been shown to mediate chemokine transcytosis in dermal microvessels (84).

This presentation of cutaneous-derived chemokines on HEVs in draining LNs, termed *remote control*, allows the rapid recruitment of circulating monocytes, which express CCR2, the receptor for CCL2 (49). Monocytes do not express CCR7 or CXCR4, and are therefore excluded from resting PLNs. However, by discharging CCL2 into the lymph, inflamed peripheral tissues project a potent monocyte chemoattractant signal onto HEVs in draining LNs, which triggers integrin activation (49). Within the LN, monocytes can differentiate into macrophages or DCs and participate in the ensuing immune response. In addition, inflammation induces mRNA for CXCL9 (monokine induced by gamma-interferon [MIG]) in draining LNs and presentation of this chemokine on a subset of HEVs that supports monocyte adhesion in vitro (127). It is not known whether CXCL9 is produced by the inflamed HEVs themselves or by other intra- (or extra-) nodal cells from where the chemokine might have been transported to the HEVs.

The ability to remotely modulate the multistep adhesion cascade in HEVs by discharging chemokines into the lymph enables peripheral tissues to control the composition and function of leukocytes in draining LNs. However, recent work suggests that there also may be counter-regulatory mechanisms. Lymphatic ECs express the nonsignaling serpentine receptor D6, which binds promiscuously to a number of chemokines, including CCL2 (128). Upon ligation, D6 triggers the rapid internalization and degradation of its cargo (129), and recent studies have shown that this ability of D6 to clear chemokines is critical for helping to resolve continuous leukocyte influx into inflammatory sites (130). The expression of D6 on lymphatic endothelium suggests that D6 also may function to prevent uncontrolled seepage of chemokines through the lymph to draining PLNs.

### **Transendothelial Migration**

The final step of the adhesion cascade, transmigration, is also the most poorly understood at the molecular level. The EC has solved the apparent paradox of letting a leukocyte pass to the abluminal side to access the tissue without compromising vascular integrity (131), and HEVs have further evolved to allow this process to occur constitutively and continually. Adhesion molecules including platelet-endothelial cell adhesion molecule (PECAM)-1 (CD31) (132) and CD99 (133) play roles in transendothelial migration of inflammatory cells in nonlymphoid tissues; however, their contribution to lymphocyte diapedesis across HEVs has yet to be demonstrated. One candidate are the junctional adhesion molecules (JAMs), which are found at intercellular boundaries in HEVs and

normal endothelium and contribute to leukocyte transmigration in vitro and in vivo (134–136). It remains unknown whether the JAM family members contribute to lymphocyte transmigration through HEVs. Integrins function during transmigration (137), and a recent study has demonstrated that transmigrating leukocytes form a *transmigratory cup* composed of LFA-1–ICAM-1 interactions (138). Recently, ephrinA1 has been detected on HEVs and, in vitro, ephrinA1 enhances CD4 T-cell migration to CCL19 and CXCL12 and increases actin polymerization (139). These findings suggest that ephrinA1 may promote CD4 transmigration across HEVs, although further investigation is needed.

One interesting question is whether leukocytes transmigrate between adjacent ECs or directly through an individual EC. Recent evidence suggests that a significant fraction (5%–10%) of migrating neutrophils, monocytes, and lymphocytes take a transcellular route through a human umbilical vein EC monolayer in vitro (138). In vivo, a transcellular route of migration of lymphocytes through HEVs has been suggested by EM studies (1,140); however, definitive evidence is still lacking.

### Additional High Endothelial Venule Adhesion Molecules

In addition to the selectins and integrins, other classes of adhesion molecules have been implicated in lymphocyte trafficking to SLOs. Vascular adhesion protein (VAP)-1 is an amine oxidase that is expressed on HECs of PLNs as well as on ECs from vessels supplying inflamed sites (141,142). Antibodies against VAP-1 and VAP-1-deficient mice have demonstrated a clear role for VAP-1 in regulating lymphocyte trafficking to PLNs and PPs, as well as at sites of inflammation (143,144). In particular, the absence of VAP-1 results in an increased leukocyte rolling velocity, indicating that VAP-1 strengthens leukocyte–endothelial interactions. All reports suggest that the enzymatic activity of VAP-1 is critical to its function, although it remains unclear what molecule(s) undergo modification to strengthen leukocyte rolling interactions.

Common lymphatic endothelial and vascular endothelial receptor (CLEVER)-1 is a large (270–300-kDa) glycoprotein that was identified on lymphatic and high ECs (145). Although it is not known whether CLEVER-1 presents MECA-79-reactive antigen or can bind L-selectin, antibodies against CLEVER-1 block lymphocyte adhesion to HEVs in addition to rolling and transmigration of leukocytes on vascular endothelium in vitro (145,146). The exact function of CLEVER-1, however, is unclear, because other reports have suggested that CLEVER-1 functions as a scavenger receptor (147).

