We next tested whether the EPC-derived cells would incorporate DiI-acetylated-low-density lipoprotein (DiI-Ac-LDL), form capillary-like structures in Matrigel, and upregulate vascular cell adhesion molecule (VCAM)-1 in response to cytokine stimulation, which are some characteristics of ECs. To better visualize whether cord blood or adult ECs form capillary-like structures in Matrigel, early passage (1–2) cord and adult cells derived from the initial EPCs were transduced with a retrovirus encoding the enhanced green fluorescent protein (EGFP) and selected for EGFP expression. Both cord blood and adult cells subcultured from the adherent EC colonies uniformly incorporated DiI-Ac-LDL, formed capillary-like structures in Matrigel, and upregulated VCAM-1 in response to recombinant human interleukin (IL)-1 stimulation. Thus, these studies confirm that the cell progeny derived

from cord blood- and adult blood-derived EPCs were endothelial in origin and were not contaminated with or derived from hematopoietic cells.

#### ASSAYS TO QUANTITATE THE PROLIFERATIVE POTENTIAL OF ENDOTHELIAL PROGENITOR CELLS

As a first estimate of the proliferative potential of EPC-derived cord blood and adult ECs, cells were passaged *in vitro*. Remarkably, cord blood EPC-derived ECs could be expanded for at least 100 population doublings without obvious signs of replicative senescence. In contrast, adult EPC-derived ECs could not be cultured for much beyond 30 population doublings (17). To quantitate and compare the proliferative kinetics of cord blood and adult EPC-derived ECs, we calculated the population doubling times (PDTs) and cumulative population doubling levels (CPDLs) during a defined time in culture (60 days). There was a 2.5-fold decrease in the PDTs and a 1.5-fold increase in the CPDLs of cord blood EPC-derived ECs compared to adult EPC-derived cells. Similar PDTs and CPDLs of adult peripheral blood-derived ECs has been reported by others, who tested the proliferative kinetics of EPC-derived cells isolated from healthy adult donors (17).

As a second strategy to compare the growth potential of the EPC-derived ECs, we replated cord blood and adult blood EPC-derived ECs at 1 to 2 passages in limiting dilutions in

culture medium defined for optimal EC growth in vitro. At cell concentrations of  $\leq 100/\text{cm}^2$ , one could readily discern colonies of cells varying in size and cell morphology in addition to many single adherent ECs. Cord blood EPC-derived ECs formed more colonies that were larger in size than those EC colonies emerging from the replated adult blood EPC-derived ECs. These data suggested that EPC-derived ECs demonstrate a wide variability in proliferative potential and that some of the EPC-derived ECs from cord blood display much higher proliferative potential than any of the ECs derived from adult blood EPCs.

To quantitatively and stringently interrogate the proliferative potential of individual EPCs, we devised a single cell assay for the clonal analysis of EPC colony forming activity (Figure 171.2) (17). Cord blood and adult blood EPC-derived ECs at 1 to 2 passages were transduced with a retrovirus encoding EGFP and 24 hours later, EGFP<sup>+</sup> cells were removed from the plates and sorted as single cells into 96-well plates using a FACS Vantage sorter. Wells were examined the following morning to assure that at least one cell was present in each well and any wells with more than one cell were eliminated from consideration. After two weeks of culture, wells were examined to determine the percentage of wells that contained more than one cell and the total EC number of each colony formed.

Remarkably, the percentage of single cells undergoing at least one cell division was increased fivefold for cord blood

EPC-derived ECs compared to ECs from adult EPCs. Further, the average number of cell progeny derived from a single-plated cord blood EPC-derived ECs was 100-fold greater compared to the number of cells derived from an individual adult EPC-derived ECs. Greater than 80% of the single adult ECs that divided gave rise to small colonies or clusters of cells ranging in number from 2 to 50 cells. A small population of single adult ECs did form colonies containing greater than 500 cells. In contrast, at least 60% of the single-plated cord blood EPC-derived ECs that divided formed well-circumscribed colonies containing between 2,000 and 10,000 cells in the 14-day culture period. A representative of the photomicrograph of the colonies derived from single cord or adult cultured cells is shown in Figure 171.3. These single-cell studies demonstrated that there are different types of endothelial colony forming cells which could be discriminated by their cell autonomous proliferative potential, and that EPC-derived ECs display a hierarchy of proliferative potentials similar to the hematopoietic progenitor cell hierarchy.

In the hematopoietic cell system, the most proliferative progenitor cell type that can be cultured in vitro in the absence of a stromal cell monolayer is termed the *HPP-CFC* (discussed earlier). We tested whether a cell with similar proliferative potential is present within adult and cord blood EPC-derived ECs to further define and classify the EPC hierarchy. The clonal progeny derived from single-plated cord blood or adult

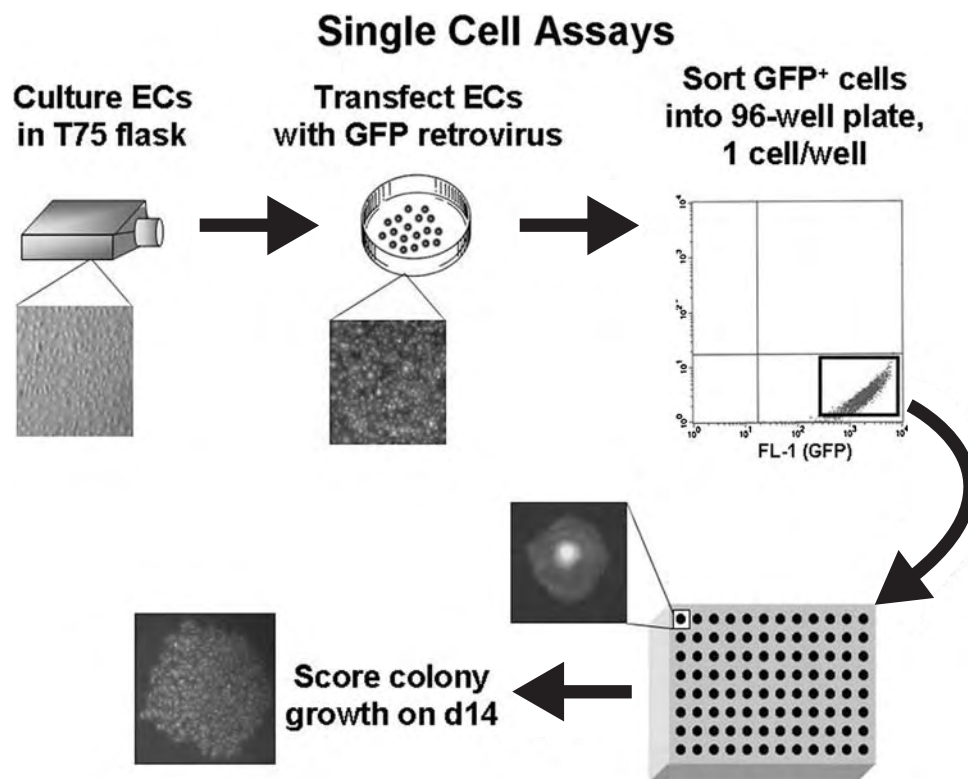

Figure 171.2. Method to identify the proliferative potential of individual ECs. ECs derived from cord or adult blood EPCs were transduced with a retrovirus encoding green fluorescent protein and the expressing cells identified and single cells plated using a flow cytometric sorter. The green fluorescing cells were visualized through a fluorescence microscope and the number of cells in each well directly counted.

## Model of endothelial development “Endopoiesis”

Figure 171.3. Endopoiesis: the process of EC development. We propose that high proliferative potential-endothelial colony forming cells (HPP-ECFCs) are the most proliferative endothelial progenitor cells (EPCs) and that these cells demonstrate high replating potential. HPP-ECFCs can give rise to at least secondary HPP-ECFCs and all other EPCs and mature ECs. Low proliferative potential-endothelial colony forming cells (LPP-ECFCs) do not replat into secondary LPP-ECFCs but do form EC clusters and mature ECs. Endothelial cluster forming cells give rise only to mature nondividing ECs.

EPC-derived ECs were trypsinized, replated, and cultured into 24-well tissue culture plates for seven days. After replating the clonal progeny of over 1000 single adult EPC-derived cells (those primary wells containing >50 cells), we detected only one secondary colony in the wells (1 of 1,000 plated) after 14 days of culture. In contrast, approximately one-half (205 of 421 plated) of the clonal progeny of single-plated cord blood EPC-derived ECs (those primary wells >50 ECs) formed secondary colonies or rapidly grew to confluence in 24-well plates. Secondary colonies or confluent cell monolayers derived from single cord blood ECs were serially passaged into progressively larger tissue culture plates. Strikingly, some single-plated cord blood EPC-derived ECs yielded at least  $10^{12}$  cells in long-term culture and all (11 independent clones tested) produced at least 10 million progeny. These data suggested that the cord blood EPCs contained ECs with additional EPC activity that was similar to the HPP-CFC activity displayed by highly proliferative hematopoietic progenitor clones (cells that can give rise to high numbers of progeny and that can be replated into at least secondary HPP-CFCs).

Given that murine genetic studies clearly show that the origin of ECs is closely linked to hematopoietic cell development, it is not surprising that our data showed that EPCs can be discriminated by similar clonogenic and growth characteristics. We have proposed that EPCs can be identified using similar terminology to that utilized for defining hematopoietic cell progenitors (Figure 171.3) (17). High proliferative potential-endothelial colony forming cells (HPP-ECFCs) give rise to macroscopic colonies that form secondary and tertiary colonies upon replating. We have provided evidence that HPP-

ECFCs give rise to all subsequent stages of endothelial progenitors in addition to replating into secondary HPP-ECFCs. Low proliferative potential-endothelial colony forming cells (LPP-ECFCs) form colonies, which contain greater than 50 cells, but do not form secondary LPP-ECFC colonies upon replating. This EPC stage represents the most proliferative population of EPCs that can be isolated from normal adult peripheral blood. They do give rise to EC clusters. EC clusters are composed of groups of fewer than 50 cells and do not replat into colonies or clusters. Our data have also indicated that mature differentiated ECs can be resolved in the single cell assay and are defined as cells that are nonproliferative. Thus, the circulating EPCs emerging from cord and adult blood represent EPCs possessing different proliferative potentials and at different stages of EPC development. The fact that EPC-derived ECs further display EPC activity raises the question of whether vessel-derived ECs also possess EPC activity.

### VESSEL-DERIVED ENDOTHELIAL CELLS AND ENDOTHELIAL PROGENITOR CELLS

To compare the clonogenic capacity of single ECs derived from vessel walls, we established monolayers of ECs derived from cord blood circulating EPCs and from ECs isolated from human umbilical veins and human aorta (18). Cord blood EPC-derived ECs, HUVECs, and human aortic ECs (HAECs) expressed the EC surface antigens CD31, CD141, CD105, CD146, CD144, vWF, and FLK-1 but not the hematopoietic cell surface antigens CD45 and CD14. Thus, cord blood

EPC-derived ECs, HUVECs, and HAECs expressed a similar profile of EC-specific antigens.

Utilizing the single cell assay for EPC colony-forming activity, we compared the percentage of single-plated ECs that divided at least once and the distribution of HPP-ECFCs, LPP-ECFCs, and endothelial clusters derived from cord blood EPC-derived ECs, HUVECs, and HAECs. The percentage of single cord blood ECs undergoing at least one cell division was 55%. Similarly, 52% of single HUVECs and 53% of single HAECs divided after 14 days. Nearly half (47%) of the single cord blood ECs that divided possessed HPP-ECFC activity and gave rise to colonies of >2000 ECs. Strikingly, 28% of single dividing HUVECs and 27% of single dividing HAECs also possessed HPP-ECFC activity. In addition, single cord blood ECs, HUVECs, and HAECs possessed LPP-ECFC activity and formed smaller colonies that contained between 51 and 500 cells. Thus, similar to the circulating EPCs, the ECs lining umbilical veins and the human aorta comprise resident EPCs at different stages of maturation possessing different levels of proliferative potential.

These data suggest a new conceptual framework for determining both the origin and function of EPCs in maintaining vessel integrity. Whereas HUVECs and HAECs have long been considered to be fully differentiated mature ECs, we have now shown that a complete hierarchy of EPCs can be identified in HUVEC and HAEC monolayers and discriminated by their clonogenic potential (18). These data explain why HUVECs and HAECs can be passaged extensively *in vitro* given that HPP-ECFCs and LPP-ECFCs are present at nearly 50% frequency in HUVEC and HAEC populations. Future studies may clarify whether the sites of EC proliferation previously identified in the tritiated thymidine labeling studies can be confirmed to be the sites of EPC residence in the endothelium lining vessels *in vivo*.

#### ENDOTHELIAL PROGENITOR CELLS IN DISEASE AND DIAGNOSTIC IMPLICATIONS

Great emphasis has recently been placed on defining the role of circulating marrow-derived EPCs in repair of damaged vascular endothelium or in the process of tumor angiogenesis. Data obtained in murine studies appear to confirm a role of circulating EPCs in vessel repair following a variety of experimentally induced vascular injuries or following implantation of certain tumors. Likewise, marrow-derived EPCs appear to contribute to sites of vascular turnover in both animal and human transplantation studies (6,7). However, other studies employing highly sophisticated marking strategies indicate that marrow-derived EPCs play no role or a minimal role in neovascularization, vessel repair, or normal vessel growth and development (8–10). The controversies surrounding this question may be clarified by utilizing methods of detection that clearly discriminate between EPCs with high proliferative potential identified using the single cell assay and the more numerous marrow-derived EPCs, which can be cultured short-term *in vitro* into

small colonies of cells that co-express certain monocyte and macrophage antigens, as well as more typical EC surface proteins, but fail to give rise to EC progeny that can be significantly passaged *ex vivo* (7,19–22). The latter human EPCs cannot be cultured at a single cell level and thus clonal analysis of proliferative potential cannot be determined. As suggested by some authors, these EPCs may be better defined as angiogenic progenitors or vascular progenitors than as EPCs (20).

The newly identified HPP-ECFC and associated progenitors have not been enumerated in the blood or blood vessels of many patients with diseases. One recent preliminary report suggests that the concentration of the HPP-ECFCs in patients with cardiovascular ischemic disease correlates with patient status such that the higher the concentration of the HPP-ECFCs, the higher the risk that the patient has ongoing severe ischemic disease (22). Further comparative studies with circulating marrow-derived EPCs will be required to determine the interrelationship of these cells with the HPP-ECFCs and associated progenitors in the pathogenesis of cardiovascular ischemic disorders.

Likewise, novel strategies will need to be developed to assay for the number and distribution of HPP-ECFCs and associated EPCs that reside in large and small arterial and venous vessels and capillaries. One method would be to biopsy readily accessible vessels with an intravascular catheter and then enumerate the number and distribution of the EPCs using the single cell EPC colony forming assay. A more invasive procedure would be to use open biopsy of superficial arterial and venous vessels to obtain ECs for enumeration of the various HPP-ECFCs and associated EPCs. Alternatively, some unique cell surface markers for the HPP-ECFCs and associated EPCs may be soon isolated that will permit sampling of the blood for cells that are mobilized from the vessels and can be detected by flow cytometric methods.

#### THERAPEUTIC IMPLICATIONS OF HIGH PROLIFERATIVE POTENTIAL-ENDOTHELIAL COLONY FORMING CELLS

The finding that vascular ECs comprise HPP-ECFCs and associated EPCs provides a new context to reexamine the process of angiogenesis. As mature ECs derived from umbilical veins and human aortas fail to divide *in vitro*, it is unlikely that these cells play a significant role in the migration, proliferation, and neo-capillary development at sites of new vessel formation. Rather, the HPP-ECFCs and associated EPCs are more likely to be the targets of recruitment by the growth factors and molecules secreted to recruit the cells with proliferative potential out of the existing endothelial intima and into the tissues via sprouting.

The availability of an *in vitro* assay to identify these cells may now permit screening for additional molecules that may play a role in neoangiogenesis and, alternatively, provide a potentially new strategy to screen for antiangiogenic molecules. These approaches may identify new families of molecules that

may be tested and applied to treat the vast number of patients with cardiovascular disease.

### GOALS FOR BRIDGING BENCH-TO-BEDSIDE GAP

Identification of this novel hierarchy of EPCs that both circulate and reside in the endothelial intima of arterial and venous vessels will provide new pathways for correlating the biology of these EPCs with specific disease states and may permit opportunities for consideration of cell replacement therapies. Although numerous clinical studies are contemplating the use of whole bone marrow cells or a particular subset of marrow-derived EPCs with certain cell surface markers as a therapy for patients with critical ischemic limb disease or following myocardial ischemic disease, it is unclear if the cells under consideration will be long-lasting contributors to formation of a replenished endothelial pool of HPP-ECFCs and associated EPCs in the new vessels. The recent identification of HPP-ECFCs in several large animal species (bovine, porcine, canine, nonhuman primate; M. C. Yoder, unpublished observations) now opens the possibility for comparative analysis of marrow-derived EPCs and vessel-derived ECs with EPC activity to determine the specific roles that each of these cells plays in new vessel formation in animal models that will be relevant to human disease.

#### KEY POINTS

- The vascular system represents a stem and progenitor cell niche for the endothelial lineage.
- Circulating EPCs represent a hierarchy of progenitors with different proliferative potentials.
- The proliferative potentials of EPCs can be quantitated.
- The complete hierarchy of endothelial stem/progenitor cells is present in the endothelium of arterial, venous, and capillary vessels.

#### Future Goals

- To pursue future studies that will permit prospective isolation of these stem/progenitor cells, determine when vascular endothelium becomes seeded with these cells, and determine the role these cells play in vascular repair and regeneration

**PART IV**

**DIAGNOSIS AND  
TREATMENT**

## Introductory Essay

### Diagnosis and Treatment

---

Mansoor Husain

*Physiology and Laboratory Medicine & Pathobiology, University of Toronto; Division of Cell  
& Molecular Biology, Toronto General Hospital Research Institute, Ontario, Canada*

In previous sections of this textbook, chapters have been assembled to convey the molecular and cellular basis of organ pathophysiology, as viewed through the lens of vascular biology in general and the endothelium in specific. How the endothelium interacts with adjacent vascular smooth muscle cells, circulating blood cells, and the underlying parenchyma of each organ have been exemplified, and specific chapters have focused on particular organs and their disease states. These sections provided the knowledge upon which the ensuing chapters are built, but which focus now on diagnosis and treatment.

The endothelium has remarkable, yet largely untapped diagnostic potential. From a bedside physician's viewpoint, the endothelium is difficult to assay. It is hidden from view and cannot be inspected, palpated, percussed, or auscultated. Moreover, the endothelium is poorly circumscribed and therefore not readily amenable to conventional radiological studies. However, the endothelium has several properties that make it an ideal target for therapy. First, it is widely distributed and therefore provides a window into every organ in the body. Second, it is rapidly and preferentially exposed to systemically delivered agents. Third, as an input–output device, the endothelium is highly malleable and responsive to exogenously administered compounds.

In Part IV, the authors provide their perspective on how current knowledge may affect real or potential advances in the diagnosis and treatment of endothelial-based diseases. Advances in diagnosis include the measurement of circulating soluble mediators (Chapter 173), and circulating blood endothelial cells (Chapter 174); or circulating microparticles (Chapter 175). Other diagnostic assays include molecular imaging (Chapter 176), real-time imaging (Chapter 177), and flow studies (Chapter 178). Chapters on therapy focus on statins (Chapter 179), steroids (Chapter 180), nitrates (Chapter 181), alteration of flow (Chapter 182), drug-coated stents (Chapter 183), tissue engineering (Chapter 184) and drug/viral targeting (Chapters 185 and 186).

In this introductory essay, I will posit how information such as this may enable a conceptual shift in the classification and approach to therapy of cardiovascular diseases. It is my hope that readers of this section may likewise imagine and eventually actualize the clinical value of the collected writings to other areas of medicine.

The World Health Organization has determined that cardiac and vascular diseases are now the leading causes of mortality in our world, accounting for one of every three deaths.<sup>1</sup> This holds true for both the developed and developing worlds, where aging populations and rapid industrialization are ever increasing the incidence of high blood pressure, stroke, heart attack, and heart failure. Indeed, it can be stated that diseases of the heart and blood vessels are an enormous health care burden poised only to worsen in the coming decades. As an organ crucially involved in the maintenance of normal cardiac and vascular structure and function, the endothelium has emerged as a pivotal target in the fight against this global pandemic. Moreover, an appreciation for how primary or secondary abnormalities in function of this cell type may affect and inform on cardiovascular disease progression has begun to change the way in which we think about this challenge.

Much excitement has been raised about the potential to harvest and therapeutically employ circulating endothelial progenitor cells or bone marrow–derived progenitors of other cell lineages. Although still in its infancy, the opportunity at hand for truly regenerative medicine has never been greater. However, current proposals for cell-based treatments of end-stage heart failure resemble on some level the indiscriminate treatment of anemia with a blood transfusion. Would not knowing the basis of the problem help us better design these trials? It would seem obvious that dramatic improvements in our *diagnostic* capabilities will be as important and

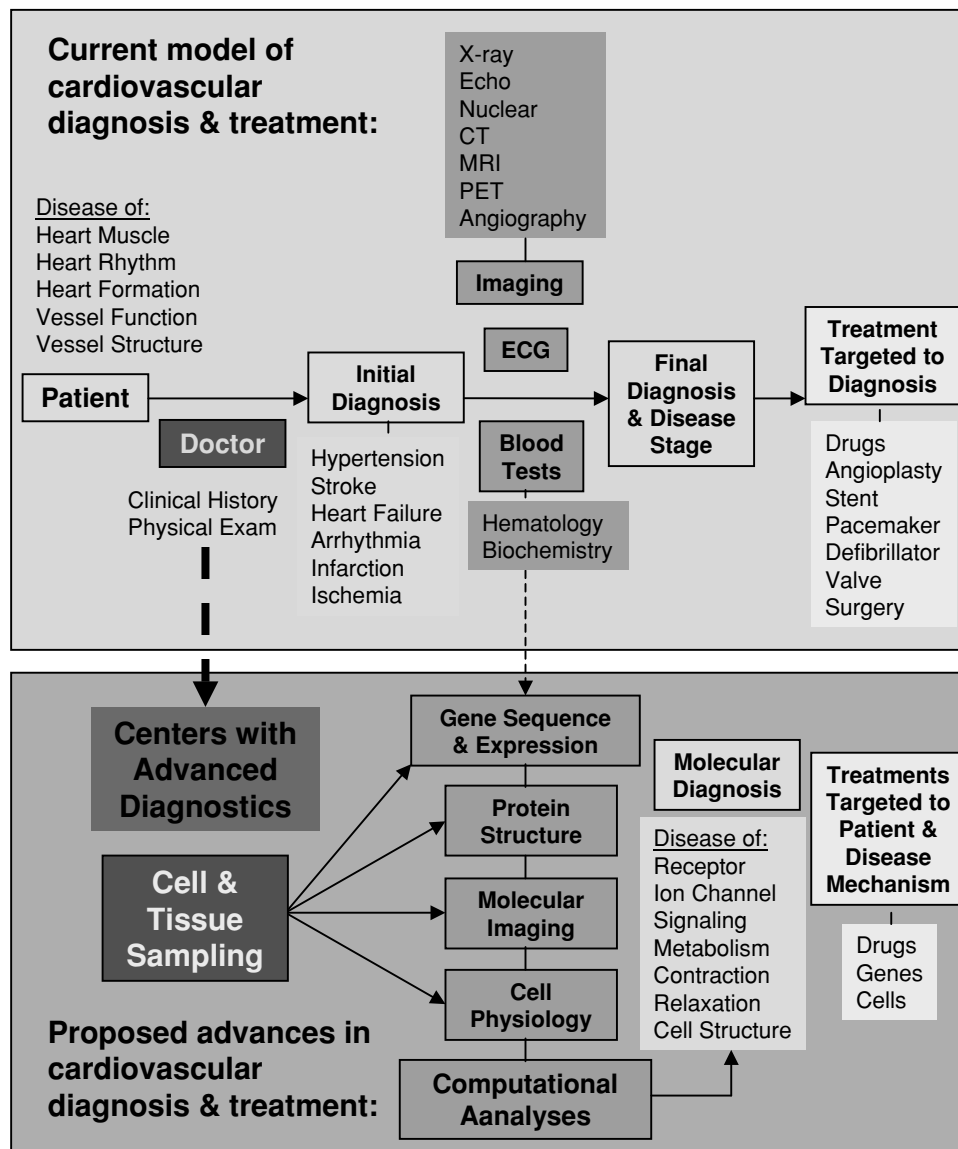

Figure 172.1. Staging of cardiovascular disease.

are as imperative as our need to implement advanced therapies.

Currently, “modern” approaches to the diagnosis and treatment of cardiovascular (and other) diseases are based on a physician’s ability to obtain a history of illness from the patient and to integrate that information with findings from a physical examination and tests such as electrocardiogram, imaging, and blood chemistry. Together, these data are used to classify a patient as having a particular disease or not, stage its degree and extent, and to begin treatment based on this categorization (Figure 172.1). Unfortunately, existing diagnostic methods remain superficial in their level of interrogation, with many different genetic, environmental, and complex molecular contributors to disease remaining unrecognized. Although advanced assessments of endothelial function are being developed, few centers in the world have

widely implemented noninvasive or ex vivo assays of the molecular physiology of endothelial, cardiac, or vascular muscle cells or applied them to the rationale design of treatment regimens. As such, our patients are lumped together in relatively crude diagnostic groupings and are treated as if they were identical. Recognition of the limits and hazards of this paradigm is increasing, however until we individualize treatments on the basis of a deeper understanding of the fundamental mechanisms underlying disease, only some of our patients benefit, others do not, and some may even be harmed by current strategies.

Taking, for example, a widespread disease as simple in pathophysiology and yet as complex in cause as hypertension, we recognize that far too many patients go unrecognized, require multiple classes of antihypertensive medications to normalize their blood pressure, or remain poorly controlled

despite polypharmacy. For this and many other diseases, it seems logical that the more precise a “match” between mechanism and treatment, the better the efficacy of treatments will be, with fewer unnecessary side effects.

We should seek to identify people at risk earlier in the development of their disease and to individualize care based on mechanisms that may be unique to a given patient and their particular genetic–environment interactions. To enable this, a novel approach is proposed, which seeks to acquire and integrate diagnostic data from more fundamental levels of interrogation, yielding a more informed “molecular” classification of disease. To accomplish this, healthcare institutions must first develop an infrastructure that increases the levels of interrogation currently available for cardiovascular disease. Furthermore, to realize the full potential of a corresponding revolution in genomic and proteomic analyses, such an infrastructure must also be able to integrate this information in comprehensive databases allowing computational analyses of the “systems biology” of each disease, correlating these with clinical outcomes. Such an infrastructure is critical to the formation of new models of cardiovascular disease and to the

development of the next generation of more targeted therapeutic strategies (Figure 172.1).

Linking and harnessing the knowledge from this and other textbooks with that of public and private repositories of genomic, proteomic, physiomic, and clinical data will determine future advances in care. Bioinformatic approaches designed to interrogate such data sets are where connections and inter-relationships currently invisible to healthcare researchers and practitioner may emerge. Training programs will be equally critical. The education of medical personnel will need to include a thorough understanding of the relevant novel diagnostic techniques and methods of complex data acquisition, management, and analysis. Where there is greatest need, and where centers that initiate such an infrastructure may excel, is in the opportunity to develop truly *translational* individuals, who can interpret the language and needs of both fundamental and clinical scientists and act as synergistic intermediaries to the benefit of both. Close collaboration and regular exchanges with like-minded institutions and infrastructure will accelerate significantly the integration of this conceptual shift in the principles and practices of medicine.

## Circulating Markers of Endothelial Function

Andrew D. Blann, William Foster, and Gregory Y.H. Lip

*City Hospital, Birmingham, United Kingdom*

The vascular endothelium is a dynamic and metabolically active organ with numerous functions, including regulation of the coagulation cascade and local blood flow, control of fluid passage into the media, and the regulation of cell migration through the vascular intima (1,2). These many functions are reflected in the variety of molecules expressed at the cell surface and secreted by endothelial cells (ECs). The appearance of such molecules in measurable quantities in the blood allows indirect measurement of the status of the endothelium, which can exist in various different states: resting, activated, and/or dysfunctional. Stimulation of resting endothelium (e.g., by inflammatory cytokines) results in an activation state, characterized by the upregulation of various cell adhesion molecules and procoagulant molecules. Dysfunction can be thought of as an inability of the endothelium to carry out its normal physiological functions (2,3).

The ideal test of endothelial function would be simple, quick, and inexpensive to perform, sensitive, endothelial-specific, correlated with a known disease process, and deranged in a predictable way in disease processes. In other words, it would be a reliable surrogate marker for a specific endothelial disease process. In addition, the marker would be stable enough to measure reliably in the laboratory, yet also have sufficiently rapid turnover or short half-life to provide a meaningful measure of current endothelial status. These criteria effectively remove nitric oxide (NO) from a list of useful markers because it cannot be measured directly or in a simple manner in the laboratory. Other well-established molecules, such as plasminogen activator inhibitor (PAI)-1, soluble intercellular adhesion molecule (ICAM)-1, and soluble vascular cell adhesion molecule (VCAM)-1, suffer from the disadvantage that they are also expressed by non-ECs (e.g., platelets, adipocytes, activated leukocytes, and smooth muscle cells) and are thus nonspecific.

Those plasma markers that fulfill these criteria include von Willebrand factor (vWF), soluble E-selectin, endothelin (ET)-1, soluble thrombomodulin (sTM), and tissue-type plasminogen activator (t-PA) (4). In addition to these soluble markers, there is increasing evidence that cellular markers, including endothelial microparticles (EMPs) and circulating

ECs (CECs), provide important insights into the status of the endothelium (5,6). In this chapter, we first review molecular plasma markers of endothelial integrity and then discuss the present status of cellular markers.

### CIRCULATING SOLUBLE MARKERS

#### von Willebrand Factor

vWF, the prototype marker of endothelial damage, was first described as such 30 years ago (7). vWF is a multimeric procoagulant protein encoded on chromosome 12, whose expression is limited to ECs and megakaryocytes. The vWF gene is highly complex, consisting of 52 exons and encoding a 250 kDa protein that forms the basic monomer. The mature molecule comprises numerous monomers forming polymers or multimers and is subject to post-translational modification before it becomes functional, reaching a size of up to 1 MDa (8). The importance of vWF in promoting hemostasis is clear from the clinical consequences of its deficiency – namely, the hemophilia-like disorder, von Willebrand disease. vWF binds and stabilizes factor VIII and mediates platelet adhesion to the site of vessel injury and aggregation by binding platelets and collagen. It is also the most extensively studied circulating marker of endothelial function.

vWF is constitutively secreted by the endothelium in low levels in healthy individuals, but further release can occur from preformed intracellular stores (i.e., Weibel-Palade bodies) when ECs are stimulated or damaged in vitro by a variety of stimuli, including inflammatory cytokines (e.g., interleukin [IL]-1, tumor necrosis factor [TNF]- $\alpha$ ), histamine, elastase, and vasopressin (7–9). Whether the same processes occur in vivo is unclear but is widely presumed.

Levels of vWF rise in a number of nonpathological situations, notably in normal pregnancy and following exercise; levels are also determined by the ABO blood group (9–11). However, circulating levels are also elevated in many pathological conditions, including atherosclerosis; inflammatory connective tissue diseases, such as rheumatoid arthritis and systemic lupus erythematosus; and in many cancers (9). Increased levels

are associated with each of the major risk factors for atherosclerosis (cigarette smoking, hypertension, diabetes mellitus, obesity, and elevated serum cholesterol) (12,13), as well as several minor risk factors including impaired glucose tolerance (14), chronic renal impairment (15), and rheumatoid arthritis (16). Effective treatment of cardiovascular risk factors results in a lowering of vWF levels (17).

High vWF levels have been shown to have prognostic significance, conferring, for example, an increased risk of first and subsequent myocardial infarction, stroke, thromboembolism, complications from peripheral vascular disease, and death (9,18). As a short-term prognostic marker, elevated levels of vWF following admission for acute coronary syndromes were found to predict later adverse events (19). This also applied to patients with preexisting myocardial disease (20). Even in apparently healthy, asymptomatic individuals, elevated levels of vWF predict an adverse cardiovascular outcome (21).

Thus, vWF is unequivocally raised in patients with major risk factors for atherosclerosis and in those with frank disease, and raised levels carry a poor prognosis. Furthermore, given the established role of vWF as a procoagulant, the increased levels may contribute to pathogenesis, rather than simply serving as a marker for EC dysfunction (9).

### Soluble Thrombomodulin

TM is an endothelial transmembrane protein that binds thrombin. This binding causes a conformational change in the structure of thrombin, increasing its affinity for protein C. Thus thrombomodulin has anticoagulant properties and is partly responsible for the prevention of intravascular thrombus formation (22). sTM can be measured in plasma and serum and presumably reflects the loss of the molecule from the endothelial surface into the blood (23–25). Elevated serum levels of sTM may thus reflect increased surface expression with normal surface loss, increased loss of the molecule with normal expression, or a combination of the two. The antithrombotic effects of the soluble form of TM have been shown experimentally by injecting mice with thrombin; those mice pretreated with TM were protected against widespread, lethal thrombus seen in the other mice (26).

Increased levels of sTM have been found in prothrombotic conditions, including acute and chronic atrial fibrillation, advanced heart failure, disseminated intravascular coagulation, and normal pregnancy (27–31). Levels of sTM have been found to correlate with the presence and severity of atheromatous disease – e.g., carotid intima-media thickness (32) – and extent of peripheral vascular disease (33). sTM is also elevated in patients with ischemic heart disease (34).

In terms of predicting future cardiovascular events, sTM is elevated in patients with many of the classical cardiovascular risk factors, including hypertension, type I and type II diabetes mellitus, and obesity (35–37). Smoking has been associated with both increased (38) and decreased (39) levels. sTM has also been found to be predictive of future cardiovascular events in patients with established atherosclerosis (40,41). However,

interestingly, patients not known to have atherosclerotic disease do not have this association; the presence of elevated sTM levels actually predicted a *lower* risk of incident coronary artery disease in subjects investigated for the ARIC study (42).

Following peripheral angioplasty, elevated levels predict late restenosis (43). However, there is controversy as Gerdes and colleagues (44) reported that raised sTM predicts stroke, but not myocardial infarction, in a group of patients who had had a recent myocardial infarction or ischemic stroke or who had peripheral arterial disease. Low sTM levels occurred in smokers, whereas elevated levels were associated with diabetes, although there was no relationship between sTM and mild peripheral (lower limb) artery disease (45). More recently, the same group showed an interaction between low levels of sTM and the nonspecific inflammatory marker sICAM-1 in predicting the development of coronary heart disease, with sICAM-1 only being associated with worse outcomes when sTM levels were low (46).

Thus, levels of sTM, produced as the consequence of shedding or cleavage of anticoagulant membrane thrombomodulin, are increased in association with most risk factors for atherosclerosis. However, there is debate as to the power of such data in predicting adverse cardiovascular outcome.

### Endothelin

ET is a 21-amino acid peptide that results from cleavage of so-called big ET by the action of ET converting enzyme (ECE), which is located on the EC membrane. Although three isoforms of ET (ET-1, ET-2, and ET-3) exist, ET-1 appears to be the predominant form in the cardiovascular system. Constitutive release of ET-1 by the endothelium is important for the maintenance of vascular tone (47). However, ET-1 stored in Weibel-Palade bodies may be released upon endothelial activation, resulting in further vasoconstriction (48). In fact, ET-1 is one of the most potent vasoconstrictors known.

ET binds to two receptor types, ETA and ETB. Although vascular smooth muscle cells express both types of receptor, ET-1-mediated activation of the ETA receptor is primarily responsible for mediating vasoconstriction (49). In contrast to ETA, which is predominantly expressed by vascular smooth muscle cells, ETB is found in a variety of tissues including endothelium, macrophages, and vascular adventitia (50,51). Experimentally, ET-1 produces powerful vasoconstriction (particularly at higher doses; lower doses may initially cause vasodilatation) in isolated human lung and pulmonary artery samples (52). Other data have shown that *in vivo* infusions of ET-1 produce endothelial dysfunction in healthy volunteers (defined as impaired forearm blood flow increase in response to infused acetylcholine) (53). Moreover, blockade of ETA receptors by specific antagonists improved endothelial function in people with endothelial dysfunction in the context of atheroma. This fits well with other studies of the internal mammary artery (harvested at the time of coronary artery bypass grafting), where ETA receptor blockade improved endothelial function *in vitro* (54).

Increased circulating levels of ET-1 are found in the plasma of patients who have endothelial dysfunction as measured by other means. This is clearly demonstrable following local endothelial injury caused by coronary artery angioplasty and stenting (55), where levels are elevated immediately post procedure. Other data from patients with coronary endothelial dysfunction (based on abnormal vasoconstrictor response to intracoronary acetylcholine injection) support this, with ET-1 levels higher in these subjects (56). Physiologically, ET-1 levels rise in normal pregnancy, but diabetic women and women who develop preeclampsia have particularly high levels (57,58).

Many of the classical cardiovascular risk factors are associated with increased ET-1 levels, and in most cases the level normalizes with effective treatment of the risk factor. In the case of hypertension, blood pressure treatment with an angiotensin-converting enzyme inhibitor (ACEI) lowered ET-1 levels. It is not clear whether this is a blood pressure lowering effect or a direct effect of ACEIs on ET release, as previous work has suggested that *in vitro* release of ET from cultured human ECs is inhibited by ACEIs (59). In hypercholesterolemic patients, ET-1 production is also increased, and treatment with the statin Pravastatin has been found to reduce ET-1 levels (60,61). Levels of ET-1 are elevated in patients with type I and type II diabetes mellitus, even when the diabetes is well controlled and without complications, but levels are elevated further in the presence of diabetic vasculopathy (62–64). Some clarification of the possible mechanisms underlying this observation comes from experimental work involving infusion of insulin into the forearm circulation of healthy volunteers; ET-1 activity was found to increase in response to the insulin infusion (65). Other experimental work using human umbilical vein ECs (HUVECs) has shown that stimulating these cells with TNF- $\alpha$  resulted in increased secretion of ET-1 (66). This not only provides an intriguing link between inflammation and endothelial dysfunction, but also fits with work in obesity, where ET-1 levels have been found to correlate with TNF- $\alpha$  levels (67).

Perhaps surprisingly, whereas ET-1 levels are higher in hypertensive patients and hypercholesterolemic patients, increased levels do not independently predict future cardiovascular events in these groups (68). Cigarette smoking is associated with increased ET-1 levels, and levels rise in the immediate time after smoking a cigarette (69,70).

Thus, increased levels of ET-1 are associated with in most of the risk factors for cardiovascular disease and generally fall with treatment of the risk factor (with the notable exception of diabetes); levels are also elevated following vascular injury and in patients with endothelial dysfunction. However (in contrast to vWF and sTM), levels are not directly related to prognosis.

### Soluble E-Selectin

E-selectin, an endothelial-specific surface ligand that facilitates leukocyte rolling, is a marker of endothelial activation.

The membrane-bound form is not found on normal, resting endothelium (71) but is expressed by ECs when activated by various stimuli (72). Soluble E-selectin, presumed to be shed or digested from the membrane, is found in the plasma of healthy persons and is increased in various patient groups. Lack of the cytoplasmic domain suggests proteolytic cleavage as the mechanism of release (73).

Consistent with the experimental observation that HUVECs express E-selectin in response to activation by inflammatory cytokines is the observation that soluble E-selectin is elevated in a number of inflammatory conditions such as Wegener and systemic vasculitis (74,75). In hyperlipidemic patients, levels are higher than in controls; lipid-lowering treatment has been shown to reduce the levels (76,77). Higher soluble E-selectin levels are also associated with a Western diet, smoking, hypertension, and diabetes mellitus (78–81), where it correlates with hemoglobin A1C (HbA1c), and increased levels predict future development of diabetes (82–84). Furthermore, treatment of diabetic patients (and healthy controls) with an ACEI has been shown to lower soluble E-selectin levels, although other studies have failed to correlate soluble E-selectin with HbA1c (85,86).

Finally, soluble E-selectin levels rise in the hours following myocardial infarction but return to baseline by five days; levels are also elevated in acute ischemic stroke (87–89). In addition, plasma levels of soluble E-selectin predict restenosis in patients who have undergone peripheral arterial balloon angioplasty (90). However, although one follow-up study found soluble E-selectin to be significantly related to future death, another found that measurement of this adhesion molecule is unlikely to add much predictive information compared to that obtained from established risk factors (91,92). For a recent review on soluble E-selectin, see reference 93.

Soluble E-selectin is therefore a marker of endothelial (inflammatory) activation and is elevated in a variety of situations in which the endothelium is stimulated or dysfunctional. Although levels are increased in many high-risk patients, and elevated levels appear to predict the onset of diabetes in patients at risk, debate continues.