Although all adhesion molecules previously described promote lymphocyte adhesion, CD43 negatively regulates lymphocyte homing to SLOs (148). The large and negatively charged CD43 is thought to decrease the ability of circulating lymphocytes to interact with endothelial adhesion molecules.

## HIGH ENDOTHELIAL VENULE-SPECIFIC LYMPHOCYTE TRAFFIC MOLECULES

### Peripheral Lymph Node Ligands and MECA-79

The mAb MECA-79 immunoprecipitates a set of glycans on the surface of HECs in both murine and human lymphoid tissues (20,90,149). Affinity-purified MECA-79-reactive glycoproteins support L-selectin binding in vitro (90), and a relatively high dose of MECA-79 blocks short-term lymphocyte recruitment to PLNs (20,36), as well as rolling in HEVs in vivo (45,150). Tissue sections stained with MECA-79 reveal reactive material on both the luminal and abluminal surface of PLN HECs (Figure 170.4C; for color reproduction, see Color Plate 170.4), but only on the abluminal side of PP HECs (20,151). The physiological role of abluminal MECA-79 antigen is not understood, but it is clear that it is biosynthetically distinct from the luminal material (151,152). IVM studies of the localization of fluorescent MECA-79 and MECA-79-conjugated fluorescent latex beads have shown that MECA-79 antigen is highly restricted to cortical HEVs within the PLN vasculature (36,148) (Figure 170.4A,B). In the HEV lumen, MECA-79 localizes to microvillous-like protrusions, which may facilitate L-selectin-dependent tethering of circulating lymphocytes (34). The transition from MECA-79<sup>+</sup> to MECA-79<sup>-</sup> ECs is typically very abrupt, from one EC to the next (36). This transition in immunoreactivity is located at the cortico-medullary boundary, and can be so accurate that a vessel running parallel to the juncture can be immunoreactive on the side that faces the cortex, while the endothelium on the medullary side remains negative for MECA-79 (153).

The MECA-79 epitope decorates several sialomucins identified in PLNs. These include GlyCAM-1 (Sgp50), a secreted glycoprotein (154,155); CD34 (Sgp90) (156); podocalyxin (157); and one (or more) large molecular specie(s) termed Sgp<sup>200</sup>, which remain(s) to be identified (158). Two additional proteins that may support lymphocyte recruitment to PLNs are endomucin (159,160) and endoglycan (161,162). Endomucin is expressed on HEVs, can carry the MECA-79 epitope, and can bind L-selectin (163), whereas endoglycan functions as an L-selectin ligand requiring tyrosine sulfation and glycosylation, but is not recognized by MECA-79. Given our current knowledge, these glycoproteins probably serve as interchangeable scaffolds that are functionally redundant, at least in the context of L-selectin ligand presentation. For example, CD34 is a major component detected by MECA-79 in human tonsils (164), but CD34-deficient mice have normal lymphocyte migration to lymphoid tissues (Table 170-1) (165).

Glycosylation-dependent cell adhesion molecule (GlyCAM)-1 expression is restricted to HEVs and mammary epithelial cells (166), podocalyxin was originally described in the kidney, and CD34 is expressed on many different cell types, including non-HEV endothelium and cells of hematopoietic origin (167). However, on non-HEV cell types, none of these molecules react with MECA-79 or support L-selectin binding. Indeed, L-selectin ligand presenting sialomucins undergo

Figure 170.4. MECA-79 antigen expression is restricted to HEVs in PLNs. (A) False-color intravital micrograph showing MECA-79 coated fluorescent microspheres bound to small diameter venules (order III to V) within the venular tree of a mouse subiliac LN. Beads do not accumulate in arterioles or lower order venules. (B) Intravital micrograph showing the distribution of intravenously injected MECA-79 (*top panel*). The lower panel provides a schematic reference to help assign branching orders to the venules and to locate the superficial epigastric artery (SEA) and vein (SEV) in this preparation. (C) Immunohistochemistry reveals MECA-79 staining of a PLN HEV, illustrating the presence of MECA-79 on the luminal and abluminal (basement membrane) surface of the HECs. Panels in (B) and (C) were modified with permission from Stockton BM, Cheng G, Manjunath N, et al. Negative regulation of T cell homing by CD43. *Immunity*. 1998;8:373–381, and Stein JV, Rot A, Luo Y, et al. The CC chemokine thymus-derived chemotactic agent 4 (TCA-4, secondary lymphoid tissue chemokine, 6Ckine, exodus-2) triggers lymphocyte function-associated antigen 1-mediated arrest of rolling T lymphocytes in peripheral lymph node high endothelial venules. *J Exp Med*. 2000;191(1):61–76, respectively. For color reproduction, see Color Plate 170.4.

extensive HEV-specific post-translational modifications that are essential for their function in lymphocyte migration.