### Tissue-Type Plasminogen Activator

Thrombogenesis and thrombolysis occur *in vivo* as a dynamic balance that maintains vascular integrity and prevents excessive bleeding. This balance is brought about partly by the complex relationship between prothrombotic and anticoagulant factors. However, once thrombosis has started there is a balance between production and breakdown of the particular thrombus. *In vivo*, plasmin is produced by cleavage of the proenzyme plasminogen, by the action of t-PA. However, *in vivo*, free plasmin (i.e., plasmin not bound to fibrin) is rapidly inactivated, and t-PA activity is potently inhibited by the action of PAI-1 and PAI-2, the two endogenous inhibitors of t-PA. Both t-PA and PAI are endothelial products, although the latter may also arise from platelets and adipose tissue (4,94,95).

**Table 173-1: Follow-up Studies Allowing Comparisons between Plasma Markers of Endothelial Function**

<i>Patients Recruited (Refs.)</i>	<i>Years of Follow-up</i>	<i>Markers Studied</i>	<i>Conclusion</i>
Post-MI, age < 70 years (100)	4.9	vWF, t-PA	vWF predicts MACE
Rheumatoid arthritis (101)	2	vWF, t-PA	vWF predicts thromboembolism
On oral anticoagulation (102)	3.8	vWf-t-PA	vWF predicts all cause and vascular mortality
Angina pectoris (20)	2	vWF, t-PA	t-PA ( $p = 0.02$ ) > vWF ( $p < 0.05$ ) predicts MACE
Hypertension (103)	3	vWF, sE-selectin	vWF predicts MACE
Hypercholesterolemia (104)	4	vWF, sE-selectin	vWF predicts MACE
Post-MI (41)	4	sTM, sE-selectin	sTM predicts MACE
Post MI, age < 70 years (105)	10	vWF, t-PA	vWF ( $p = 0.006$ ) > t-PA ( $p = 0.025$ ) predicts MACE
Unstable CAD (107)	14 days and 30 days	vWF, ET	Acute rise in vWF predicts MACE
Mixed CAD and PAD (107)	3.8	vWF, sTM	vWF ( $p < 0.001$ ) > sTM ( $p < 0.01$ ) predicts MACE
Free of PAD but some CAD (108)	5	vWF, t-PA	vWF predicts development of new PAD
Peripheral angioplasty (109)	0.5	vWF, sTM sE-selectin	None predict restenosis
Essentially healthy (110)	2–2.5	vWF, sTM	Neither predicted stroke
Diabetics (111)	9	vWF, t-PA sE-selectin	vWF and t-PA both predict mortality
Stable CAD (112)	13	vWF, t-PA	t-PA predicts coronary events
Free of CAD (113)	5	vWF, sTM	vWF predicts “hard” CAD

MACE, major adverse cardiovascular event (myocardial infarction [MI], stroke; coronary artery bypass grafting; etc. – see individual references for details); CAD, coronary artery disease; PAD, peripheral artery disease.

Levels of t-PA are frequently described as abnormal following cardiovascular events (96,97). However, the pathophysiological significance of elevated (or suppressed) levels of this molecule (and PAI-1) is very difficult to ascertain, not least because the actual level of any one molecule may well be less important than the biological activity of that molecule, which is of course a complex interaction involving the amount of molecule, its location, the amount and location of substrate, and the activity of its inhibitors (98,99). Nevertheless, in patients with atherosclerosis, levels are altered in those who go on to develop coronary artery disease, and it is therefore predictive of primary cardiovascular events in at-risk patients. (4,20,100–102).

Thus, whereas the clinical value of t-PA and its analogues in treating acute thrombotic events is now established, its value as an endothelial marker and/or predictor of adverse cardiovascular events is not as well accepted, possibly for technical reasons.

### Which Plasma Marker Is Most Useful?

The previous discussion has indicated various examples of studies promoting vWF, sTM, ET, soluble E-selectin, and t-PA as endothelial markers predictive of adverse outcome, generally thrombosis precipitating myocardial or cerebrovas-

cular infarction. However, few have placed these molecules side-by-side to allow a comparison (Table 173-1). Because of their (direct) involvement in hemostasis, the most frequently compared are vWF and t-PA, and of these, most studies find vWF to be the better predictor of adverse outcomes (100–113). Although most studies have focused on cardiovascular disease, both vWF and soluble E-selectin predict outcome in patients acutely ill with multisystem organ failure and/or sepsis (114).

## CELLULAR MARKERS

### Circulating Endothelial Cells

Recent research has recognized new populations of non-hematopoietic cells in the blood. One of these cell types, the CEC, may be defined by the expression of membrane glycoprotein CD146 (115). Small numbers of CECs are found in health, but raised numbers are present in a wide variety of human conditions, including inflammatory, immune, infectious, neoplastic, and cardiovascular disease and seem likely to be evidence of profound vascular insult (5,116). They are thought to originate when ECs are sloughed from the vessel wall following some form of pathological insult. Precise phenotypic characterization is required under the microscope or

**Table 173-2: Summary of Soluble Plasma Endothelial Markers in the Risk Factors of Atherosclerosis, in Actual Disease, and as Predictors of Disease**

Marker	Association Smoking	Association Diabetes	Association Hypertension	Association Hypercholesterolemia	Association Atherosclerosis	Association Others	Predict Primary Events	Predict Secondary Events
vWF	✓ (1)	✓ (1)	✓ (1)	✓ (1)	✓	Pregnancy, ABO blood group, RA, SLE, many cancers	✓, AMI	✓, AMI, stroke
sTM	+/-	✓	✓	??	✓	Thrombotic conditions, AF, DIC	??	✓ (stroke < AMI)
ET	?	✓ (But does not reverse with good diabetic control)	✓ (Reverses with therapy)	✓ (Reverses with therapy)	✓ (Coronary artery EC dysfunction)	Postangioplasty, stenting, pregnancy.	No	No
sE-selectin	+/-	✓ (+/- correlates with HbA1c, reverses with therapy)	✓	✓ (Reverse with therapy)	✓ (Weakly)	Inflammatory disease, cancer, sepsis	No	No
t-PA	? ✓	✓	✓ (Also predicts hypertension)	??	✓	Some cancers, e.g., raised in glioma, not in multiple myeloma.	✓ (AMI, stroke)	✓ (AMI)

Abbreviations as in Table 173-1, plus ET, endothelin; AMI, acute myocardial infarction; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus. (1) reduced as the risk factor recedes. ✓ common agreement.

flow cytometer by the expression of endothelial markers (e.g., vWF, vascular endothelial [VE]-cadherin) together with the absence of the expression of leukocyte (CD45) and immaturity markers (CD133) (5).

Although increased numbers of CECs correlate with other markers of vascular disease (e.g., vWF, soluble E-selectin) (117,118), questions regarding the precise definition, cell biology, and origin of CECs remain. For example, CECs may be alive, apoptotic, damaged, or necrotic, and they may possess procoagulant and/or proinflammatory properties. However, because these cells seem to be representative of in situ endothelium, their phenotype may provide useful information about their vascular bed of origin. Indeed, whatever their phenotype, there is growing evidence that CECs may well be a novel biomarker, the measurement of which will have utility in various clinical settings related to vascular injury. Despite this promise, progress is impeded by the diversity of methodologies used to detect these cells. Accordingly, results are sometimes inconclusive and even conflicting. Nevertheless, increased CECs in coronary artery disease (119,120) predict future adverse cardiovascular events (121) suggesting they may move from being simply a research index to having a role in the clinic.

### Endothelial Microparticles

Cellular activation, damage, and apoptosis may lead to the release of EMPs (6,122,123). Although the significance of EMPs remains unclear, there is a growing view that EMPs can function as important diffusible mediators of cytokines and adhesins, thus promoting cellular signaling and activity (124). In vitro stimulation of HUVECs by angiogenic growth factors (vascular endothelial growth factor [VEGF], fibroblast growth factor 2 [FGF2]) resulted in EMP formation rich in matrix metalloproteinases and capillary cordlike structures, suggesting a potential in vivo role in angiogenesis (125).

There may be a role for EMPs in thrombotic disease as they display procoagulant activity, defined by platelet factor 3 activity and expression of tissue factor (126–129). In prothrombotic states such as sickle cell disease, raised tissue factor-positive EMPs in patients compared with controls correlated strongly with procoagulant activity (129). Of note, Boulanger and colleagues (130) reported severe endothelial dysfunction in rat aorta after incubation with human EMPs, affecting the endothelial NO transduction pathway, but not NO synthase expression. EMPs may also be proinflammatory as they tend to bind and activate monocytes, resulting in cytokine release (e.g., TNF- $\alpha$ , IL-1 $\beta$ ) which causes further paracrine and/or autocrine activation of monocytes and endothelium (6).

These studies raise the possibility of EMPs being mediators of vascular insult and inflammation in disease, rather than just markers of endothelial dysfunction. More data are required to answer these issues, particularly in its relationship with cancer, of which there are currently no reports to the best of our knowledge.

### CONCLUSION

Recent reviews have underlined the importance of the endothelium in a variety of human diseases (1–3,131). The endothelium releases/sheds circulating cells and molecular markers (of which the most promising and most frequently cited is vWF) (9,132) that reflect its integrity and activity. In most cases markers are released in health as well as disease, with the levels varying according to the general particular disease process (e.g., hypertension); in others the release of the marker is only in response to a particular (acute or precipitating) event or events (e.g., septicemia) (Table 173-2). Nevertheless, a knowledge of patterns of release of such cells and molecules allows a greater understanding of relationship between the vascular tree and cardiovascular physiology and pathology and thus the targeting (e.g., by ACEIs, statins) of particular disease processes.

### KEY POINTS

- Endothelial physiology can be determined by certain cells and molecules in the plasma.
- Plasma makers include vWF, sTM, soluble E-selectin, ET, and t-PA.
- vWF is the most reliable plasma marker of endothelial perturbation: raised levels consistently predict adverse cardiovascular events.
- CECs are present in the blood of subjects with a variety of cardiovascular diseases and in cancer.

## Blood Endothelial Cells

Robert D. Simari\*, Rajiv Gulati†, and Robert P. Hebbel‡

\*Mayo Clinic College of Medicine, Rochester, Minnesota; †University of Birmingham, United Kingdom; ‡University of Minnesota Medical School, Minneapolis

In 1963, in an attempt to define the source of endothelium on vascular grafts, Stump and colleagues suspended a Dacron patch within the lumen of a prosthetic vascular graft in the aorta of a juvenile pig (1). As early as 14 days following placement, islands of endothelial cells (ECs) were identified on the patch surface. Because the patch had been isolated from contact with both the prosthesis and native vascular tissue, these findings implicated circulating blood as the source of ECs. These observations were not actively pursued from an experimental or clinical context until recently.

This original observation of a vascular source of endothelium has been corroborated in chimeric transplantation models that have enabled the discrimination of host- and donor-derived cells by genetic markers. These studies have revealed bone marrow–derived circulating progenitors to contribute to both endothelial and intimal smooth muscle cell formation in multiple models of vascular injury as reviewed by Sata (2). Moreover, treatment with 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase inhibitors (statins) appears to accelerate the incorporation of bone marrow–derived ECs following arterial denudation in rodent models (3,4). These studies confirm the presence of cells with either an endothelial phenotype or endothelial potential within human blood. Furthermore, strategies have been developed to utilize these cells for the prevention and treatment of vascular disease. In this chapter, identification, classification, and potential translational uses of these cells will be discussed.

### CIRCULATING ENDOTHELIAL CELLS

#### Definition and Phenotype

The blood of normal individuals contains circulating ECs (CECs) as well as monocytic cells with the potential to develop endothelial features in culture (culture-modified mononuclear cells – CMMCs) and progenitors capable of differentiation into ECs (so-called *true endothelial progenitor cells* [EPCs]). Investigators studying CECs have recently produced a consensus report (5). Interpretation of this literature is

dependent, of course, on methods used to define CECs. Older studies, using identification methods limited to histochemical staining and morphology, suggested a frequency of around 1 CEC per 1 million nucleated cells in normal blood. Modern studies, using monoclonal antibodies to identify CECs, have confirmed this frequency (5). A variety of surface markers have been used to identify CECs. Most commonly this has been carried out using monoclonal antibodies to CD146 plus another endothelial marker (e.g., vascular endothelial [VE]-cadherin or von Willebrand factor [vWF]). Insofar as *true* EPCs exhibit some phenotypic overlap with mature ECs in terms of markers (6), it may be that CEC counting includes some progenitors. However, available data on the latter cell type suggest they are represented in blood at much lower frequency than are CECs.

Based on the literature (5) and our own experience (7), we believe that application of rigorous and appropriate methods should identify <10 CECs per mL of blood from normal individuals. Then, there are outlier studies, such as one which applied fluorescence-activated cell sorting (FACS) technology and detected up to 7,000 “CECs” per mL in normals (8). It is probable that the latter study was identifying microparticles, if not outright artifacts, rather than true CECs. We, therefore, recommend a definition that includes the CECs actually being shown to be nucleated (7), and we have used this in our own studies described in the next section. FACS has been successfully used to enumerate CECs (9).

#### Origin of Circulating Endothelial Cells

It is believed that CECs are derived from the vessel wall. Evidence for this was provided by examination of sex chromosomes in CECs of currently healthy humans who had previously undergone a gender-mismatched bone marrow transplant (10). Virtually all CECs exhibited the recipient genotype. This presumably indicates a natural, low-level turnover of endothelium, in which injured or apoptotic cells depart from the vessel wall. The residence time of CECs in blood has not been directly measured, but the rapid changes in CEC counts we have observed in sickle cell anemia suggest

rapid turnover. Elevated CEC counts have been reported in a broad spectrum of inflammatory, cardiovascular, infectious, and blood diseases. Examples include septic shock, lupus, vasculitis, scleroderma, coronary syndromes and manipulation, venous insufficiency, arteritis, pulmonary hypertension, peripheral vascular disease, cytomegalovirus (CMV), Rickettsial infection, sickle cell anemia, and thalassemia. A common thread in the pathophysiology of these conditions is the existence of vascular damage, which may account for the increased CEC counts (5). However, in the absence of genetic marking data for CECs in these various disease states, the true origin of these cells remains speculative.

### Usefulness of Circulating Endothelial Cell Enumeration

Individual CEC counts should be interpreted cautiously. For example, in sickle cell anemia we found that CEC counts fluctuated chaotically for individual subjects followed longitudinally (7). In fact, sickle cell anemia is a disease in which vascular damage is believed to be chronic and ongoing (and to fluctuate in intensity), so it perhaps is not surprising to see significant changes in CEC counts in that disease. However, if this observation holds true for other disease situations (and this is not known), this indicates that single time-point CEC counts would be of limited value for an individual patient.

On the other hand, examination of groups of subjects reveals instructive trends. For example, CEC counts tend to be higher in rough proportion to disease activity or severity in sickle cell anemia, coronary syndromes, peripheral artery disease, Mediterranean spotted fever, lupus, and inflammatory vasculitis, among others (5). Encouragingly, CEC counts have been observed to correlate with plasma vWF level in patients with cardiovascular disease (11). If confirmed and extended, such associations may reveal that CEC level is a measure of degree of vascular injury. In studies of lupus patients, number of CECs was observed to correlate with brachial artery endothelial dysfunction (9). However, before CEC counts can be used diagnostically, it will be important to establish the temporal stability or lack thereof in any given disease situation.

### Clinical Usefulness of Circulating Endothelial Cell Phenotype

We have demonstrated that CEC phenotype can be used as a surrogate marker of vessel wall endothelium activation status (7,12). We find that CEC phenotype is the same for live versus dead, or for apoptotic versus nonapoptotic cells. So we believe that phenotype is acquired before cell death and has been governed by the same milieu as has the vessel wall endothelium. Such phenotyping possibly can be instructive in a variety of situations.

Two-thirds of CECs in normals exhibit evidence of apoptosis (TUNEL positivity and fragmented nuclei). Undoubtedly this reflects the EC's well-known intolerance of being unanchored, so that once dislodged from vessel wall it rapidly

undergoes apoptosis. In sickle disease patients, only one-third of CECs are apoptotic (13). Although this could reflect the presence of a younger population of CECs (e.g., due to ongoing vascular insult), it is interesting that such a degree of CEC apoptosis correlated inversely with plasma levels of vascular endothelial growth factor (VEGF), a major survival and apoptosis-inhibiting factor for ECs. We suggest that monitoring CEC apoptosis could be a surrogate indicator for "apoptotic tone" of the vessel wall, possibly useful for following disease activity or antiangiogenic therapeutics.

Analysis of CECs might provide insights into the pathogenesis of disease. For instance, CECs express tissue factor in sickle cell anemia, but not in normal subjects (14) (Figure 174.1; for color reproduction, see Color Plate 174.1). Studies of CECs in sickle cells anemia reveal the spectrum of phenotypic features that can be evaluated on CECs – e.g., antigen expression, mRNA presence, binding function, and biochemical activity of tissue factor (Figure 174.1). Endothelial adhesion molecules (intercellular adhesion molecule [ICAM]-1, vascular cell adhesion molecule [VCAM]-1, selectins) are abnormally expressed by CECs in sickle cell anemia (7) and scleroderma (9). In lupus, CECs are described as having lowered levels of endothelial protein C receptor (5). Such findings are consistent with the procoagulant states of these diseases.

### Biological Significance of Circulating Endothelial Cells

CECs are present in such small numbers that it seems highly unlikely that they would directly have an impact on disease pathobiology – e.g., as procoagulant cells. On the other hand, we believe that CECs, as surrogate markers, provide insight into the biology of endothelium remaining in the vessel wall. Direct evidence for this is limited to sickle transgenic mice, where CECs had an activated/pro-adhesive phenotype and so did tissue endothelium (12).

One wonders about the state of the vessel wall from which CECs have been liberated. Although there are no data that address this, the CEC counts achieved in the sickle cell disease model (up to 70/mL) would represent perhaps 20 cm<sup>2</sup> of denuded vessel wall, which is not a trivial amount. We will not be surprised if CEC counts are eventually found to correlate with thrombotic risk because of the concomitant denuded surface.

### ENDOTHELIAL-LIKE CELLS GROWN FROM BLOOD: BLOOD OUTGROWTH ENDOTHELIAL CELLS AND ENDOTHELIAL PROGENITOR CELLS

*Endothelial-like* cells can be generated from continued culture of peripheral blood samples from human (10), sheep (15), mice (16), rabbit (17), and dog (R. Hebbel, unpublished observations) in endothelial growth conditions. For clarity, we use the term *blood outgrowth ECs* (BOECs) for homogenous populations of cells generated in culture having endothelial morphology (typically cobblestone) and expressing markers

Figure 174.1. CECs express tissue factor. These studies of tissue factor expression by CECs illustrate the spectrum of methods that can be productively applied to these cells. A single cell is shown to be positive for endothelial marker P1H12 (A) and tissue factor antigen (B). CECs identified via P1H12 show a positive hybridization signal for *tissue factor* mRNA (C), which is not seen for control probe (D). Fluorescent factor VIIa binds to tissue factor-positive CECs (E), which is blocked by anti-tissue factor antibody (F). A chromogenic assay shows tissue factor function on tissue factor antigen-positive CECs (G) which is blocked by anti-tissue factor antibody (H). Tissue factor antigen-positive CECs show a positive hybridization signal (I) that is not seen for control probe (J). For color reproduction, see Color Plate 174.1.

of mature differentiated ECs, but not myelomonocytic markers such as CD14 or CD45, nor the stem cell marker AC133. In contrast, shorter-term cultures of peripheral blood can also yield a heterogeneous population of spindle-shaped cells that share endothelial and myelomonocytic markers. This heterogeneous population of spindle-shaped cells (18), often mistakenly referred to as EPCs, are also known as CMMCs. BOECs are most likely derived from true endothelial progenitors, whereas CMMCs arise from monocytes (18). Additionally, although CECs have limited proliferative potential, they cannot be formally excluded as a source of endothelial-like cells obtained in culture.

### Blood Outgrowth Endothelial Cells

Lin and colleagues first demonstrated robust true endothelial outgrowth from human blood, yielding  $10^{19}$  BOECs (10). Examination of the genotype of BOECs grown from blood in humans who had previously received a gender-mismatched marrow transplant allowed for identification of the bone marrow as the source of the outgrowth cells. The strategy for generating BOECs in vitro is highly reproducible. Using unfractionated peripheral blood, mononuclear cells are plated onto collagen I and grown with 2% fetal bovine serum and endothelial growth factors. Nonadherent cells are discarded on the second day of culture. Endothelial growth exhibits two phases. The early outgrowth phase is relatively slow and includes limited expansion of recipient-derived CECs. The second, delayed phase consists of robust outgrowth from a transplantable marrow-derived cell in peripheral blood, a putative bona fide EPC (Figure 174.2). During this second phase, cells acquire cobblestone morphology and express distinct endothelial markers, including vWF, thrombomod-

ulin, CD34, CD31, CD36, VE-cadherin,  $\alpha_v$  integrin, FLK-1, and P1H12. Moreover, they contain Weibel-Palade bodies. BOECs are negative for CD14 (a monocyte marker), CD45 (a marker for hematopoietic cells), and AC133 (a stem cell marker) (Figure 174.3). Thus, BOECs share markers of differentiated ECs, do not possess myelomonocytic markers (typical of loosely defined EPCs), and have a cobblestone morphology.

Figure 174.2. Endothelial expansion from buffy coat mononuclear cells of normal blood. On day 2 and for subsequent passages (arrows), the number of ECs was confirmed by staining for P1H12 and vWF, and that number was consistent with the cell count by morphology. All data points plotted as mean  $\pm$  SD ( $n = 5$  for culture up to passage 6;  $n = 4$  for subsequent passages).

Figure 174.3. Flow cytometry analysis of outgrowth EC phenotype. In each graph, the black line outlines the region of fluorescence intensity for cells labeled with negative control antibody. The filled region identifies cells labeled with antibody for the expression marker indicated above each graph. Outgrowth cells are negative for CD14 (monocyte marker) and positive for FLK-1, vWF, CD36, and the endothelial-specific marker VE-cadherin.

### Endothelial Progenitor Cells

For purposes of clarity, we propose that the term *EPCs* be restricted to putative endothelial progenitors located in either peripheral blood or marrow. The putative circulating *EPCs* and marrow *EPCs* may well be the same, as there is precedent for spillage of marrow stem cells into the peripheral circulation. Unfortunately, the literature on *EPCs* is greatly confused due to application of inappropriate terminology and unproven assumptions.

#### “True” Endothelial Progenitor Cells

There is strong *in vitro* and *in vivo* evidence – including the BOEC findings described – for presence of “true” *EPCs* in blood and bone marrow (6,10,19–22). Phenotypic data need to take into account that few markers are endothelial-specific. In aggregate, data suggest that the true *EPC* has the phenotype CD34<sup>+</sup>, FLK-1<sup>+</sup>, FGFR1<sup>+</sup>, AC133<sup>+</sup>. The population of blood and marrow cells that carries these markers tends to also express *c-kit*, *Tie2*, *P1H12*, and *VE-cadherin*, but to be negative for *vWF* and uptake of acetylated low-density lipoprotein (acLDL). The relevant cell may reside in the *c-kit* bright subpopulation (21). It should be noted that all studies of *EPCs* to date have been performed on bulk populations of cells and have not yet been critically tested by studies using single-cell culture.

A stem cell should be self-renewing, multipotent, and transplantable. True endothelial progenitors can be transplanted in humans (10,23) and animals (24), but whether the true *EPC* has self-renewing capacity has not been defined. *EPCs* may be committed progenitors rather than a self-renewing or pluripotent progenitor cell. It has been suggested that the source of *EPCs* is a hemangioblast, analogous to that seen in early development (25,26). Evidence suggests that adult mice do have hemangioblasts, able to be transplanted as a single cell and able to generate both endothelial and hematopoietic lineage cells (24). A report from human studies will require confirmation (27). Other possibilities exist. The enormous plasticity of some marrow cells has been noted (28), and multipotent adult progenitor cells (MAPCs) have recently been generated in culture and are capable of generating *ECs* (29).

#### Culture Modified Mononuclear Cells

Asahara and colleagues established cultures of CD34<sup>+</sup> cells (but only at 16% purity in a population of mononuclear cells) from blood and obtained modified cells they referred to as *EPCs* (16). Unfortunately, no evidence was provided to support the designation of these cells as progenitors. Moreover, unlike BOECs, the morphology of these cells was spindle shaped, and the cells expressed rather low levels of endothelial markers and CD34 and very high levels of myelomonocytic markers – e.g., 27% CD45 positive and approximately 90% CD14 positive (16,30,31). It would seem that these “*EPCs*” are more likely to have been CMMCs, absent evidence to the contrary.

In our opinion, the term *EPC* has been inappropriately applied in a number of recent publications to cells that are actually CMMCs (e.g., 16,30–36) or even BOECs (15). The term *EPC* has been repeatedly applied to cells within short-term cultures of peripheral blood mononuclear cells that exhibit dual-positivity for uptake of acLDL and *Ulex europaeus* lectin binding. In fact, Rehman and colleagues used the Asahara method but found that the majority of “*EPCs*” expressed monocyte/macrophage markers and that the dual labeled acLDL/*U. europaeus* positive cells are derived from monocytes/macrophages (37). Taken together, we regard this as insufficient evidence for an *EPC*, because neither of these markers is specific for *ECs* and, in fact, both also identify monocytes (37,38), the cell population within which the so-called *EPCs* reside. In our experience, short-term cultures of peripheral blood mononuclear cells are dominated by cells of monocytic origin.

Other spindle-shaped cells are characteristic of Kaposi sarcoma and may be obtained by culturing blood (39). The origin of these cells is thought to be from cells lining splenic sinuses. The culture of these cells is promoted by cytokines (39) and simulated by high concentrations of growth factors used by some to culture “*EPCs*” – e.g., high serum concentrations. CMMCs grown from blood are elongated, and they exhibit both endothelial and myelomonocytic markers (e.g., CD14) (39). Such cells at best can be regarded only as “endothelial-like” cells.

Fernandez-Pujol and colleagues reported culture of CD14<sup>+</sup> positive peripheral blood monocytes on fibronectin with endothelial growth factors. The resulting cells were of mixed morphologies, including spindle shapes, and were called “endothelial-like” because they exhibited not only endothelial markers but also CD14 and CD68 (40). Similarly, culture of monocytes on fibronectin and with endothelial growth factors (41) or bovine brain extract (42) yields spindle-shaped cells that share endothelial and macrophagocytic lineage markers. Interestingly, CMMCs derived from CD34<sup>+</sup> cells can be incorporated into vessel walls as endothelial-like cells, as long as there is help from cocultured CD34<sup>+</sup> positive cells (42). It is also important to note that CMMCs exhibit endothelial functions such as tube formation in vitro, as well as uptake of acLDL and binding of *U. europaeus* lectin, markers sometimes used with the unwarranted assumption that they are endothelial specific.

#### **THERAPEUTIC USES OF BLOOD OUTGROWTH ENDOTHELIAL CELLS AND ENDOTHELIAL-LIKE CELLS OBTAINED FROM BLOOD**

Therapeutic vascular interventions are limited by sequelae initiated by mechanical damage to the vessel wall. Disruption of the endothelial layer exposes the subendothelial surface and induces a cascade of events, resulting in impaired vasorelaxation, thrombus formation, and intimal hyperplasia. Restoration of endothelial integrity has been shown to modify these events in multiple animal models, resulting in improved vascular remodeling.

Re-endothelization of injured vascular segments is associated with attenuation of neointimal formation. Indeed, early restoration of endothelial integrity through local delivery of VEGF was associated with reduced intimal formation, providing evidence to support a role for re-endothelization in suppressing intimal hyperplasia (43). This approach is undergoing phase I clinical evaluation following both coronary and peripheral intervention (44,45).

In addition to indirect approaches to enhance endothelization such as growth factor delivery, direct strategies have been used to enhance re-endothelization at the site of injury. The ability to generate BOECs and endothelial-like cells from peripheral blood supports a strategy that obviates surgical harvest of mature endothelium. In a rabbit model, we generated CMMCs from peripheral blood, demonstrating this population to contain true precursors to BOECs (46). Balloon injury to a clamp-isolated segment of carotid artery was performed under direct vision, followed by intraluminal administration of autologous CMMCs (cultured for seven days from peripheral blood). CMMCs were then allowed to dwell for 20 minutes prior to restoring normal arterial flow (Figure 174.4; for color reproduction, see Color Plate 174.4). By labeling CMMCs with a fluorescent membrane dye prior to administration, we were able to identify delivered cells in the vessel wall up to 4 weeks after injury. Labeled cells were seen lin-

ing the lumen expressing markers of endothelial – but not monocyte/macrophage – lineage. It could not be determined whether these cells arose from monocytic transdifferentiation or from true, rare endothelial precursors. Labeled cells were also detected in deeper layers expressing macrophage but not endothelial markers, indicating either defined adoption of macrophage phenotype or phagocytosis of delivered (labeled) cells by resident macrophages.

Encouraged by the detection of delivered cells up to 4 weeks following delivery, we proceeded to evaluate the effect of CMMCs on parameters of vascular structure and function, comparing local delivery of a saline-cell suspension immediately after balloon injury with saline alone as a control. To evaluate the effect of CMMC delivery on vascular reactivity we examined excised carotid rings in an organ chamber 4 weeks after balloon injury and cell delivery. CMMC delivery was associated with a marked improvement in endothelium-dependent vasorelaxation compared with saline, although vasorelaxation responses did not achieve those of normal, uninjured vessels (Figure 174.5). Interestingly, we also demonstrated that CMMC delivery was associated with a 55% reduction in neointimal thickening. Finally, by exploiting the ability of endothelium to block extravasation of Evans blue dye, we determined that CMMC delivery was associated with significantly enhanced arterial re-endothelization (46).

BOECs have also been tested for their vasculoprotective effects. Kaushal and colleagues demonstrated that seeding of decellularized vascular grafts with autologous ovine BOECs dramatically improved graft patency (15). We and others have evaluated the effect of local BOEC delivery following balloon injury of a native artery in a rabbit model (47,48). We hypothesized that BOEC delivery after arterial injury may modify the vascular response in an endothelium-dependent manner. Importantly, we also elected to compare the effect of delivering peripheral blood mononuclear cells (PBMCs) as a control for cultured cell therapy. Our results, together with those of Griese and colleagues, indicated that BOEC delivery was associated with an overall reduction in neointimal formation compared to delivery of both saline (47,48) and PBMCs (47).

It is interesting to note that the functional and structural effects of BOEC delivery are almost identical with those of CMMC delivery (46,47). Acknowledging that this comparison has limitations, it remains somewhat surprising that BOECs, with their more distinct endothelial properties and with their delivery in approximately 10-fold greater numbers than CMMCs, were not clearly superior in their vascular protection, as measured by vasorelaxation and neointimal formation.

Other investigators have tested the strategy of vasoprotection with blood-derived ECs using complementary approaches. Fujiyama transplanted subpopulations of human mononuclear cells (MNCs) into balloon-injured arteries of athymic rats (49) following pretreatment with gene transfer of monocyte chemoattractant protein (MCP)-1. The authors demonstrated that local delivery of CD14<sup>+</sup> monocytes was associated with accelerated endothelization and reduced

Figure 174.4. Administered CMMCs incorporate into vessel wall after balloon carotid injury. (A) Carotid section demonstrating labeled CMMCs on luminal border 4 weeks after local delivery. Colocalization staining of endothelial antigens CD31 (B) and BS-1 lectin (C) but (D) negative staining for macrophage marker RAM-11. (E) Hematoxylin, and eosin staining of adjacent arterial section. (F) Labeled cells also detected in neointima that (G) do not costain for CD31 but (H) do stain for RAM-11, consistent with macrophage lineage. (I) Hematoxylin and eosin staining of adjacent arterial section. Gray indicates CM-DiI fluorescence; light gray, CD31; arrows, colocalization of neointimal CMMCs with RAM-11. Magnification  $\times 40$ . For color reproduction, see Color Plate 174.4.

neointimal formation compared to delivery of CD34<sup>+</sup> cells or unselected MNCs. It was suggested that the delivered monocytes were able to “transdifferentiate” into mature ECs in vivo. This was concluded from the coexpression of endothelial antigens and lack of monocytic markers on prelabeled delivered cells. However, is not possible to exclude an effect

of MCP-1 in explaining these observations. Moreover, delivered monocytes may have fused with resident endothelium, as has been proposed in other studies (50). In a splenectomized mouse model, Werner determined that systemic delivery of cultured spleen-derived mononuclear cells homed to mechanically injured vessel segments. Cell administration accelerated

Figure 174.5. Enhanced endothelium-dependent vasoreactivity in carotid rings from CMMC-treated rabbits. Vessels from CMMC-treated rabbits show markedly enhanced vasoreactivity to acetylcholine 4 weeks after injury. Data expressed as mean % relaxation  $\pm$  SEM (\* $p < 0.05$  for CMMC- vs. saline-treated injured arteries). Uninjured left carotid arteries retained largest responses ( $p < 0.05$  for maximal relaxation and  $EC_{50}$  compared with CMMC rings). RCA indicates right carotid artery; LCA, left carotid artery.

re-endothelization and reduced neointimal formation at the site of injury (51). These recent findings underscore the need for additional studies aimed at determining whether monocyte–endothelial transdifferentiation is a genuine pathophysiological process.

#### MECHANISM OF EFFECTS OF CELL DELIVERY

The modification of vascular responses by cell therapy is likely to be at least in part related to restoration of endothelial integrity and the resultant barrier properties conferred. Additionally, ECs may modulate vascular structure and function through secreted factors (52). Given this, it is entirely possible that nonluminally located ECs (47) may also contribute to the vascular protection conferred by cell delivery. Furthermore, it is not clear how much endothelial resurfacing relates directly to incorporation of delivered cells. For example, Griese (48) used retroviral labeling to enable the identification of delivered BOECs following balloon injury and demonstrated at 4 weeks no labeled cells were apparent in the same location. Despite this apparent loss of delivered cells, overall arterial re-endothelization was enhanced. Similarly, Conte noted loss of genetic label following delivery of cultured venous ECs in a rabbit model (53). Similarly, we found CMMC-derived cells to be detectable on a minority of the luminal arterial surface 4 weeks after balloon injury and cell delivery, despite markedly increased endothelization (46). Although loss of label or genetic marker may account for some of these findings, it is also likely that a potential mechanism of the benefit seen with cell delivery occurs through paracrine mechanisms. Cultured monocyte-lineage cells have been shown to secrete growth factors and cytokines in vitro (37). These factors include a variety of growth factors and cytokines that may promote vascular healing (54). These findings demonstrate the need for more studies to define the relative contribution

of direct re-endothelization and associated paracrine mechanisms involved in delivery of BOECs and endothelial-like cells in models of vascular disease.

#### CONCLUSION

The dogma that vascular cells are limited to the vasculature and have vascular precursors has been proven incorrect. Normal human blood contains ECs and cells with the potential to develop an endothelial phenotype in culture. Our understanding of blood ECs and cells capable of developing an endothelial phenotype will increase our fundamental understanding of basic physiological and pathophysiological mechanisms of hematologic and vascular disease. In addition, the understanding of the origin and function of these cells has led to novel diagnostic and therapeutic opportunities. Yet, the hopes for new therapies would be best served by a shared accuracy of definitions and lack of hyperbolic claims of potency.

#### KEY POINTS

- Circulating blood contains mature ECs from vascular origins.
- Evidence suggests that circulating blood contains “bona fide” endothelial progenitors that have not been fully characterized.
- Circulating monocytic cells can develop endothelial features in culture and these cells have been mislabeled “endothelial progenitor cells.”
- Autologous delivery of cells with endothelial features has been shown to modify vascular form and function with translational potential.

#### Future Goals

- To identify “bona fide” bone marrow and circulating endothelial precursors and effect the translation of strategies that use these cells for autologous vascular repair

# Endothelial Microparticles

## Biology, Function, Assay, and Clinical Application

---

Yeon S. Ahn, Lawrence Horstman, Eugene Ahn, Wenche Jy,  
and Joaquin Jimenez

*University of Miami School of Medicine, Florida*

Endothelial cells (ECs) have long been implicated in the pathogenesis of various clinical disorders such as thrombosis, inflammation, and vascular diseases (1,2). However our knowledge of precisely how ECs contribute to the pathogenesis of human disease remains limited. A major obstacle to the study of endothelial disturbances is the difficulty in sampling ECs from patients for investigation. Clinical tests to assess or monitor EC perturbations are not widely available, yet there is an urgent need for diagnostic assays that are clinically useful, simple, and economical. The availability of such methods promises new insights into the role of ECs in the pathogenesis of vascular disorders and will assist clinicians in the early diagnosis and prevention of common atherothrombotic conditions, the leading cause of mortality in our hemisphere.

This situation has improved in the last few years, as it has become evident that ECs, like other blood cells, shed membranous vesicles, termed *endothelial microparticles* (EMPs), in amounts and phenotypes that reflect the health of the parent cell. EMP assays offer a new and sensitive means of assessing endothelial status (3).

ECs normally present a nonadhesive and anticoagulant surface to flowing blood, but EC injury can provoke cell adhesion and initiation of coagulation with consequent thrombosis and inflammation (1,4). EMPs consist of somewhat heterogeneous species of microparticles ( $<1 \mu\text{m}$  diameter) carrying many biomarkers of the parent cells, the analysis of which can therefore provide useful information about EC status (3). For example, it has been shown that EMPs released upon activation exhibit distinctive antigenic phenotypes and functional properties compared to those released upon apoptosis (5).

Elevated EMPs have been reported in large vessel (macrovascular) diseases such as acute myocardial infarctions (MI) and coronary artery disease (CAD), as well as in small vessel (microvascular) diseases such as thrombotic thrombo-

cytopenic purpura (TTP), preeclampsia, and diabetes mellitus (DM) (3). Subsequently, elevation of EMPs was also documented in several autoimmune and inflammatory disorders, most notably systemic lupus erythematosus (SLE) and multiple sclerosis (MS). The list of diseases associated with elevated EMPs continues to grow.

The goal of this chapter is to highlight the emerging role for EMPs as a diagnostic marker in clinical disease. The first part discusses their mechanisms of generation, phenotypic heterogeneity, assay methods, and putative functions. The second part reviews clinical studies of EMPs in various human disorders. Future prospects for EMP research are considered at the end of the chapter.

### WHAT ARE ENDOTHELIAL MICROPARTICLES?

As their name implies, EMPs are submicroscopic membranous particles (vesicles) of size range below about  $1.0 \mu\text{m}$ , which are shed from the parent ECs upon stimulation by activating agents such as tumor necrosis factor (TNF)- $\alpha$  or during apoptosis. The process of MP release is termed *vesiculation* and appears to follow an earlier stage of membrane budding or blebbing before pinching off as free particles. They carry with them many of the membrane proteins and phospholipids (PLs) of the parent cell (3).

In many respects, EMPs resemble the MPs shed into plasma from the circulating blood cells – i.e., platelet MPs (PMPs), leukocyte MPs (LMPs), and red blood cell MPs (RMPs). A 1999 review article on PMPs covers many topics relevant also to EMPs (6).

It is important to note that our use of the term *MP* refers strictly to plasma membrane-derived microparticles and not to recently described “exosomes,” which are generated from intracellular membranes (late endosomes), and have specialized functions such as antigen presentation (7). Exosomes,

which are smaller at 60 to 80 nm than most plasma-membrane derived MPs, are not included in this chapter although there may be some overlap because of certain shared antigens and uncertainty about relevant size ranges of exosomes and limit of size detection of EMPs (8).

## HISTORICAL CONSIDERATIONS

Wolf first described MPs derived from platelets (PMPs) in 1967, referring to them as *platelet dust* (9). In 1977, employing electron microscopy, Zucker-Franklin observed PMPs together with RMPs in the blood of patients with immune thrombocytopenic purpura (ITP) (10). EMPs were first explicitly studied by Hamilton and colleagues, who in 1990 used flow cytometry to detect their release from human umbilical vein ECs (HUVECs) in tissue culture following stimulation by complement (11). These methods had been developed by members of the same group in their earlier pioneering studies of PMPs. EMPs were detected in part by fluorescent antibody against the stimulus, complement, leading to the observation that much or most of the added complement was shed off from the HUVECs (attached to EMPs), depleting the parent cell of added complement.

However, reliable measurement of EMPs in patient blood is more challenging than studies in cell culture because blood contains many different kinds of MPs. A further complication is that at least some types of EMPs may adhere to other blood cells, suppressing their detection. As a result, clinical applications of EMP assays went unexploited for almost a decade.

Since 1990, our lab has been investigating PMPs, particularly in certain subgroups of ITP patients. ITP is an autoimmune disorder in which auto-antibodies bind to platelets, inducing their immune-mediated destruction by different mechanisms (12,13). Patients with ITP are usually at risk for bleeding due to low platelet counts. However, we identified a subgroup of patients who rarely bleed despite severe thrombocytopenia and showed that their blood contained high levels of procoagulant PMPs, apparently functioning to protect them against hemorrhage (13,14). In related studies, we found that PMPs bind to and activate neutrophils to form grape-like cell aggregates, suggesting a role for PMPs in inflammation as well as hemostasis (15). In 1998, our interest shifted from PMPs to EMPs due to increasing awareness of the need for novel diagnostic assays in endothelial-based diseases.

Our first studies of EMPs appeared in early 2000 (16), followed later that year by findings *in vivo* (17) and other publications soon thereafter (18,19). The first reported clinical application of EMP assay appeared in 1999 by Combes and colleagues (20). Since then, an exponentially growing number of publications on EMPs has appeared, and steady progress has been made in measurement methodologies and understanding their clinical significance.

## ENDOTHELIAL CELL PERTURBATION

Under resting conditions, ECs provide a nonthrombogenic, nonadhesive surface and regulate vascular permeability and tone by release of nitric oxide (NO) and other agents to maintain smooth blood flow in the vasculature (21). The hallmark of perturbed ECs is a phenotypic change toward a procoagulant, pro-adhesive state, promoting adhesion of blood cells, coagulation, and inflammation. EC “perturbation” encompasses a wide range of pathologies but for present purposes may be divided into endothelial *activation* and *apoptosis*.

### Endothelial Cell Activation

As used here, EC activation refers to the reversible response of ECs to pro-inflammatory cytokines such as TNF- $\alpha$ , interleukin (IL)-1 or interferon (IFN)- $\gamma$  (22). These are genetic responses requiring 4 to 24 hours, characterized by profound morphological and phenotypic changes (22,23). Activation of nuclear factor (NF)- $\kappa$ B and ensuing induction of pro-survival genes of the *iap* and *xiap* family promote EC survival (23,24). The same sequence of events induces surface expression of pro-adhesive molecules such as vascular cell adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1, and E-selectin (22–24), facilitating leukocyte adhesion and migration, and release of IL-6, IL-8, and monocyte chemoattractant protein (MPC)-1, which further augment the inflammatory response (25). TNF- $\alpha$  also elicits release of large multimers of von Willebrand factor (vWF) and P-selectin from Weibel-Palade bodies. The large vWF multimers promote platelet adhesion to the endothelial surface, leading to their activation and aggregation (26). In addition, activated ECs express higher levels of plasminogen activator inhibitor (PAI)-1 and lower levels of tissue-type plasminogen activator (t-PA) (4,21). Activated ECs may express tissue factor and promote blood coagulation, at least *in vitro* (27).

### Endothelial Cell Apoptosis

Apoptotic ECs exhibit distinctive procoagulant properties. Loss of membrane symmetry exposes anionic PL such as phosphatidyl serine (PS), together with release of PS-rich membrane blebs that support thrombin generation (28,29). EC detachment resulting from apoptosis exposes the extracellular matrix, which potently activates platelet aggregation (30). Despite many features shared between activated and apoptotic ECs, the intracellular mechanisms are distinct. Known inducers of EC apoptosis include chemotherapeutic agents, high glucose and advanced glycation end-products, hypoxia, hyperoxia, and growth factor deprivation (31,32).

### Markers of Endothelial Cell Dysfunction

A variety of soluble molecules released from ECs have been assayed by enzyme-linked immunosorbent assay (ELISA) to

**Table 175-1: Responses of EC and EMP Release during EC Activation or Apoptosis**

Marker	Cell Line	Activation (TNF- $\alpha$ )		Apoptosis (GFD)		Untreated (Control)

The table shows EC responses and EMP release as judged by fluorescent-labeled antibodies to markers indicated at left, on whole ECs and EMPs after 24 hours of treatment to induce either activation (TNF- $\alpha$ ) or apoptosis (growth factor deprivation, GFD). Whole ECs were measured by flow cytometry after detachment by trypsin in terms of mean fluorescent intensity; EMPs are relative numbers detected per mL of media supernatant. Results are shown for three cell lines: renal microvascular ECs (RmVEC), brain microvascular ECs (BmVEC), and coronary artery macrovascular ECs (CMVEC). The arrows indicate increase (*up*) or decrease (*down*) relative to untreated control values at right: ↑ = 15% to 2-fold; ↑↑ = 2- to 10-fold; ↑↑↑ = >10-fold; ↓ = 15% to 25% reduction; ↓↓ = 25%–50%; ↓↓↓ = >50% reduction. EMP results at right are in terms of numbers detected  $\times 10^6$ /mL. All experiments were repeated at least three times and reproducibility was good as shown by  $\pm \sigma$ . The upper three markers are constitutive; the lower four (*beneath heavy line*) are inducible – i.e. respond to stimulation. Apoptosis was evaluated by TUNEL assay and checked for viability by trypan blue dye exclusion: only 0.5% to 2% of TNF- $\alpha$ -treated cells were positive for apoptosis; whereas 50%  $\pm$  10% and 65%  $\pm$  10% of RmVEC and BmVEC, respectively, were positive following deprivation of growth factor. However, CMVEC resisted apoptosis, only 5%  $\pm$  3% being positive after this treatment.

assess endothelial dysfunction (33). These include VCAM-1, ICAM-1, E-selectin, thrombomodulin (TM) (34), and vWF (3,35). However, none of them is yet widely accepted for clinical testing. A major drawback of these methods is lack of specificity. ICAM-1, for example, is expressed by activated cells of many lineages. Similarly, vWF is not specific for ECs, because it is also released by megakaryocytes and platelets (35). Some of these soluble markers have been shown to be partly bound to MPs (3), and therefore their measurement may overlap with EMP assay.

Circulating ECs (CECs) have been described in patients with cardiovascular diseases (36,37). Because CECs are present in quite small numbers, a large volume of blood is required for their measurement. In recent years, the EMP assay is emerging as a promising new marker of endothelial dysfunction, as

reviewed in the following sections. However, there is a limitation of EMP study as well. EMPs may not carry certain markers of parent cells, and biologic markers of parent cells are not equally expressed on EMPs, as seen in Table 175-1. Accordingly, combined analysis of both CECs and EMPs should improve overall evaluation of ECs.

**MECHANISMS OF ENDOTHELIAL MICROPARTICLE GENERATION**

EMPs are released from the parent cells under many conditions, including: (a) activation or apoptosis induced by numerous agents, (b) partial or complete lysis such as by complement, (c) oxidative injury, and (d) other insults such as high shear

stress (38). The detailed mechanisms of MP release remain obscure. However, a rise in cytosolic calcium concentration, either from internal stores or from plasma, appears to be a necessary triggering event or common pathway for vesiculation in ECs and other cells. Elevated calcium can induce cytoskeletal contraction, thought to be the driving force for apoptotic membrane blebbing (39). Shedding of membrane blebs requires partial breakdown of the cytoskeleton. It was shown that calcium-dependent proteases such as calpain and caspase (40) are capable of breaking down cytoskeleton to facilitate MP release.

The mechanism of EMP release is probably similar to that for other cells such as platelets (6). More recently, Jy and colleagues have shown by fluorescent microscopy that release of CD31 (platelet-endothelial cell adhesion molecule [PECAM]-1)<sup>+</sup> EMPs is preceded by localized accretions of CD31 on the cell surface of renal microvascular ECs, a phenomenon known as capping (41). Specifically, we showed that EMP release correlated with the percentage of fully capped cells, measured at different time intervals (0, 2, 4, 8, 24 hours from addition of agonist TNF- $\alpha$ ). Fluorescent images of caps resolved numerous MPs apparently in the act of being shed from microvilli (or pseudopodia) protruding from the caps. These observations suggest that capping of membrane proteins (or other focal adhesions) is a necessary prelude to the shedding of at least some species of EMPs (Figure 175.1). It is now well known that membrane surface proteins are quite mobile and can agglomerate by virtue of lipid rafts (42,43), areas of distinctive lipid and protein composition, studied by differential solubility in detergents, a topic now overlapping with phenomena such as patching and capping, focal adhesions, and receptor clustering. A variety of enzymes, known or hypothetical, have been implicated in membrane blebbing and vesiculation, including scramblase, floppase, calpain,

Figure 175.1. Models of microparticle shedding from endothelium. (A) Model of random shedding: endothelial microparticles (EMPs) were shed randomly from membrane surface of endothelium. Each microparticle carried all or most surface antigens of endothelium. (B) Programmed shedding from specific caps: cell stimulation induces surface antigens clustering/capping, followed by shedding of EMPs from different caps. This process will result in different species (phenotypes) of EMPs.

and PL translocase (6). Many lines of evidence suggest that EMP generation is not a random or unregulated response but is a programmed shedding, varying with specific stimuli to result, for example, in EMPs expressing characteristic phenotypes or functions in defined proportions, *in vitro* and *in vivo*.

## HETEROGENEITY OF ENDOTHELIAL MICROPARTICLES

EMPs display heterogeneity in size, density, and antigenic profile. These differences may occur in response to the same agonist, owing to variation in timing, incubation conditions, or the vascular origin of the ECs. Phenotypic heterogeneity of EMPs is also seen with different agonists. For example, Jimenez and colleagues employed flow cytometry of seven markers in three different EC types to show that TNF- $\alpha$  and growth factor deprivation result in different phenotypes of ECs and EMPs (Table 175-1) (5). In these studies, it was noted that the ratio of EMPs counted by two markers, CD62E (E-selectin)<sup>+</sup> EMPs/CD31<sup>+</sup> EMPs, was always more than 4.0 in activation but less than 4.0 in apoptosis. CD54 (ICAM-1)<sup>+</sup> EMPs/CD31<sup>+</sup> EMPs gave similar discrimination. Whether these criteria can be applied to interpret the EC status in clinical settings has not been established. The answer to this could influence treatment modalities or preventive strategies.

When applied to patients with TTP, the above criterion (ratio of CD62 [E-selectin]<sup>+</sup> EMPs/CD31<sup>+</sup> EMPs) led to the conclusion that EMPs in TTP are activated, not apoptotic (5). These data are consistent with our findings that neither TNF- $\alpha$  nor plasma from TTP patients induces EC apoptosis *in vitro* (5,18). Others have shown that TTP plasma does induce apoptosis of certain EC subtypes in cell culture (44). One likely explanation for these discrepancies is that other investigators have used “proapoptotic” conditions prior to adding the plasma of TTP patients (44). These conditions include decreased levels of growth factors in contrast to culture conditions in which ECs are maintained in optimal growth conditions at all times. Thus, it is conceivable that ECs cultivated in the presence of suboptimal levels of growth factors and fetal calf serum may be more susceptible to apoptosis (45).

This method may be applicable to other diseases to resolve the same question, such as whether apoptotic ECs are prominent in specific coronary conditions, a continuing controversy. Further potential applications of EMP phenotype analysis are under investigation.

## Electron Micrographic Evidence of Endothelial Microparticle Heterogeneity

Representative electron micrographs of EMPs from TNF- $\alpha$ -activated or serum-deprived apoptotic renal microvascular ECs are shown in Figure 175.2. The principal

Figure 175.2. Electron microscopy of EMPs induced by apoptosis or activation. Morphology of EMPs released from (A) apoptotic or (B) activated renal ECs.

observations are that (a) EMPs exist in a range of sizes and densities; (b) EMPs derived from activated ECs mainly comprise plasma membrane vesicles, lacking significant granule or electron-dense material (Figure 175.2A); and (c) EMPs resulting from EC apoptosis consist mainly of electron-dense vesicles and/or fragments of granules (Figure 175.2B). For other examples of electron micrographs of EMPs, the reader is referred to (20,46).

### Clinical Evidence of Endothelial Microparticle Heterogeneity

In studies of MS (19) and CAD (47), it was found that the diagnostic significance of EMP levels depended on which marker was used to identify and count them. For example, when CD51 (vitronectin receptor) positivity was the crite-

rium, patients with MS showed chronic elevation irrespective of exacerbation or remission; but when CD31 positivity was the criterion, significant elevation during exacerbation compared to remission was clear (19). This was also observed in a study of EMPs in CAD: CD31<sup>+</sup> EMPs identified acute disease whereas CD51<sup>+</sup> EMPs identified chronic stage (47) (discussed later). Consistent with the link between CD51 and chronic stage disease, Simak and colleagues reported that in patients with paroxysmal nocturnal hemoglobinuria (PNH), CD105 (endoglin)/CD54 (ICAM-1) EMPs were elevated during chronic activation (and failed to correlate with hemolysis) whereas CD105 (endoglin)/CD144 (vascular endothelial [VE]-cadherin) EMPs were detected in acute states (48). This is consistent with our findings in MS and CAD.

### COMPOSITION OF ENDOTHELIAL MICROPARTICLES (AND OTHER MICROPARTICLES)

MPs consist mainly of PLs and proteins, but their composition depends on cell origin and the stimulating agent or condition inducing their release. Some MPs may carry cytoplasmic materials. The lipid bilayers of the plasma membrane have been shown to be disturbed prior to release of MPs (29), leading to expression of negatively charged PS on the MPs, which has been shown to play an important role in blood coagulation (29).

Weerheim and colleagues analyzed the PL composition of MPs in normal blood and found that they include 60% phosphatidylcholine (PC) with the remainder being sphingomyelin, phosphatidylethanolamine (PE), and PS (49). In contrast, Fourcade and colleagues reported that MPs obtained from synovial fluids from the inflamed joints of arthritis patients contained more evenly distributed PC, PE, sphingomyelin, and lysophospholipids (50). MPs in the synovial fluids are mainly derived from leukocytes whereas MPs in blood are mainly released from platelets (51,52). It is possible that differences in lipid composition of MPs may be due to different cell origins or types of stimulation.

Profiles of surface antigens on MPs may provide information about the status of the parent cell. We have found in vitro that EMPs from activated ECs are enriched in CD62E (E-selectin) and CD54 (ICAM-1) antigens. In contrast, EMPs derived from apoptotic ECs are enriched in CD31 antigens (5). However, not all surface antigens of the parent cells are necessarily expressed on MPs. For example, T-cell-derived MPs lack CD28 and CD45 antigens, although they are among the most abundant antigens on the parent T-cells (53). We also observed that CD51 antigens are highly expressed on ECs but weakly on EMPs in EC tissue culture stimulated with TNF- $\alpha$ . It therefore appears that MP shedding is a highly selective and variable process (Figure 175.2). It may involve selective variations in membrane antigen clustering (or capping) associated with distinctive types of lipid rafts (41,54), depending on particular activation pathways.

## MEASUREMENT OF ENDOTHELIAL MICROPARTICLES

### Methods of Endothelial Microparticle Assay

#### Flow Cytometry

The majority of studies to date have employed flow cytometry to assay EMPs. Most commonly, platelet-poor plasma (PPP) is incubated with fluorescence-labeled, endothelium-specific antibodies (or annexin V [AnV]) for 20 to 30 min and then sorted by FACS (3). Results are usually expressed in counts per L or mL. However, detailed procedures vary significantly in different laboratories. Among the most important inter-lab differences are speed of centrifugation to prepare PPP and the labeling of antibodies used for identification. At this time, no consensus or standardized protocols for EMP assay by flow cytometry exist.

A preferred method in our laboratory is the use of 2-color combination of PE-labeled anti-CD31 and FITC-labeled anti-CD42 (55,56) in a single run. Because CD31 occurs also on platelets, platelet-specific CD42 allows for distinction between PMPs (CD31<sup>+</sup>, CD42<sup>+</sup>) and EMPs (CD31<sup>+</sup>, CD42<sup>-</sup>). The CD31 marker has the further advantage of being quite bright (abundant), as shown in the EMP assay, and therefore is sensitive. Other investigators report favorably on use of CD144 VE-cadherin).

This basic method is simple with fast turnaround time and is thus well suited for clinical testing. In addition, by using whole blood samples and multiple markers, interaction of EMPs with other populations of cells can be investigated; new studies exploring the interaction of EMPs with leukocytes and platelets have been reported in several laboratories including ours (57,58). Similar studies were performed with PMPs or LMPs, delineating cell-cell interactions mediated by various MPs (e.g., PMP-leukocyte interactions) (6,15).

EMPs can be further characterized using additional markers. These can be tentatively classified into two groups based on patterns of EC expression: (a) inducible markers reflecting EC activation including CD54 (ICAM-1), CD62E (E-selectin), CD106 (VCAM-1), tissue factor, and MCP-1; and (b) constitutive markers, expressed in the resting state, including CD51/CD61 (vitronectin receptor,  $\alpha_V\beta_3$  integrin complex), CD31, CD105 (endoglin), CD144 (VE-cadherin), and CD146 (S-endo1). In several studies, inducible antigens have been reported to be more elevated during the acute phase of some diseases relative to constitutive antigens. However, some of these markers, notably CD54 (ICAM-1) and tissue factor, are not EC-specific, but rather are widely expressed by other activated cells. However, MPs from nonendothelial origin can be excluded by using a second antibody specific to the non-ECs.

#### Annexin V/Prothrombinase Assay

In this widely used method (59–63), MPs are captured by their binding to AnV in the presence of calcium, then assayed for prothrombinase activity. This involves incubation of immobilized (captured) MPs with factors Xa and Va as well as prothrombin and starting the reaction by addition of cal-

cium. Thrombin generation is monitored using a chromogenic substrate. Quantity of PL expressed on MPs is inferred from a standard curve obtained with defined liposomes. Secondary identification of MP types (PMPs, EMPs, LMPs) is performed by ELISA with cell-specific antigens.

The most serious objection to this method is that only a fraction of EMPs are positive for AnV (small fraction for activated MPs, larger fraction for apoptotic MPs). AnV binding depends on anionic PLs, chiefly PS, which is largely responsible for prothrombinase activity; thus, this assay will miss all MPs that are negative for AnV binding and selectively favors EMPs from apoptotic ECs.

### Limitations Associated with Endothelial Microparticles Assays

Although EMPs are now regarded as highly promising new markers of EC perturbation, many problems remain to be resolved before EMP assays reach the clinical mainstream (64,65). A major limiting factor has been the lack of consensus or standardization of methods, making it difficult or impossible to compare data between labs. As a first step toward addressing this problem, a committee was organized under auspices of the International Society of Thrombosis and Haemostasis. The recent forum detailed methods of detection from six labs (including our own) (55) (Table 175-2). Future workshops will address the need for and implementation of a uniform method, or at minimum the use of a reference standard sample for MP assay.

## POTENTIAL FUNCTIONS OF ENDOTHELIAL MICROPARTICLES (AND OTHER MICROPARTICLES)

As of yet, little is definitely established about EMP functions. However, circumstantial evidence has led to a growing consensus that EMPs can act as diffusible messengers, carrying molecules to specific targets and interacting with blood cells to modulate inflammation and thrombosis.

Figure 175.3 summarizes recent concepts of EMPs in blood coagulation, inflammation, and thrombosis.

### Coagulation

Coagulation is usually triggered by tissue factor but completing the coagulation cascade requires a membrane surface exposing anionic PLs such as PS to facilitate assembly of the tenase and prothrombinase complexes. Most (but not all) MPs do in fact carry anionic PLs, especially PS, as well as tissue factor (66). Both of these procoagulant activities are known to occur on EMPs, LMPs, and PMPs (18,46,59,61,67). In addition, some MPs also carry tissue factor pathway inhibitor (TFPI) (68). However, the relative magnitude of tissue factor and TFPI activities on different types of MPs is not yet clear, nor is the importance of these activities on MPs

**Table 175-2: Techniques for Measuring of Endothelial Microparticles by Different Laboratories**

Authors (Refs.)	Principal Technique	Quantitation	Anticoagulant	Prepare PPP	Isolation MP Pellet	Generic MP Detection	Endothelial Markers

known in relation to the procoagulant properties of whole cells.

Tissue factor activity in particular has been difficult to quantify, with conflicting reports, apparently because of variable expression of cryptic tissue factor and masking by TFPI (69,70); we have attributed variable results partly to sensitivity to sulfhydryl redox state, masking by TFPI and to variably prolonged lag phase (71). Although the majority of MPs are procoagulant, some reports have demonstrated that MPs may be anticoagulant under certain conditions. Tans and colleagues suggested that PMPs could serve an anticoagulant function by supporting the protein C/S/TM pathway (72). Gris and colleagues demonstrated that a large fraction of protein S is MP-associated and that clinical assays using PEG precipitation cause underestimation of protein S because much of it

is precipitated with MPs (73). More recently, Berckmans and colleagues have shown that low levels of thrombin generation by MPs in normal controls is via the contact pathway (independent of tissue factor) and may serve an anticoagulant function, on the grounds that protein C could thereby be activated by the trace of thrombin (51). It is now appreciated that a low but steady state of tissue factor activity is essential to normal hemostasis, but held in delicate balance, possibly regulated by MPs.

**Leukocyte Adhesion and Transmigration**

Jy and colleagues first demonstrated that PMPs interact with leukocytes (15). They showed that PMPs can bind to leukocytes via a P-selectin-dependent pathway. The binding of PMPs to leukocytes leads to leukocyte activation and aggregation, with formation of large grape-like clusters of leukocyte-PMP complexes (15). Barry and colleagues showed that PMPs interact with ECs to result in upregulation of CD54 (ICAM-1) on ECs and the subsequent adhesion of monocytes to ECs (74). Mesri and Altieri also showed that LMPs can interact with ECs to induce IL-6 release (75).

Recently Sabatier and colleagues demonstrated that EMPs can bind to and activate cultured THP-1 monocytic cells, as judged by induced expression of tissue factor antigen, and that this effect could be largely inhibited by anti-CD54 (ICAM-1) antibodies (76). Similarly, Jy and colleagues reported that EMPs induce expression of the activation marker CD11b in whole blood-derived leukocytes via a CD54 (ICAM-1)-dependent mechanism (58). In the latter study, EMPs interacted most strongly with monocytes, less so with neutrophils, and hardly at all with lymphocytes.

Interestingly, EMPs derived from TNF- $\alpha$ -activated ECs had a greater effect on leukocytes compared with those derived from ECs undergoing apoptosis resulting from serum deprivation (58). In binding studies, EMPs prelabeled with CD54 (ICAM-1) exhibited greatest binding to U937 monocytic cells,

**Figure 175.3. Potential functions of EMPs.** Several subspecies of EMPs and their potential functions have been identified: (A) tissue factor positive (TF<sup>+</sup>) EMPs have been demonstrated to initiate and promote blood coagulation; (B) CD54<sup>+</sup> or CD62E<sup>+</sup> EMPs are capable of binding to leukocytes and inducing leukocyte activation; (C) von Willebrand factor positive (vWF<sup>+</sup>) EMPs may cause platelet adhesion and aggregation.

compared with EMPs prelabeled with PECAM-1 (CD31), E-selectin (CD62E), or vitronectin receptor (CD51). Moreover, the CD54 (ICAM-1)-labeled EMPs were largely depleted in the cell-free supernatant, consistent with the majority having bound to the U937 cells (58). Based on these observations, it was proposed that the unexpectedly low concentration of CD54 (ICAM-1)<sup>+</sup> EMPs found in blood in various disease states may be explained by their preferential binding to leukocytes, reducing their free concentration.

Finally, Jy and colleagues also demonstrated that monocytes with adherent EMPs were facilitated in their passage through an endothelial monolayer (58). Taken together, these findings suggest that at least one function of EMPs may be to modulate inflammation via leukocyte activation and transendothelial migration. The complex interactions among EMPs, platelets, and leukocytes is summarized in Figure 175.3.

### Endothelial Cell Function

It has been reported that MPs released from platelets or leukocytes can influence endothelial function. For example, Boulanger and colleagues reported that MPs from patients with acute MI impaired endothelium-dependent relaxation in isolated arteries (77). In contrast, MPs isolated from patients with nonischemic chest pain had no such effect. High concentrations of MPs from MI patients affected neither endothelium-independent relaxation to sodium nitropruside nor expression of the endothelial NO synthase (eNOS). The origin of the MPs isolated from MI patients was not identified. In another study, VanWijk and colleagues demonstrated that MPs isolated from preeclampsia patients impaired endothelium-dependent relaxation in isolated myometrial arteries (78,79). It was suggested that these MPs may contain oxidized PLs, which are potent inhibitors of endothelium-dependent arterial relaxation (80). However, some MPs may have a beneficial effect on endothelium. Barry and colleagues showed that PMPs can transfer arachidonic acid to ECs and result in prostacyclin production, which will induce vascular relaxation (81). Recently, it was reported that PMPs promote proliferation, survival, migration, and tube formation in HUVECs (82). These results suggest that the lipid component(s) of the PMPs may be major active factor(s) and that protein component(s) may be minor contributor(s). Other pro- and antiangiogenic factors associated with PMPs were recently reviewed (8).

### Endothelial Microparticles as Diffusible Biomessengers

EMPs and other MPs are now considered as important biomessengers, delivering adhesins, peptides, cytokines, and pro- and anticoagulant factors to modulate thrombosis and inflammation, and perhaps other functions—e.g., antigen presentation (8) and angiogenesis (82). However little is known of the details of such putative roles.

Recent studies demonstrated that EMPs carry unusually large vWF (ULvWF) multimers and participate in thrombosis and hemostasis (57,83). EMP-associated vWF promotes formation of platelet aggregates that are more stable (less dissociable, more irreversible) than aggregates formed by free vWF (57).

A multitude of adhesion molecules (adhesins) are associated with EMPs, including VCAM-1, E-selectin, CD54 (ICAM-1), CD144 (VE-cadherin), and vitronectin receptor, as well as cytokines and pro- and antiangiogenic factors such as vascular endothelial growth factor (VEGF). In addition, conformationally distinctive prion proteins, believed to aid in the propagation of spongiform encephalopathies (SEs), have been detected on EMPs released by infected ECs (84). This finding suggests that EMPs may be active players in the infectious process of SEs.

A recent report from Hussein and colleagues documented caspase-3 inside of EMPs and other MPs (85). They speculate that caspase-3 may be involved in membrane vesiculation and that shedding of caspase-3 in MPs is one way ECs minimize or escape from apoptotic commitment. They also propose the possibility that caspase-3 in MPs may be delivered to other cells, inducing apoptosis in the target cell. Consistent with this hypothesis are studies demonstrating that incubation of MPs from acute coronary syndrome (ACS) patients with ECs in vitro induces EC dysfunction (77,86). The functional role of caspases in MPs, if any, remains unclear. However, it is tempting to speculate caspase-positive MPs deliver death signals to other cells. It is easy to imagine them being phagocytosed, thus liberating active caspase-3 in phagocytes. (It is known that PS signals phagocytosis via a PS receptor (87,88), although the specificity of this is recently questioned (89).

## CLINICAL APPLICATIONS

### Coronary Artery Disease

Mallat and colleagues first reported elevated cell-derived MPs in patients with ACS (67). They used the AnV/prothrombinase (ELISA) assay to measure procoagulant activity of cell-derived MPs and specific antibodies (anti-CD146 (S-endo1), anti-CD31, anti-CD3, anti-CD11a, and anti-GP1b) to determine their origin. The circulating procoagulant MPs were significantly higher in patients with acute MI and unstable angina (UA) than in those with stable angina (SA) or controls who had negative angiographic findings for CAD but were not different between SA and controls. In ACS, MPs did not discriminate acute MI from UA. ACS was associated with MPs positive for CD146 (S-endo1) or CD31, but not for GP1b (platelet marker), CD3 (lymphocyte marker), CD11a (marker for activated leukocytes). They concluded that CD31<sup>+</sup>/CD146 (S-endo1)<sup>+</sup> MP are of endothelial origin and contribute to thrombin formation in the injured endothelium.

Using flow cytometry for EMP assay, Bernal-Mizrachi and colleagues reported elevated EMPs in ACS, contributing a number of new insights (47). Two species of EMPs

(CD51<sup>+</sup> and CD31<sup>+</sup>/CD42b<sup>-</sup>) as well as PMPs were measured in patients with MI, UA, SA, and healthy controls. CD31<sup>+</sup>/CD42b<sup>-</sup> EMPs and PMPs were elevated in patients with ACS (acute MI plus UA) relative to SA and healthy controls. However, CD51<sup>+</sup> EMPs were similarly elevated in both ACS and SA, suggesting that these two species of EMPs reflect different aspects of the pathology (89). Thus, CD31<sup>+</sup> EMPs mark acute ischemic injury whereas CD51<sup>+</sup> EMPs mark chronic injury. Also of interest was the observation that patients with a first episode of ACS had significantly higher CD31<sup>+</sup> EMPs than in those with chronic recurrent episodes, suggesting that the capacity for generation of EMPs is reduced in those with recurring ischemia. In those having a first episode, EMPs were significantly higher in acute MI than UA, suggesting that EMP levels reflect severity of vascular lesions. In a recent study, EMP levels were compared between various angiographic lesions in patients with ACS, revealing that EMP levels were higher in those with high risk lesions compared to low risk lesions by Ambrose classification (90).

In a prospective, randomized study, Morel and colleagues (91) evaluated the effect of the antioxidant vitamin C on AnV<sup>+</sup>/CD31<sup>+</sup> EMP generation in patients with acute MI. Administration of vitamin C significantly decreased EMP generation in those with dyslipidemia and other high-risk factors compared to placebo group. This may suggest that oxidation underlies endothelial injury in hyperlipidemia and other risk conditions.

A recent study by Boulanger and colleagues demonstrated that circulating MPs from patients with acute MI caused impaired relaxation of rat aortic rings in vitro and caused severe endothelial dysfunction in healthy blood vessels by affecting endothelial NO transduction pathway, whereas MPs isolated from patients with nonischemic diseases had no such effect (77). Heloire and colleagues (92) observed that EMPs released from ECs in culture bind to platelets to form EMP-platelet aggregates and found that circulating EMP-platelet aggregates varied among stable CAD, acute MI, and healthy controls. They reported that EMP-platelet aggregates were significantly increased in patients with stable CAD compared with healthy controls. However the levels were lower in the first hours following acute MI, suggesting that EMPs released from activated ECs on atherosclerotic plaques were consumed locally and contributed to recruitment of platelets and formation of thrombus in injured coronary arteries. These findings indicate that EMPs are not only the markers of EC injury but also play a role in the pathogenesis of occlusive vascular disorders.

### Metabolic Syndromes and Postprandial Hyperlipidemia

#### Metabolic Syndrome

Metabolic syndrome is a combined disturbance of insulin and glucose metabolism, obesity, dyslipidemia, and hypertension, which affects some 10% of middle-aged males in the United States. This condition presages atherosclerosis and CAD and is thus a serious challenge to public health (93,94).

We observed elevated EMPs (CD31<sup>+</sup> or CD54 [ICAM-1]<sup>+</sup>), PMPs (CD62P<sup>+</sup>), and platelet-leukocyte conjugates in patients with metabolic syndrome, suggesting underlying activation of the endothelium, platelets, and white blood cells (95). These findings indicate that early prophylactic intervention is called for with this syndrome, and that EMP assay can assist by monitoring the status of metabolic syndrome.

#### Postprandial Hyperlipidemia

Ferreira and colleagues documented a rapid rise of EMPs in parallel with postprandial hyperlipidemia, at 1 and 3 hours following ingestion of a high-fat meal in young healthy volunteers, free of known risk factors (96). Correlation analysis revealed a positive association between levels of CD31<sup>+</sup>/CD42<sup>-</sup> EMPs and triglyceride ( $p = 0.003$ ) (96). However, EMPs measured by CD62E (E-selectin) showed no such relation, providing further evidence for the existence of distinct EMP species. There was no significant increase in EMPs or triglyceride levels following an isocaloric low-fat meal, indicating that neither the caloric intake nor the postprandial state alone affected EMP release.

In sum, these studies indicate that EMPs are sensitive markers of endothelial disturbance in different stages of atherosclerosis. EMPs were released from normal healthy endothelium upon transient injury brought on by hyperlipidemia following fatty meals, in early chronic stages of atherosclerosis (metabolic syndrome) and in late advanced states of atherosclerosis (acute MI) in CAD.

#### Thrombotic Thrombocytopenic Purpura

In TTP, EC injury elicits platelet adhesion and aggregation in the microvasculature, leading to consumptive thrombocytopenia, microangiopathic hemolytic anemia, and fluctuating neurological dysfunction. Unusually large multimers of vWF (ULvWF) released from injured ECs are normally rapidly proteolyzed by ADAMTS13 in plasma. In TTP, a deficiency of ADAMTS13 results in impaired proteolysis of unusually large vWF. These multimers, in turn, play a pivotal role in initiating platelet adhesion and aggregation within the microvasculature. The presence of procoagulant EMPs in patients with TTP was first reported by Jimenez and colleagues (18). Compared to normal controls or ITP patients, both CD31<sup>+</sup>/CD42b<sup>-</sup> and CD51<sup>+</sup> EMPs were significantly elevated in TTP (18,97); levels rose in acute phases, returning toward normal with approach to remission (18). In a sequential study in patients with recurring TTP, we observed that EMP elevation appeared to precede other markers of disease activity such as thrombocytopenia and LDH. In more recent studies, CD62E (E-selectin)<sup>+</sup> EMPs were shown to be a more sensitive marker of TTP compared with CD31<sup>+</sup> EMPs (5,83). CD62E (E-selectin)<sup>+</sup> EMPs have other properties of interest, as discussed in the following section.

Recently, it was shown that many of the EMPs (particularly the CD62 [E-selectin]<sup>+</sup> population) in TTP are positive for vWF (83). This observation is significant, given the putative

pathophysiological role for aberrant ADAMTS13-mediated processing/cleavage of ULvWF in TTP (98). It has recently been shown by a ristocetin-based assay that platelet aggregates induced by vWF-positive EMPs are significantly more stable (resistant to dissociation) than aggregates formed by free soluble vWF (57). This effect is expected to enhance formation of platelet-rich thrombi *in vivo* at sites of EC injury. These data raise the interesting possibility that vWF<sup>+</sup> EMP-platelet interactions contribute to TTP pathogenesis.

### Preeclampsia

Gonzalez-Quintero and colleagues conducted a prospective study investigating CD31<sup>+</sup>/CD42b<sup>-</sup> and CD51<sup>+</sup> EMPs in pregnant women with preeclampsia and found that both types of EMPs were elevated in preeclampsia compared to normal pregnancy (99). EMPs in normal pregnancy were also higher than nonpregnant normal controls. More recently, the same group detected the presence of CD31<sup>+</sup>/CD42b<sup>-</sup> or CD62E (E-selectin)<sup>+</sup> EMPs in a larger number of patients with preeclampsia and gestational hypertension (100). Both EMP populations were significantly elevated in preeclampsia (> gestational hypertension > normal pregnant controls). They also observed a correlation between mean arterial pressure and both subsets of EMPs. Moreover, EMP levels paralleled the degree of proteinuria.

VanWijk and colleagues (78,101) investigated various subsets of MPs from ECs, T-helper and suppressor cells, B cells, platelets, granulocytes, monocytes, and erythrocytes in patients with preeclampsia, normal pregnancy, and nonpregnant healthy women. They observed that total numbers of MPs were similar in all three groups and that PMPs constituted the largest proportion of MPs in all groups. In patients with preeclampsia, MPs derived from T-helper and suppressor cells and granulocytes were significantly increased compared to normal pregnant women. Elastase concentration was also significantly increased and it correlated with granulocyte MPs and with blood pressure. Although EMP levels (CD62E [E-selectin]<sup>+</sup> and CD144 [VE-cadherin]<sup>+</sup> EMPs) were higher in preeclampsia, the difference was not statistically significant in this small number of patients. They suggested that activations of immune system, inflammatory cells, and endothelium are present in preeclampsia and could play a central role in the pathogenesis.

Bretelle and colleagues (102) investigated total MPs (defined as AnV<sup>-</sup> positive), EMPs (CD51<sup>+</sup>), and PMPs (CD41<sup>+</sup>) in normal pregnancy and pregnancy complicated by preeclampsia and intrauterine growth restriction (IUGR). They reported increased total MPs (with increased procoagulant activity), EMPs, and PMPs in normal pregnancy compared with normal nonpregnant women. Unexpectedly in pathologic pregnancy, total MPs, PMPs, or EMPs were lower or not different compared to normal pregnancy. It was speculated that MPs might be sequestered in placenta or bound to other cells (102).

Conflicting reports on MPs in preeclampsia among these different studies remain to be explained. However these inves-

tigations employed different assays, measured different species of MPs and included a relatively small number of patients. Nevertheless, the discordance exemplifies the problems associated with MP assays and underscores the need for standardization of the MP assay.

### Diabetes Mellitus

Sabatier and colleagues measured CD51<sup>+</sup> EMPs, CD41<sup>+</sup> PMPs, CD45<sup>+</sup> or CD66b<sup>+</sup> LMPs, and total AnV<sup>+</sup> MPs in patients with type I and 2 DM and age matched healthy controls (103). In type 1 DM, EMPs, PMPs, and total AnV<sup>+</sup> MPs were significantly elevated compared to the healthy controls. Total MPs were associated with increased procoagulant activity, which in turn was correlated with HbA1c. The levels of EMPs were correlated with albuminuria in type 1 DM and highest among those with microvascular complications. In contrast, in type 2 DM, total AnV<sup>+</sup> MPs were significantly elevated without concomitant increase of their procoagulant activity. These latter patients demonstrated increased levels of LMPs but not EMPs or PMPs. Nomura and colleagues documented elevations of EMPs, PMPs, soluble P-selectin, and CD40L as well as antioxidized LDL antibodies in DM (104). EMP levels correlated with nephropathy and antioxidized LDL antibody titers. Taken together, these studies suggest that procoagulant cell-derived MPs may play a role in the pathogenesis of diabetic vasculopathy, and that EMPs can serve as a marker for endothelial dysfunction in this disease.

### Hypertension

Preston and colleagues studied CD31<sup>+</sup>/CD42b<sup>-</sup> EMPs and CD41<sup>+</sup> PMPs in patients with severe malignant hypertension (diastolic blood pressure >120 mm Hg), moderate hypertension (95–100 mm Hg), and normotensive controls and found that CD31<sup>+</sup>/CD42b<sup>-</sup> EMPs were most significantly elevated in malignant and moderate hypertension compared to normotensives (105). EMPs correlated with systemic and diastolic blood pressure. PMPs were increased in malignant hypertension but not in moderate hypertension. EMPs were highest in malignant hypertension followed by moderate hypertension, whereas elevated PMPs were seen only in malignant hypertension. They also measured conventional soluble markers of EC disturbance, finding that sVCAM-1, sICAM-1, and vWF did not correlate with blood pressure. Among soluble markers of EC activation, only sVCAM-1 was significantly correlated with EMP levels. These findings indicate that EMPs are a more sensitive marker of endothelial injury associated with hypertension than more widely used soluble markers.

### Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus

Combes and colleagues first reported elevated EMPs in 30 patients with positive lupus anticoagulant (LA) (20). CD31<sup>+</sup>/CD51<sup>+</sup> EMPs in patients with LA were significantly

elevated relative to controls. EMP levels were about twofold higher in LA patients with a history of thrombotic events compared to those without a history of thrombosis. No association was observed between EMPs and age, sex, or anticoagulation.

Recently, Dignat-George and colleagues compared EMPs in five groups of patients: group 1 with antiphospholipid antibody syndrome (APS); group 2 with SLE without thrombosis but with positive antiphospholipid antibodies (APLA); group 3 with SLE without thrombosis and negative APLA; group 4 with thrombosis without SLE or APLA or autoimmune disease; group 5 normal controls matched for sex and age (63). They found elevated CD51<sup>+</sup> EMPs in groups 1 and 2 but not in groups 3 or 4. In parallel studies, plasma from different groups of patients was tested for its ability to generate EMPs in EC culture. They found that only APS plasma induced release of EMPs in vitro. They concluded that autoimmune processes associated with APLA induce release of EMPs, predisposing to thrombosis in APS.

### Multiple Sclerosis

Minagar and colleagues first documented elevated levels of EMPs in patients with MS (19). Two EMP phenotypes were assayed: CD31<sup>+</sup>/CD42b<sup>-</sup> and CD51<sup>+</sup>. CD31<sup>+</sup> EMPs were significantly higher in patients with exacerbation compared to those in clinical remission and healthy controls and correlated well with gadolinium enhancement in brain MRI and clinical disease activity. On the other hand, CD51<sup>+</sup> EMPs did not differ between patients in exacerbation and in remission yet were significantly higher than in healthy controls. These data are consistent with those observed in patients with CAD, providing further evidence that CD31<sup>+</sup> EMPs are a marker of acute endothelial injury, whereas CD51<sup>+</sup> EMPs reflect chronic endothelial dysfunction.