Recent studies have demonstrated that not all L-selectin ligands in PLNs are reactive with MECA-79. Indeed, medullary PLN venules support L-selectin-dependent rolling, yet they do not stain with MECA-79 (36); the biochemical nature of this medullary venule-expressed L-selectin ligand is not currently understood, although it does require  $\alpha$  (1,3)-fucosylation (discussed in the next section). Additionally, HEC-*GlcNAc6ST*<sup>-/-</sup> mice completely lack MECA-79 antigen on the luminal surface of PLN HEVs, although L-selectin ligands are still present (150).

### Post-Translational Modification of Peripheral Lymph Node High Endothelial Venule Proteins

The importance of HEV-specific carbohydrate modifications of HEV proteins for lymphocyte trafficking was first suggested by observations that specific mono- and polysaccharides inhibit lymphocyte binding to LN HEVs (168–170). Detailed biochemical studies of affinity-purified MECA-79 and L-selectin-reactive material (170–173) have shown that most HEV-expressed L-selectin ligands are sialylated, fucosylated, and sulfated O-linked carbohydrates that decorate a select group of sialomucins in HEVs (Table 170-2), and studies in knockout mice have revealed the contributions of enzymes responsible for these modifications in vivo (Table 170-3).

### Sialic Acid

Rosen and colleagues demonstrated that removal of sialic acid from LN sections with sialidase blocked lymphocyte binding to HEVs (174), and intravenous injection of sialidase inhibited lymphocyte homing to PLNs (21). Interestingly, sialic acid modification of HEV glycoproteins is not necessary for MECA-79 reactivity (175), but sialylation is essential for L-selectin binding (176). Indeed, the major capping group that binds L-selectin is a sulfated form of sialyl Lewis X, or sLe<sup>x</sup> (NeuAc $\alpha$ 2–3Gal $\beta$ 1–4[Fuc $\alpha$ 1–3]GlcNAc $\beta$ 1–) (172,173). Sialic acid is not essential for lymphocyte migration to PPs, since treatment of PP HEVs with sialidase does not affect lymphocyte binding or homing to PPs (21,174). However, treatment of purified MAdCAM-1 with sialidase blocked in vitro L-selectin binding to MAdCAM-1 (123), suggesting that the interaction of  $\alpha$ 4 $\beta$ 7 integrins with MAdCAM-1 does not depend on sialylation, whereas L-selectin binding to MAdCAM-1 requires it. The family of  $\alpha$ 2,3 sialyltransferases is large, and the sialyltransferase(s) responsible for the sialylation of L-selectin ligands in PLN HEVs remain(s) to be determined.

### $\alpha$ (1,3)-Fucosylation

$\alpha$ (1,3) Fucosylation is essential for the activity of virtually all physiological selectin ligands, including those in HEVs. Fucosyltransferases-IV (FucT-IV) and FucT-VII are essential for the generation of selectin ligands on leukocytes and ECs

(see Tables 170-2 and 170-3) (177–180). Neutrophil recruitment in *FucT-VII*<sup>-/-</sup> mice is severely impaired due to an inability of cells to generate functional E- and P-selectin ligands (178). Lymphocyte trafficking to PLNs is reduced by approximately 80% in *FucT-VII*-deficient mice (178). *FucT-IV/VII* double knockout mice have a significantly more complete (>95% reduction) defect in lymphocyte homing to PLNs compared with *FucT-VII*-deficient mice, indicating that both *FucTs* can generate L-selectin ligands in HEVs (180). *FucT-VII*<sup>-/-</sup> and *FucT-IV/VII*<sup>-/-</sup> mice also have a decreased inflammatory response, related to decreased P- and E-selectin ligand activity (178,180). Surprisingly, *FucT-IV*-deficient mice have moderately increased lymphocyte homing to PLNs and MLNs (36).

To explain this counterintuitive observation in *FucT-IV*<sup>-/-</sup> PLNs, one must consider the acceptor preferences of *FucT-IV* and *FucT-VII* (181,182). *FucT-VII* requires an  $\alpha$  (2,3)-

sialylated terminal lactosamine to generate sLe<sup>x</sup>-like selectin ligands. *FucT-IV* also can use the sialylated lactosamine substrate, albeit less efficiently than *FucT-VII*. However, unlike *FucT-VII*, *FucT-IV* additionally fucosylates internal GlcNAc residues in poly-lactosamine (181) and uses nonsialylated lactosamine to generate Lewis<sup>x</sup>-like structures (180), which do not interact with selectins. Thus, *FucT-IV* may compete with  $\alpha$ (2,3)sialyltransferase(s) and/or *FucT-VII* for terminal lactosamine as a shared precursor substrate on O-linked glycans. Consequently, *FucT-IV* may divert some terminal lactosamine acceptor moieties toward the Lewis<sup>x</sup> pathway that does not yield L-selectin ligands, and thus away from the  $\alpha$ (2,3)sialyltransferase/*FucT-VII* synthetic route. In wild-type mice, *FucT-IV* thus attenuates *FucT-VII*-dependent production of sLe<sup>x</sup>-based L-selectin ligands. Without *FucT-IV*, increased acceptor availability for  $\alpha$ (2,3)sialyltransferase/*FucT-VII* permits increased selectin ligand