In a later study, Jy and colleagues demonstrated increased EMP–monocyte conjugates (EMP–mo–C) in patients with MS (58). EMP–mo–C were measured by two-color flow cytometry using anti-CD45 with anti-CD54 (ICAM-1) or anti-CD62E (E-selectin). EMP–mo–C were significantly elevated in patients with MS in exacerbation compared to those in remission or healthy controls. Moreover, EMP62E–mo–C were positively correlated with free CD62E (E-selectin)<sup>+</sup> EMP levels and the gadolinium enhancement in MRI lesions. However, CD54 (ICAM-1)<sup>+</sup> EMPs were much lower than CD62E (E-selectin)<sup>+</sup> EMPs and EMP54–mo–C were not correlated with free CD54 (ICAM-1)<sup>+</sup> EMPs. Under in vitro conditions, EMPs were shown to bind preferentially to monocytes (compared with neutrophils or lymphocytes) and to induce monocyte activation and transendothelial migration (58). CD54 (ICAM-1)<sup>+</sup> EMPs were most avid in binding, and this would explain very low CD54 (ICAM-1)<sup>+</sup> EMPs in peripheral blood of patients with MS (i.e., it exists but in bound form, not free). This study provided clues to the functional role of EMPs in MS, an inflammatory disorder. A more recent study confirmed these findings and extended them to gain insight on therapy with interferon (106).

### Systemic Vasculitis

Brogan and colleagues studied CD62E (E-selectin)<sup>+</sup> and CD105 (endoglin)<sup>+</sup> EMPs, along with PMPs, in pediatric systemic vasculitis (107). An elevation in CD62E (E-selectin)<sup>+</sup> EMPs and to a lesser extent CD105 (endoglin)<sup>+</sup> EMPs was observed in this disorder, relative to healthy or febrile controls. EMPs correlated with the activity of vasculitis and acute phase reaction products and were significantly higher than in patients who underwent remission. The elevation in EMPs in this disorder provides further evidence of EC injury (activation) in vasculitis.

Combes and colleagues reported increased CD51<sup>+</sup> EMPs in pediatric patients with uncomplicated malaria, cerebral malaria, and severe malaria with coma (108). EMPs were elevated upon admission in cerebral malaria compared to uncomplicated malaria or normal controls. Those with severe malaria presenting with coma had the highest EMP levels at admission. This finding indicates EC injury in severe and cerebral malaria and supports previous evidence for EC involvement in *P. falciparum* infection (108).

In a study by Ogura and colleagues, CD31<sup>+</sup>/CD54 (ICAM-1)<sup>+</sup> EMPs and EMP–neutrophil conjugates (EMP–N–C; CD31<sup>+</sup>/CD62E [E-selectin]<sup>+</sup>) were evaluated in patients with severe systemic inflammatory response syndrome (SIRS) (109). Patients exhibited elevated platelet and leukocyte counts, high C-reactive protein, and increased soluble markers such as thrombin–antithrombin III complexes, PAI-1, and D-dimer. Also elevated in SIRS were soluble CD62E (E-selectin), TM, PAI-1, and leukocyte oxidative activity. Circulating EMPs were significantly increased in SIRS patients, however, no significant correlation was observed between EMPs and soluble CD62E (E-selectin), TM or PAI-1. EMPs from SIRS were found to bind preferentially to neutrophils to form EMP–neutrophil complexes that were significantly elevated in SIRS. Based on these findings, it was hypothesized that EMPs bind to neutrophils to promote inflammation and thus may play an active role in SIRS-associated inflammation.

### Sepsis

Sepsis is associated with high mortality, and endothelial activation and apoptosis have been implicated in systemic multiorgan failure. The high mortality in sepsis was attributed in the past to uncontrolled hyperinflammation but recent findings challenge this, indicating that immunosuppression and impaired inflammatory reaction contributes to mortality (110). Soriano and colleagues studied EMP profiles in sepsis, along with intracellular NO (111), and investigated whether EMP profiles can predict mortality. Thirty-five patients with severe sepsis were recruited and EMPs (CD31<sup>+</sup>/CD41<sup>-</sup> EMPs, CD62 [E-selectin]<sup>+</sup> EMPs) and platelet–leukocyte conjugates were assayed along with other markers on days 1, 2, and 3 of admission. EMP levels were compared between survivors and nonsurvivors. Overall mortality was 51% at 28 days. CD31<sup>+</sup> EMPs and platelet–leukocyte conjugates were significantly

depressed, whereas NO in leukocytes was increased in nonsurvivors compared to survivors. However CD62E (E-selectin)<sup>+</sup> EMPs did not differ between two groups. EMP profiles measured at diagnosis of sepsis appear to be useful in predicting mortality in sepsis and support the hypothesis that reduced EC activation and impaired inflammatory response is related to mortality in sepsis. Therapeutic measures that suppress inflammatory responses should be carefully reassessed in the treatment of sepsis.

### Sickle Cell Disease

Shet and colleagues investigated circulating MPs in patients with sickle cell disease (SCD) crises, those with steady-state SCD, and normal controls (66). MPs were assayed by flow cytometry. Tissue factor expression and procoagulant activity of MPs was also evaluated. Multiple kinds of MPs were detected in patients with SCD, with MPs derived from erythrocytes (RMPs) being most abundant, followed by EMPs, PMPs, and LMPs. Total MPs were elevated in crisis compared to steady-state. EMPs and monocyte-derived MPs were positive for tissue factor and had procoagulant activity. Total MPs and tissue factor-positive MPs were highest in crisis, lowest in healthy controls, and intermediate in steady-state SCD. In functional studies, MPs from SCD but not from controls exhibited increased procoagulant activity. These data are consistent with the established role for inflammation and endothelial dysfunction in SCD and raise the possibility that

procoagulant MPs may contribute to the thrombotic phenotype in this disease (66).

### Paroxysmal Nocturnal Hemoglobinuria

Simak and colleagues measured EMPs and MPs derived from platelets, leukocytes, and erythrocytes in patients with PNH, SCD, aplastic anemia (AA), and normal healthy controls (48). Employing three-color flow cytometry, EMPs were defined as CD105 (endoglin)<sup>+</sup>/CD41<sup>-</sup>, CD45<sup>-</sup>; PMPs as CD41<sup>+</sup>, CD105 (endoglin)<sup>-</sup>, CD45<sup>-</sup>; LMPs as CD45<sup>+</sup>, CD105 (endoglin)<sup>-</sup>, CD41<sup>-</sup>; and RMPs as CD235a<sup>+</sup>, CD105 (endoglin)<sup>-</sup>, CD45<sup>-</sup>. PS-positive MPs were detected by AnV-binding. They observed that CD105 (endoglin)<sup>+</sup> EMPs expressing AnV were significantly higher in SCD and PNH than in AA or healthy controls; highest in SCD followed by PNH. An even more striking difference was seen when EMPs expressing inflammatory markers (CD105 (endoglin)<sup>+</sup>, CD54 [ICAM-1]<sup>+</sup> EMPs) were compared. MPs derived from platelets, leukocytes, and erythrocytes were also investigated and it was found that AnV<sup>+</sup> MPs and CD41<sup>+</sup> PMPs were significantly higher in SCD and PNH, whereas MPs derived from erythrocytes and leukocytes were significantly higher in SCD compared to PNH, AA, and healthy controls. Other species of EMPs (CD144 [VE-cadherin]<sup>+</sup> CD105 [endoglin]<sup>+</sup> MPs) were also increased in SCD and PNH over AA and controls. They concluded that MP profiles suggested inflammatory status of activated endothelium in SCD

and PNH, but not in AA and that analysis of EMPs appears promising to provide useful information on the status vascular endothelium.

**KEY POINTS**

- EMPs are membranous vesicles released upon perturbation of ECs such as activation or apoptosis. They are heterogeneous in size, density, phenotypes, and likely functions and carry membrane proteins and PLs of the parent cells. Accordingly, EMP analysis can provide valuable information regarding the status of ECs.
- EMP assays is emerging as a useful biomarker reflecting endothelial disturbances in various thrombotic, inflammatory, and vascular disorders. Main types of clinical disorders to which EMP analysis are now applied include (a) thrombotic disorders such as ACS, hypertension, DM; (b) small-vessel diseases such as TTP, preeclampsia, and some ischemic dementias; (c) autoimmune and inflammatory disorders such as MS, SLE, APS, systemic vasculitis, and sepsis; and (d) hemolytic disorders such as SCD and PNH. By employing extended panels of markers for phenotype analysis, the assay can detect multiple species of EMPs, and their interaction with other cells that have been applied in clinical studies (Table 175-3).

**Future Goals**

- To achieve standardization of methods, which is a major challenge that must be surmounted before EMP assays can enter the mainstream of clinical testing (55)
- To understand the mechanisms of release, which are important to relating type of injury to molecular pathways responsible for a specific phenotype of EMPs. Our finding that capping seems to precede release of at least some species of EMPs (40) is also a step in that direction. Some workers are developing methods that specifically inhibit MP release, a potentially valuable research tool.
- To understand the functions of EMPs. There is growing consensus that EMPs and other MPs can act as diffusible messengers, transporting bioactive agents to initiate and mediate coagulation, inflammation, and cell-to-cell interactions (64). EMPs are also known to express tissue factor, promote coagulation, carry off complement, activate leukocytes, and enhance leukocyte transmigration (57,74). The role of EMPs in binding large-multimer vWF, promoting unusually stable platelet aggregates is recently docu-

mented in TTP (57). New roles of EMPs remain to be elucidated in the future.

- To search for greater specificity. Clinical studies showed that EMP assay can yield specific information such as activation versus apoptosis and acute versus chronic injury and even mild or transient or advanced EC perturbations. However, greater specificity of the assay is needed to distinguish various endothelial perturbation in clinical disorders. It is expected that more refined phenotypic profiling of EMPs along with functional assay will lead to further improvements in discriminating specific disease states or kinds of endothelial injury. Ideally, future research could lead to the ability to identify the site of vascular injury (organ or vascular bed), because it is already known that each organ or vascular bed contains unique markers (“addresses”), which might be carried on EMPs. This will further improve the sensitivity and specificity of the assay.

<sup>§</sup>Technical University Munich, Germany

Clinical assessment of the endothelium and vasculature by magnetic resonance imaging (MRI) has conventionally focused on assessment of lumen integrity using contrast and noncontrast angiographic techniques and assessment of macroscopic alterations in vessel wall structure (1–5). Phase-contrast MRI may be employed to measure intravascular flow velocity, and cine MRI may be used to assess vascular distensibility (6). These techniques can be applied to detect endothelial dysfunction as measured by flow-mediated dilation (as has been studied more extensively using ultrasound techniques) (7). Thus, MRI offers a range of applications for the assessment of the macroscopic structure and function of the vascular system. In addition, MRI may be used to assess microvascular characteristics and effects, including microvascular density and vascular permeability (8,9), regional tissue perfusion (10), and microvascular obstruction (11). Building on these MRI capabilities, the development of molecular MRI targeted to detect alterations in the endothelial cell (EC) and its environment may allow integration of novel information about the state of the endothelium into conventional MRI vascular assessment. The endothelium is a particularly appealing site for targeting by molecular probes because of its functional importance and because it is bathed by the bloodstream into which such probes are conventionally administered.

The imaging of molecular targets is a developing method for improving the characterization and detection of normal and disease states. MRI can provide high spatial resolution and structural definition, which is useful for imaging processes at the molecular and cellular level (12). Furthermore, the availability of a wide range of MR scanners, ranging from small-bore animal scanners to whole-body clinical systems, provides a means to bridge the gap between experimental models and clinical application. The availability of high-field animal scanners is especially important because many basic molecu-

lar imaging experiments are first performed in small animals for which particularly high spatial resolution is required for meaningful detection and localization. In contrast to some of the other imaging modalities (e.g., single photon emission computed tomography [SPECT], positron emission tomography [PET]), however, MRI has inherently lower sensitivity for probe detection, which complicates its use for imaging low quantities of molecular markers.

The goals of this chapter are to provide an overview of the MR physics important for molecular imaging and to review the current state of molecular MRI of the endothelium. The initial sections first review the basic principles of MR, with an emphasis on signal and contrast manipulation and instrumentation requirements and then discuss how the properties of instrumentation have an impact on the development of contrast agents. The later sections focus on the basic properties of targeted contrast agents, including target identification, targeting approaches, and signal amplification strategies. Finally, current and potential applications of cardiovascular molecular MRI will be described.

### PRINCIPLES OF MAGNETIC RESONANCE

MRI is based on the principle of nuclear magnetic resonance. Nuclei consisting of an odd number of protons and/or neutrons have a magnetic moment. When placed inside a strong magnetic field, some of the nuclei align with the magnetic field, establishing a net longitudinal magnetization with the proton nuclei of water (hydrogen nuclei from water are the most abundant in the body). The nuclei precess at a frequency directly proportional to the strength of the main magnetic field. Recovery of magnetization in the longitudinal direction (T1) and decay of magnetization in the transverse plane (T2, T2\*) are the basis of soft-tissue contrast in MRI.

### Magnetic Resonance Signal Intensity

Signal intensity in MRI primarily depends on the local values of the longitudinal ( $1/T_1$ ) and transverse ( $1/T_2$ ) relaxation rate of water protons. Depending on the pulse sequence, signal usually tends to increase with shorter  $T_1$  (higher  $1/T_1$ ) and decrease with shorter  $T_2$  (higher  $1/T_2$ ) relaxation times. The environment in which the nuclei are located determines the MR signals created. Therefore, by manipulating the chemical environment around the protons, the signal can be altered. MR contrast agents have been developed as a way to modulate the chemical environment inside an organism. The relaxivities  $r_1$  and  $r_2$ , which are commonly expressed in  $(\text{mM} \times \text{s})^{-1}$ s indicate the increase in  $1/T_1$  and  $1/T_2$  per concentration of contrast agent:

$$1/T_1 = 1/T_{10} + r_1 [\text{contrast agent}] \quad (\text{Equation 1})$$

$$1/T_2 = 1/T_{20} + r_2 [\text{contrast agent}] \quad (\text{Equation 2})$$

with  $T_{10}$  and  $T_{20}$  being the relaxation times of native tissue (i.e., tissue devoid of exogenous contrast agent).

Gadolinium (Gd)-based contrast agents usually increase  $1/T_1$  and  $1/T_2$  in similar amounts ( $r_2/r_1 \cong 1-2$ ) (13–15) whereas iron particle-based contrast agents have a much stronger effect on increasing  $1/T_2$  ( $r_2/r_1 > 10$ ) (16). Gadolinium-based contrast agents therefore lead to a positive contrast effect (detected as an increase in signal intensity or brightness), whereas iron particle-based contrast agents usually cause a negative contrast effect (detected as a decrease in signal intensity or darkness). MR pulse sequences that emphasize differences in  $T_1$  and  $T_2$  are commonly referred to as  $T_1$ - and  $T_2$ -weighted sequences. Apart from their effect in increasing  $1/T_2$ , iron particles also increase  $1/T_2^*$  due to their effect on the local magnetic field  $B_0$ , thus causing local field inhomogeneities  $\Delta B_0$ . This additional effect leads to even more severe signal decay.

$$1/T_2^* = 1/T_2 + \gamma \Delta B_0 \quad (\text{Equation 3})$$

Iron-based contrast agents are therefore best imaged using  $T_2^*$ -weighted imaging sequences. For signal quantification,  $T_2$ -weighted multiecho spin echo sequences or  $T_2^*$ -weighted multiecho gradient echosequences can be used to generate  $T_2$  or  $T_2^*$  maps. Typical  $r_1$  and  $r_2$  values of currently approved Gd-based contrast agents are in the range of  $r_1 = 3-5 (\text{mM} \times \text{s})^{-1}$  and  $r_2 = 5-6 (\text{mM} \times \text{s})^{-1}$ . The relaxivities of iron-based contrast agents are significantly higher  $r_1 = 20-25 (\text{mM} \times \text{s})^{-1}$  and  $r_2 = 100-200 (\text{mM} \times \text{s})^{-1}$ . Due to the low concentrations at which molecular imaging targets are generally found, relaxivity is important in the design of molecular contrast agents and will be discussed further in the second part of this chapter.

### Magnetic Resonance Image Acquisition

For cardiac imaging, cardiac as well as respiratory motion must be effectively handled. Motion compensation requirements for

noncoronary vessels such as the aorta or the carotid arteries are less stringent.

### Cardiac and Respiratory Motion Compensation

MRI signal generation and detection are governed by nuclear magnetic resonance physics and subject to instrumental constraints. Because magnetic resonance processes are time-dependent, sufficient time is required for data collection and image generation. Often, the time required for data acquisition is long enough to encompass several cardiac or respiratory cycles. Motion occurring during the acquisition period can dramatically diminish image quality. Therefore, significant work has gone into developing “gated” imaging protocols to eliminate motion artifacts during data acquisition. When data are acquired over multiple cardiac and respiratory cycles (segmented data acquisition), synchronization with the electrocardiogram (ECG) and/or the position of the diaphragm is mandatory. Because the ECG is distorted (elevated T-wave) when recorded from a patient in a high magnetic field, state-of-the-art MR scanners use four or more leads for R-wave detection ( $\geq 2$  ECG traces) to differentiate between the R-wave and the so-called T-wave artifact (17). The T-wave artifact is caused by the magneto-hydrodynamic effect (MHD). The deflection of rapidly moving ions by the main magnetic field produces additional voltage that is superimposed on the ECG signal. The MHD artifact is strongest during maximal flow in systole and increases with increasing field strengths.

Small-bore animal scanners are commonly equipped with less sophisticated ECG gating hardware and software. In most cases, R-wave detection is performed by simple threshold algorithms. In addition, both clinical and small-animal systems are equipped with respiratory sensors (bellows) that enable respiratory motion gating. However, simple gating mechanisms may cause an interruption in MR data acquisition and thus signal variations due to altered MR steady-state conditions. This can lead to artifacts, especially if inversion recovery sequences are used in concert with contrast agents. Gating schemes that acquire data at a near-constant TR and subsequently label data as accepted or rejected based on the respiratory position of the diaphragm help overcome this limitation. A drawback of all gating schemes is the increased scanning time they entail.

### Molecular Magnetic Resonance Imaging Sequences

MRI sequences can be divided into spin echo (SE) (typically 2D) and gradient echo (GRE) (typically 3D) sequences. Several types of SE or GRE imaging sequences are used for optimal contrast depending on the type of agent, location, motion, and other variables. Table 176-1 outlines the general parameters for the most common classes of sequences.

### Spin Echo Sequences

ECG-triggered and nontriggered  $T_1$ - and  $T_2$ -weighted spin echo (SE) sequences belong to the standard sequence repertoire of every MR scanner. These sequences are used extensively for neurological, body, and musculoskeletal imaging

**Table 176-1: Magnetic Resonance Imaging Sequences**

	<i>Spin Echo</i>		<i>Steady-State GRE</i>	<i>IR GRE</i>	<i>GRE</i>
Weighting	T1w	T2w	T1w	T1w	T2*
Prepulses	(DIR)	(DIR)	(REST)	IR	–
ECG gating	Yes	Yes	No	Yes	(Yes)
Respiratory gating	Yes	Yes	(Yes)	Yes	(Yes)
TR	TE	>5 msec	Shortest	~5–10 msec	>2,000 msec
TR effective	300–700 msec	>2,000 msec	–	TR <sub>IR</sub> ≥ 1 HB	–
TE	5–15 msec	50–150 msec	Shortest	< 5 ms	4–10 msec
Flip angle	90	90	30–50	30–50	5–20

DIR, double inversion prepulse; REST, regional saturation band; IR, inversion recovery prepulse; GRE, gradient echo; HB, heart beat; (), optional

since they provide excellent image quality and can provide variable T1 or T2 weighting by adjusting the echo (TE) and repetition time (TR). T1-weighted SE sequences are characterized by short TEs (5–15 msec) and TRs (300–700 msec), whereas T2-weighted SE sequences have long TEs (50–150 msec) and TRs (>2,000 msec). In the presence of a T1-lowering contrast agent, high-resolution images with excellent soft-tissue contrast with concomitant T1 weighting can be achieved. In applications for which morphological details or hypointense blood (*black blood*) appearance in concert with visualization of contrast uptake are required, spin echo approaches are often the method of choice. A disadvantage of fast spin echo (FSE) sequences is their inability to demonstrate increasing contrast effect from higher contrast agent concentrations (15) and frequently observed suboptimal contrast-induced signal enhancement due to the relatively high signal from surrounding tissues.

The maximum MR signal is reached at Gd concentrations of approximately 1 mM for a typical contrast agent with a relaxivity  $r_1$  of 4 (mM × s)<sup>-1</sup>. For higher concentrations, the T2 effect begins decreasing the maximal achievable signal due to the finite achievable TE, whereas T2 weighting increases with increasing contrast agent concentrations (18).

#### ***T1-Weighted Three-Dimensional Gradient Echo Sequences***

Non-ECG-triggered fast radio frequency (RF) spoiled three-dimensional (3D) gradient echo sequences (TE < 5 msec, TR < 10 msec, flip angle = 30°–50°) are heavily T1 weighted and exhibit a near-linear relationship between contrast agent concentration and MR signal intensity (15).

These sequences are therefore especially well suited for higher contrast agent concentrations. Due to their short scan times (5–60 sec) and excellent background suppression, these sequences are the workhorse in first-pass contrast-enhanced angiography of the large vessels and in molecular imaging of nonmoving tissues and organs. A disadvantage of this approach is that it generally produces a hyperintense (bright) appearance of blood, which makes it a suboptimal candidate for molecular imaging of the vessel wall. The use of saturation pulses can help minimize the inflow (blood signal enhancing)

effect, as demonstrated in a study using molecular MRI on fibrin (19).

#### ***T1-Weighted Inversion Recovery Three-Dimensional Gradient Echo Sequences***

T1-weighted inversion recovery sequences are particularly useful if ECG triggering or respiratory gating is required for suppression of cardiac or respiratory motion artifacts. Typical scan parameters include TE < 5 msec, TR = 5 to 10 msec, flip angle = 30° to 50°, 10 to 30 RF excitations per heart beat, and bandwidth = 100 to 300 Hz/pixel. The choice of the inversion repetition time (TR<sub>IR</sub>) (≥1 heart beat) determines the optimum inversion delay TI:

$$TI = \ln 2 \times T1 - T1 \times \ln(\exp(-TR_{IR}/T1) + 1) \quad (\text{Equation 4})$$

and thus the maximum achievable signal intensity of the administered contrast agent. T1 is the longitudinal relaxation time of the suppressed tissues. Longer inversion repetition times TR<sub>IR</sub> (>1 cardiac cycle) lead to longer optimal inversion delays TI and thus to higher signal intensities at the site of contrast uptake. The drawback of this approach is the increased scanning time that it requires. An example of this approach was provided by early proof-of-concept work (20) in which an IR gradient echo sequence was used in the detection of coronary thrombi that had been labeled with Gd-DTPA fibrinogen in vitro (Figure 176.1).

Advantages of inversion recovery sequences are their excellent background suppression and flow insensitivity. Due to little signal contamination from surrounding tissues, these sequences are particularly useful for the visualization of small amounts of contrast uptake at a specific target site. A limitation is the lack of morphological information provided, although it is possible to acquire morphological information in a separate scan and overlay the images to obtain anatomical localization. Unlike images produced by nontriggered 3D-gradient echo sequences, this approach provides images in which blood signal is well suppressed, and thus allows for targeted imaging of the endothelium, vessel wall, or intraluminal thrombus.

Figure 176.1. Example of an ECG-gated inversion recovery (IR) sequence for in vivo imaging of Gd-labeled coronary thrombus. Note the high contrast-to-noise ratio due to the excellent suppression of surrounding tissues and blood. This approach is well suited for determining whether the chosen target is present or absent. (Reproduced with permission from Botnar RM, Buecker A, Wiethoff AJ, et al. In vivo magnetic resonance imaging of coronary thrombosis using a fibrin-binding molecular magnetic resonance contrast agent. *Circulation*. 2004;110:1463–1466.)

### T2\* -Weighted Gradient Echo Sequences

Due to the prominent T2\* effect of iron-based contrast agents, imaging using these agents is done using predominantly T2\*-weighted gradient echo sequences. Typical parameters include TE = 4 to 10 msec, TR  $\geq$  2,000 msec heart beat, and flip angle = 5° to 20°. Due to the overall low signal in T2\*-weighted images, morphological information is limited and sometimes requires additional scans to allow for colocalization between the site of contrast uptake and the corresponding morphological image.

### Spatial Resolution

Due to the small size of the molecules and cells to be investigated by molecular MRI, spatial resolution is an important limiting factor. The spatial resolution necessary to identify molecules or cells that underlie biological processes depends heavily on the imaging sequence employed and the question to be answered. If the task is to identify the presence or absence of biological markers, low-resolution images (~1–2 mm) may be sufficient, and imaging is best done with T1-weighted IR sequences in conjunction with the use of Gd-based contrast agent or with T2\*-weighted sequences in conjunction with the use of iron oxide-based contrast agent. If identification and localization of a molecular marker with respect to small anatomical structures is desired, spatial resolution and partial volume effects become crucial. Because limited data are currently available, general recommendations cannot be made. However, for minimization of partial volume effects, IR sequences appear very promising, because native tissues can be quite effectively nulled over a wide T1 range (e.g., myocardium = 800 msec; blood = 1,200 msec) thereby creating

high contrast between the agent and the surrounding tissues (see Figure 176.1).

## Magnetic Resonance Imaging Scanner

### Field Strength

The field strength of most clinical scanners is 1.5 T (64 MHz). Recently introduced high-field systems operate at 3 T (128 MHz) and have been shown to be advantageous for neurological applications because of the twofold gain in the signal-to-noise ratio (SNR). Body imaging at 3 T has not yet been as successful due to greater technical hurdles, which are primarily related to B<sub>0</sub> field inhomogeneities (suboptimal shimming), limited RF penetration, and increased RF heating. Nevertheless, the potential increase in SNR that a higher field strength can provide may prove useful for imaging at the molecular and cellular level using targeted contrast agents.

For development of T1-lowering contrast agents, the field strength dependency of the longitudinal relaxivity r<sub>1</sub> plays a critical role. This field strength dependency also is referred to as nuclear magnetic resonance dispersion (NMRD) (15,21). If the product between the Larmor frequency  $\omega$  (which equals field strength) and the correlation time (fluctuation of local magnetic field induced by contrast agent)  $\tau_c$  exceeds 1, r<sub>1</sub> begins to decrease (15,21). Most contrast agents in clinical use today were optimized for 1.5 T ( $\tau_c \cong 2.5$  nsec). When developing contrast agents for 3 T or higher field systems, lower correlation times should be sought to achieve maximal longitudinal relaxivities r<sub>1</sub>. Conversely, the transverse relaxivity r<sub>2</sub> has a different behavior and may even increase at higher field strengths. Thus, at higher field strengths, the ratio r<sub>2</sub>/r<sub>1</sub> usually increases. T2\* agents, such as iron oxide particle-based agents, therefore should be well suited for use in 3 T and higher field MR systems. On the other hand, T1 agents, such as Gd-based agents, demonstrate less contrast effect at higher field strengths.

### Physiological Monitoring and Motion Compensation

Most clinical MR scanners are equipped with ECG sensors and peripheral pulse units (PPU) to allow for scan synchronization with the patient's heartbeat. In addition, respiratory bellows or MR navigators are used to monitor and correct for respiratory motion. The newest scanner generations are also equipped with blood pressure cuffs and blood oxygen saturation sensors to allow constant monitoring of vital signs in critically ill patients.

### Receiver Coils

In cardiac MRI, phased-array coils (four to six coil elements) are required to meet current standards for imaging. This is because of the need for submillimeter resolution, especially when coronary artery or vessel wall imaging is included. Imaging of processes at the molecular level is likely to require even higher spatial resolution. Cardiovascular molecular imaging will benefit from improvements in phased-array

coil technology, which has recently advanced to 16- and 32-channel receiver technology. Analogous to developments in multislice computed tomography (CT) technology, such improvements can be expected to reduce imaging time, which should reduce motion and other image artifacts. Furthermore, evidence from recent work (22) suggests that phased-array coil technology is likely to increase SNR, which would be particularly beneficial for imaging small molecular and cellular targets.

## Data Analysis

### T1 Measurements

Measurements of the T1 relaxation time are usually performed using inversion recovery sequences. By changing the inversion delay, TI, between the nonselective inversion prepulse and data acquisition, signal from tissue A ( $T1 = T1_A$ ) will be nulled if the inversion delay TI fulfills the condition  $TI = T1_A \times \ln 2$ . Most T1 measurement approaches are based on the Look and Locker sequence, which acquires multiple images along the T1 relaxation curve after an initial inversion prepulse (23). Several new approaches have been proposed to reduce imaging time (24) and to enable T1 measurements in moving organs such as the heart (25).

### T2\* Maps

T2\* maps are acquired by sampling the signal along the free induction decay (FID) curve using multiple echo times (TE) at a constant repetition time (TR). The most common approaches are based on gradient echo sequences with signal sampling along Cartesian trajectories (26,27). The drawback is the relatively long scanning time when using this approach. In a recent study, Schaeffter and colleagues proposed a faster approach by taking advantage of the undersampling properties of radial imaging (28). Undersampled radial subimages with differing echo times (TE) were reconstructed from a complete radial data set that was acquired using multiple TEs. An exponential pixel-by-pixel fit of the FID as derived from the undersampled subimages then allows generation of T2\* maps (Figure 176.2; for color reproduction, see Color Plate 176.2) (29).

## ENDOGENOUS CONTRAST

Recently, groups have taken advantage of the intrinsic T1 and T2 differences of diseased tissues to image both thrombus (30,31) and vulnerable plaque (32–34). The presence of methemoglobin in thrombi produces T1 shortening, leading to high signal intensity on T1-weighted images of thrombi, such as in deep vein thrombosis (35) and pulmonary embolism (36). However, this effect declines over time as the thrombus becomes organized.

Toussaint and Yuan have characterized plaques using four types of contrast weightings (T1, T2, proton-density, and 3D

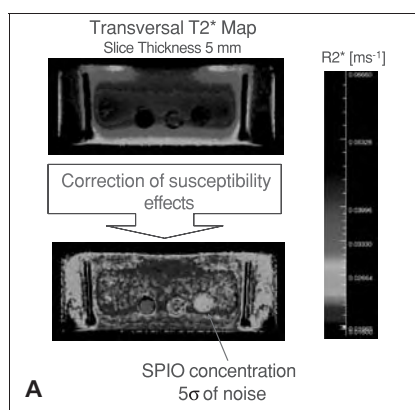

Figure 176.2. T2\* maps of water tubes filled with SPIO contrast agents (A). Without susceptibility correction, no significant differences can be observed between the different tubes. After correction, SPIO concentrations as low as 5 standard deviations above the noise level could be detected. (B) In vivo T2\* maps of the liver before and after susceptibility correction. time-of-flight) and shown good correlation with histopathological examination in carotid endarterectomy specimens (32,37). Fayad and colleagues have performed similar studies in the aorta using T1, T2, and proton density-weighted sequences (38).

## TARGETED CONTRAST AGENTS

Although advances in MRI hardware are important to improved molecular imaging, advances in molecular imaging with MRI are increasingly dependent on the development of exogenous probes. Successful molecular probe development requires the selection of appropriate biologically and clinically relevant targets and effective strategies for meeting the challenges of sensitivity, specificity, spatial localization, and safety required for accurate diagnosis. Methods that provide for significant signal amplification are needed to detect molecular markers effectively.

### Probe Detection by Magnetic Resonance

The sensitivity of a molecular imaging probe depends on the *distribution of the probe*, the *strength of the probe signal*, and the *means of detection of the probe*. The distribution of a probe is determined by the mode of its administration, its compartmentalization (degree of passage into various intravascular, extracellular, and intracellular spaces), and its mechanisms and speed of clearance. Probe distribution, together with probe-target affinity, determines the concentration of probe at the target for detection. For magnetic resonance, the strength of the achievable probe signal is determined by the concentration of contrast agent and the relaxivity of the agent. However, probe signal may not increase proportionately to increases in probe concentration (see next section). In addition, the distribution of probe in nontargeted regions is an important consideration for timing of imaging following contrast administration and for methods of probe detection to optimize the target-to-background signal ratio. The plasma half-life of an agent must be sufficient to expose target receptors to the agent. On the other hand, it may be necessary to wait for plasma concentrations of agent to fall sufficiently to distinguish luminal contrast content from vessel wall contrast uptake, although methods may be employed to reduce this requirement (39).

### Magnetic Resonance Signal Amplification – General Considerations

MR contrast agents are not detected directly, but by their effect on water protons. Molar concentrations of water protons are required to provide a sufficient effect on signal intensity, so high local concentrations of contrast agents (for example, typically  $\mu\text{M}$  to  $\text{mM}$  for those agents having a  $r_1$  in the 4–20  $\text{mM}^{-1}\text{s}^{-1}$  range) are needed to alter the chemical environment sufficiently for detectable signal effects. Because many molecular targets are found in the  $\text{nM}$  range in the body, new methods of signal generation are being developed to enable the MRI of such molecular targets.

#### T1 Effects

Most MR contrast agents are based on Gd complexes (14,15,21) (Figure 176.3A) or, less commonly, iron oxide particles (Figure 176.3B) (16). Gd(III) is ideally suited for use as an MRI contrast agent not only because it has seven unpaired electrons, but also the symmetry of its electronic states produces an electron spin relaxation time slow enough to interact significantly with neighboring water protons (15,21).

Relaxivity is affected by a number of contrast agent properties including *hydration number*, the *distance between the ion and the solvent proton*, *solvent exchange rate*, *electronic relaxation time*, and *rotational correlation time*. The hydration number (number of water molecule coordination sites) for Gd chelates is generally 1 or greater (4,21). Obtaining the minimal distance between the ion and bound protons ( $r$ ) is important because the relaxation rate is inversely proportional

Figure 176.3. (A) Example of a Gd complex demonstrating the chelation of the otherwise toxic  $\text{Gd}^{3+}$  metal. The free water interacts with the surrounding protons, thereby locally changing the T1 and thus increasing the MR signal strength on T1-weighted images. Reproduced with permission from Caravan P, Ellison JJ, McMurry TJ, Lauffer RB. Gd(III) chelates as MRI contrast agents: structure, dynamics, and applications. *Chem Rev.* 1999;99:2293–352. (B) Example of a dextran-coated iron oxide particle.

to  $r$  (6). The ability of the bound protons to rapidly exchange with free water allows for distribution of the relaxation effects throughout the bulk water (Figure 176.4). A longer electronic relaxation time also leads to higher relaxivity.

The rotational correlation time ( $\tau_R$ ) is approximately 0.1 ns for approved agents. Because increases in rotational correlation time ( $\tau_R$ ) enhance relaxivity, various efforts in contrast agent design have focused on increasing this parameter (40).  $\tau_R$  is lengthened by the formation of conjugates between the metal ion complex and slowly moving structures such as proteins, polymers, or dendrimers. However, the increase in relaxivity resulting from an increase in molecular weight of the contrast complex may be less than expected due to internal flexibility of the molecular structure (21).

Molecular MRI probes frequently involve attachment of Gd complexes to small ligands (e.g., small molecules, peptides) that in turn attach to slowly moving targets (e.g., proteins); thus, lengthening of the rotational correlation time is accomplished, providing a convenient means of amplifying the detection of contrast agents positioned at molecular targets. Because the unbound fraction of molecular probe will retain a lower

Figure 176.4. Schematic of water exchange between bound and bulk water. Fast water exchange leads to a more efficient energy transfer between Gd and bulk water, thereby creating a higher relaxivity  $r_1$ . Reduction of the tumbling motion (rotational relaxation rate) of the Gd-chelate increases the relaxivity  $r_1$  as well. Binding to a target or construction of macromolecular agents (i.e., dendrimers) is a means of slowing down the rotational motion of Gd compounds.

$r_1$ , a good target-to-background signal ratio is achieved. This has been termed *receptor-induced magnetization enhancement* (RIME) (41,42). An early example of this type of contrast agent is MS-325 (EPIX Pharmaceuticals, Cambridge, MA). MS-325 is an intravascular contrast agent that reversibly binds

to albumin in plasma. When bound to albumin, the relaxivity increases to approximately 20 to 23  $\text{mM}^{-1}\text{s}^{-1}$  from the 6  $\text{mM}^{-1}\text{s}^{-1}$  observed in buffer at 65 MHz (15).

A different approach to improve T1 effects without improvement in the relaxivity per Gd atom is by increasing the number of Gd per targeting complex (i.e., ligand, nanoparticle, micelle, or liposome), thus producing multivalency of Gd attachment to ligand (43). Such multivalency within the targeting complex may be sufficient to offset the flat or even diminished relaxivity effect of individual Gd atoms. This effect can be exploited for both Gd chelate-polymer (consisting of Gd chelate covalently or noncovalently bound to peptide, protein, or antibody) probes as well as for iron-oxide or Gd particulate probes, although the potential magnitude of this effect is much greater for particles (e.g., Gd/antibody ratio of  $\sim 20$  Gd/antibody molecule vs.  $\sim 100$  Gd/20 nm nanoparticle vs.  $\sim 300,000$  Gd/300 nm nanoparticle). Thus, particulate probes offer the potential for greatly improved sensitivity over conventional chelated complexes because of the much higher achievable concentration of Gd (or iron oxide).

Estimates for the minimal Gd concentration required for detection depend on the relaxivity of the given Gd complex, which varies with the field strength. As noted earlier, for T1 agents, the maximum relaxivity attainable decreases with increasing field strength. Aime and colleagues found that, for an agent with high relaxivity ( $\sim 80 \text{ mM}^{-1} \times \text{s}^{-1}$ ), the threshold for detection was  $4 \pm 1 \times 10^7$  complexes/cell or approximately 15  $\mu\text{M}$  (44). In an animal study of coronary

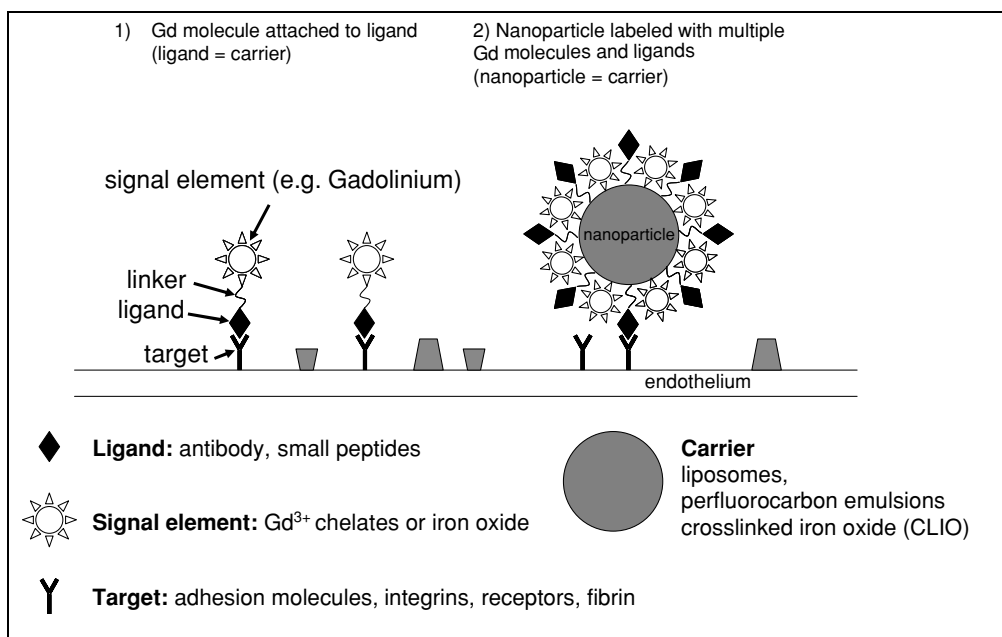

Figure 176.5. Schematic of molecular contrast agents targeted against endothelial activation. The basic components of each molecular contrast agent consist of a ligand that binds to a specific target and a signal element, which, in case of MR, is made of a  $\text{Gd}^{3+}$  chelate or an iron oxide. These two basic components can be directly (1) linked to each other or may be attached to or incorporated within a larger nanoparticle (or carrier) as demonstrated in (2).

**Table 176-2: Examples of Magnetic Resonance Molecular Imaging Probes**

CNS, central nervous system; CVD, cardiovascular disease.

thrombosis, we found that Gd concentrations between 100 and 150  $\mu M$  translated into an SNR of approximately  $11 \pm 2$ , which allowed for target detection (20).

As alluded to earlier, the effects of MR contrast agent concentration are nonlinear. Although contrast agent distribution has an impact on contrast concentration, contrast agent compartmentalization and local phenomena may alter local agent relaxivity. As Gd concentration increases, T<sub>1</sub> falls. However, if  $T_1 < TR/2$  ( $TR =$  repetition time for imaging), tissue will recover nearly fully before the subsequent RF pulse. Also, at high concentrations, Gd will reduce T<sub>2</sub> to the order of the TE (echo time) so increasing concentrations will decrease MR signal intensity. As noted earlier and demonstrated in Figures 176.2 and 176.3, fast T<sub>1</sub>-weighted gradient-echo sequences (especially 3D ones) typically have a larger scalable range than do spin-echo sequences (15).

### T<sub>2</sub>\*

The synthesis and use of stable, nanosized iron oxide particles for use as MR contrast agent have been extensively described (16,45). Iron oxide particles have differential effects

on  $1/T_1$  and  $1/T_2$ , depending on their size. Superparamagnetic iron oxide (SPIO) particles produce much larger increases in  $1/T_2$  than in  $1/T_1$ , so they are best imaged with T<sub>2</sub>-weighted scans, which reveal signal decrease (45). SPIO particles produce a marked disturbance in surrounding magnetic field homogeneity, especially apparent when a nonhomogeneous distribution produces a T<sub>2</sub>\* susceptibility effect. On the other hand, ultra-small superparamagnetic particles of iron oxide (USPIOs) have a greater effect on  $1/T_1$  than do SPIO particles, so they can be used for T<sub>1</sub>-weighted imaging (46).

Although iron oxide-based agents have greater relaxivity per metal atom than do Gd-based agents, Gd-based agents provide positive T<sub>1</sub> signal enhancement, which is more readily distinguished from artifact than is negative signal effects and has a larger potential scalable range for detection.

### Safety

Although GdCl<sub>3</sub> is very toxic, chelating Gd(III) (as with diethylenetriamine pentaacetate [DTPA]) largely reduces its toxic profile (47–49). With a high thermodynamic stability

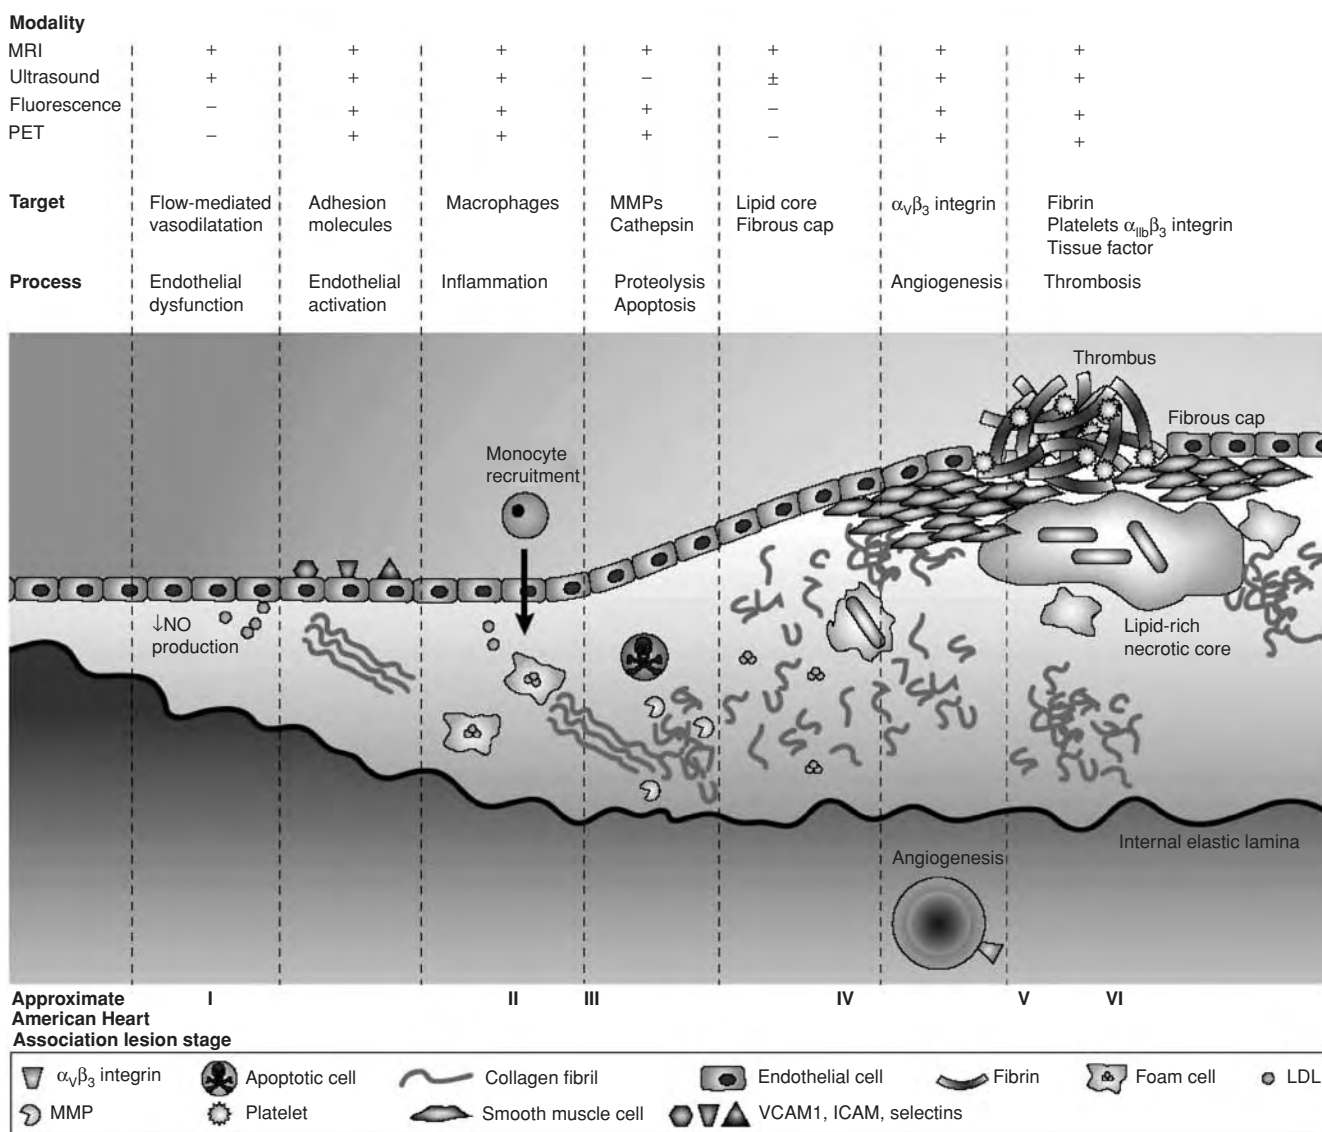

Figure 176.6. Imaging targets in atherothrombosis. Illustration of processes of atherogenesis ranging from prelesional endothelial dysfunction (*left*) through monocyte recruitment, to the development of advanced plaque complicated by thrombosis (*right*). The mechanisms are grossly simplified but focus on components (for example, cell adhesion molecules, macrophages, connective tissue elements, lipid core, and fibrin) and processes (for example, apoptosis, proteolysis, angiogenesis, and thrombosis) in plaques that have been imaged or that present useful potential imaging targets. Symbols indicate the feasibility (+ or -) of imaging using each of the modalities listed (see text for details). ICAM, intercellular cell adhesion molecule; LDL, low-density lipoprotein; MMP, matrix metalloproteinase; MRI, magnetic resonance imaging; NO, nitric oxide; PET, positron emission tomography; VCAM, vascular cell adhesion molecule. (Adapted with permission from Choudhury RP, Fuster V, Fayad ZA. Molecular, cellular and functional imaging of atherothrombosis. *Nat Rev Drug Discov*. 2004;3:913–925.)

constant ( $K_{gd-L} = 10^{26}$  for Gd-DTPA), the chelated metal complex is essentially inert and is cleared at a significantly faster rate than the rate of dissociation of the metal ion from the complex. However, the plasma clearance rate of chelated Gd is still sufficiently slow to provide ample contrast for MRI applications. Thus, the chelation process transforms an otherwise highly toxic salt into a useful diagnostic reagent (18,50,51).

Although conventional Gd chelates are not hydrophobic and therefore generally remain extracellular, some novel

molecular contrast agents are more likely to enter cells, raising concern for greater potential for toxicity. Other imaging probes, such as macromolecular intravascular agents, also may have longer elimination half-times than conventional contrast agents, with potential increased risk of *in vivo* Gd chelate dissociation (51). Additional concerns include antigenicity and biological interaction. When selecting a suitable target for imaging, the selected target would preferably not be involved in biological processes that might be inhibited by the binding of

a targeting molecular imaging probe. Additionally, for probes designed for clinical use, it is important to ascertain whether binding of the molecular probe to its target or to other sites, such as serum proteins, affects binding of therapeutic agents that might have an impact either on drug efficacy or pharmacokinetics.

### Target Identification

Molecular probe target selection criteria include substantiality of biological and clinical relevance and feasibility of target identification, which depends on factors such as adequacy of target density and accessibility of targets to probes.

### Targeting

A specific disease process or cell type may be targeted by a contrast agent using either passive or active means. Although the term *molecular imaging* may be most accurately applied to probes that bind to specific molecular markers (*active targeting*), similar targeting effects may be obtained using probes having distribution characteristics that favor concentration in particular cell types or in regions of disease activity (*passive targeting*).

#### Passive Targeting

Examples of passive targeting agents are iron oxide particles that may be used to label components of the reticuloendothelial system (RES). SPIO nanoparticles (diameter ~200 nm) are recognized by the RES and are rapidly removed from the bloodstream (52). SPIO uptake detectable by MRI and histology has been found in the atherosclerotic plaques of hyperlipidemic rabbits in regions of high macrophage content (53). USPIOs (diameter ~18 nm) are not immediately scavenged by the hepatic and splenic RES, so they have a longer intravascular half-life, and are small enough to transigrate the capillary wall via vesicular transport and interendothelial junctions (16). USPIOs are also phagocytosed by macrophages in plaque in hyperlipidemic rabbits (54) and humans (55).

#### Active Targeting

A particular cell type or disease process may be identified by targeting specific molecular markers. Potential targets may be selected from a variety of molecular markers associated with various cell types or diseases. The targeting of cells has generally focused on binding to cell surface receptors through the use of ligands such as antibodies or low-molecular-weight targeting molecules (56). MRI-targeted probes are constructed by linking such ligands to contrast agent with paramagnetic or superparamagnetic properties.

Cell surface markers (such as CD4, CD8, Mac1) on immune cells may be targeted by labeled antibodies to image areas of immune response, such as murine encephalitis (57).

Figure 176.7. (A) Reformatted view of a coronal 3D data set showing the subrenal aorta approximately 20 hours post EP-1873 administration. Three well-delineated mural thrombi (arrows) can be observed, with good contrast between thrombus (numbered), arterial blood (dotted arrow), and the vessel wall (dashed arrow). The in-plane view of the aorta allows simultaneous display of all thrombi, showing head, tail, length, and relative location. (B–D) Corresponding cross-sectional views show good agreement with histopathology (E–G). (Reproduced with permission from Botnar RM, Perez AS, Witte S, et al. In vivo molecular imaging of acute and subacute thrombosis using a fibrin-binding magnetic resonance imaging contrast agent. *Circulation*. 2004;109:2023–2029.)

Monoclonal antibodies against tumor-associated antigens (e.g., Ra96, HER-2/neu receptor) may serve as ligands to identify the presence of tumor cells (58,59). Aime and colleagues have proposed an alternative approach in which negatively charged contrast agent noncovalently binds to positively charged polyamino acids that preferentially accumulate on the surface of tumor cells (60).

However, even if contrast enhancement with a targeted probe is observed in or around the specified target, the results must be initially interpreted with caution because nontargeted contrast agents may accumulate in areas of interest; for example, the accumulation of nontargeted Gd-based agents in areas of atherosclerotic plaque (39,61–63). That is, contrast may accumulate at sites of interest due to compartmental kinetics rather than molecular targeting. Therefore, careful use of controls and competition experiments are necessary to help establish the basis of contrast effect.

Following the contact of probe with the cell surface, the internalization of probe within cells by endocytosis or phagocytosis may serve as a useful mechanism to increase local contrast agent concentration (56). Non-receptor-mediated endocytosis may be exploited in tumor cells and other dividing cells (56,64). Receptor-mediated endocytosis may be a useful

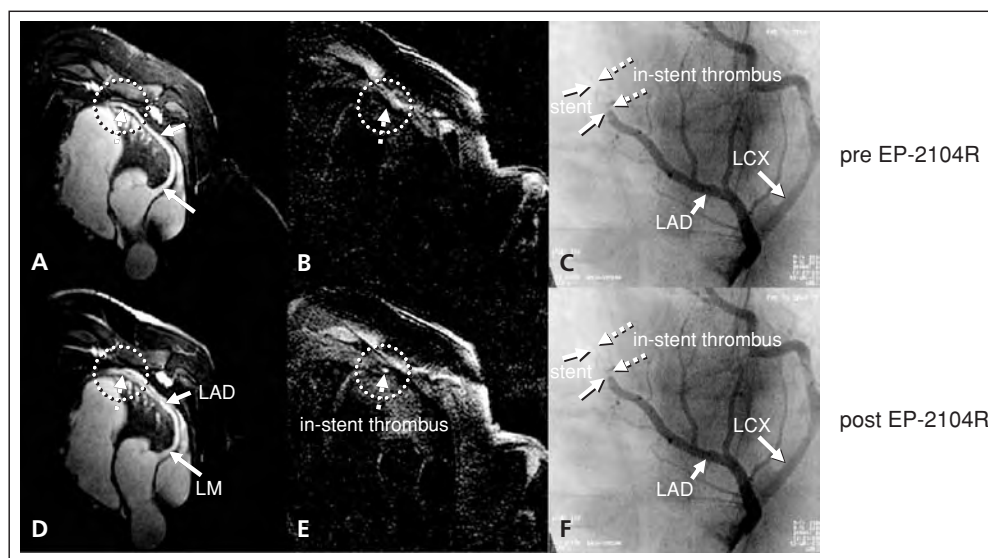

Figure 176.8. In vivo MR molecular imaging of coronary in-stent thrombosis. Bright blood images of the left main and left anterior descending coronary arteries before (A) and after (D) stent placement and injection of a fibrin-binding Gd-labeled contrast agent, EP-2104R. No apparent thrombus and no stent artifacts are visible on the post-stent placement and post-EP-2104R bright blood images (D). Black blood IR images before (B) and after stent placement and EP-2104R (E). A bright spot (*arrow*) is visible after intracoronary injection of EP-2104R (E). Thrombus was subsequently confirmed by x-ray angiography (C, F). (Reproduced with permission from Botnar RM, Buecker A, Wiethoff AJ, et al. In vivo magnetic resonance imaging of coronary thrombosis using a fibrin-binding molecular magnetic resonance contrast agent. *Circulation*. 2004;110:1463–1466.)

mechanism for internalization for other types of cells, including ECs (65). Phagocytosis of particulate imaging probes may serve as a useful means for contrast enhancement, as observed for identification of atherosclerotic plaque through uptake of SPIOs by macrophages within plaque. However, phagocytosis of particulate probes by the RES, particularly the Kupffer cells in the liver, may limit the availability of such probes to other targets. Therefore, mechanisms for evading the RES, such as surface coverage by poly(ethylene glycol) (PEG), an amphiphilic polymeric surfactant, are under investigation (66).

### Ligand Identification

Once an appropriate molecular target has been identified, appropriate candidate ligands must be identified and selected. Methods for creating and screening libraries of peptides, such as phage display technology, are useful in identifying optimal peptide ligands for various proteins, such as receptors and antibodies. Using such an approach, a ligand with high affinity (low  $K_d$  value) for the target can be identified.

### Imaging Probe Construction

Following the identification of an appropriate targeting ligand, a molecular imaging probe may be constructed by attaching

the ligand to a suitable signal element (typically Gd[III] or Fe oxide). The agent carrier may be the ligand itself or a larger construct to which the ligand and contrast agent is attached (Figure 176.5). For MRI, the imaging probe is generally in the form of a metal chelate bound to a ligand (such as a peptide) or a carrier such as a nanometer-sized particle or liposome with associated signal elements (Gd or Fe oxide) and attached targeting ligand.

The avidity of the molecular probe to target may be optimized by conjugating multiple ligands to the contrast agent carrier (multivalency of ligands). An important consideration in such attachment is the preservation of specificity and affinity of binding of the ligand to the target molecule following carrier and signal element attachment. In vitro binding studies are useful to assess whether avid ligand–target binding has been retained.

On the other hand, the impact on signal of the molecular probe may be enhanced by attaching multiple signal-enhancing molecules (such as Gd chelate or iron oxide) per ligand or carrier (as discussed earlier under MR Signal Amplification).

To verify that the T1 shortening effect of a molecular probe is due to the effect of paramagnetic Gd molecules bound to its chosen specific ligand, a nonparamagnetic analog of the probe can be synthesized (for example, Gd replaced by yttrium [Y] or lanthanum [La]). Y and La have negligible MR

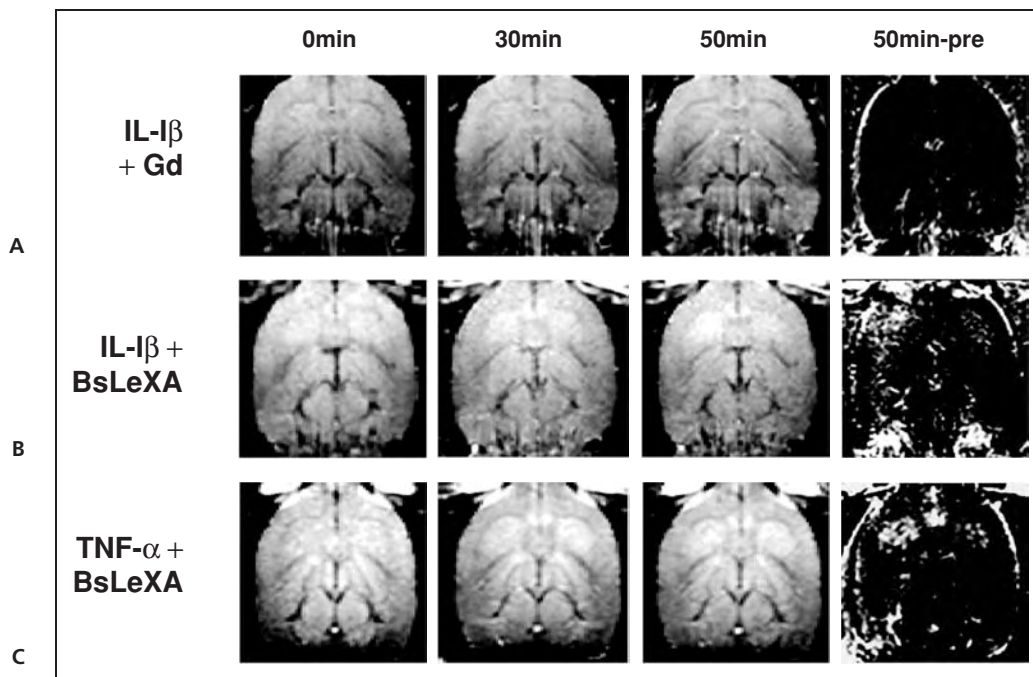

Figure 176.9. (A) T1-weighted images from an animal injected intracerebrally with IL-1 $\beta$  and intravenously with Gd-DTPA-BMA, acquired 0, 30, and 50 minutes after contrast agent administration. No changes in signal intensity were observed at any time (as shown by the difference [50 min-pre] image), indicating that there is no blood–brain barrier breakdown and entry of the contrast agent into the brain tissue. (B) T1-weighted images from an animal injected intracerebrally with IL-1 $\beta$  and intravenously with Gd-DTPA-B(sLe<sup>x</sup>)A acquired at 0, 30, and 50 minutes after contrast agent administration. A region of increased signal intensity can be seen in the injected striatum (*left*). The degree of signal change appeared to be maximal approximately 50 minutes after contrast agent injection, and is more apparent in the difference (50 min-pre) image. This finding was consistent in the three animals injected with IL-1 $\beta$  and Gd-DTPA-B(sLe<sup>x</sup>)A. (C) T1-weighted images from an animal injected intracerebrally with TNF- $\alpha$  and intravenously with Gd-DTPA-B(sLe<sup>x</sup>)A, acquired 0, 30, and 50 minutes after contrast agent administration. A region of increased signal intensity can be seen in the injected striatum (*left*), and again the degree of signal change appeared to be maximal at approximately 50 minutes. (Reproduced with permission from Sibson NR, Blamire AM, Bernades-Silva M, et al. MRI detection of early endothelial activation in brain inflammation. *Magn Reson Med*. 2004;51:248–252.)

contrast properties. Displacement of Gd-labeled ligands by nonparamagnetic labeled ligands can then be demonstrated by MR imaging in cell cultures or animal models using an excess (i.e., 10-fold dose) of the nonparamagnetic labeled agents.

### SOME POTENTIAL APPLICATIONS FOR ENDOTHELIAL ASSESSMENT BY MOLECULAR MAGNETIC RESONANCE

#### Targeted Imaging

A variety of MR probes have been developed to study various biological processes (e.g., thrombosis, angiogenesis, inflammation, neoplasia) and diseases (e.g., cancer, cardiovascular disease, stroke, diabetes) by targeting a spectrum of molecular markers, as summarized in Table 176-2. Molecular probes generally target either changes in receptor expression or alterations in metabolic processes (67). Most of these agents are

in the preclinical stage, with only a few approved for clinical use. Table 176-2 provides examples of contrast agents under development for investigational and diagnostic purposes, with potential application for monitoring of cardiovascular therapies. Of note, probes being developed for use in one context may well have applicability for other disease processes. For example, markers of angiogenesis may be important for the study of neoplasia and atherosclerotic lesions, as well as in the study of therapies aimed to stimulate new vessel growth (Figure 176.6). Figure 176.6 demonstrates the role of the endothelium in the initiation, progression, and complication of atherosclerosis (68). The course of disease can be divided into multiple sequential steps, characterized by distinct biological processes associated with various molecular targets (68).

As noted earlier, the endothelium is a convenient site for targeting since it is directly adjacent to the bloodstream into which contrast agents are conventionally administered.

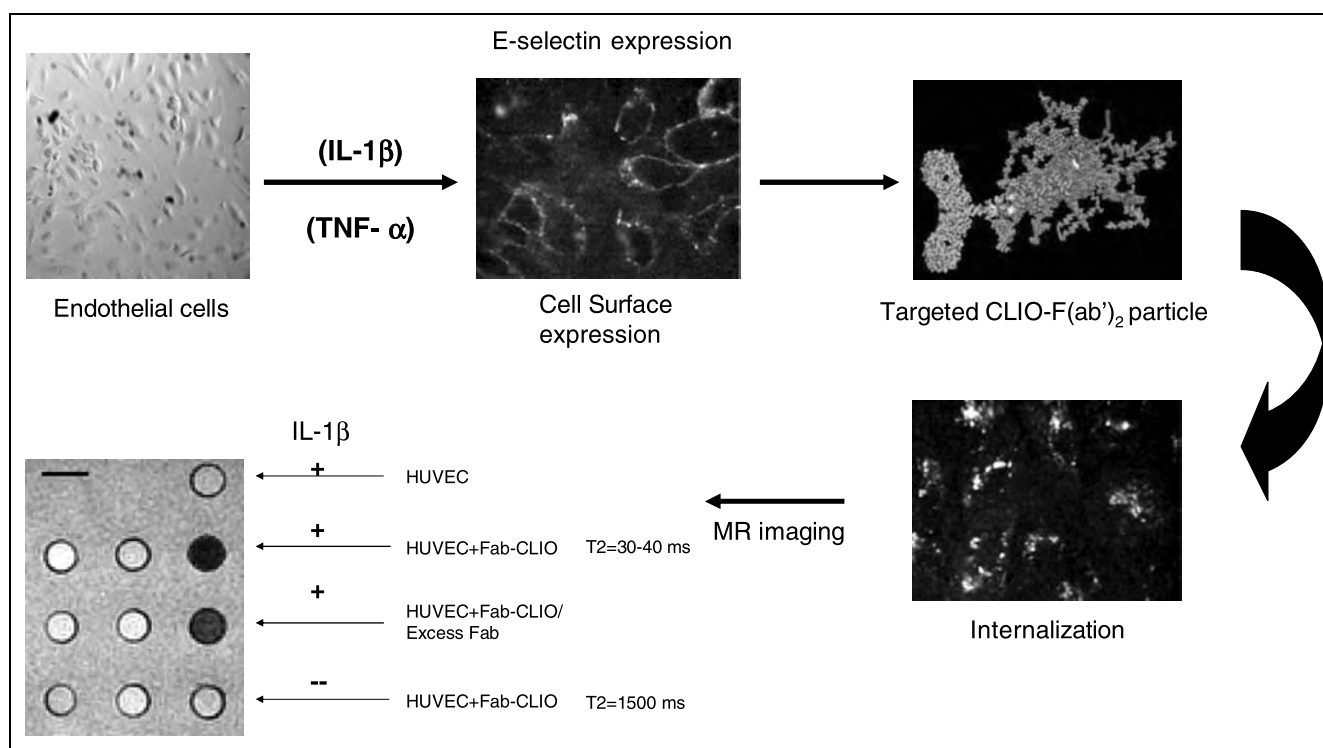

Figure 176.10. EC activation after treatment of cells with  $IL-1\beta$  or  $TNF-\alpha$ . Subsequently, an E-selectin targeted CLIO-F(ab')<sub>2</sub> particle was administered. After internalization of the contrast agent, MR imaging was performed. In the unbound state (before  $IL-1\beta$  and  $TNF-\alpha$  injection), the T<sub>2</sub> relaxation time was approximately 1,500 msec (*bright image*). Conversely, T<sub>2</sub> was reduced to approximately 30 to 40 msec when CLIO-F(ab')<sub>2</sub> was bound to E-selectin (*dark image*). The binding of CLIO-F(ab')<sub>2</sub> to  $IL-1\beta$ -activated cells was approximately 100 to 200 times higher than for nonactivated ECs. (Reproduced with permission from Kang HW, Josephson L, Petrovsky A, et al. Magnetic resonance imaging of inducible E-selectin expression in human EC culture. *Bioconjug Chem.* 2002;13:122–127.)

Thus, the barriers to probe delivery encountered when targeting parenchymal cells (69) may be avoided. However, probe access to potential targets for investigation within the *subendothelium* may be limited by probe size (70).

#### Magnetic Resonance Imaging of Thrombosis

Imaging of fibrin has potential clinical applications for the diagnosis of several significant medical conditions, including acute coronary syndromes, deep venous thrombosis, and pulmonary emboli. In recent studies by Yu (71), Flacke (72), and our group (19,20), Gd-labeled fibrin-avid nanoparticles and small peptides have been successfully used to image thrombus in the jugular vein (72), aorta (19), and the pulmonary (73) and coronary arteries (20,73). Figure 176.7 demonstrates the imaging of acute thrombus in an animal model of plaque rupture using EP-1873. Gd concentrations as low as approximately  $50 \mu\text{M}$  ( $r_1 \cong 21 \text{ mM}^{-1} \times \text{s}^{-1}$  per Gd) were sufficient for ready visualization of mural and lumen-encroaching thrombus. A similar compound, EP-2104R, enabled the imaging of coronary in-stent thrombosis (Figure 176.8) (20) and pulmonary embolism (73) in an experimental animal model. The administered dose was 4 to  $7.5 \mu\text{mol/kg}$ , much lower than that for conventional nontargeted Gd-based contrast agents (typically  $\sim 0.1 \text{ mmol/kg}$ ).

#### Magnetic Resonance Imaging of Atherosclerotic Plaque Using HDL-Like Nanoparticles

Frias and coworkers investigated the use of a high-density lipoprotein (HDL)-like nanoparticle loaded with Gd-DTPA-DMPE phospholipid, as well as fluorescent phospholipid, to target atherosclerotic plaque (70). Potential advantages of such a particle include its small size ( $\sim 9 \text{ nm}$  diameter), its localization to atherosclerotic plaque, its composition of mainly endogenous, protein and lipid components, and its contrast agent content (15–20 Gd-DTPA-DMPE per particle), which yields a relaxivity ( $r_1$ ) of  $10.4 \text{ mM}^{-1}\text{s}^{-1}$ . MRI performed 24 hours following administration of this particle to ApoE-knockout mice revealed a mean normalized enhancement ratio for the atherosclerotic aortic wall of 35%. Confocal fluorescence microscopy revealed some intracellular macrophage localization.

#### Magnetic Resonance Imaging of Endothelial Activation and Injury

Vascular inflammation and associated endothelial activation are believed to play an integral role in the initiation and progression of atherosclerosis. Endothelial activation is characterized by the upregulation of leukocyte adhesion molecules (intercellular adhesion molecule [ICAM]-1 and

vascular adhesion molecule [VCAM]-1, E-selectin, and P-selectin) on the EC surface (74). The adhesion molecules facilitate tethering, adhesion, and transendothelial migration of leukocytes, including monocytes. Differentiation of monocytes into macrophages and subsequent digestion of lipoproteins by macrophages occurs in a later stage and eventually leads to the accumulation of lipid-filled macrophages, which are believed to be a precursor of rupture-prone vulnerable plaque. Although the specific mechanisms by which the adhesion molecules contribute to this process have not yet been determined, studies of atherogenic mice with various adhesion molecule deficiencies has indicated some role for each of the inducible adhesion molecules, particularly VCAM-1 and P-selectin (74–76).

In recent work by Sibson and colleagues (77) and Barber and coworkers (78), early endothelial activation was observed in focal ischemia in mice brains (Figure 176.9) (77) and in brain inflammation in rats (after interleukin [IL]-1 $\beta$  and tumor necrosis factor [TNF]- $\alpha$ -induced E- and P-selectin upregulation) using a novel MR contrast agent. This novel Gd-labeled contrast agent, Gd-DTPA-B(sLe<sup>x</sup>)A (79) consists of the sialyl Lewis<sup>x</sup> (sLe<sup>x</sup>) carbohydrate, which interacts with both E- and P-selectin. The relaxivity was measured as 3.5 mM<sup>-1</sup>  $\times$  s<sup>-1</sup> at 1.5T and thus is similar to Gd-DTPA.

Kang and colleagues have studied an antihuman E-selectin antibody, F(ab'), attached to a cross-linked iron oxide (CLIO) nanoparticle (80). This novel targeted contrast agent was tested in human umbilical vein ECs (HUVECs) culture before and after IL-1 $\beta$ - and TNF- $\alpha$ -induced E-selectin expression. In the unbound state (before IL-1 $\beta$  or TNF- $\alpha$  injection), the T2 relaxation time was approximately 1,500 msec. T2 was reduced to approximately 30 to 40 msec when CLIO-F(ab')<sub>2</sub> was bound to E-selectin (Figure 176.10). The binding of CLIO-F(ab')<sub>2</sub> to IL-1 $\beta$  activated cells was approximately 100 to 200 times higher than for nonactivated ECs. An antibody-based approach was also taken by Sipkins and colleagues, who developed antibody conjugated paramagnetic liposomes (ACPLs) targeted to ICAM-1 to identify autoimmune encephalitis (81).

Kelly and coworkers developed a novel VCAM-1-targeted MRI and fluorescence imaging agent (65). They identified several VCAM-1-mediated cell-internalizing peptides through the use of iterative phage display performed on endothelium under physiological flow conditions. The selected peptide was found to have 12-fold higher target-to-background ratios compared to VCAM-1 monoclonal antibody. Studies using the VCAM-1-targeted peptide attached to a magnetofluorescent nanoparticle demonstrated the successful identification of ECs activated by TNF- $\alpha$  as well as VCAM-1-expressing cells in atherosclerotic lesions in *ApoE*<sup>-/-</sup> mice.

An alternative approach for the identification of vascular injury has been studied by Yamamoto and coworkers, who developed a novel contrast agent, EB-DTPA-Gd, based on the chemical structure of Evans Blue dye (82). Using this contrast agent, significant signal enhancement was observed at the site

Figure 176.11. Percent enhancement maps from individual aortic segments of cholesterol-fed rabbit at renal artery, mid-aorta, and diaphragm 2 hours after treatment in cholesterol-fed rabbit given  $\alpha v\beta 3$ -targeted nanoparticles (*upper row*). No to minimal enhancement in cholesterol-fed animal after administration of nonspecific contrast agent (*middle row*). Similarly, no enhancement in a control animal after injection of  $\alpha v\beta 3$ -targeted nanoparticles (*lower row*). (Reproduced with permission from Winter PM, Morawski AM, Caruthers SD, et al. Molecular imaging of angiogenesis in early-stage atherosclerosis with alpha(v)beta3-integrin-targeted nanoparticles. *Circulation*. 2003;108:2270–2274.) For color reproduction, see Color Plate 176.11.

of common carotid balloon injury in the rat. These promising methods merit further study, with potential applications for various models of endothelial activation.

### Magnetic Resonance Imaging of Angiogenic Endothelium

As noted earlier, the identification of angiogenesis may be useful in studying tumors and atherosclerotic plaque as well as for assessing therapies aimed at stimulating new vessel growth. Integrins, such as  $\alpha v\beta 3$ , are overexpressed in activated neovascular ECs, which are believed to play an integral role in tumor growth and the initiation and development of atherosclerosis. Wickline, Lanza, and coworkers have developed perfluoro-nanoparticles that can carry as many as 90,000 paramagnetic Gd chelates per particle and can be targeted against various biomarkers by attaching appropriate ligands. They have developed methods for identifying angiogenic vessels by targeting the  $\alpha v\beta 3$  integrin (83). A probe consisting of Gd-perfluorocarbon nanoparticle linked to anti- $\alpha v\beta 3$  monoclonal antibody produced MRI signal enhancement of the capillary bed in a corneal micropocket model of angiogenesis (83). A similar approach was taken by Gucione, Li, and Bednarski, who attached anti- $\alpha v\beta 3$  antibody to a lipid-based polymerized vesicle to image an angiogenic tumor (67). A non-antibody-based approach was also taken by Wickline and coworkers, who attached a peptidomimetic vitronectin antagonist to the nanoparticles to again target  $\alpha v\beta 3$  integrin. Using

this approach, they were able to image angiogenic vessels in nascent Vx-2 rabbit tumors (84) and in early-stage atherosclerosis (Figure 176.11; for color reproduction, see Color Plate 176.11) (85).

### Endothelial-Targeted Therapy

Targeted imaging probes could potentially serve as vehicles for targeted cell therapy. An example of such an approach was provided by Hood and colleagues, who modified polymerized nanoparticles targeted with anti- $\alpha v \beta 3$  antibody to contain a plasmid with a mutant form of the gene encoding Raf-1 (86). This mutant form was known to promote apoptosis of ECs and suppress angiogenesis in vivo. Following injection of the modified nanoparticles, significant reductions in tumor burden were observed in mice bearing melanoma and metastatic colorectal cancer (86).

### CONCLUSION

Molecular MRI has great promise as a tool to improve our understanding of biological processes as well as to aid in clinical diagnosis. These methods may assist not only in monitoring response to treatment but also may provide vehicles for targeted therapies. Although progress in the field must overcome numerous technical challenges to optimize imaging methods and to develop novel targeted agents, a multidisciplinary approach to these problems will lead to further advances in this field.

### ACKNOWLEDGMENTS

We thank Alexei Bogdanov PhD, Peter Caravan PhD, Hannes Dahnke PhD, Tobias Schaeffter PhD, Nicola Sibson PhD, and Sam Wickline MD for providing some of the material for the illustrations. Drs. Yeon, Spuentrup, and Botnar have received research grant support from EPIX Pharmaceuticals, Inc. Dr. Manning receives research grant support from Philips Medical Systems and EPIX Pharmaceuticals, Inc. He is also a consultant to EPIX Pharmaceuticals, Inc.

## Real-Time Imaging of the Endothelium

---

Peter L. Gross

*St. Michael's Hospital, University of Toronto, Ontario, Canada*

Real-time imaging offers a powerful diagnostic tool to evaluate the many endothelial functions in an organism. Although the clinical use of real-time imaging of the endothelium is in its infancy, the use of this tool in diagnosing endothelial dysfunction in animal models is widespread and, in many cases, state-of-the-art.

The initial attraction of real-time imaging was the “wow factor.” A picture tells a thousand words – and a movie is even better! Seeing images that put in place concepts that previously were only imagined is a powerful tool.

But the real attraction of real-time imaging of the endothelium is that it allows for the spatial and temporal evaluation of experimental systems that are at a higher order of complexity (1) compared with traditional static assays. Historically, ignoring such complexity has impeded progress in endothelial research. Although studying protein structure in a crystal is complex and no doubt yields useful information, the function of that protein in a membrane, let alone in a cultured cell, is not always predictable. Similarly, the response to a stimulant of endothelial cells (ECs) in culture does not predict the response of ECs in vivo. Real-time imaging provides a window into functioning endothelium in the context of its native microenvironment (Table 177-1).

The aim of advancing technology is to allow observations in the natural, undisturbed environment. Until this is optimal, imaging of the endothelium has tended to suffer “the observer’s paradox,” in which the observation affects the outcome. To obfuscate this has often meant that real-time imaging of the endothelium is limited to the microcirculation of organ surfaces or thin tissues, with a few exceptions.

The goals of this chapter are to (a) catalogue established windows on the endothelium, (b) outline which endothelial functions are evaluable using real-time techniques, (c) provide a technical update on novel microscopic techniques that allow for real-time imaging of the endothelium, and (d) discuss translational and potential clinical applications of these tools.

### WINDOWS ON THE ENDOTHELIUM – FROM BENCH TO BEDSIDE

The inefficiency of light penetration into tissue (reflective- or epi-illumination) or through tissue (transillumination) has limited the types of organs (and locations within an organ) where the endothelium can be evaluated both in real-time and in vivo. Clinically, only the retinal vascular bed is visualized easily and routinely. This is underscored by the importance of funduscopy as a clinical skill. Although basic scientists have designed methods to visualize vessels in myriad organs, most of these require skill to be reproducible.

### BENCH

Retinal vessels are evaluated routinely by basic scientists (2). The most notable examples are antiangiogenic studies in proliferative retinopathy (3). The ear vessel of a mouse or rat is visible by transilluminated light. The autofluorescence of hair has, however, limited the broad use of this window using fluorescence in vivo microscopy; shaving introduces inflammatory artifacts but in some reports hairless mice have been used (4).

Since Atherton and Born (5) first described the technique of surgically exposing the mesentery through an abdominal wall incision, the mesenteric circulation is easily visualized (6). This technique has limitations; because of the need to stabilize the tissue only single vascular branches are visualized and very small capillaries are not seen.

The dorsal skin fold implant on mice has been the basis of a plethora of reports describing the process of angiogenesis. A glass window within a metal holder is surgically implanted on the dorsum of the animal such that the window allows observation of blood vessels of the skin from below. Arteries, veins, and capillaries can be seen. The window can be observed for as long as the animal is immobilized; the implants have been reported to last for at least 14 days (7). Vessels in tissue

**Table 177-1: Windows on the Endothelium**

<i>Window</i>	<i>Depth Limited</i>	<i>Surgery Required</i>	<i>Applicable to Clinic</i>
Skull bone marrow	Yes, by microscopy	Yes	No
Brain	Yes, by microscopy	Yes	No
Ear vessels	Yes, by microscopy	No	No
Tongue microvasculature	Yes	No	Yes
Carotid artery	No	Yes	No
Lymph Nodes	Yes, by microscopy	Yes	No
Liver	Yes, by microscopy	Yes	No
Mesentery	No, can see whole tissue	Yes	No
Skin	Yes, by microscopy	No	Yes
Skin Fold	No	Yes, but it heals	No
Cremaster muscle	No, can see whole tissue	Yes	No
Tendons	No	Yes	No

*Depth limited* refers to whether visualization of the whole tissue can be achieved using standard microscopic techniques, and whether depth penetration techniques are required (multiphoton or near-infrared).

allografts (e.g., lung or tumor tissue) can be studied after surgically placing allografts in dorsal skin fold implants (8).

Surface vessels of the liver (9), lymph nodes (10), skull bone marrow (11), and brain (12) have been evaluated; all also require surgical exposure. These windows are limited in that only surface vessels can be studied. New techniques such as two-photon microscopy and near-infrared (IR) fluorescence allow the visualization of deeper vessels. The recent description of the T-cell activation in six dimensions that occurs in lymph nodes represents state-of-the-art in real-time imaging (13,14).

The cremaster muscle allows for visualization of capillaries, arteries, and veins. Branches can be followed over long distances, allowing the study of events on interactions later in the circulation (15). Limitations include the requisite use of male mice, the requirement for surgical exposure, motion artifacts from arterial pulsations, and an upper limit on the size of vessels (rarely larger than 100 μm in diameter).

Larger vessels, such as the carotid artery of experimental rodents, have been visualized using real-time imaging. To accomplish this, the artery must be surgically exposed so that a special light device can be inserted under the vessel to tran-

silluminate it from below. This technique has been used to evaluate thrombotic occlusion models (16).

**Bedside**

Retinal vessels are evaluated routinely by clinicians. Direct visualization allows for the surveillance of many diseases of the retinal circulation, such as proliferative retinopathy in diabetes and arteriolar sclerosis.