Table 170-2: Sialyl Lewis<sup>x</sup> Structures and HEV Carbohydrate Synthesis Enzymes

Enzyme	Enzyme Reaction

HEC-GlcNAc6ST (GlcNAc6ST-2) <sup>1</sup> , GlcNAc6ST-1 <sup>2</sup>	 <p>Internal sulfations may or may not be present.</p>
FucT-VII (FucT-IV)	<p>These fucosylated, sialylated, sulfated structures represent <i>bona fide</i> L-selectin ligands.</p> 
FucT-IV <sup>3</sup>	 

<sup>1</sup>HEC-GlcNAc6ST generates luminal MECA-79 antigen on LN HECs.

<sup>2</sup>GlcNAc6ST-1 generates abluminal MECA-79 antigen on LN and PP HECs.

<sup>3</sup>Unlike FucT-VII, FucT-IV fucosylates nonsialylated carbohydrates and internal GlcNAc residues on extended lactosamines; however, fucosylation of terminal GlcNAc residues can also occur. In addition, FucT-IV fucosylates glycolipids (not depicted) (222,223). Biantennary glycans arise from a core1 branch at R<sub>1</sub> or a core2 branch at R<sub>2</sub>.

**Table 170-3: Phenotype of HEC-Modifying Enzyme Knockouts**

Enzymes	Knockout Phenotype			References
	Lymphocyte Homing to PLNs	MECA-79 Staining of HEVs	L-selectin IgM Staining of HEVs

<sup>1</sup>NA, Data not available.

production, whereas FucT-VII deficiency has a lesser impact, since sLe<sup>x</sup>-based L-selectin ligands could still be generated if FucT-IV is abundantly expressed.

Experimental evidence supports this scenario and has revealed additional complexity, because FucT-IV and FucT-VII are not uniformly expressed within the venular tree in PLNs (36). For example FucT-IV is expressed at higher levels in the medullary collecting venules of mouse PLNs than in para- and subcortical HEVs. In medullary venules, FucT-IV is required to generate an additional L-selectin ligand distinct from PNA<sup>d</sup> (36). Although MECA-79 staining highlights para- and subcortical HEVs and requires primarily FucT-VII (148), the medullary L-selectin ligand is not recognized by MECA-79, but still supports rolling of L-selectin<sup>+</sup> lymphocytes (36).

### Sulfation

The critical role of sulfation of HEV proteins was first suggested by the unique ability of HEVs among vascular endothelium to incorporate large amounts of sulfate (78). Indeed, metabolic inhibition of sulfation reduces L-selectin ligand activity in PLNs (171). There are two sulfated sLe<sup>x</sup> moieties in PLNs, one containing Gal-6-SO<sub>4</sub> (6'-sulfo Lewis<sup>x</sup>) and the other containing GlcNAc-6-SO<sub>4</sub> (6-sulfo Lewis<sup>x</sup>) (see Table 170-2) (173), but only 6-sulfation of sLe<sup>x</sup> is thought to enhance L-selectin binding (183,184), although some in vitro evidence suggests that the 6'-sulfo modification can also promote L-selectin binding (185). The GlcNAc-6-O-sulfotransferases responsible for generation of L-selectin ligands in HEVs are GlcNAc6ST-1 (186) and HEC-GlcNAc6ST/LSST/GlcNAc6ST-2 (Table 170-2) (187,188). In reconstitution experiments, GlyCAM-1-IgG coexpressed with HEC-GlcNAc6ST and FucT-VII supports greater rolling of L-selectin<sup>+</sup> cells than does GlyCAM-1-IgG expressed with FucT-VII alone (189). Similar results were obtained with CD34 (188). Mice deficient in HEC-GlcNAc6ST have hypocellular PLNs, impaired (~50%) lymphocyte homing to PLNs, reduced L-selectin binding to HEVs, and a near absence of

MECA-79-reactive material in the lumen of HEVs (151,190). The latter is not surprising, since the epitope recognized by MECA-79 requires 6-sulfation of sLe<sup>x</sup> (158,175). GlcNAc6ST-1 is the sulfotransferase responsible for the generation of abluminal MECA-79 antigen in PLN and PP HEVs (152), and mice deficient in GlcNAc6ST-1 have a 20% to 30% reduction in lymphocyte homing to PLNs and PPs, suggesting that GlcNAc6ST-1 is also responsible for the biosynthesis of some luminal L-selectin ligands on HEVs (see Table 170-3) (152).