Capillaroscopy is an established procedure for the evaluation of dermal vessels. Traditionally, this has been used to visualize vessels in the nail-bed but now is used to visualize vessels at other skin sites (17). Capillary density and shape are evaluated and typical changes occur with psoriasis, vascular insufficiency, diabetes, and aging.

Submucosal vessels have been evaluated using orthogonal polarization spectral imaging (OPS) (18). Taking advantage of the properties of polarized light, the device allows a probe, generally placed under the tongue, to visualize the submucosal microcirculation. This technique allows for visualization of undisturbed human vessels. Because the technique relies on polarized light, fluorescence techniques are not possible. Blood vessel diameter, flow, and leukocyte–endothelial interactions have been evaluated in the context of diabetes, hypertension, anesthesia, solid organ transplantation, and sepsis (19). Small studies have reported that parameters derived from OPS can predict patient survival in sepsis (20) and predict rejection of intestinal transplants (21). The system is available commercially as a product called Cytoscan from Cytometrics, of Philadelphia, Pennsylvania ([www.cytometrics.com](http://www.cytometrics.com)).

**ENDOTHELIAL FUNCTIONS EXPLORED BY REAL-TIME IMAGING**

**Permeability**

Tagged-albumin has been used extensively to measure vascular permeability. This approach has been adapted using fluorescent-tagged albumin to measure vascular leakage in the microvasculature in real-time (22).

**Cell Adhesion Molecule Expression**

The dynamic adhesion of leukocytes to ECs is the oldest and most studied endothelial function explored by real-time imaging. For example, P- and E-selectin expression in endothelium is routinely evaluated by quantifying leukocyte rolling in these vessels. This is an indirect method to study a process involved in inflammatory cell recruitment but, by using gene-deleted animals, it can be very specific for EC adhesion molecule expression in the specific condition studied (23). Because many cell adhesion molecule interactions have shear dependency, vessels with similar hemodynamic properties are usually compared. The state-of-the-art in this method involves using dynamic tracking of a transfused, fluorescent

dye-labeled leukocyte to describe the required length of the endothelium and cell adhesion molecules required for leukocyte arrest on the endothelium(15). Fluorescent-tagged antibodies also can be used to determine the luminal expression of molecules on the endothelium; this is most profoundly demonstrated by the spatial separation of two L-selectin ligands using the monoclonal antibody MECA-79 and a MECA-79-independent,  $\alpha(1,3)$ -fucosyltransferase-IV-dependent molecule (24).

Similar techniques have been used for evaluating the EC adhesion molecules involved in the transmigration of cells through the endothelial barrier. Multiphoton imaging has been used to visualize the movement of breast cancer cells through the extracellular matrix toward vessels and then their intravasation into the vessel (25). This technique is ripe for evaluating the role of EC adhesion molecules in mediating this "reverse" transport.

Finally, real-time imaging has proved useful in understanding the pathogenic role for the endothelium in sickle cell occlusion. It seems that the endothelium is a central player, linking inflammation and occlusion. Leukocytes adhere to inflamed endothelium in postcapillary venules via P-selectin and E-selectin. Then sickled red blood cells adhere to the leukocytes, and this results in vasoocclusion (26,27).

#### *Coagulant and Thrombotic Activity*

Recently, the real-time imaging of thrombosis in animal models has advanced knowledge in this field. Thrombotic clots, previously induced by chemical endothelial denudation, can now be induced by subtle injury to a single EC (28). The roles of platelet-endothelial cell adhesion molecule (PECAM)-1 (29) and endothelial P-selectin (29,30) in thrombus formation have been elucidated using these techniques. Soon, the roles of other endothelial molecules on thrombus formation in these models will be reported.

#### **Vasomotor Tone**

Techniques exist to study blood velocity and vessel diameter, specifically in small vessels and even capillaries using real-time imaging. Given these parameters, shear can be measured continuously and in real-time (31). The effect of nitric oxide (NO) inhibitors, vasoactive drugs, and the effects of gene deletions in this pathway have been studied.

#### **Regeneration**

Some aspects of our burgeoning knowledge of angiogenesis and vessel repair have been tested using real-time imaging. Angiogenesis is quantified by measuring vessel density. The expression of genes involved in angiogenesis, the source of the new endothelium, and physical properties of the young vessels have been evaluated with real-time imaging (7). Currently, most reports have involved the dorsal skin fold model, which is the only model ideal for evaluation of processes over days.

The early processes of angiogenesis have not been tested with real-time imaging.

### **MICROSCOPE METHODOLOGIES**

#### **Bright-Field Microscopy**

Traditional bright-field microscopy has been used to image vascular beds in real-time. The limitations of this approach include poor penetration of light through the tissue, limited accessibility of vascular beds, and difficulty in identifying cellular elements without specific markers. Nonetheless, because of the low cost and the lack of interfering factors, this technique remains powerful and ubiquitous. Polarization techniques offer enhanced contrast between objects based on their different refractive indices. Properly implemented, polarization allows clearer images that make cellular identification easier.

#### **Fluorescence Microscopy**

Fluorescence microscopy adds specificity to the identification of objects, cellular or molecular. Historically, limitations have been photobleaching of the fluorophore, photodamage by the excitation light, and the slow speed required to image multiple fluorescent colors. Recent advances in microscopy have lessened each of these limitations.

More affordable, sensitive imaging devices (driven by military and consumer demand) and better methods to switch excitation and/or emission filters have allowed for an increase in the speed with which multiple-color fluorescent images can be obtained (32). This also has lessened the intensity of excitation light, thus limiting tissue damage.

Confocal microscopes offer two advantages over traditional systems. Confocal images allow for better quantification of the amount of fluor using optical slice techniques. Tomograms of closely spaced images allow for quantification of fluor. Confocal images also allow for the evaluation of true optical resolution colocalization, and they can be used to determine if two fluors are optically colocalized.

Costly multiphoton systems offer all the advantages of confocal systems but also allow for deeper penetration into tissue. The longer wavelengths used in multiphoton systems scatter less at refractive-index changes. Multiphoton systems also have better colocalization than standard multiprobe confocal systems because, in the latter, the excitation beams are not the same single-point source. Finally, second-harmonic generation allows for imaging of  $\alpha$ -helical proteins, such as collagen and laminin in the extracellular matrix, without the need for a fluorescent label (25).

#### **Fluorescent Tags**

The progress in imaging fluorescence warrants a review of the techniques that couple fluorophores to biologically relevant molecules.

Traditional fluorophores had variable permeability into the cell. Now fluorophores are conjugated to lipophilic substances through bonds that are broken once the molecule enters the cell (33), thus making it almost impossible for the fluorophore to leave the cell.

Newer fluorophores (Alexa series from Molecular Probes, probes.com) are brighter and more bleach-resistant than traditional fluorescent dyes such as fluorescein. Quantum dots (34) (available at qdots.com) are semiconductor nanocrystals that are brightly fluorescent, bleach-resistant, and excited by white light, which limits tissue damage. The technologies used to attach quantum dots to biological molecules are improving, as are efforts to decrease in vivo toxicity (35). Quantum dots that emit in the near IR have been described (36).

Traditional and newer fluoros can be linked to even tiny amounts of protein, especially antibodies. Peptides can be synthesized with single amino acids prelabeled with fluor. Fluor/quencher combinations allow the evaluation of protease activity through the process of fluorescence resonance energy quenching (FRET). This has been explored to evaluate the activities of thrombin (37) and cathepsin B (38).

The cloning of the green fluorescent protein (GFP) from the bioluminescent jellyfish *Aequorea victoria* and the generation of gain-of-function mutants, most of which are available in expression vectors, have allowed gene products to be visualized using real-time imaging. GFP is a 27-kDa monomeric polypeptide that needs no substrate or cofactor to fluoresce. It is specific, relatively bright, and physiologically compatible. The advantages of GFP over luciferase in similar gene-based assays are that it has at least a 100-fold increased signal to noise ratio, no need for substrate, and the ability to image directly with multicolors using GFP family molecules (YFP, etc.) (39,40). GFP has been linked to a growing list of gene promoters, including Tie2 (41) and vascular endothelial growth factor (VEGF) (42).

The development of technology to use near-IR fluorescent probes as markers offers the promise of extending real-time imaging to larger and deeper vessels. The scatter of light is inversely proportional to wavelength and directly proportional to refractive index changes. Thus, longer wavelengths can penetrate tissue (where multiple refractive index changes occur) more deeply using the same tolerable amount of scatter. Fluorescent probes in the near IR have imaged cathepsin B activity to delineate atherosclerosis in living mice (38). Similar probes have the potential to allow visualization of probes as deep as 2 cm below the surface.

## CONCLUSION

Real-time imaging of endothelial function is currently limited largely to visible vessels, most commonly in animal models. In the future, advances in imaging modalities such as multiphoton microscopy and near-IR probes will allow real-time imaging to move to clinical use. Until then, lessons learned

in animal models using real-time imaging will allow advances in ultrasound and magnetic resonance imaging (see Chapter 176) to be applied in the clinic (43).

## KEY POINTS

The limitation of real-time imaging of the endothelium is light penetration into the tissue. Strategies to overcome this limitation include (a) the use of thin tissue, (b) the observation of vessels only at the surface of organs, (c) the use of brighter and more biocompatible fluorophores, (d) the use of near-IR fluorophores, and (e) multiphoton microscopy.

## Diagnosing Endothelial Cell Dysfunction

Aristides Veves and Roy Freeman

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

One of the major developments in medicine during the last two decades is the delineation of the role of endothelium in the development of cardiovascular disease. Soon after the first observations in animals, methods were devised that could evaluate endothelial function in humans. The initial methods were invasive, but subsequently noninvasive methods were established. During the last decade, these noninvasive methods have been standardized and widely used for the clinical research, while the possibility of using them in standard clinical practice is also raised. In this chapter we review the most commonly employed methods for assaying endothelium-dependent vasodilation in both the macro- and microcirculation.

### MACROCIRCULATION

#### Endothelium-Dependent versus Endothelium-Independent Vasodilation

Although the endothelium regulates the vascular tone by the balanced secretion of vasoconstrictors and vasodilators, it should be remembered that this is mainly achieved by the action of these vasomodulators on the vascular smooth muscle cell (VSMC). This can have serious implications in the interpretation of the results of various tests in humans. Thus, in the theoretical case in which VSMC vasodilatory capacity is impaired, those tests that assess the ability of endothelial cells (ECs) to produce vasodilators such as nitric oxide (NO) – endothelium-dependent vasodilation – will be abnormal. Therefore, correct interpretation of the data requires the consideration of both the endothelium-dependent and -independent vasodilation measurements that are collectively referred to as *vascular reactivity measurements*.

#### Venous Plethysmography

Venous plethysmography, or venous occlusive plethysmography, was the first technique used to measure vascular reactivity

(1). This technique employs a mercury in-silastic strain gauge coupled to a plethysmograph. The gauge is placed at the upper third of the forearm. An arm blood pressure cuff with rapid inflators that applies a 40 mm Hg pressure is used to achieve forearm venous occlusion. The average forearm blood flow (FBF) from at least five measurements performed at 10- to 15-second intervals is usually recorded. In some laboratories, the hand blood flow is excluded from the analysis. To achieve this, the blood flow to the hand is blocked at the wrist level by a cuff that is inflated to suprasystolic pressure levels. Once the baseline FBF has been measured, it is usually followed by brachial intra-arterial infusion of substances that produce either endothelium-dependent vasodilation (typically acetylcholine [ACh] or methacholine) or endothelium-independent vasodilation (typically sodium nitroprusside). The change in FBF usually is expressed as milliliter (mL) per minute per 100 mL of tissue. In addition, the ratio of the mean blood pressure to FBF represents the vascular resistance. In most laboratories, the opposite hand is employed as a control by injecting normal saline and performing the same FBF measurements. In a laboratory with appropriate training and experience, this technique has a satisfactory reproducibility, especially after the infusion of vasodilators, ranging from 0.90 to 0.97 over a 3-week period (2).

Venous plethysmography has been used extensively in human studies that examined the effect of various conditions (such as diabetes and hypertension) on vascular reactivity and the possibility of reversing endothelial dysfunction after various therapeutic interventions (3–5).

#### Invasive Blood Flow Measurements Using the Thermodilution Technique

The thermodilution technique was developed by Ganz and colleagues and employs a double-lumen, 5-French thermodilution catheter that can evaluate the instantaneous mixing of an infused indicator (cold saline) in the vein and measure blood flow in this vessel (6). This technique has been used

mainly to measure blood flow in the leg through the catheterization of the femoral vein and the infusion of vasodilators in the femoral artery (7–8).

### **Noninvasive Assessment of Brachial Artery Vascular Reactivity**

The noninvasive measurement of brachial artery vascular reactivity using standard ultrasound techniques is currently the most commonly used method to evaluate the function of the endothelium and vascular smooth muscle. The technique was first described by Celermajer and colleagues in 1992 (9). The main principle of the technique is to use high-resolution ultrasound to follow changes in the brachial artery diameter after employing methods that either directly stimulate the endothelium and cause endothelium-dependent vasodilation or act directly on the VSMC and result in endothelium-independent dilation. Detailed guidelines regarding subject preparation, image acquisition, data analysis, and quality control have been published in a technical report by the International Brachial Artery Reactivity Task Force (10).

Of the noninvasive measurements, flow-mediated vasodilation (FMD) is the main technique used to measure endothelium-dependent vasodilation. In brief, the subject is placed in a supine position, and the brachial artery is imaged above the antecubital fossa in the longitudinal plane (Figure 178.1). A 7-MHz or greater linear array transducer is used and two-dimensional grayscale scans are taken at rest and after the stimulation that leads to artery dilation. To measure the endothelium-dependent vasodilation, FMD stimulation is employed. This method involves inducing upper limb ischemia by occluding the brachial artery with a pneumatic tourniquet that is inflated 50 mmHg higher than the systolic blood pressure. The cuff can be placed either at the upper arm, an area proximal to the area where ultrasound imaging of the artery is performed, or on the upper forearm, an area distal to the ultrasound probe. The artery typically is occluded for 5 minutes. This leads to tissue hypoxia and pH changes in the tissues distal to the occlusion, mainly the muscles. As a result, immediately after the removal of the occlusion, a vasodilation occurs in the muscle and skin microcirculation that is directly related to hypoxia, changes in the tissue pH, and accumulation of deoxyhemoglobin. This causes a brief period of high blood flow in the brachial artery (reactive hyperemia), which creates increased shear stress that leads to the stimulation of the endothelium and causes vasodilatation. The brachial artery dilation typically peaks around 60 seconds after the removal of the occlusion, and the ultrasound images are taken 30 to 120 seconds after removal of occlusion. The baseline and highest postinflation brachial artery diameter are measured using sophisticated computer programs. Vessel diameter measurements are taken at end diastole, incident with the R-wave on the electrocardiogram (ECG). The percent of the postinflation increase of the artery diameter over the baseline indicates the FMD.

Initial studies employed forearm occlusion, whereas subsequent studies used upper arm occlusion (11). Upper arm occlusion leads to higher FMD values, but forearm occlusion has an advantage in that the brachial artery does not collapse during the occlusion period, making the image acquisition easier. Previous studies in our unit have shown a very satisfactory correlation in measurements taken with either upper arm or forearm occlusion in the same subjects (12). Therefore, both techniques are equally reliable and can be employed in clinical studies.

The most important factor that determines the reproducibility of the technique is the training of the personnel who are involved in the data acquisition and analysis. Because this method is technically challenging, only well-trained examiners should perform the tests. Various manual or semiautomatic techniques also are available for the image analysis, but they also require examiners with considerable experience. In well-organized laboratories, the interobserver difference has been found to be around 1.7%, and the coefficient of variation 1.4% (9). In addition, satisfactory reproducibility also has been demonstrated in longitudinal studies in both normal subjects and subjects with reduced FMD. Thus, the measurement error (1%–3%) was significantly less than the difference between normal and abnormal FMD responses (7%–10%) (9,10).

FMD can be measured in other peripheral arteries, such as the radial, axillary, and superficial femoral arteries (13,14). However, the reproducibility of these measurements is less than that of the brachial artery, and they are not widely accepted.

### **Endothelial Function Assessment of Coronary Arteries**

Coronary artery vascular tone is maintained by the same mechanisms that are involved in the maintenance of the vascular tone in the peripheral arteries. Because the coronary arteries are not easily accessible, the measurement of diameter changes is more difficult to quantify. The invasive method is most commonly used, and it involves infusion of ACh into the left coronary artery. The changes in the coronary artery diameter are assessed by quantitative angiography. In healthy vessels, ACh produces vasodilation, whereas in vessels with endothelial dysfunction, it causes vasoconstriction (15). The functional state of the myocardial microcirculation can be assessed using coronary intravascular Doppler that can measure changes in the blood flow in resistant vessels during the infusion of substances that produce endothelium-dependent or -independent vasodilation (16). Both these measurements can be performed in the same patient during the same session.

The correlation between coronary and peripheral artery functional measurements is very comparable. This is not surprising given the systemic nature of mechanisms that cause endothelial dysfunction and indicates that the changes in the endothelial dysfunction are comparable (17). As a result, peripheral artery measurements have been proposed as a

Figure 178.1. (A) The assessment of flow-mediated vasodilation in the brachial artery. A 7.0-MHz or greater linear array transducer is used to image the brachial artery above the antecubital fossa in the longitudinal plane. A regular sphygmomanometer is employed to occlude the artery blood flow. The sphygmomanometer can be placed either at the forearm (A) or the upper arm level (B). Two-dimensional grayscale scans are taken, one at rest at rest, before the cuff inflation (C) and 1 minute after the cuff deflation that leads to artery dilation (D). The percentage of the postocclusive artery diameter increase over the baseline represents the FMD.

surrogate means of identifying subjects at risk of cardiovascular events (18).

### Anatomic Imaging of the Vessels

#### *Common Carotid Artery Intimal-Medial Thickness*

An increase in the intimal-medial thickness (IMT) of the carotid artery is one of the first morphological changes that occurs early in the course of atherosclerotic development. IMT changes can be easily detected and quantified using high-resolution ultrasound B-mode imaging. This non-invasive technique allows visualization of early atherosclerotic plaque formation prior to the luminal narrowing caused by the late stages of atherosclerosis. Imaging usually is performed with high-resolution real-time scanners equipped with 7- to 8-MHz probes. The ultrasound pattern is characterized by two parallel echogenic lines separated by a hypochoic or anechoic space. This scan pattern is defined as the “double line pattern.” The inner (luminal) line, which is generally more regular, smooth, and thin than the outer one represents the

intima, the hypochoic line the media, and the outer echogenic line the adventitia. The distance from the inner echogenic line to the interface between the hypochoic line and the second echogenic line represents the IMT of the vascular wall (Figure 178.2) (19).

The technique is easy to perform and has a satisfactory reproducibility, with an interobserver coefficient of variation around 10% and an intraobserver coefficient of variation of approximately 5% (20). Furthermore, numerous studies have shown that IMT is associated with conventional risks for the development of atherosclerosis, and that it can predict the development of cardiovascular events (21,22). As a result, at present, IMT measurements are widely employed in clinical trials.

#### *Pulse Wave Velocity*

This technique uses Doppler probes to measure the speed of propagation of the forward-going pulse wave in the absence of reflections from the periphery, and is a surrogate measurement of the compliance of the studied artery. Pulse wave

Totowa, NJ: Humana Press; 2005:431–450.)

velocity (PWV) depends on the biophysical properties of the artery, and is increased in conditions that lead to stiff arteries, such as diabetes mellitus, hypercholesterolemia, coronary artery disease, and renal failure (23,24). Alternatively, the elastic properties of the aorta can be measured by employing cardiovascular magnetic resonance imaging (MRI). The major advantage of this technique is its accuracy, which allows for the detection of small differences and can be very useful for carrying out clinical trials with limited numbers of participants (25). Despite initial encouraging results, neither PWV nor MRI has gained universal acceptance, and these techniques have not been widely used in clinical trials.

## MICROCIRCULATION

### Measurements of Microcirculatory Blood Flow Using Laser Doppler Flowmetry

Laser Doppler flowmetry is a well-established and widely used technique for evaluating blood flow in the skin microcirculation. This technique measures the microcirculatory flux,

which is determined by a combination of velocity and the number of moving red blood cells (RBCs) within the arterioles, capillaries, and postcapillary venules.

Laser Doppler flowmetry utilizes the coherent properties of laser light to measure the velocity of a collection of moving RBCs within the illuminated area. A laser beam is delivered to the skin via a fiber optic light guide. The reflected light is gathered by a second set of light guides (photodetectors) and the Doppler-shifted fraction of the light signal and the mean Doppler frequency shift is calculated. A value, measured in mV, is obtained that is proportional to the quantity of moving RBCs and the mean velocity of those cells within the sample volume of cutaneous tissue. This value is a measure of superficial microvascular perfusion. This technology does not permit the assessment of absolute perfusion values (e.g., mL/min/100 gram tissue). The technique has been validated in a study comparing direct measurements of the capillary flow velocity using dynamic capillaroscopy with laser Doppler flowmetry (26).

Either a single-point laser probe, which evaluates the microvascular blood flow at one point of the skin, or a laser perfusion scanner, which evaluates the blood flow in an area of skin, can be used (Figure 178.3). In contrast to the single-point laser probe, which assesses blood flow at a single point across time, the perfusion scanner sequentially scans up to several hundred points in an area of skin, producing a local image of cutaneous microvascular perfusion. Cutaneous blood flow has temporal and spatial heterogeneity. The single-point Doppler overcomes the deficiencies in temporal heterogeneity, whereas the laser Doppler perfusion scanner overcomes the spatial heterogeneity. Integrating flow probes may help increase the cutaneous sampling area compared to single-point flow probes. The measuring area of the probe has several “probe tips.” Each probe tip has its own delivery fiber and photodetecting fiber. The values from each tip are optically integrated into one value. This method allows measurement over a larger area and thereby minimizes the effects of spatial heterogeneity and improves reproducibility of the technique.

## Provocative Techniques

### Vasoactive Drug Delivery

Iontophoresis and microdialysis are techniques in which agents can be delivered to local area with precision while minimizing the systemic effects associated with oral ingestion or parenteral infusions. Iontophoresis is a noninvasive method of introducing charged substances into the skin. A small charge allows the transcutaneous delivery of substances in high concentration without or with minimal trauma or pain. The number of molecules transported is a function of the length of stimulation, the current used, and the size of the stimulator. ACh, a positively charged ion, is delivered using anodal current, whereas the anion sodium nitroprusside is delivered using cathodal current.

The minimally invasive technique of microdialysis permits the delivery of larger, water-soluble molecules that lack a

Figure 178.3. (A) Measurements of direct and indirect effect of vasoactive substance using single-point laser probes: One probe is used in direct contact with the iontophoresis solution chamber (*shaded ring*) and measures the direct response. The center probe measures the indirect response (nerve axon-related effect). A small quantity (<1 ml) of 1% ACh chloride solution or 1% sodium nitroprusside solution is placed in the iontophoresis. A constant current of 200 mA is applied for 60 seconds achieving a dose of 6 mC/cm<sup>2</sup> between the iontophoresis chamber and a second nonactive electrode placed 10 to 15 cm proximal to the chamber (black strap around the wrist). This current causes a movement of solution to be iontophoresed toward the skin. (B) Laser Doppler flowmetry: A helium-neon laser beam is emitted from the laser source to sequentially scan the circular hyperemic area (seen surrounding the laser beam) produced by the iontophoresed vasoactive substance to a small area on the volar surface of the forearm.

charge. Microdialysis probes are inserted into the upper dermis under needle guidance and perfused with saline or Ringer's solution at a rate of 2 to 5  $\mu$ L/min. This technique is well tolerated and also can be used to sample water-soluble molecules within the extracellular space.

#### Vasoactive Agents

In studies, ACh is typically used to provoke endothelial-dependent vasodilation, whereas the NO donor, sodium nitroprusside, is used to provoke endothelial-independent vasodilation. ACh can be delivered by iontophoresis or microdialysis.

ACh binds to M<sub>2</sub> muscarinic receptors on the endothelial surface and elicits an increase in cutaneous blood flow by a direct receptor-mediated effect. Acting via a G-protein-coupled receptor and catalyzed by constitutively expressed endothelial NO synthase (eNOS), ACh stimulates the production of NO, which is a potent mediator of endothelium-dependent vasodilation. Other factors released by the microvascular endothelium in response to ACh include vasoactive prostanoids and endothelium-derived hyperpolarizing factors (EDHF). Thus, intradermal delivery of exogenous ACh produces vasodilation via these nitridergic and non-nitridergic mechanisms.

Although NO plays a prominent role in vasodilation, the relative contribution of these factors, and most importantly NO and vasoactive prostanoids, to ACh-mediated cutaneous vasodilation is not definitively resolved. We and others (27–29) have reported that iontophoresed ACh-mediated vasodilation of the forearm microcirculation is not

substantially mediated by a prostanoid-dependent mechanism (Figure 178.4), whereas others have suggested that a prostanoid-dependent mechanism may play a prominent role in ACh-mediated vasodilation (30,31). The different results obtained in these studies may relate to the use of different acetylsalicylic acid (ASA) and other cyclooxygenase (COX) inhibitor formulations and doses, different routes of administration, varying iontophoretic protocols, and differing amounts of anodal current, which may cause vasodilation via a prostanoid-dependent pathway.

Microdialysis allows the use of NOS inhibitors such as N(G)-nitro-L-arginine methyl ester (L-NAME) to inhibit NOS production, and COX inhibitors, such as the non-selective COX inhibitor, ketorolac, to inhibit generation of prostanoid and thromboxane products, thereby permitting the elucidation of the relative contributions of NO and vasoactive prostanoids to ACh-mediated vasodilation. Nevertheless, microdialysis studies have not definitively resolved this issue. Kellogg and colleagues (32) reported that both NO and vasoactive prostanoids play a role in ACh-provoked vasodilation, whereas Holowatz and colleagues (33) suggested that vasoactive prostanoids play a prominent role in ACh-mediated vasodilation. Different microdialysis protocols may be responsible for the different results.

Endothelium-independent vasodilation is provoked by iontophoresis or microdialysis of the NO-donor, sodium nitroprusside. Vasodilation evoked by sodium nitroprusside is typically one-third less than that evoked by iontophoresis of ACh (34,35) and is equivalent to that achieved by increasing the local skin temperature to 42°C (36,37).

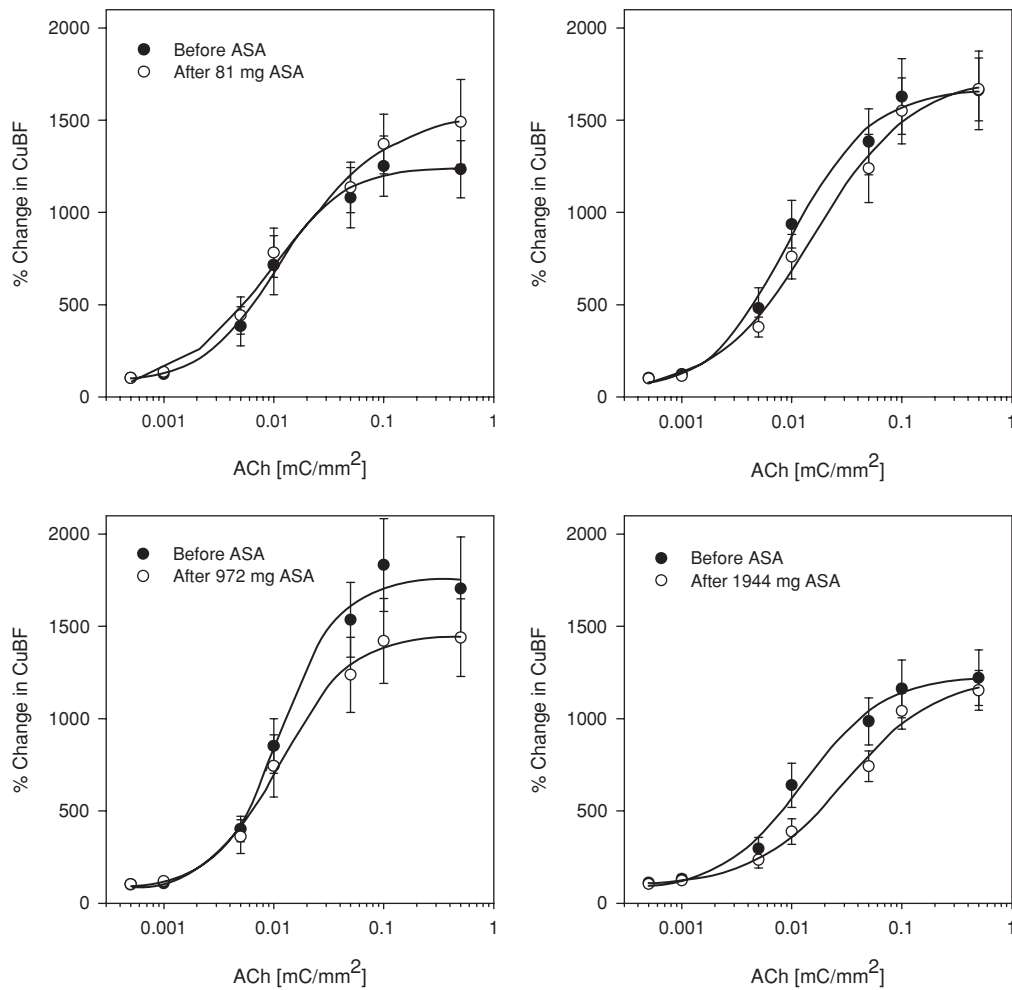

Figure 178.4. Iontophoresis of the endothelium-dependent vasodilator ACh resulted in a significant increase in cutaneous blood flow both before and after the administration of ASA (ANOVA,  $p < 0.0001$ ). This response was not changed by any of the four doses of ASA. Data are expressed as mean  $\pm$  SEM.

### Local Heat

Local heating of the skin also provokes vasodilation. Although the mechanisms underlying the vasodilatory response to local heating are still incompletely understood, it is recognized that vasodilation is mediated by neurogenic reflexes and locally released neurotransmitters and neuromodulators. Although there is some variability in the response to local heating – in part related to the peak and starting temperature, the duration of heat application, and the rate of heat increase – there is a stereotyped response that appears generalizable across experimental paradigms. An initial brisk vasodilatory response peaks within minutes. This is followed by a short nadir that is, in turn, followed by a secondary dilation to a sustained plateau.

The initial vasodilatory response to local warming is evoked by local axon reflex-mediated antidromic neurotransmitter release from sensory afferents; this response is reduced by topical anesthesia in the region of local heating and is not attenuated by more proximal nerve blockade. The vasodila-

tory response primarily is mediated by the release of calcitonin gene-related peptide (CGRP) and substance P from C-fiber nociceptors. The sustained plateau phase of local heating-induced vasodilation is mediated by local generation of NO. This response is attenuated by pretreatment of the locally warmed area of skin with the NOS inhibitor, L-NAME. The interaction between the mediators of these two responses to local heating is not fully elucidated.

### Clinical Utility of Microvascular Assessment

Laser Doppler flowmetry has been widely used to evaluate endothelial function in the limbs of diabetic patients (34,38,39). Impairment of endothelium-dependent vasodilation alone and in combination with endothelium-independent microvascular blood flow has been shown in different studies. The differences between studies depend on the duration of diabetes, the severity of the vascular complications of diabetes, and the site of study: Endothelium-dependent

Figure 178.5. The endothelium-dependent and -independent vasomotor response to ACh and nitroprusside iontophoresis (DN, diabetic neuropathy; DV, diabetic vascular diseases; DA, Charcot arthropathy; D, Diabetic controls; C, Controls).

and -independent vasodilatation are significantly lower at the foot level when compared to the forearm level in both healthy controls and in diabetic patients (40). The drug delivery protocol also has an important influence on study results.

For example, we studied endothelial-mediated microvascular blood flow in neuropathic diabetic patients with a predisposition to ulceration. Vasodilation on the dorsal foot in response to heating and iontophoresis of a single, maximal dose of ACh (endothelium-dependent response) and sodium nitroprusside (endothelium-independent response) were measured using single-point laser Doppler and laser Doppler imaging in diabetic patients with neuropathy, diabetic patients with neuropathy and peripheral macrovascular disease, diabetic patients with Charcot arthropathy, diabetic patients without complications, and in healthy control subjects. The endothelial-mediated response to ACh was reduced in the patients with diabetic neuropathy, diabetic patients with Charcot arthropathy, and diabetic patients with peripheral macrovascular disease compared with control patients with diabetes and healthy control subjects. The nonendothelial-mediated response to sodium nitroprusside also was reduced in the patients with diabetic neuropathy, diabetic patients with Charcot arthropathy, and diabetic patients with vascular disease compared with control patients with diabetes and healthy control subject groups. A significant reduction in vasodilation occurred in the vascular disease group compared with all other groups (39) (Figure 178.5). Using the same iontophoretic protocol but assessing microvascular function in the forearm with laser perfusion imaging, endothelial-dependent and -independent vasodilation was observed in patients with impaired glucose tolerance and in relatives of type 2 diabetic patients (41).

In a follow-up study, we examined less severely afflicted patients at the forearm, a site that is less susceptible to peripheral neuropathy and vascular disease. In addition, we modified the iontophoretic protocol, using incremental doses of

Figure 178.6. The endothelium-dependent vasomotor response to ACh iontophoresis. Application of ACh led to an increase in endothelium-dependent blood flow that is impaired in diabetic patients ( $p < 0.005$ ). The maximum blood flow increase in type 2 diabetes is reduced compared to controls ( $p = 0.001$ ). A trends is noted toward impaired endothelial-mediated blood flow in type 1 diabetic patients compared with controls. A rightward shift of the dose-response curves occurs in the diabetic subjects that did not reach significance. Data are expressed as mean  $\pm$  SEM.

vasoactive agents to reveal subtle changes in the reactivity of the microcirculation. Using this dose-response technique, endothelium-dependent vasodilation of the forearm cutaneous microcirculation was attenuated in both diabetic subject groups. The response was significantly less in type 2 diabetic subjects than in type 1 subjects. There was no significant abnormality in endothelium-independent vasodilation in either diabetic group.

The duration of diabetes in type 2 diabetics was a significant predictor of the maximum endothelium-mediated vasodilation. These data suggest that, in type 2 diabetic patients, endothelial dysfunction precedes VSMC dysfunction (34). There was evidence of mild or early small fiber impairment in the forearm in both patient groups; both type 1 and type 2 diabetic subjects had impaired axon reflex (C-fiber)-mediated vasodilation. (Figure 178.6). In contrast, patients with primary (AL; immunoglobulin light-chain associated) amyloidosis had impaired forearm endothelial-dependent vasodilation with normal endothelium-independent and C-fiber-mediated vasodilation (35).

### Clinicopathological Correlations

Skin biopsy has been used to examine the relationship between microvascular function and pathological changes in the skin. One possible mechanism for impairment of endothelial function in diabetic neuropathy is the reduction in the expression of the eNOS activity. We have tested this hypothesis by evaluating the immunohistochemistry staining for eNOS of foot skin biopsies taken from diabetic neuropathic patients with or

without peripheral vascular disease and healthy subjects. The results showed reduced staining for the diabetic patients when compared with the healthy subjects (39). Similar results were reported by other investigators using immunohistochemistry and Western blotting techniques (42).

Recently, data has emerged showing poly (ADP-ribose) polymerase (PARP) to be involved in endothelial dysfunction as well. PARP is a nuclear enzyme that responds to oxidative DNA damage by activating an inefficient cellular metabolic cycle, leading to cell necrosis. PARP activation was higher in patients with type 2 diabetes, patients with glucose intolerance, and individuals with a family history of type 2 diabetes groups than in the healthy controls (43). The activation of PARP was associated with changes in the vascular reactivity of the skin microcirculation in forearm biopsies taken from these subjects, supporting the hypothesis that PARP activation contributes to changes in microvascular reactivity. Further study is required to prove this association.

#### KEY POINTS

- The function of both the EC and VSMC can be reliably evaluated in both the microcirculation and macrocirculation. This has contributed to the understanding of the pathophysiology of atherosclerotic development in humans.
- Although the first described techniques were invasive, these assessments can be currently performed in the peripheral arteries and skin microcirculation using noninvasive methods.
- Noninvasive techniques are robust enough to be employed for the conduction of interventional studies.
- The assessment of endothelial function in the coronary arteries still requires invasive techniques.

#### Future Goals

- To standardize techniques so that collaboration between various centers and the conduction of multicenter studies will be facilitated
- To acquire more information regarding the correlation between changes in the micro- and macrocirculation and changes in the microcirculation of various organs

## Statins

James K. Liao

*Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts*

Risk factors for cardiovascular disease, such as cigarette smoking, hypertension, and elevated serum lipid levels impair endothelial function and lead to the development of atherosclerosis. Recent studies suggest that 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase inhibitors or statins reduce cardiovascular events, in part, by improving endothelial function. Statins reduce plasma cholesterol levels, thereby decreasing the uptake of modified lipoproteins by endothelial cells (ECs). There is increasing evidence, however, that statins may also exert effects beyond cholesterol lowering. Many of these cholesterol-independent or "pleiotropic" vascular effects of statins appear to involve restoring or improving endothelial function by increasing the bioavailability of nitric oxide (NO), promoting re-endothelization, reducing oxidative stress, inhibiting inflammatory responses, and increasing fibrinolysis. Thus, the endothelium-dependent effects of statins may contribute to many of the beneficial effects of statin therapy in cardiovascular disease.

### STATINS AND ENDOTHELIAL FUNCTION

Statins inhibit an early rate-limiting step in cholesterol biosynthesis (Figure 179.1). This leads to increased hepatic low-density lipoprotein (LDL) receptors and enhanced uptake of cholesterol by the liver. Indeed, therapeutic doses of statins potentially reduce serum cholesterol levels in humans, and several large clinical trials have demonstrated that inhibition of HMG-CoA reductase by statins markedly decreases the incidence of cardiovascular events in hypercholesterolemic individuals (1,2). Because of the strong association between elevated serum cholesterol levels and coronary atherosclerotic disease, the reduction of serum cholesterol levels by statins has been proposed to be the predominant mechanism underlying the beneficial effects of these drugs. Indeed, acute plasma LDL aphaeresis improves endothelium-dependent vasodilatation (3), suggesting that statins could restore endothelial function, in part, by lowering serum cholesterol levels.

In some studies with statins, however, restoration of endothelial function occurs before significant reduction in serum cholesterol levels, suggesting that there are additional effects on endothelial function beyond those of cholesterol reduction. Some of the early benefits of statin therapy include improvement in vasomotor response to endothelium-dependent agonists (4), enhancement in coronary blood flow (5), and reduction of adhesion molecule expression in vivo (6) (Table 179-1). The mechanism is due, in part, to statin's ability to increase endothelial NO production by stimulating and upregulating endothelial NO synthase (eNOS) (7,8). Furthermore, statins have been shown to restore eNOS activity in the presence of hypoxia (9) and oxidized low-density lipoprotein (ox-LDL) (8), conditions which lead to endothelial dysfunction. Statins also increase the expression of tissue-type plasminogen activator (t-PA) (10) and inhibit the expression of endothelin (ET)-1, a potent vasoconstrictor and mitogen (11). Statins, therefore, exert many favorable effects on the endothelium and attenuate endothelial dysfunction in the presence of atherosclerotic risk factors.

### MECHANISMS UNDERLYING THE PLEIOTROPIC EFFECTS OF STATINS

#### Changes in Endothelial Nitric Oxide Synthase and Nitric Oxide – a Common Mechanistic Thread

There is growing appreciation that statins exert many of their pleiotropic effects via eNOS/NO. Statins decrease the extent of cerebral and myocardial ischemia-reperfusion injury in rodents without changes in serum cholesterol levels (12,13). The vascular protective effects of statins are associated with increased blood flow, attenuated P-selectin expression, and decreased leukocyte adherence (14). Pretreatment with statins increases eNOS mRNA expression as well as eNOS activity, and vascular protection by statins is completely abolished in eNOS-knockout mice or after cotreatment with the NOS inhibitor, N(G)-nitro-L-arginine methyl ester L-NAME (12,13).

Figure 179.1. Inhibition of HMG-CoA reductase by statins decreases the synthesis of isoprenoids and cholesterol. The isoprenoid, geranylgeranyl (GG), is an important lipid attachment for Rho, which permits the subsequent membrane translocation and activation of Rho and Rho kinase. Inhibition of Rho/Rho-kinase activity by statins leads to an increase in eNOS expression and activity. Furthermore, statins activate eNOS by stimulating the PI3K/Akt pathway by a yet unidentified mechanism.

A clue to the mechanisms by which statins alter eNOS/NO activity (and exert other pleiotropic effects) is found in the biochemistry of the HMG-CoA reductase pathway. Inhibition of the HMG-CoA reductase pathway not only reduces cholesterol production, but also prevents the formation of various isoprenoid intermediates (see Figure 179.1). For example, farnesylpyrophosphate (FPP) and geranylgeranylpyrophosphate (GGPP) serve as important lipid attachments for the post-translational modification of a variety of proteins, including the subunit of heterotrimeric G-proteins and small guanine triphosphate (GTP)-binding protein Ras, and Ras-like proteins, such as Rho, Rab, Rac, Ral, or Rap. Protein isoprenylation allows the covalent attachment, subcellular localization, and intracellular trafficking of several membrane-associated proteins. Although the effects of statins on Ras and Rho isoprenylation are reversed in the presence of FPP and GGPP, respectively, the effects of statins on eNOS expression are only reversed with GGPP and not by FPP or LDL cholesterol (15). Indeed, direct inhibition of GGPP or Rho leads to increases in eNOS expression (15,16). These find-

ings are consistent with a non-cholesterol-lowering effect of statins and suggest that inhibition of Rho by statins mediates the increase in eNOS expression. Statins upregulate eNOS expression by prolonging eNOS mRNA half-life but not eNOS gene transcription (15). Because hypoxia, oxidized LDL, and cytokines such as tumor necrosis factor (TNF)- $\alpha$  decrease eNOS expression by reducing eNOS mRNA stability, the ability of statins to prolong eNOS half-life may make them effective agents in counteracting conditions that downregulate eNOS expression.

Furthermore, it has been recently reported by Kureishi and colleagues that statins can activate protein kinase Akt (7). The serine-threonine kinase Akt is an important regulator of various cellular processes including cell metabolism and apoptosis. Stimulation of receptor tyrosine kinases and G-protein-coupled receptors leads to the activation of phosphoinositide 3-kinase (PI3K), the products of which, namely 3' phospholipids, promote the phosphorylation and activation of Akt. Inhibitors of PI3K, such as wortmannin, block the effects of statins on Akt activation (7). Akt has been shown to modulate

**Table 179-1: Statin Mediators, Effects, and Benefits**

<i>Effect</i>	<i>Mediator</i>	<i>Benefit</i>
Reduction in activity of NADPH oxidase	Rac1	Reduction of oxidative Stress
Decrease in synthesis of ET-1	Rho	Improvement of endothelial function
Decrease in the expression of AT <sub>1</sub> -receptor	Rho	Improvement of endothelial function
Decrease in the expression of t-PA	Rho	Reduction in thrombosis
Increase in the expression of PAI-1	Rho	Reduction in thrombosis
Decrease in the expression of adhesion molecules	LFA-1, Rho	Reduction of inflammation
Increase in eNOS activity	Rho, Akt	Improvement of endothelial function
Increase in number and differentiation of circulating ECs	Akt	Increase in neovascularization and re-endothelization
Inhibition of apoptosis	Akt	Increase in cell survival

several targets, such as caspase-9 and eNOS, by phosphorylation. Consequently, activation of Akt by statins inhibits apoptosis and increases NO production in cultured ECs. Therefore, in addition to stabilizing eNOS mRNA by inhibition of Rho, there is increasing evidence that activation of the PI3K/Akt pathway also may contribute to the endothelium-dependent effects of statins, although the precise mechanisms by which PI3K is activated by statins are not yet identified.

### Vasomotor Tone

In addition to their effects on eNOS/NO statins may have other effects on the balance of vasomotor mediators. Several vasoconstrictors, including ET-1 or angiotensin (Ang)-II, counteract the vasodilating effect of NO and thus contribute to endothelial dysfunction and the development of atherosclerosis. Circulating concentrations and tissue immunoreactivity of ET-1 are increased in patients with severe atherosclerosis (17–19). ET-1 has also been shown to function as a mitogenic agent. Exposure to ox-LDL leads to an increased production and release of ET-1 (20), which promotes neointimal proliferation of atherosclerotic lesions (20). Statins have been shown to inhibit *pre-proET-1* mRNA expression in a concentration-dependent manner and to reduce immunoreactive ET-1 in bovine ECs, a phenomenon which has been suggested to be mediated by Rho proteins (11,21). Furthermore, statins modulate the renin-angiotensin-system by downregulating the expression of angiotensin receptor subtype 1 (AT<sub>1</sub>) in a Rho A-dependent manner and attenuating the biological function of Ang-II in vascular smooth muscle cells (VSMCs) (22).

### Redox State

Another potential mechanism by which statins may improve endothelial function is through their antioxidant effects. For example, statins attenuate Ang-II-induced free radical production in cultured VSMCs by inhibiting Rac1-mediated nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity and downregulating angiotensin AT<sub>1</sub>-receptor expression (23). More recently, Wassmann and colleagues reported that atorvastatin reduced VSMC mRNA expression of essential NADPH oxidase subunits *p22<sup>phox</sup>* and *NOX1* by a mechanism that might involve the translocation of Rac1 from the cytosol to the cell membrane (23,24). Because NO is scavenged by reactive oxygen species (ROS), these findings indicate that the antioxidant properties of statins also may contribute to their ability to improve endothelial function. Furthermore, withdrawal of statin treatment in mice has been shown to impair endothelium-dependent relaxation by increasing vascular superoxide anion generation via a pathway involving the Rac-dependent activation of the gp91<sup>phox</sup>-containing vascular NADPH oxidase (25). ROS directly affects the endothelial function, and the endothelium itself has also been shown to generate ROS (26).

### Inflammation

Atherosclerosis is a complex inflammatory process that is characterized by the presence of monocytes or macrophages and T lymphocytes in the atheroma. Inflammatory cytokines secreted by these macrophages and T lymphocytes can modify endothelial function, VSMC proliferation, collagen degradation, and thrombosis. An early step in atherogenesis involves monocyte adhesion to the endothelium and penetration into the subendothelial space. Statins have been shown to reduce the number of inflammatory cells in atherosclerotic plaques and therefore possess anti-inflammatory properties. The mechanisms have yet to be fully elucidated, but may involve inhibition of adhesion molecules such as intercellular adhesion molecule (ICAM)-1, interleukin (IL)-6, and IL-8, which are involved in the recruitment of inflammatory cells. In addition, a recent study has shown that statins can suppress the inflammatory response independent of HMG-CoA reductase inhibition by binding directly to a novel regulatory site of the  $\beta_2$  integrin, leukocyte function antigen (LFA)-1 (27). This regulatory site serves as a major counter-receptor for ICAM-1 on leukocytes. The non-NO mechanism of the anti-inflammatory properties of statins was further elucidated by Yoshida and colleagues, who recently demonstrated that cerivastatin reduced monocyte adhesion to vascular endothelium by decreasing expression of integrins such as vascular endothelial adhesion molecule (VCAM)-1 and actin polymerization through the inactivation of RhoA (28).

A clinical marker of inflammation is high-sensitivity C-reactive protein (hs-CRP). hs-CRP is an acute phase reactant that is produced by the liver in response to proinflammatory cytokines such as IL-6, and reflects low-grade systemic

inflammation. Elevated levels of hs-CRP have been shown to be predictive of increased risk for coronary artery disease (CAD) (29). CRP could contribute to the development of atherosclerosis by binding to modified LDL within atherosclerotic plaques (30) and inhibiting eNOS (31,32). However, further studies are needed to fully elucidate the role CRP plays in atherosclerosis.

Statin therapy lowers hs-CRP levels in hypercholesterolemic patients. In the Cholesterol and Recurrent Events (CARE) trial, statins significantly decreased plasma hs-CRP levels over a 5-year period in patients who did not experience recurrent coronary events (33). Similarly, an analysis of baseline and 1-year follow-up from the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) demonstrated that hs-CRP levels were reduced in statin-treated patients who were free of acute major coronary events (34). These studies, therefore, indicate that statins are effective in decreasing systemic and vascular inflammation. However, any potential clinical benefits conferred by lowering hs-CRP are difficult to separate from those of the lipid-lowering effects of statins without performing further clinical studies.

### Fibrinolysis

Plasminogen activator inhibitor type (PAI)-1 is the major endogenous inhibitor of t-PA, and it also plays a pivotal role in the regulation of fibrinolysis. High PAI-1 plasma levels and decreased levels of t-PA activity have been shown to be associated with coronary heart disease (35). *PAI-1* mRNA has also been found in human atherosclerotic lesions, underscoring its potential role in the development of these disorders. Increasing evidence from in vitro studies suggest that statins positively affect the fibrinolytic system of cultured ECs. In these studies, a decrease in PAI-1 and an increase in t-PA was observed after treatment with statins in ECs (10,36). Statins may therefore interfere with the progression of the atherosclerotic plaque as well as with thrombotic events in hyperlipidemic patients, independently of their ability to reduce plasma cholesterol, but further studies are needed to delineate its physiological significance.

### STATINS AND RE-ENDOTHELIZATION

Stimulation of re-endothelization or neovascularization is a therapeutic aim to reduce ischemia-induced tissue injury. Postnatal neovascularization was mainly attributed to angiogenesis, that is, the proliferation, migration, and remodeling of preexisting ECs. However, some studies have recently demonstrated that bone marrow-derived endothelial precursor cells (EPCs) also are involved in this process. EPCs can be grown out of isolated CD133<sup>+</sup> or CD34<sup>+</sup> cells. Transplantation of these cells leads to postnatal neovascularization in the ischemic hindlimb, augments ischemia-induced neovascularization in vivo (37), and even improves postischemic cardiac function (38).

Recent studies revealed that statins also promote vasculogenesis. Llevadot and colleagues demonstrated in vitro that

simvastatin evokes proliferation, migration, and cell survival of EPCs (39). The signal pathway for this effect includes activation of protein kinase Akt, which was confirmed by functional blocking with dominant negative Akt overexpression. Dimmeler and colleagues showed in vitro and in vivo that statins not only increase the number of circulating ECs, but also induce their differentiation (40). This might be of clinical relevance, because it has been recently reported by Walter and coworkers that induction of these cells with statins is associated with an accelerated re-endothelization after carotid balloon injury (41).

In contrast, some studies report an antiangiogenic effect of statins, which might be mediated by RhoA (42). These conflicting effects of statins may be related to the dose used. Low doses of a statin may activate endothelial Ras and promote Akt and eNOS phosphorylation and lead to an angiogenic effect, whereas higher statin doses are antiangiogenic although they promote an increase in eNOS protein expression (43). This hypothesis remains controversial because high doses of statins also have been shown to be angiogenic (44), and further studies are necessary to clarify this topic.

### KEY POINTS

- Although the reduction of plasma cholesterol levels by statins improves endothelial function and limits atherosclerosis, statins may exert cholesterol-independent effects on the endothelium
- The endothelial-protective effects of statins could lead to further improvements in vascular function.
- Most of noncholesterol effects of statins are mediated by inhibition of isoprenoid synthesis and increases in NO release or bioavailability.

### Future Goals

- To determine which of the statin effects are more predominant, in terms of clinical outcome, in patients with low or average cholesterol levels, although both direct and indirect endothelium-dependent effects of statins play important roles in vascular protection

### ACKNOWLEDGMENTS

The work described in this article was supported in part by the National Institutes of Health (HL-52233 and NS-10828) and the American Heart Association Bugher Foundation Award.

## Steroid Hormones

James K. Liao

*Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts*

Many cellular responses to steroid hormones involve the transcriptional modulation of target genes by the prototypical nuclear receptor, the steroid hormone receptor. In the classic model of steroid hormone action, steroid hormones such as estrogen and glucocorticoids function essentially as ligand-dependent transcription factors by either activating or repressing gene expression through direct interactions with DNA or other transcription factors. However, recent evidence suggests an important role for the nontranscriptional effects of steroid hormones in the vascular system, particularly in endothelial cells (ECs), where they mediate the rapid activation of endothelial nitric oxide synthase (eNOS).

For example, the activated estrogen receptor (ER) mediates signaling cascades that culminate in direct protective effects such as vasodilation, inhibition of response to vessel injury, limiting myocardial injury after infarction, and attenuating cardiac hypertrophy. These effects of ER are mediated by rapid signaling pathways at the membrane and in the cytoplasm via various second messengers including protein kinases. Similarly, the nontranscriptional actions of the glucocorticoid receptor (GR) involve the rapid activation of protein kinases, such as phosphoinositide 3-kinase (PI3K) and Akt, leading to the activation of eNOS. These rapid, nongenomic pathways of estrogen and glucocorticoids may provide the pharmacological basis for future therapeutic approaches to cardiovascular diseases (Table 180-1).

### SIGNALING PATHWAYS MEDIATED BY STEROID HORMONES

The study of steroid hormone action has provided many important insights into the regulation of cellular functions by nuclear receptors and, at the same time, has revealed surprising levels of biological complexity. Upon binding to steroid hormones, steroid hormone receptors such as ER and GR homodimerize (3,33), recruit coactivators and corepressors (34–36), and act as ligand-dependent transcription factors, which regulate gene expression through interaction with their corresponding DNA enhancer sequences called *steroid*

*response elements* (SREs) (37). In the case of ER and GR, these SREs are ERE and GRE, respectively (2,38). However, recent studies suggest that not all the actions of estrogen and glucocorticoids are mediated via this classical genomic pathway. For example, in the heart and vasculature, some of the rapid, non-nuclear effects of ER and GR include vasodilation (6,11,12), inhibition of response to vessel injury (6,11), and reduction in myocardial and cerebral injury after infarction (11,12). In contrast to the hours required for transcription-dependent effects to become evident, nonnuclear steroid actions (alternatively referred to as *nontranscriptional* or *nongenomic*) in multiple cell types peaks minutes after stimulation. Other characteristics include immunity to inhibitors of RNA synthesis and recruitment of membrane or cytosol-localized signaling components. These include second messengers (e.g., calcium and nitric oxide [NO]), receptor tyrosine kinases (e.g., epidermal growth factor receptor [EGFR] and insulin-like growth factor-1 receptor [IGFR]), G-protein-coupled receptors (GPCRs), and protein kinases (e.g., PI3K, serine-threonine kinase [Akt], mitogen-activated protein kinase [MAPK] family members, nonreceptor tyrosine kinase [Src], and protein kinases A and C).

### ESTROGEN SIGNALING IN ENDOTHELIAL CELLS

#### Nongenomic Pathways

The PI3K/Akt signaling cascade is one downstream target of nonnuclear estrogenic signaling (6,7,39). In the vasculature, short-term exposure to estrogen leads to vasodilation via NO-dependent pathways (40). The secretion of NO by healthy vessels relaxes vascular smooth muscle cells (VSMCs) and inhibits platelet activation in a cyclic guanosine 3',5'-monophosphate (cGMP)-dependent mechanism. In cultured ECs, estrogen enhances NO release within minutes without altering the expression of eNOS (6–8,41). ER activates PI3K activity by association with the p85 $\alpha$  regulatory subunit of PI3K in a ligand-dependent manner (6) (Figure 180.1). Furthermore, the chaperone heat shock protein 90 (HSP90) interacts with both eNOS and Akt, and modulates

eNOS activity by acting as a scaffold to regulate Akt-dependent phosphorylation of eNOS (42).

MAPKs are a common target of non-nuclear estrogenic signaling. Induction of eNOS and inducible NOS (iNOS) in cardiac myocytes is blocked by the MAPK inhibitor PD98059 (43), which may have clinical relevance because NO inhibits caspase activation and prevents the development of congestive heart failure (44). Estrogen also activates extracellular-signal-regulated kinase (ERK1/2) in ECs, cardiomyocytes, colon cancer, breast cancer, and bone; and inhibits ERK1/2 in VSMCs and lung myofibroblasts (20,21,45,46). In the heart, ER also selectively activates the p38 isoform of MAPK to modulate the development of pressure-overload hypertrophy, which is consistent with recruitment of p38 MAPK in other models of cardiac hypertrophy (20). In cultured ECs, estrogen preserves the actin cytoskeleton during ischemia, prevents cell death, and enhances angiogenesis after injury by rapidly and selectively activating antiapoptotic p38 $\beta$  MAPK and inhibiting proapop-

otic p38 $\alpha$  MAPK, leading to upregulation of MAPK-activated protein kinase (MAPKAPK)-2 and phosphorylation of HSP27 (28). Downstream effects include preservation of stress fiber formation and membrane integrity, prevention of hypoxia-induced apoptosis, and induction of both EC migration and the formation of primitive capillary tubes (9,21,22,47).

**Membrane Estrogen Receptors**

Membrane binding sites for estrogen have been implicated in downstream signaling. Additional indirect evidence for a membrane ER comes from immunohistochemistry and studies with membrane-impermeable ligands or overexpressed nuclear receptor. The trafficking of classical ER to different cellular compartments may be regulated by the nature of stimulation. For example, in VSMCs transfected with ER, MAPK activation mediates nuclear translocation of ER $\alpha$  from the membrane fraction by both estrogen-dependent and -independent mechanisms (48). Indeed, recent studies suggest that ER and an alternatively-spliced form of ER, ER46, are targeted to the membrane by palmitoylation (49,50). ER appears to associate with membrane caveolae through palmitoylation of Cys<sup>447</sup> (50). For example, in fractionated EC plasma membranes, ER has been localized to caveolae, and estrogen stimulates eNOS in isolated caveolae in an ER- and calcium-dependent manner (9,51,52). Within the caveolae, evidence suggests that HSP90, eNOS and Cav-1 exist in a heterotrimeric complex in ECs that modulates eNOS activity depending on intracellular calcium levels (53,54).

Non-nuclear ER signaling also involves membrane heterotrimeric G proteins. In Chinese hamster ovary cells transfected with ER $\alpha$  cDNA, ER $\alpha$  in the membrane fractions activated G $\alpha_q$  and G $\alpha_s$  and rapidly stimulated inositol phosphate production and adenylyl cyclase activity, respectively (55). The G-protein activation also has been shown in ECs, where estrogen activation of eNOS can be inhibited with ICI 182,780, RGS-4 (a regulator of G-protein signaling specific for G $\alpha_i$  and G $\alpha_q$ ) and pertussis toxin (specific for G $\alpha_i$ ) (17).

**SELECTIVE ESTROGEN RECEPTOR MODULATORS**

An increasingly detailed understanding of the ER signaling network and its pleiotropic cellular effects has made the receptor an attractive pharmacological target. Selective ER modulators (SERMs) are ER ligands, which can have varying degrees of agonist or antagonist activities depending on the cell, promoter, and coregulator context.

Tamoxifen, the prototypical SERM, has indirect cardiovascular protective effects via reduction of serum total cholesterol and low-density lipoprotein (LDL) levels (56). Unfortunately, its strong agonist activity in the endometrium leads to endometrial hyperplasia and low-grade cancers. Raloxifene, a nonsteroidal compound, is similar to tamoxifen but it is less agonistic in the endometrium (57). Although administered

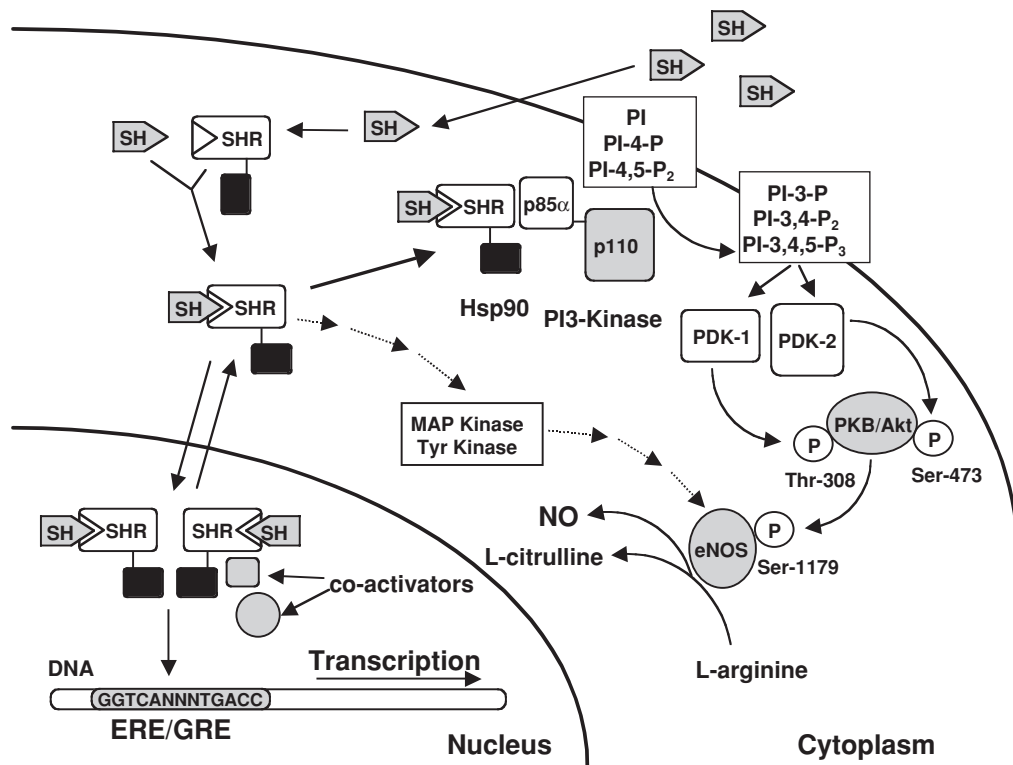

Figure 180.1. Nuclear and non-nuclear actions of the estrogen and glucocorticoid receptor. Association of steroid hormone receptor (SHR) with the regulatory p85 subunit of PI3K stimulates formation of 3'-phosphorylated phosphatidylinositols (e.g., phosphatidylinositol 3,4,5-trisphosphate, PIP<sub>3</sub>) from phosphatidylinositol phosphate precursors (e.g., phosphatidylinositol 4,5-trisphosphate, PIP<sub>2</sub>). This leads to the subsequent recruitment and activation of protein kinase Akt, which enhances NO release through phosphorylation of eNOS. In the nucleus, SHR binds either directly to estrogen or glucocorticoid response elements (ERE or GRE) or modulates the function of other transcription factors.

primarily for bone preservation, raloxifene also reduces serum triglycerides and serum fibrinogen levels. Like estrogen, raloxifene and its analog LY117018 (58) stimulate eNOS activity in ECs via PI3K- and ERK-dependent pathways (59), suggesting a possible mechanism for coronary artery relaxation (60). Raloxifene also improves endothelium-dependent vasorelaxation in hypertensive rats by enhancing the expression and activity of nitric oxide synthase (NOS) (61).

EM-800, a nonsteroidal compound, has higher affinity for ER than any other SERM (62). In addition to demonstrating potent antitumor activity in the uterus and breast, EM-800 may also prevent bone loss and lower serum cholesterol and triglyceride levels (63). Furthermore, *in vitro* studies in ECs suggest that EM-800, like estrogen, enhances NO release by sequential activation of MAPKs and PI3K/Akt, implicating a direct vascular protective effect (64).

## GLUCOCORTICOIDS AND VASCULAR DISEASE

Corticosteroids are essential for normal development and the stress responses through the regulation of intermediary metabolism and the immune system (65,66). Produced by

the adrenal glands under the regulation of the hypothalamus-pituitary gland axis, corticosteroids were among the first hormones to be identified and were later found to exert their effects through a specific DNA-binding protein, the GR (33). Molecular analysis of the anti-inflammatory actions of GR, however, later revealed a second important mechanism of GR function in the nucleus. Activated GR could negatively regulate expression of inflammatory genes through direct protein-protein interaction with proinflammatory transcription factors without DNA binding (termed *transrepression*) (67,68). Recent findings suggest that there is yet another level of GR action with particular importance for the vascular system. Similar to ER, the rapid, nontranscriptional effect of GR was found to mediate tissue protection in myocardial infarction (MI) and stroke through activation of eNOS, which was mediated by the PI3K/Akt pathway (11,12).

Corticosteroids have been used in the treatment of cardiovascular disease, such as acute MI and stroke, with conflicting results (69). Several features make steroids attractive candidates for the treatment of acute ischemia. The degree of ischemic tissue damage is related to the extent of the inflammatory response, which is coordinated through the interaction of leukocytes with activated vascular endothelium.

Corticosteroids inhibit EC activation and leukocyte-endothelial interaction, thereby exerting prominent, and very rapid, anti-inflammatory effects on the vasculature via transrepression mechanisms and eNOS activation (70). Steroid treatment improves the survival of patients with acute MI and protects the myocardium from experimental ischemic injury (71–73). In ischemic stroke, steroids can improve clinical outcome in a subset of patients with severe stroke, and administration of high doses of corticosteroids substantially reduces tissue damage in experimental focal cerebral ischemia (74–77). In addition, high-dose steroid treatment decreases vascular inflammation and ischemic tissue damage after myocardial infarction and stroke through direct vascular effects involving the nontranscriptional activation of eNOS (11,12).

The prolonged use of glucocorticoids, however, is often limited by their adverse effects, attributed to a delayed genomic response initiated by GR. This is exemplified by the clinical syndrome of hyperglycemia, dyslipidemia, hypertension, osteoporosis, and impaired wound healing in patients with chronic corticosteroid excess (i.e., Cushing syndrome) (78). In contrast to short-term high-dose steroid treatment with increases eNOS activity, the downregulation of eNOS expression by chronic steroid treatment is thought to contribute to steroid-induced hypertension (79). Indeed, continued low-dose steroid administration increases ischemic injury after global ischemia of the brain (80). In MI, impaired wound healing and cardiac remodeling can lead to cardiac rupture within 2 weeks of MI (81,82), and this has led to discontinuation of steroid treatment for acute ischemia. Therefore, defining the exact molecular mechanisms involved in the beneficial and detrimental effects of GR could have important therapeutic implications.

### Rapid Actions of GR

Similar to estrogen, corticosteroids appear to exert very rapid “nontranscriptional” effects (83). However, it should be noted that this concept of nongenomic effects of steroid hormones does not exclude the possibility of indirect downstream transcriptional modulation secondary to the initiated signaling pathways. Corticosteroids alter amphibian behavior and increase inositol trisphosphate in VSMCs within minutes of administration (84,85). In mice, the antianaphylactic effect of high-dose corticosteroids occurs acutely and is unaltered by the transcriptional inhibitor actinomycin D (86). Furthermore, in patients with active rheumatoid arthritis, steroids rapidly inhibit leukocyte recruitment into inflamed joints (87). In MI and ischemic stroke, high-dose steroids cause a transient decrease in blood pressure and systemic vascular resistance accompanied by an increase in coronary and cerebral blood flow within minutes of administration (12,72,88).

There is growing evidence for other rapid nontranscriptional actions of GR, especially with regard to inflammation (89,90). The synthetic corticosteroid dexamethasone (Dex) rapidly inhibits cytosolic phospholipase A2 (cPLA<sub>2</sub>) activity and release of arachidonic acid in immune cells, which are

important mediators of inflammation. Inhibition was reversed by the GR antagonist RU486 (mifepristone) and by pharmacological inhibition of Src, suggesting that rapid inhibition of cPLA<sub>2</sub> by GR is mediated by Src (24). Whether this pathway is important in ECs remains to be determined. Interestingly, a nongenomic effect of GR on rapid kinase signaling is also involved in the inhibition of AP-1 by steroids through transrepression mechanisms. The transcriptional activity of the AP-1 subunit, c-Jun, is enhanced through phosphorylation on Ser63/73 by members of the c-Jun-N-terminal kinase (JNK) subfamily in response to inflammatory cytokines (91). Indeed, activated GR prevented phosphorylation of c-Jun by blocking the JNK signaling cascade (92). Furthermore, acute Dex treatment interfered with JNK activation in the cytoplasm and nucleus without altering JNK subcellular distribution. These effects did not involve direct interaction between JNK and GR and were independent of DNA binding, since a dimerization-defective GR mutant, which lacks transcriptional capacity, is still able to suppress JNK activation in response to Dex (93).

### Glucocorticoid and Endothelial Nitric Oxide Synthase

Many beneficial actions of corticosteroids in vivo involve the vascular endothelium. An important endogenous mediator of vascular integrity is endothelium-derived NO (94). NO produced by eNOS possesses anti-inflammatory, antiatherogenic, and anti-ischemic properties (95,96). Enhanced NO production by administration of the eNOS substrate, L-arginine, or upregulation of eNOS by statins, confers stroke protection (97–99), and transgenic mice overexpressing eNOS show decreased leukocyte accumulation and reduced vascular lesion formation following vascular injury (100). Conversely, mice with targeted disruption of eNOS (*eNOS*<sup>-/-</sup>) exhibit increased vascular inflammation and larger cerebral infarctions following experimental ischemia (101,102), whereas inhibition of NOS activity decreases cerebral blood flow (CBF) and increases infarct size after ischemia (103).

In two different mouse models of ischemic injury, transient myocardial ischemia and transient focal cerebral ischemia, the protective effects of steroids were mediated by the nontranscriptional activation of eNOS by GR (11,12). High-dose corticosteroids significantly reduced ischemic tissue damage to the heart and the brain, whereas low doses were ineffective. Cotreatment with the GR antagonist RU486 completely reversed the effects of Dex, suggesting that GR mediated tissue protection. Furthermore, protection from ischemia was mediated by NO, since the beneficial actions of steroids were absent in *eNOS*<sup>-/-</sup> mice or blocked by cotreatment with the NOS inhibitor N(G)-nitro-L-arginine methyl ester (L-NAME) (11,12). Steroid treatment acutely increased eNOS activity in vitro and in vivo, which led to decreased vascular inflammation and increased vasorelaxation and regional cerebral blood flow in a NO-dependent manner (12).

Corticosteroids have recently been reported to activate protein kinase Akt (6,11,12,104), which is an important regulator of cell cycle progression and mediator of cellular

survival downstream of PI3K (105). In a ligand-dependent manner, corticosteroids activate PI3K and Akt in ECs and reconstituted COS cells, which is blocked by cotreatment with RU486 or the PI3K inhibitor, LY294002, but not by transcriptional inhibitors (11,12). Although induction of nontranscriptional actions requires high doses of steroids (in contrast to estrogen, which occurs at physiological concentrations), these effects are nevertheless specifically mediated by GR. This was demonstrated in transfection studies in COS7 cells, which lack endogenous GR. Whereas Dex did not activate PI3K or Akt in the absence of GR, it readily induced Akt kinase activation after transfection with GR, or the dimerization defective GR mutant (A458T), which is unable to transactivate target genes (12). This suggests a DNA binding-independent mechanism of activation. The fact that PI3K activation can be suppressed by the GR antagonist RU486 further argues against the involvement of transrepression in this process, because the RU486 compound still induces transrepression of AP-1-dependent gene expression in reporter assays (106).

Recently, we found that the binding of thyroid hormone to the thyroid hormone receptor- $\alpha$ 1 (TR $\alpha$ 1) activates PI3K/Akt and eNOS, leading to the rapid nongenomic neuro-protective effects of thyroid hormone in stroke (107).

#### KEY POINTS

- Steroid hormones, such as estrogen and glucocorticoids, can exert vascular protective effects through nongenomic mechanisms.
- A prominent feature of both ER and GR is their ability to rapidly activate the PI3K/Akt pathway in ECs, leading to the activation of eNOS.
- By enhancing endothelial NO production, steroid hormones decrease postischemic vascular inflammation and increase regional blood flow.
- The therapeutic use of steroid hormones is limited by their side effects, which are typically associated with their genomic actions.

#### Future Goals

- To explore the rapid, nontranscriptional actions of steroid hormones in ECs, so that the biological and pharmacological actions of these steroid hormones could be considerably broadened, thus leading to the development of a novel class of drugs that selectively activates their nontranscriptional actions

## Organic Nitrates

### Exogenous Nitric Oxide Administration and Its Influence on the Vascular Endothelium

---

John D. Parker\* and Tommaso Gori†

\*University Health Network Hospitals, University of Toronto, Ontario, Canada;

†University of Siena, Italy

Nitroglycerin (GTN) and other nitrates have been used in cardiovascular medicine for more than 120 years. GTN was first synthesized in 1847 by an Italian, Ascanio Sobrero, who described a “violent headache” upon self-administration of a “minute quantity” of the drug (1). Because of this side effect, investigation of possible pharmacological applications of GTN was limited for several years, until the reports of Brunton and Murrell, who employed nitrates in the treatment of angina (2,3). Although sublingual GTN has been commonly used for more than a century to treat acute attacks of angina, the development of organic nitrates with sustained activity was limited by their poor oral bioavailability. Eventually, this difficulty was overcome and long-acting formulations of GTN and other long-acting organic nitrates, including isosorbide dinitrate, isosorbide-5-mononitrate, and pentaerythritol tetranitrate, have been developed and marketed. More details on the pharmacologic characteristics, formulations, and indications of different nitrates have been reviewed recently (4).

#### BIOTRANSFORMATION AND HEMODYNAMIC EFFECTS

Organic nitrates are prodrugs that release their active principle, nitric oxide (NO) or a NO-containing compound, via an intracellular enzyme-dependent denitrication (5) (Figure 181.1). The exact determination of the enzyme system involved in this bioconversion has remained elusive, despite extensive investigation. Multiple enzymatic candidates have been identified, including cytochrome P450, endothelial NO synthase, and glutathione transferase (6–10). There has been intense interest in identifying the denitrication pathway because it was felt that the development of abnormalities in this process might explain the loss of nitrate effects during sustained therapy, a phenomenon termed *nitrate tolerance*

(discussed later). Spontaneous thiol-dependent denitrication of GTN also has been proposed as the mechanism of GTN biotransformation. However, today it is believed that enzyme-bound, rather than free, thiol groups play an important role in the biotransformation of GTN. Indeed, more recent and convincing studies have proposed a role for a mitochondrial aldehyde dehydrogenase that catalyzes the formation of NO or a NO-containing compound from GTN (8,11–13). This mechanism appears to depend on the oxidation of two cysteine residues in the active site of the enzyme, a finding that is compatible with the thiol-dependence of GTN bioactivation described by Needleman more than 30 years ago (14) (Figure 181.1). Evidence in support of the importance of this pathway consists of the lack of a vasodilator effect of GTN in vitro and in animals in vivo after administration of specific inhibitors for this mitochondrial enzyme, as well as significant stimulation of cyclic guanosine monophosphate (cGMP) formation by GTN in the presence of the enzyme. Furthermore, there are observations of reduced hemodynamic responses to GTN in Asian subjects who are genetically deficient in the enzyme aldehyde dehydrogenase (13,15,16).

Regardless of the mechanism, GTN biotransformation results in exogenous (nitrate-derived) NO, which like its endogenous (endothelial-derived) counterpart, then activates the soluble guanylate cyclase to increase cyclic GMP synthesis. The molecular cascade triggered by increased cGMP bioavailability can mediate vasorelaxation through the activation of protein kinases and the subsequent phosphorylation of different proteins involved in the regulation of intracellular calcium ( $\text{Ca}^{2+}$ ) levels, such as the sarcoplasmic  $\text{Ca}^{2+}$ -ATPase (17). Additional proposed biochemical consequences of NO donors, which might also be involved in NO-induced vasodilation (and its other effects; see following paragraph) include thiol modification, regulation of mitochondrial respiration, modulation of potassium ( $\text{K}^+$ ) channel activity (18), and

Figure 181.1. The mechanism of activation of GTN by the mitochondrial aldehyde dehydrogenase as proposed by Chen and associates (13). This process yields the dinitrate metabolites glyceryl-1,2-dinitrate (1,2-GDN) and glyceryl-1,3-dinitrate (1,3-GDN) via a thiol-dependent denitration. Of note, several other enzymes have been identified that are capable of mediating the denitration of GTN, including the glutathione *S*-transferases and the cytochrome P450. In nitrate-tolerant tissues, the biotransformation of GTN is attenuated, an effect that might be due to oxidation of thiol groups in the active site of aldehyde dehydrogenase during GTN denitration.

protein nitration, although less evidence is available concerning the therapeutic relevance of these effects (19–21).

The potent vasodilator effects of organic nitrates are preferentially exerted at the level of capacitance veins and conductance arteries (22), resulting in a reduction in cardiac preload and oxygen consumption and, theoretically, an increase in oxygen supply to areas of myocardial ischemia (23). Nitrates have limited effects on resistance vessels (22), which may limit coronary steal phenomena.<sup>1</sup> Therefore, important differences exist in the tissue selectivity of the nitrates versus endothelial NO: in particular, although endothelial NO is believed to play a (relatively) more important role in resistance arteries as compared to conduit arteries and veins, possibly due to a higher metabolic activity of the arterial endothelium (flow-mediated dilation is both more potent and rapid in the peripheral circulation) (24), nitrate-derived NO is more potent at the level of conductance vessels. This site-specific differential potency of nitrates appears to result from differences in nitrate biotransformation rate, through a negative feedback inhibition of GTN biotransformation by the endogenous NO (25).

## CLINICAL USE

The organic nitrates are among the most commonly used drugs in the treatment of cardiovascular disease, including

1 Blood flow steal is caused by a difference in vascular resistance between two branches of a vascular bed. Selective dilation of resistance (distal) arteries (e.g., with calcium antagonists) causes a marked decrease in vascular resistance in the vessels where no conduit artery stenosis is present. Therefore, blood flow meant for the territories distal to a conduit artery stenosis is “stolen” by the other vessels, causing ischemia.

congestive heart failure and coronary artery disease. In the United States, a recent survey showed that 91% of physicians treat congestive heart failure patients with drugs of this class (26), a figure that is likely to be even higher when patients with coronary artery disease are considered. The clinical applications of nitrates reflect their hemodynamic effects. Stable angina guidelines state that “in patients with exertional stable angina, nitrates improve exercise tolerance, increase the time to onset of angina, and decrease ST-segment depression during the treadmill exercise test. Combined with  $\beta$ -blockers or calcium antagonists, nitrates produce greater antianginal and anti-ischemic effects in patients with stable angina” (27). Short-acting nitrates such as sublingual formulations of GTN or isosorbide dinitrate are employed in the treatment and/or prevention of anginal episodes in patients with coronary artery disease (3,28), whereas long-acting nitrates serve as a chronic treatment for the prevention of these episodes. Of note, guidelines recommend the use of long-acting nitrates in the case of chronic stable angina only as second- or third-line therapy, for cases that are refractory to treatment with drugs such as calcium antagonists and/or  $\beta$ -blockers. In the treatment of acute coronary syndromes, nitrates are recommended by published guidelines as Class I intervention<sup>2</sup> for the relief of acute ischemia and associated symptoms (29), an indication that is based on “experts’ consensus in the absence of randomized trials” (level of evidence C), due to the lack of any clear documentation that nitrates have a positive effect on overall clinical outcome and/or mortality in this setting (30,31). As mentioned earlier, nitrates also are commonly employed in the setting of congestive heart failure for their beneficial hemodynamic effects, mediated by a decrease in preload, which is associated with a reduction in symptoms of congestion and a decrease in the severity of mitral regurgitation (26,32,33).

Because they release NO, organic nitrates have been proposed as possible alternate NO sources in the setting of endothelial dysfunction (34,35). Some authors have postulated that the protective effects of endothelial NO might be restored by the administration of these drugs. The following paragraphs will describe the current knowledge regarding the interactions between the organic nitrates as exogenous NO donors and the endothelium and will critically analyze the hypothesis that they can act as surrogate (and replacement) NO sources.

## THE “PLEIOTROPIC” EFFECTS OF ORGANIC NITRATES

Beyond their hemodynamic effects, other important beneficial effects of organic nitrates have been proposed (Table 181-1). These include antiplatelet effects and the ability to prevent

2 Class I intervention: conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Level of evidence A: recommendation based on large, randomized trials; B: based on smaller trials or observational registries; C: based on experts’ consensus.

**Table 181-1: Effects of Endothelial and Nitrate-Derived NO**

<i>Endothelial NO</i>		<i>Nitrate Therapy</i>	
		<i>Acute or Chronic Intermittent</i>	<i>Chronic Continuous</i>
Platelet	Antiaggregant	Antiaggregant	Controversial: in vitro: antiaggregant; in vivo: proaggregant
Vascular tone			
Conduit arteries	Potent vasodilator	Potent vasodilator	Vasodilator
Resistance arteries	Vasodilator	Mild vasodilator	No effect (tolerance)
Veins	Weak dilator	Potent vasodilator	No effect (tolerance)
Exercise tolerance	?	Increased	No effect (tolerance)
Endothelial function	Major determinant	Potentiating	Causes dysfunction
Modulation of atherogenesis	Beneficial	Retards oxidative stress and intima-media thickening*	Possibly accelerating
Ischemic preconditioning	Acts as mediator	Protective effect <sup>†</sup>	Controversial, possibly deleterious <sup>‡</sup>

\*Only animal data of intermittent, high-dose, isosorbide mononitrate eccentric administration available

<sup>†</sup>Only data of acute nitrate treatment

<sup>‡</sup>Only animal data available

atherosclerosis as well as “preconditioning-mimetic” properties.