### O-Linked Carbohydrates

O-linked glycans in core2 (i.e., GlcNAc $\beta$ 1,6[Gal $\beta$ 1,3]-GalNAc) and core1 (i.e., GlcNAc $\beta$ 1,3[Gal $\beta$ 1,3]-GalNAc) linkages represent the major components of L-selectin ligands in HEVs (191) (see Table 170-2). Two enzymes, core2  $\beta$ -1,6-*N*-acetylglucosaminyltransferase-1 (C2GlcNAcT-1) (192) and core1- $\beta$ 1,3-*N*-acetylglucosaminyltransferase (C1GlcNAcT) (175) have been identified as being expressed in PLN HECs and are suggested to contribute significantly to the synthesis of L-selectin ligands in PLNs. Although C2GlcNAcT-1 is critical for the generation of P- and E-selectin ligands, no defect was observed in lymphocyte trafficking to peripheral lymphoid organs of mice deficient for this enzyme (193), although more recent data indeed suggests that these animals have defects in lymphocyte trafficking to PLNs (89,190) (see Table 170-3). Residual L-selectin ligand activity in C2GlcNAcT-1-deficient mice may be due to additional core2  $\beta$ -1,6-*N*-acetylglucosaminyltransferases and/or the activity of C1GlcNAcT, which has been shown in vitro to be critical in the generation of MECA-79-reactive glycans and to contribute to the synthesis of L-selectin ligands (175) (see Table 170-2).

### Mucosal Addressin Cell Adhesion Molecule-1

MAdCAM-1 in MLN and PP HEVs can support L-selectin interactions if appropriately glycosylated. Interestingly, MAdCAM-1 contains Ig domains capable of binding to

integrins, including  $\alpha 4\beta 7$  and, more weakly, to  $\alpha 4\beta 1$ , but it also has a mucin-like region rich in serine and threonine, which bears O-linked carbohydrate modifications that can support L-selectin binding (194). MECA-79 can immunoprecipitate MAdCAM-1 from MLNs, but not PPs, and MAdCAM-1 from MLNs supports L-selectin binding in vitro (123). However, MAdCAM-1 in PP HEVs can also present L-selectin ligands (which are not recognized by MECA-79) and support L-selectin tethering and rolling in vivo (44).

## PLASTICITY OF ENDOTHELIUM AND HIGH ENDOTHELIAL VENULES

### Perinatal Switch

In the developing mouse, the main addressin expressed in both LN and PP HEVs is MAdCAM-1 (195). It is thought that a population of  $CD45^+CD4^+CD3^-IL7R\alpha^{hi}$  cells is required to provide the signals necessary for the further development of LNs and PPs (196). These rare cells (1%–2% of total peripheral blood lymphocytes in the mouse fetus) express  $\alpha 4\beta 7$  integrin and must bind to MAdCAM-1 to migrate to LNs (195). On the other hand, studies in rats found almost no HEVs in LNs prenatally (197). ECs in cortical vessels acquired a cuboid morphology only gradually after birth, indicating that HEV commitment may be uniquely regulated in different species.

### Lymph-Borne High Endothelial Venule Differentiation Factors

Once developed, the mature HEV phenotype requires constant maintenance signals. Hendriks and colleagues reported that HEVs from PLNs that had undergone occlusion of their afferent lymphatics became flat and lost their characteristic morphology (198). Subsequent studies showed that lymphocytes do not adhere to the lymph-deprived HEVs (199), and genes that contribute to the generation of L-selectin ligands are turned off (200,201). The nature of the HEV-sustaining lymph-borne signal is still mysterious. Lymph flow per se is probably not essential, since HEVs are also found in PPs, which do not possess afferent lymphatics.

### Ectopic High Endothelial Venules

Normal endothelium can differentiate into HEVs when given the appropriate stimuli (see Chapter 155). Chronic inflammation in the setting of certain infections and autoimmune diseases can promote the organization of cellular infiltrates into lymph node–like structures that contain T and B follicles, DCs, and HEVs in a process termed *lymphoid neogenesis* (202–204). Postcapillary venules in these aggregates assume a HEV-like morphology, express PNA<sup>d</sup> and/or MAdCAM-1, and recruit naïve T cells from the blood (205). These de novo HEVs express the repertoire of carbohydrate-modifying enzymes including core1- $\beta 3$ GlcNAcT, core2 GlcNAcT-1, FucT-VII, and HEC-

GlcNAc6ST, typically found in bona fide HECs (190,206). Induced expression of CCL19, CCL21 or CXCL13 is sufficient to cause lymphoid neogenesis, at least in certain organs such as the pancreas (207–209).

How the recruitment of naïve lymphocytes induces the differentiation of ectopic HEVs is not yet clear. A likely player is lymphotoxin (LT $\alpha$ ), a member of the TNF family that is expressed by activated CD4 and CD8 T cells (210), and also by the above mentioned  $CD4^+CD3^-IL7R\alpha^{hi}$  cells that seed nascent LNs. Indeed, LT $\alpha\beta$ , its receptor (LT $\beta$ R), and downstream signaling components including I $\kappa$ B kinase complex- $\alpha$  coordinate the genesis of SLOs and several important genes including GlyCAM-1, HEC-GlcNAc6ST, and the chemokines CCL19, CCL21, and CXCL13 (211–214). Moreover, expression of LT $\alpha\beta$  is sufficient and necessary to induce lymphoid neogenesis (204,208,214).

Recent studies have demonstrated a significant role for stromal cells in the induction of SLOs. When a thymus-derived stromal cell line expressing LT $\beta$ R, VCAM-1, and LT $\alpha$  was injected into the renal subcapsular space, the transplanted cells could induce the formation of SLO-like tissue containing organized T- and B-cell areas and HEVs (215). Aggregate formation was enhanced when activated DCs were coinjected with the stromal cells. MLN cell suspensions from newborn mice injected intradermally into the skin of newborn or adult mice generate ectopic lymphoid aggregates (205). These newborn MLN suspensions contained stromal cells that expressed VCAM-1, ICAM-1, and LT $\beta$ R, as well as  $CD45^+CD4^+CD3^-$  hematopoietic cells; however, if the MLN cells were derived from LT $\alpha^{-/-}$  mice, ectopic aggregates could not form. Interestingly, in this system, the donor MLN cells gave rise to the lymphatic endothelium, HEVs, stromal cells, and FRCs, but the hematopoietic components were of host origin. These two systems could prove to be very powerful tools for further dissecting the molecular events necessary for normal and ectopic lymphoid organogenesis.

## CONCLUSION

Although the past two decades have seen considerable progress in our understanding of the functions and molecular and biochemical underpinnings of HEVs, many fundamental questions remain to be answered. What does it take to make an HEV? As we have seen, environmental input from constitutive lymph flow or factors arising from chronic inflammation are required to maintain HEVs and to turn regular ECs into HECs, respectively. What are the unique signaling and transcriptional events that induce and sustain this dramatic phenotypic alteration? Can we interfere with these signals for therapeutic purposes? Can we use them to grow and study HECs in vitro? What makes a PLN HEV different from a PP HEV, and are these different from ectopic HEVs? Another gray area is how lymphocytes transmigrate across HEVs. Is leukocyte recruitment regulated at this last step of the adhesion cascade, or is diapedesis a default process? To answer these questions,

novel technologies have begun to be employed together with established techniques.

### KEY POINTS

- HEVs are highly specialized postcapillary venules that have evolved to function as the portal for leukocyte access to most SLOs.
- ECs forming HEVs display a distinct pattern of gene expression aimed at maximizing their efficiency in recruiting lymphocytes.
- HEVs in PLNs have the unique capability of efficiently recruiting naïve T cells through a three-step cascade mediated by sequential interactions between L-selectin: PNAd, CCR7:CCL21, and LFA-1:ICAM-1.
- Although HEVs are usually found in secondary lymphoid organs, any venular endothelium can acquire an HEV-like phenotype during chronic inflammation; conversely HEVs in SLOs can revert to normal flat endothelium when lymph drainage is interrupted.

### Future Goals

- To determine the molecular mechanism of transmigration of lymphocytes across HEVs
- To identify molecular signals that convert flat to HEV-like endothelium in inflamed tissues, in order to develop novel approaches to control chronic inflammation and autoimmunity

## Hierarchy of Circulating and Vessel Wall–Derived Endothelial Progenitor Cells

---

Indiana University School of Medicine, Indianapolis*

The level of endothelial cell (EC) proliferation in normal, mature vessels in most mammals remains poorly defined but in general is reported to be extremely low, if not nonexistent. In fact, until approximately 50 years ago, the predominant view held that ECs lining vessels do not undergo mitosis. However, the advent of tritiated thymidine labeling studies and modifications of the Hautchen preparation permitted direct analysis of EC mitosis in vessels recovered after labeling in vivo (1). In some experimental animals, such as rats, guinea pigs, pigs, and dogs, the tritiated thymidine labeling studies demonstrated 0.1% to 3.0% EC turnover daily (2,3). Endothelial proliferation rates were correlated with the age of the subject and appeared to decline rapidly after birth with most adult vessel endothelium displaying mitosis in <1% of the cells daily (4). Furthermore, the sites of endothelial replication were not homogeneously distributed but appeared to occur in clustered areas nearest vessel bifurcations where flow was disturbed and often turbulent (2). Whether these dividing ECs were unique and possessed proliferative potential that was lacking in other mature endothelium or these focal areas of replicating cells merely represented the sites of greatest vessel injury and endothelial turnover has not yet been determined. It has been well documented that EC division may reach 50% of the cells in the thoracic aorta following experimentally induced hypertension, re-endothelialization of organized clots or injured vessels after arterial denudation, or following experimentally induced vascular constriction (5).

In marked contrast to the slow turnover of ECs in normal vessels, in vitro plating of ECs derived from human or animal vessels is associated with brisk EC proliferation. For example, human umbilical vein ECs (HUVECs) and bovine aortic ECs (BAECs) are two commonly studied models for in vitro analysis of EC functions. Both HUVECs and BAECs proliferate well initially, but cell division wanes with time and cells eventually develop replicative senescence and fail to divide after approx-

imately 40 population doublings. It is unknown if each EC derived from the vessels possesses similar proliferative potential or if only some of the cells can divide.

Angiogenesis is the process of new vessel formation from preexisting vessels; this is the process reported to give rise to new vessels in adult subjects. Recently, bone marrow–derived circulating endothelial progenitor cells (EPCs) have been identified and have been reported to play a vasculogenic role in new vessel formation, at least in some experimental murine ischemic or tumor models (6,7). Contrasting evidence indicates that bone marrow–derived EPCs do not contribute significantly to the endothelial lining of normal arterial, venous, and capillary vessels during development and play only a minor role in murine tumor neoangiogenesis (8–10). A comparison between the proliferative potential of circulating EPCs and the ECs that reside in normal vessels has not been previously addressed.

Emerging evidence to support the use of EPCs for angiogenic therapies or as biomarkers to assess a patient's cardiovascular disease risk and progression is accumulating and is gathering enthusiasm. However, there is no uniform definition of an EPC, which makes interpretation of these studies problematic. Although a hallmark of stem and progenitor cells (e.g., hematopoietic, intestinal, neuronal) is their ability to proliferate and give rise to functional progeny, EPCs are primarily defined by the expression of selected cell surface antigens (determined using monoclonal antibodies and flow cytometry), growth as transient colonies in vitro, incorporation into host vessels or new vessel formation, and release of angiogenic molecules in animal models of vascular disease. Reliance on cell surface expression of molecules as a definitive means for progenitor cell identification can be problematic because the expression may vary with the physiological state of the cell. Until this point, there has been no assay developed to assess the proliferative potential of individual ECs or EPCs and thus no comparative analysis completed.

## PROGENITOR CELL PARADIGMS FOR OTHER CELL LINEAGES

Assays to measure the clonal growth of hematopoietic stem and progenitor cells are relatively new tools available to the researcher. Some of the earliest methods of identifying hematopoietic clones arose while investigating the mechanisms used by the host to recover from radiation injury. Whole-body irradiation of animals was noted to depress hematopoiesis and cause life-threatening deficiencies in all circulating blood cells (pancytopenia) in exposed animals (11). In 1956, Ford and colleagues provided definitive evidence that hematopoietic cells and not plasma or subcellular molecules conferred protection to the host from death by pancytopenia following irradiation. Using donor cells from a strain of mice carrying a balanced (but morphologically identifiable) chromosome translocation, blood cells of a lethally irradiated mouse were completely replaced by those of the donor cells bearing the chromosomal marker after transplantation (12). However, evidence that single multipotent hematopoietic progenitor cells (cells giving rise to more than one lineage of blood cells) could be identified *in vivo* was not reported until 1961. By injecting donor marrow cells into a lethally irradiated recipient animal and examining the recipient spleen for hematopoietic colonies 8 to 12 days later, Till and McCulloch had devised the first *in vivo* clonal hematopoietic assay. Each colony of hematopoietic cells in the spleen was demonstrated to arise from a single precursor cell, the colony forming unit in spleen cell (CFU-S). Other assays to identify hematopoietic clones followed (13).

Pluznik and Sachs (14) and Bradley and Metcalf (15) reported that murine hematopoietic cells could be cultured *in vitro* and that addition of soluble fluid (i.e., urine or pregnant uterine extract) from several murine organs resulted in the *in vitro* formation of myeloid colonies. Furthermore, these investigators reported that each myeloid colony developing *in vitro* arose from a single precursor cell called the colony-forming unit in culture, or CFU-C. Use of this assay permitted identification of numerous hematopoietic growth factors and cytokines important for erythroid, myeloid, and multipotent progenitor cell proliferation and differentiation.

Plating of single hematopoietic cells in special double-layer agar cultures with multiple recombinant cytokines also permitted the identification of clonal hematopoietic progenitors that were highly proliferative (high proliferative potential-colony forming cells, or HPP-CFCs). HPP-CFC colonies contained >50,000 cells and were visible in the culture dishes without need for magnification. HPP-CFC clones could be plucked from the agar medium, dispersed into a single cell suspension, and replated in CFC assays with emergence of secondary HPP-CFCs, as well as committed erythroid and myeloid and multipotent progenitors (16). Due to these properties, HPP-CFCs are still considered the most primitive hematopoietic progenitor cell that can be cultured *in vitro* without the presence of hematopoietic stromal cells in co-culture.

Thus, the hematopoietic system is organized as a hierarchy of cells (Figure 171.1) that progress from the stem cell, possess-

ing the most proliferative potential, through successive progenitor cell stages that sequentially lose proliferative potential but display increasing evidence of lineage commitment, to the final mature cells of each lineage that are highly differentiated and for the most part, devoid of proliferative potential. Having established this robust hierarchical order of progenitor cell proliferative potential (at a clonal level) using the *in vitro* assays, further studies of cell surface antigen expression and *in vivo* functional analysis permitted prospective identification and further characterization of these hematopoietic progenitors.

## IDENTIFICATION OF ENDOTHELIAL PROGENITOR CELLS FROM HUMAN ADULT PERIPHERAL AND UMBILICAL CORD BLOOD

Hematopoietic progenitor cells and EPCs share a number of cell surface markers in the developing yolk sac and embryo, and genetic disruption of numerous genes affects both hematopoietic and EC development, suggesting they originate from a common precursor, the hemangioblast. Although a hierarchy of hematopoietic stem and progenitor cells has been well established (as discussed earlier), evidence to support a similar hierarchy of stem and progenitor cells (based on differences in proliferative potential) for the endothelial lineage has not been postulated. We hypothesized that a hierarchy of EPCs exists for the endothelial lineage.

To isolate EPCs to address this question, we harvested mononuclear cells (MNCs) from peripheral blood of healthy adults and umbilical cords of normal term infants and observed for endothelial colony formation (17). Interestingly, the number of EC colonies per equivalent blood volume was increased 15-fold in cord blood compared to adult samples, and the cord blood-derived EC colonies emerged in culture one week earlier than adult colonies. Further, cord blood EPC-derived EC colonies consistently appeared larger compared with adult colonies. Thus, in the process of isolating EPCs to address our experimental question, we detected distinct differences in the size, frequency, and time of appearance between adult and cord blood EPC-derived EC colonies. These observations suggested that cord blood EPCs may be derived from a different population of progenitors than those previously identified as adult EPCs.

Before testing the proliferative and clonogenic potential of cord blood and adult EPC-derived ECs, we verified that the cell progeny derived from cord blood and adult EPCs were not contaminated with other cell types (17). This is important because prior studies have shown that the cell progeny derived from some EPC-derived colonies isolated from adult and cord blood MNCs contain cells, which express the hematopoietic specific cell surface antigen CD45 or other markers of the monocyte macrophage and dendritic cell lineages. We determined that after initial EPC-derived EC passage, the cells formed monolayers of spindle shaped cells with "cobblestone" morphology.

Immunophenotyping revealed that both cord blood- and adult blood-derived ECs expressed the EC surface antigens

Figure 171.1. Hierarchical organization of the hematopoietic system stressing the progressive loss of proliferative potential associated with discrete steps in progenitor cell differentiation. Stem cells self-renew and demonstrate the highest proliferative potential, whereas mature myeloid cells are generally nonreplicative (only lymphocytes and macrophages retain replicative potential as mature cells). Colony forming unit-spleen, CFU-S; high proliferative potential-colony forming cell, HPP-CFC; colony forming unit-mixed lineage, CFU-Mix.

CD31, CD141 (thrombomodulin), CD105 (endoglin), CD146 (S-endo1), CD144 (vascular endothelial [VE]-cadherin), von Willebrand factor (vWF), and FLK-1. Importantly, both cell populations were devoid of cell surface expression of the mature hematopoietic cell proteins CD45 and CD14. However, a small percentage of both cord blood and adult cells did express CD34, AC133, and CD117 (c-kit), which are cell surface antigens previously identified on both endothelial and hematopoietic progenitor cells. Nevertheless, plating the EPC-derived ECs that expressed CD34, AC133, or CD117 (c-kit) failed to give rise to hematopoietic colony forming cells in methylcellulose assays demonstrating that these cells do not possess hematopoietic activity.