The existence of a tonic effect of endogenous NO on platelet activity is documented by the fact that the administration of an inhibitor of NO synthase increases aggregation and the expression of membrane markers of activation. This effect is completely reversed by sublingual GTN (36). To date, both human and animal studies have documented a direct antiaggregant effect of organic nitrates (36). Although this might not be of relevance in the setting of stable angina, inhibition of platelet aggregation might be of great importance in the therapy of acute coronary syndromes. In this setting, in which endothelial NO bioavailability is reduced, the antiplatelet effect of exogenous NO could substitute for it, limiting both the thrombogenic effects and the coronary spasm induced by release of vasoactive platelet-derived mediators.

Certain organic nitrates have been demonstrated to have antioxidant and protective effects in animal models of atherosclerosis. In the setting of chronic disease, it is commonly accepted that the antiproliferative, antioxidant, and anti-inflammatory effects of NO play a role in limiting the progression of vascular disease and that the loss of these effects in the presence of cardiovascular risk factors is an early occurrence in the development of atherosclerosis (37). Animal studies have reported that administration of high doses of isosorbide mononitrate and pentaerythritol tetranitrate limits the development of endothelial dysfunction, the increase in reactive oxygen species production, and plaque formation in animals genetically and environmentally prone to develop atherosclerosis (38,39). Future studies must confirm whether these

findings translate into a clinical advantage in humans with coronary artery disease.

Furthermore, organic nitrates have been attributed protective effects that mimic those of ischemic preconditioning. The concept of ischemic preconditioning was introduced after the observation that brief periods of ischemia, such as in the setting of preinfarction angina, are able to reduce the extent of the necrotic area and to improve prognosis after myocardial infarction (40,41). Interestingly, the administration of several drugs, including NO donors, has been associated with the development of an analogous protective state that has been termed *pharmacologic preconditioning*. Multiple studies in animal models of peripheral and cardiac ischemic injury have reported that treatment with GTN and/or NO donors is associated with a significant reduction of infarct size, an effect that is independent of any hemodynamic effect (42–44). Similarly, a protective effect of GTN has been demonstrated in human models of both low-flow and demand ischemia (45,46). The clinical significance of these effects remains to be determined.

Collectively, these findings suggest that endothelial- and nitrate-derived NO might have synergistic effects and that, in the case of insufficient endothelial NO production, nitrate-derived NO might substitute for it. Furthermore, a human study suggested that organic nitrates might even improve the bioavailability of endothelial NO, as demonstrated by a marked potentiation of the responses to endothelium-dependent vasodilators during low-dose GTN infusion (47). From this perspective, authors have postulated that nitrate use might have clinically important implications that go beyond the treatment of symptoms of angina and/or

congestive heart failure (35). These effects might be clinically relevant in the prevention of coronary and peripheral atherosclerosis. However, although such characteristics make organic nitrates unique and potentially powerful drugs in the therapy of cardiovascular disease, recent and ongoing experimental findings (discussed in the next section) suggest that this class of drugs might have unexpected negative effects on vascular and endothelial function.

### NITRATE TOLERANCE AND NITRATE-INDUCED ENDOTHELIAL DYSFUNCTION

Traditionally, nitrate tolerance is defined as the loss of hemodynamic and/or symptomatic effects of organic nitrates (or the requirement of higher administered doses to maintain these effects) that appears during continuous therapy (4). Tolerance is not influenced by the dosage administered (48) and occurs with all nitrate formulations (except possibly for pentaerythritol tetranitrate) (49), as long as they are administered using dosing schedules or formulations that produce significant plasma concentrations throughout the majority of the day. Tolerance has most often been described using the pharmacodynamic effects of nitrates – for example, their effects on blood pressure, cardiac filling pressures, and other physiological variables. Tolerance also occurs to the symptomatic effects of nitrates (anecdotal evidence suggests that this is also true for the side effects of nitrates, such as headache). Thus, in patients with angina, the beneficial effects of nitrates that are observed when these agents are given acutely are rapidly lost during sustained therapy.

The mechanism of tolerance has been investigated for several decades, and multiple hypotheses have been proposed (4,50,51) (Table 181-2). A schematic classification subdivides the mechanisms of this phenomenon as either due to the progressive loss of nitrate effects during continuous use (“true” tolerance) or to the reversal of nitrate effects caused by the activation of counterregulatory mechanisms (“pseudotolerance”). These counterregulatory responses include neurohormonal activation and plasma volume expansion, which would overcome the vasodilatory effects of nitrates (51,52).

**Table 181-2: Proposed Mechanisms for the Development of Nitrate Tolerance**

#### *Proposed Hypotheses for Nitrate Tolerance*

True Tolerance
Reduced biotransformation of the nitrate
Reduced NO signal transduction
Increased catabolism of NO
Pseudotolerance
Systemic neurohormonal counterregulatory responses
Plasma volume expansion
Sympathetic activation
Oxidative Stress Hypothesis

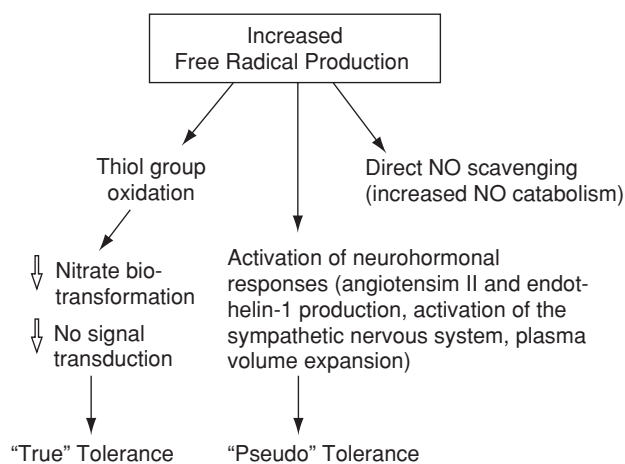

Figure 181.2. Interplay among free radical production and other proposed mechanisms for nitrate tolerance. An increased free radical production appears to be associated with many of the abnormalities observed in the setting of tolerance: these modifications include, on one side, plasma volume expansion, neurohormonal activation: these changes have the potential to reduce the ischemic threshold (“pseudotolerance”). On the other, they lead to reduced biotransformation of the nitrate to its active principle NO and to decreased signal transduction of this mediator (“true tolerance”).

monal activation and plasma volume expansion, which would overcome the vasodilatory effects of nitrates (51,52).

Recently, Munzel and colleagues have proposed the concept that sustained nitrate therapy might be associated with an increased endothelial production of reactive oxygen species, including superoxide anion and peroxynitrite (53). Since the formulation of this hypothesis, a number of enzymatic sources for this increase in oxygen free radical production have been described, including membrane-bound oxidases, the mitochondrial respiratory chain, and the endothelial NO synthase (20). Interestingly, the endothelium appears to be the source of this increased oxygen free radical production, and in vitro experiments have documented that tolerance to the vasorelaxant effects of GTN is dependent on the presence of the endothelium (53). This oxygen free radical hypothesis of nitrate tolerance provides the possibility to formulate a more complete view concerning the mechanism of nitrate tolerance (Figure 181.2). This “unifying hypothesis” was recently proposed by our group (19) and is based on the hypothesis that an increase in the bioavailability of oxidant free radical species triggered by nitrate therapy may (a) reduce the net bioavailability of NO by direct quenching, thus limiting the vasodilatory effect of the nitrate; (b) cause oxidation of important thiol groups and subsequent inactivation of several enzymes involved in the biotransformation of GTN and in NO signaling; and (c) trigger a variety of counterregulatory responses leading to pseudotolerance. The fact that nitrate therapy is associated with an increase in vascular oxygen free radical production therefore provides for the first time an explanation for other observations that have been made in the setting of tolerance, including neurohormonal activation (54), increased responsiveness and

expression of vasoconstrictors such as endothelin (ET)-1 and angiotensin II (55,56), plasma volume expansion (57), and, via oxidative inactivation of enzymes, reduced GTN biotransformation (58) and NO signaling (21). At the same time, these modifications have important implications in terms of the impact of nitrate therapy on vascular function and, possibly, on patients' prognosis.

An increased oxygen free radical production in the setting of prolonged nitrate therapy might have important effects on native NO production – i.e., endothelial function. Animal studies in which GTN was administered long term *in vivo* have repeatedly demonstrated a marked reduction in the responses to endothelium-dependent dilators (53,59,60). This evidence was more recently confirmed in human studies documenting decreased endothelial responsiveness in healthy volunteers (61) and patients with coronary artery disease (62,63). As mentioned, studies have proven the existence of multiple sources of oxygen free radicals in the setting of sustained nitrate therapy, including membrane-bound oxidases and the mitochondrial respiratory chain. Importantly, prolonged GTN therapy also appears to lead to uncoupling of NO synthase, where the oxidation of tetrahydrobiopterin to inactive dihydrobiopterin and/or a reduced L-arginine bioavailability leads to increased superoxide anion production from NO synthase itself. Evidence for the role of NO synthase uncoupling in the development of nitrate tolerance has been provided *in vitro* (64,65) and in human *in vivo* models, where administration of L-arginine or folic acid (which can substitute for and/or regenerate tetrahydrobiopterin) was able to prevent this phenomenon (66,67). Furthermore, this impairment in NO synthase function might not be limited to the vasculature. Zanzinger and colleagues recently demonstrated in a porcine model that tolerance is associated with reduced NO production in the brain stem, leading to a loss of its restraining on sympathetic efferents (68). These data were confirmed by findings from our group, which showed increased cardiac sympathetic and decreased vagal outflow to the heart in a human model of nitrate tolerance (69).

Of interest, uncoupling of NO synthase and reduced endothelial NO production have been found in the setting of hypercholesterolemia (70), diabetes mellitus (71), and in the setting of other risk factors for atherosclerosis. Therefore, uncoupled NO might represent an important mediator of the progression of coronary artery disease in the presence of these risk factors. Furthermore, nitrate-derived free radicals have been shown to lead to other important modifications, including oxidation of the enzyme prostacyclin synthase, upregulation of ET-1 production, and, importantly, of matrix metalloproteinases, which might have important implications with respect to atherogenesis (72–74).

The modifications in vascular homeostasis that follow this nitrate-induced free radical production could have other implications. Tolerance (and tolerance-associated vascular abnormalities) has been linked to an increased platelet aggregability (75) *in vivo* and with a loss of the GTN preconditioning-mimetic effect associated with an impair-

ment in the capacity to develop ischemic preconditioning in response to the exposure to brief ischemic events (76). Finally, prolonged nitrate therapy leads to the phenomenon termed *rebound*. This describes the paradoxical increase in the number of episodes of myocardial ischemia (77) and a corresponding decrease in exercise capacity (78) during periods following withdrawal of nitrate therapy. The cause of this phenomenon remains uncertain; however, it has been hypothesized that the increased free radical bioavailability during nitrate therapy would, when left unopposed following nitrate withdrawal, lead to increased vasoconstrictor responses and subsequent reduced exercise capacity (79).

### KEY POINTS

- Recent data suggest that a thorough revision of the mechanism(s) of action and of the effects of organic nitrates is necessary. These data suggest that the administration of organic nitrates has potentially important beneficial effects that go beyond any change in hemodynamics. Their antiplatelet effects might have importance in the setting of acute coronary syndromes, and the antiatherosclerotic and preconditioning-mimetic effects of nitrates deserve further attention and investigation. These effects suggest that the important “pleiotropic” effects of endothelial NO can be replaced by exogenous administration of NO donors.
- On the other hand, therapy with organic nitrates for prolonged periods (or, possibly, in high doses, in a time of exposure/administered dosage interaction) leads to toxic effects that are manifested by (but not limited to) nitrate tolerance.
- Given this background, it has to be acknowledged that important pieces of information are still missing: No study has investigated whether chronic therapy with organic nitrates has an influence on cardiovascular (or overall) mortality and morbidity, and published studies are limited to short-term nitrate therapy (30,31).
- Furthermore, it is not clear whether a dose–response relationship exists in the antianginal effects of nitrates: studies in patients with coronary artery disease have demonstrated the absence of an incremental effect for increasing administered dosages of transdermal GTN (80). Because free radicals seem to be produced in a dose-dependent (possibly stoichiometric) fashion in mitochondria (16), the administration of higher nitrate dosages might be associated with a higher incidence of side effects such as the rebound phenomenon and nitrate tolerance, which

are both likely to be mediated by free radical-based mechanisms.

- In sum, although nitrates have been used in clinical practice for more than 100 years, recent findings regarding endothelial biology and the effects of nitrates have raised important questions concerning the safety of sustained nitrate therapy. Recent investigations have yielded more detailed information concerning the mechanisms of nitrate effects and the development of tolerance. These new concepts have demonstrated that nitrate tolerance does not simply represent the loss of hemodynamic effects but is accompanied by evidence of vascular toxicity mediated by increased oxygen free radical production.

## Therapeutic Approaches to Altering Hemodynamic Forces

José A. Adams

Mount Sinai Medical Center, Miami Beach, Florida

The interaction of the endothelium with blood and its elements, circulating factors, and its active metabolic state make it an attractive target for therapeutic alterations. The location of the endothelium between blood and vascular smooth muscle is ideal for the endothelium to serve as a fine transducer of mechanical and chemical forces. Endothelial dysfunction occurs in several diseases. Many endogenous regulatory responses, such as distribution of blood flow, hemostasis, and vasomotor tone, are controlled by endothelial-derived factors. Thus, exogenous modulation of such endothelial factors is a desirable goal.

The physiological importance of the endothelium in homeostatic function has been recognized since the discovery of endothelial-derived relaxing factor (EDRF), which was later found to be endothelial-derived nitric oxide (NO). The actions of NO on adjacent endothelial cells (ECs), other circulating cells, and on adjacent myocytes make NO a valuable primary or secondary messenger of innumerable physiologic processes. Signal transduction and the importance of endothelial-derived NO and inducible NO in inflammatory processes are reviewed here. This chapter further aims to review primary methods of endothelial stimulation *in vivo* and therapeutic methods used in the past and currently to alter endothelial responses. Unlike pharmacologic interventions in which drug dosing, local availability, distribution, and side effects can outweigh the potential beneficial effects of the drug, stimulating the endothelium to produce beneficial factors has several advantages: (a) the endothelium is present in every organ, (b) actions are local, and (c) there is virtually no potential for overdosing or toxic effects.

### HEMODYNAMIC FACTORS RESPONSIBLE FOR ENDOTHELIAL OUTPUT

The frictional force engendered on the vascular endothelium by the flowing, viscous blood is termed *hemodynamic shear*

*stress*. Shear stress on a blood vessel can be summarized using the following equation: (Poiseuille's Law)

$$\tau_s = 4\mu Q/\pi R^3 \quad (\text{Equation 1})$$

Where  $\mu$  is the viscosity of blood, Q is flow, and R is the radius of the vessel. Shear stress is directly proportional to blood flow viscosity and inversely proportional to  $R^3$ .

Shear stress is a critical determinant of vessel caliber and plays a role in vascular remodeling (1–4). Two main hemodynamic factors are responsible for endothelial release of mediators: (1) laminar shear stress and (2) pulsatile shear stress. Laminar shear stress is the tangential deformation produced by blood flow across the ECs. Mechanical forces of laminar shear stress cause release of endothelial NO, prostaglandins (PGs), upregulation of vascular endothelial growth factor receptor 2 (VEGFR2) and tissue-type plasminogen activator (t-PA) in cell culture studies, and vascular endothelial growth factor (VEGF) in human clinical studies (5–9). Laminar shear stress alters expression at both the protein and mRNA level (1,10–14). The mean shear stress under physiologic conditions to which the vascular endoluminal surface is exposed to is remarkably constant: These have been reported to be in the range of 10 to 15 dyne/cm<sup>2</sup> irrespective of the arterial network considered and size of the animal. The exception appears to be the rat and mouse, for which the values reported are closer to 30 to 35 dyn/cm<sup>2</sup> (15,16). Pulsatile laminar shear stress relates to the stress induced on the endothelium by the pulsation and wave reflection of the heartbeat. Amplitude and frequency of pulsations are important stresses for generating endothelial-derived NO (17,18).

Laminar shear stress is promoted by either decreasing the radius of the blood vessel or increasing fluid viscosity. Turbulent shear stress or disturbed flow may occur in atherosclerosis or hypertension, with vascular prostheses or indwelling catheters. Here, endothelial production of NO is reduced and endothelin (ET)-1 increased (19–24).

Pulsatile shear stress, which is the force on ECs generated with each contraction of the heart, has two distinct components that affect the endothelium: frequency and amplitude. The endothelial production of endothelial-derived NO appears to be frequency encoded in the range of 2 to 6 Hz. The amplitude of each pulsation or pressure pulse also has a positive or negative effect on endothelial output (17,18,25,26). A direct relationship exists between the circumferential stress to which the vessel is exposed and the structure of the vessel wall as a form of adaptive mechanism. From one animal species to another the number of lamellar units varies according to the diameter of the blood vessel so that the circumferential stress remains constant irrespective of the size of the animal (16,27,28) (see also Chapter 28).

Circulating levels of cytokines, chemokines, and reactive oxygen species suppress production of endothelial-derived NO (29,30). Thus, sepsis-induced production of cytokines and inflammatory mediators cause both local and distal endothelial dysfunction. This causes pulmonary vasoconstriction and disruption of capillary integrity with subsequent interstitial edema (29–38). Excellent reviews of endothelial mechanotransduction mechanisms can be found in the literature (1,15,16,39).

## HEMODYNAMIC ALTERATIONS

Accounts of physical activity and inactivity producing diseases can be found in the medical literature (40–50). Although not typically recognized as such, physical activity to varying degrees increases shear stress to the endothelium. Increase in cardiac frequency is a powerful stimulus for preconditioning the heart from ischemia–reperfusion injury. This cardioprotection is mediated in part by NO (51–56). Using an exercise protocol in dogs, Vegh and associates showed that a single bout of exercise prior to coronary occlusion significantly decreased its consequences, presumably because exercise increases endothelial-derived NO, because administration of N(G)-nitro-L-arginine methyl ester (L-NAME) blunted the response (57). Further, in human subjects undergoing ventricular pacing, release of plasminogen activator inhibitor (PAI)-1, von Willebrand factor (vWF) antigen, t-PA, and prostacyclin have been documented in the coronary vessel bloodstream (58). In isolated perfused vessels, the frequency range that induces production of endothelial-derived NO production is encoded within a range of 2 to 6 Hz and may be developmental in origin (17,59). The endothelium also responds to amplitude changes of the pulse waveform. Increasing amplitude of pulse pressure while maintaining the flow rate unchanged in an isolated vessel augments vascular constriction. The vasodilatory frequency response is inhibited by the nonselective inhibitor of NO synthase L-NAME (60).

Green and colleagues found that in human subjects, forearm vascular response (a measure of endothelial function, associated with NO release) increased with increased amplitude of blood pressure. Further, this shear stress–mediated

vascular response involved an endothelial source of NO (61). Human and animal investigations during the early research period of the National Aeronautics and Space Administration (NASA) explored the effects of whole-body periodic acceleration/sinusoidal vibration in humans and animals. Such interventions increased ventilation in animals and humans and also added pulsations to the circulation without increasing the heart rate. During whole-body x-axis sinusoidal vibration (movement of the entire body headward–footward), blood pressure decreases and blood flow increases (62–64). Although such effects were initially thought to be mediated via the autonomic nervous system, a much different interpretation of these data can be provided today with the knowledge that vascular endothelium responds to pulsatile shear stress with release of NO and subsequent vasodilatation.

In the early 1970s, Arntzenius and colleagues showed that whole-body acceleration applied synchronously with the heartbeat (BASH) had the potential to serve as a cardiac assist device. These investigators proposed a platform that moved the body synchronous with the heartbeat in one direction, either headward or footward. When applied headwardly early in systole, it lowered systolic blood pressure (decrease afterload) and increased early diastolic pressure (increased coronary filling) (65–71).

Pulsatile as contrasted to steady blood flow in extracorporeal membrane oxygenation circuits and cardiopulmonary bypass improves perfusion to vital organs, enhances oxygen utilization by the vital organs, provides better distribution of blood flow to the tissues during warming and cooling, and decreases lactic acid and systemic vascular resistance (72–74).

## THERAPEUTIC EXAMPLES OF HEMODYNAMIC ALTERATIONS

### Exercise

The beneficial effects of exercise on health have been appreciated for centuries (see also Chapter 56). A large body of literature cites both beneficial effects as well as deleterious effects, particularly with strenuous exercise. How and why exercise is beneficial from the perspective of endothelial function has only recently come to light. Even when normalizing exercise as a percent of maximal predicted heart rate for different exercise types, the results are complex. Bicycling increases cardiac output and heart rate, but its effects on the endothelium appear to be mediated by shear stress (primarily through changes in cardiac output) and to a lesser extent by increased pulsatility (except at high exercise loads, heart rate is insufficiently increased to play a major role). Jogging and running increase both cardiac output and heart rate, but with every step the foot strikes the ground, transmitting an additional pulse that is superimposed on the natural pulse. Therefore, jogging and running as well as jumping rope and bouncing on a trampoline have the potential of greater upregulation of endothelial NO synthase (eNOS).

Moderate exercise improves endothelial function and, through endothelial release of NO, prevents and treats atherosclerosis. The beneficial effect of NO relates, in part, to its antioxidant and anti-inflammatory activities. In fact, regular moderate-intensity exercise can reverse endothelial dysfunction (26,75–81).

On the other hand, strenuous exercise stresses the body with subsequent activation of nuclear factor (NF)- $\kappa$ B, inducible NO synthase (iNOS) from leukocytes and ECs, and causes the accumulation of oxygen free radicals from leukocytes. Prolonged production of large quantities of NO from iNOS activation is deleterious to the tissues because it acts as an oxidant (82–90).

Based on the above considerations, moderate exercise may be beneficial to those diseases that have chronic inflammation as the basis for their symptoms, whereas strenuous exercise may worsen the symptoms. Another limitation of exercise relates to the patient's ability to perform. This is a problem in patients with such chronic inflammatory diseases as multiple sclerosis, Alzheimer disease, Parkinson disease, stroke, fibromyalgia, and arthritis.

### Enhanced External Counterpulsation

The use of multiple bladder-like pressure cuffs around the lower extremities, which inflate in synchrony with the heart-beat in diastole and deflate during systole, dates back to the 1960s, with the work of W. C. Birtwell, who employed a catheter-based system of blood withdrawal during systole and reinjection in diastole (91). In 1968, an external counterpulsation apparatus became commercially available. In 1999, the Multicenter Study (MUST)-EECP demonstrated that enhanced external counterpulsation (EECP) was effective for the treatment of chronic angina pectoris in a randomized clinical trial (92). It was originally hypothesized that diastolic augmentation relieved angina through mechanically opening coronary blood vessels during diastole. Although this may be a valid mechanism of action, it seems more likely that pulsatile shear stress to the endothelium with increased release of NO is the major basis for EECP-mediated relief of angina.

Isolated perfused vessel experiments by Kamm and his group have shown increases in eNOS mRNA and NO produced during application of a modified EECP to isolated vessels (93,94). Further, the highest level of eNOS mRNA expression was observed in a group of blood vessels that were pulsed in addition to EECP (93–95). Additionally, human data have shown an increase in plasma nitrates after EECP, which continues to rise after 1 month of treatment (7). ET-1, an endothelial-derived counter-regulatory peptide that produces intense vasoconstriction, decreases during EECP in humans (96). In humans undergoing EECP, various angiogenic factors also have been shown to increase after treatment, such as hepatocyte growth factor, basic fibroblast growth factor (bFGF), and VEGF (7). Thus, it appears that application of EECP via changes in pulsatile shear stress enhance endothelial production of beneficial mediators in both in vivo and in vitro studies

(7,93,94). EECP reduces anginal episodes, increases exercise times, and improves health-related quality of life scores (vitality, bodily pain, general health, physical functioning, social function, and others) (97). Although EECP has been limited to cardiovascular health-related pathologies, it would not be surprising that its use might extend to include other diseases with endothelial dysfunction and/or chronic inflammatory diseases processes. The effects observed with EECP are likely to be complementary to current therapy in various diseases. Investigators have reported that some of the beneficial effects of EECP in terms of mediator release can be measured for as long as 1 month after cessation of treatments (7). Adverse events reported in the MUST-EECP data set were in the order of 54.9%, with the most frequent being skin abrasion, bruise or blisters, and pain in the leg or back (92). Although the device is readily available, its cost and limited U.S. Food and Drug Administration (FDA)-approved indications have likely stifled more widespread use.

### Intraaortic Balloon Pump Counterpulsation

The principal phase of coronary arterial perfusion is during cardiac diastole. Increasing diastolic aortic pressure improves coronary blood flow. In 1953, Kantrowitz and colleagues validated the concept of diastolic augmentation through the intraaortic balloon pump (IABP), an invasive means of counterpulsation (98). The IABP consists of a vascular indwelling balloon catheter within the aorta, with inflation and deflation of the balloon synchronized with diastole and systole, respectively. This device has been in clinical use since the early 1960s as a cardiac assist device in circulatory failure (99). Its primary use has been as a support mechanism. The most common indications include hemodynamic support during or after cardiac catheterization, cardiogenic shock, weaning from cardiopulmonary bypass, preoperative employment in high-risk coronary artery bypass graft (CABG) surgery, and unstable refractory angina. Although the reported benefits of this device are widely attributed to augmentation of diastolic filling and reduction of cardiac afterload, it is likely that the added pulse during diastole increases shear stress to the endothelium. This would likely tend to promote release of NO and other shear stress-dependent mediators from the endothelium. Major complications when using IABP include embolism, limb ischemia, infarction, and balloon rupture. In addition to its invasive nature, the complication rates from 2% to 11% render this method of increasing endothelial-derived mediators generally unappealing (99–107).

### Whole-Body Periodic Acceleration

Motion of the body in a headward–footward direction imparted in a sinusoidal manner to a supine subject (in the z plane) can be produced by a motion platform. This motion, termed *periodic acceleration* (pGz), adds a pulse to the circulation as the body accelerates and decelerates with the frequency of the motion platform. These added pulses cause release of

endothelial-derived mediators in isolated blood vessels, animal models, and humans, presumably due to increased pulsatile shear stress (10,83,108–110). The motion is carried out at frequencies of 2 to 4 Hz with displacements of 1 to 5 cm producing accelerations of  $\pm 0.2$  to 0.6 Gz. Initial work on pGz was aimed at using this device for noninvasive ventilation by causing passive diaphragmatic excursions. Our laboratory has shown that pGz can adequately ventilate paralyzed animals with normal lungs as well as diseased lungs induced by meconium aspiration (111,112).

During pGz ventilation in animals with meconium aspiration syndrome, characteristically associated with pulmonary hypertension, it was found that pulmonary artery pressure decreased after treatment (111). Further, in animals with normal vascular tone, a slight decrease exists in mean arterial pressure and pulmonary artery pressure, which could be eliminated with infusion of L-NAME, a drug that blocks NO production (108). Laminar and pulsatile flow within an isolated blood vessel increased nitrite levels in the perfusate, a metabolite of NO that reflects NO, which cannot be readily measured because it is metabolized within a few seconds. Nitrite levels are significantly greater during pulsatile than laminar flow. Addition of pGz to an isolated blood vessel during pulsatile flow increased NO production an additional threefold (108).

In whole-animal models, pGz has been shown to enhance regional blood flow to the heart, brain, kidneys, liver, and gut, but not to skeletal muscle (113). This contrasts to dynamic exercise where blood flow decreases to the kidneys, gut, and liver with modest or no increase in brain blood flow in favor of large increases of cardiac and skeletal muscle blood flow. Normal animals exposed to 1 hour of pGz produce increases in vasoactive factors (NO, prostaglandin E<sub>2</sub>, and prostacyclin) and fibrinolytic factors (t-PA, PAI-1, and D-dimers) (10). No significant changes occur in thrombin and prothrombin times, activated plasma thromboplastin time, fibrinogen, factors VII and VIII, serum cortisol, and epinephrine/norepinephrine (10).

In a ventricular fibrillation animal model, pGz has been utilized as a sole method of cardiopulmonary resuscitation (CPR). A comparison of pGz CPR to an automated chest compression device (Thumper-CPR) indicates that animals undergoing pGz CPR show a higher rate of return to spontaneous circulation and significantly better postresuscitation cardiac function as assessed with echocardiography (114–117). The improved postresuscitation function is probably related to shear stress-induced release of NO and prostaglandin during CPR. Thus, pGz produces a conditioning effect during CPR.

In an animal model of asthma, pretreatment with pGz significantly decreases the antigen-induced immediate bronchoconstrictor response and eliminates the late response (118). Further, the elimination of the late response is associated with suppression of NF- $\kappa$ B in the pulmonary lavage fluid. Thus, endothelial-derived NO released with pGz probably interferes with degranulation of mast cells to account for its suppression of the immediate bronchoconstrictor response

and results in NF- $\kappa$ B-mediated inhibition of the late inflammatory bronchoconstrictor response in asthma (118).

Can whole-body pGz be utilized for therapeutic purposes in humans? The answer is yes! pGz is analogous to what mothers do when they push a baby in a carriage back and forth or gently bounce the baby from head to foot when the baby is in a vertical posture with the head and neck supported. The rate that a mother pushes a carriage back and forth ranges from 1 to 7 Hz, with accelerations of between  $\pm 0.2$  to 0.9 Gz. The higher frequencies and Gz occur when the baby is uncontrollably crying and do not last for more than 5 seconds. Normal animals exposed to 3 hours of continuous pGz have normal behavioral scores 24 and 48 hours post-pGz application. A human motion platform (AT-101, Acceleration Therapeutics, North Bay Village, FL) has been used successfully in adults who tolerate pGz well. Serum nitrite increases during pGz in healthy subjects and patients (109). Changes of the digital pulse waveform occur during pGz, which provides a measure of the vasoactivity of pGz in an analogous way to administration of organic nitrates. Whole-body pGz shows more profound changes than nitrates and is therefore likely to be more potent in its bioactivity. In normal subjects, whole-body pGz, in terms of vasoactivity, produces an effect that falls between light and moderate exercise – for example, 56% and 67% of maximum predicted heart rate (83).

Clinical benefits of pGz in humans have also been observed in patients with chronic inflammatory diseases. After ten to fifteen 45-minute sessions of pGz, there was marked improvement in the Role Physical, Bodily Pain, and Vitality categories of the SF36 health-related quality-of-life questionnaire (83,110).

Thus, accumulating evidence suggests that pGz is well tolerated and safe in humans, that it causes release of NO, and that chronically beneficial clinical effects are observed in individuals with diverse inflammatory/oxidative stress diseases and endothelium dysfunction. It is unclear for how long the benefits observed with pGz persist after discontinuation of treatments.

## CLINICAL IMPLICATIONS

Based on the information provided previously, and on the response of the endothelium to changes in pulsatile shear stress, significant opportunities to improve health clearly exist. Exercise has been shown to be very effective in a multitude of cardiovascular diseases, from atherosclerosis to inflammatory diseases, and its health benefits cannot be underestimated. The commonality of many of these diseases is endothelial dysfunction, thus a method that prevents, resolves, or treats endothelial dysfunction is clearly needed. For patients who cannot exercise, or cannot appropriately exercise, pGz and other methods of increasing pulsatile shear stress may offer a potential solution.

Various disease processes have a commonality: inflammation. How the inflammatory response is triggered can vary, but

ultimately a common endpoint of many inflammatory processes is upregulation of the transcriptional protein NF- $\kappa$ B. NO can downregulate NF- $\kappa$ B and is the subject of therapeutic interventions and research into control of inflammation (87). The ability of pulsatile shear stress to induce NO can be utilized to achieve this beneficial effect.

Prostaglandins and endothelial-derived NO have both been shown to be important in preconditioning for an ischemic/reperfusion event (119–126). Exercise preconditioning has been shown to be effective in animal models in reducing ischemia reperfusion injury; whether this can be translated to humans is likely possible.

A general understanding that the endothelium represents a target that can be stimulated by hemodynamic alterations, that responds in a potent manner, that is localized in every single organ in the body, and in which endogenous production of any of its factors occurs at the local level, leads to a greater vision of potential targets for treatment using induced pulsatile shear stress. The ultimate challenge will be to refine these methods of “tuning” the endothelium to produce the desired effect, systemically and locally.

#### KEY POINTS

- The endothelium responds to laminar and pulsatile shear stress, with an output that includes among many other factors, including NO, prostaglandins, t-PA, and VEGF.
- Addition of pulsatile shear stress to isolated vessels, whole-animal models, and humans further enhances production of these factors.
- Clinical methods to increase pulsatile shear stress are feasible and safe in humans.

#### ACKNOWLEDGMENTS

I am grateful to Marvin Sackner, MD, for his editorial comments and guidance. I also thank the Miami Heart Research Institute for their support of this project.

## Stent- and Nonstent-Based Cell Therapy for Vascular Disease

Michael R. Ward, Duncan J. Stewart, and Michael J.B. Kutryk

*St. Michael's Hospital, University of Toronto, Ontario, Canada*

Normally, blood vessels are quiescent structures that fulfill their crucial function delivering blood to tissues and organs throughout the body with remarkable efficiency over the course of the entire normal lifespan. This is accomplished through interactions among a wide variety of regulatory systems that control the structure and function of the vasculature. The endothelium not only makes up the innermost layer of all blood vessels and provides a nonthrombogenic surface, but it also produces a wide variety of vascular and growth regulatory signals and participates in repair, remodeling, and regeneration of the vasculature. The endothelium normally exhibits a very slow turnover, with a half-life of several years; however, in response to arterial injury and forms of pathological stress, widespread damage to the endothelium necessitates efficient mechanisms of repair and regeneration. Understanding the endogenous mechanisms that protect and repair this crucial layer may form the basis for new therapeutic strategies for the treatment of vascular diseases.

### LOCAL VERSUS SYSTEMIC MECHANISMS OF VASCULAR REPAIR

Until quite recently, repair of the damaged endothelium was thought to occur largely from the migration and proliferation of nearby undamaged endothelial cells (ECs) (1), and the regeneration of new blood vessels was believed to be mainly through the sprouting of ECs from preexisting blood vessels. However, several observations challenged this concept, beginning as early as 1963, when it was found that Dacron patches that were not contiguous with the vascular endothelium could become efficiently endothelialized (2), presumably by seeding from circulating ECs or endothelial progenitor cells (EPCs). In later studies using a genetic tag, it could be shown that the colonizing cells were of bone marrow (BM) origin (3). The existence of circulating BM-derived EPCs and their role in postnatal vasculogenesis in chronic ischemia mod-

els was first demonstrated with the pioneering work of Asahara and colleagues (4,5). They reported that purified CD34<sup>+</sup> hematopoietic progenitor cells could differentiate in vitro to an endothelial phenotype and incorporate into sites of neovessel formation in ischemic models in vivo. They also were the first to coin the term *endothelial progenitor cell*. The existence of "bone marrow-derived circulating EPCs" was also reported at about the same time by Shi et al (3), who showed that a subset of CD34<sup>+</sup> cells could differentiate into an endothelial-like phenotype, expressing markers such as von Willebrand factor (vWF), and take up DiI-acetylated low-density lipoprotein (LDL). EPCs were initially defined by the expression of both CD34 and vascular endothelial growth factor receptor 2 (VEGFR2, or FLK-1) (4). CD34 is also expressed to a lesser extent by mature endothelium as well as hematopoietic stem cells (HSCs). Further studies have identified that CD133 (or prominin) is a marker of the subset of CD34<sup>+</sup> cells that appears to demonstrate the best potential for endothelial differentiation (6). CD133 expression is rapidly lost from EPCs undergoing endothelial differentiation, which makes it useful as a marker of immature EPCs versus mature ECs that may be shed from the vessel wall. Interestingly, a recent report suggested that CD14<sup>+</sup> cells (monocytes) that express low levels of CD34 (undetectable with conventional techniques) may in fact contain the "true" progenitor cell population, with the greatest regenerative capacity (7). Although a consensus has not yet been achieved as to how best to identify circulating EPCs, it is generally accepted that this population is important for vascular maintenance and repair.

### THERAPEUTIC APPLICATIONS OF CELL THERAPY FOR VASCULAR REPAIR AND REGENERATION

The promotion of neovascularization represents a major focus of cell therapy for vascular disease and involves three

distinct processes: angiogenesis, vasculogenesis, and arteriogenesis. In distinction to angiogenesis, vasculogenesis involves the de novo formation of blood vessels from the differentiation of precursor cells (angioblasts or EPCs) into ECs, which eventually give rise to capillaries. In contrast, arteriogenesis refers to the increasing size and complexity of preexisting arteries by intimal and medial remodeling (8,9). A second potential application of cell therapy is to accelerate the regeneration of injured or dysfunctional endothelium of native vessels. Maintenance of an intact and functional endothelium is crucial for the prevention of the progression of atherosclerosis, intimal hyperplasia, and thrombosis. The ability of EPCs to differentiate into ECs suggests that they may incorporate into sites of endothelial damage and repair the compromised endothelium (10–12). One of the challenges to the success of such cell therapies is that patients with risk factors for coronary artery disease (CAD), which are known to cause endothelial dysfunction, have reduced circulating levels and function of EPCs (13,14). This may reduce the ability of circulating EPCs to maintain endothelial integrity (15). In addition to their ability to repair preexisting endothelium, EPCs have been shown to contribute to the endothelialization of vascular implants, a phenomenon known as *fallout endothelialization* (16,17). The ability of EPCs to regenerate the endothelium has led to several applications, discussed in later sections.

#### CELL THERAPY WITH VASCULAR STENTS AND PROSTHESES

The mechanisms of postangioplasty restenosis have been extensively studied. The restenotic process is characterized by four distinct phases: thrombosis, inflammation, proliferation, and matrix deposition/vessel remodeling (18–20). It is known that one of the most important mechanisms that contributes to arterial restenosis is endothelial denudation at the time of intervention, and that the kinetics of reendothelialization determine the magnitude of intimal hyperplasia. Many attempts have been made to seed ECs on denuded or synthetic surfaces using a variety of devices and techniques. These have shown some positive results but also have been hampered by rapid loss of the seeded cells (21–26).

##### Cell Seeding of the Native Vessel Wall

In one of the first studies, Nabel and colleagues instilled ECs into balloon-injured porcine iliofemoral arteries of syngeneic animals, achieving 2% to 11% adherence after 2 to 4 weeks (23). Subsequently, it was reported that a high level of EC attachment (36%) could be obtained in damaged human saphenous veins in vitro (26). The same investigators demonstrated 17% cell retention after 100 minutes of blood flow in previously denuded external iliac arteries of rabbits (21). To improve engraftment, ECs were grown in polymer matrices, which were then implanted into a porcine model of arterial injury (27). Despite the use of nonimmune matched

allogeneic (porcine) and xenogeneic (bovine) EC implants, experimental restenosis was significantly reduced 3 months after angioplasty compared with control by 56% and 31%, respectively. Conte and associates delivered genetically modified ( $\beta$ -galactosidase) autologous venous cells to the surface of a balloon-injured rabbit femoral artery. Four to 7 days after seeding, injured arteries displayed 40% to 90% coverage with  $\beta$ -galactosidase-transduced cells, even when seeded at subconfluent density, and an intact EC monolayer, as evidenced by scanning electron microscopy studies (22). This also significantly improved restenosis in a hypercholesterolemic rabbit model of iliofemoral injury (28); however, this method required surgical exposure of the vessels and complete interruption of blood flow for 30 minutes, which may not be clinically desirable.

More recent studies have used EPCs following angioplasty injury to enhance reendothelialization and reduce neointimal hyperplasia (29,30). It was subsequently shown that the genetic modification of EPCs with a retroviral vector expressing endothelial nitric oxide synthase (eNOS) potentiated the therapeutic benefit of the transplanted cells in a rabbit carotid injury model (11). It also has been reported that the mobilization of EPCs can lead to accelerated re-endothelialization of denuded vessels. For example, the exogenous administration of granulocyte colony stimulating factor (G-CSF) for several days to mobilize BM stem and progenitor cells before balloon injury of carotid arteries in rats resulted in enhanced reendothelialization (11). Similarly, statin (12,30) and estrogen (31) therapy increased the number of peripheral blood EPCs and reduced neointimal hyperplasia in animal models of arterial injury.

##### Cell Seeding of Intravascular Stents

In 1988, van der Giessen and colleagues (32) seeded human umbilical vein ECs on stainless steel self-expandable stents and implanted them into pig femoral arteries. Interestingly, they reported complete reendothelialization despite the obvious immunological mismatch of this “xenograft.” (32) Since this early study, there have been no further preclinical reports of cell seeding with mature ECs, other than studies demonstrating in vitro technical feasibility. There are several likely reasons for this lack of progress. Cell adherence is difficult to maintain with the restoration of blood flow, and stainless steel provides a poor platform for EC attachment. More important, stents require balloon expansion for deployment, which will damage the fragile neoendothelium. Even with the use of self-expandable stents, there is a requirement for balloon postdilatation for optimal apposition of the stent struts to the vessel wall. We have recently developed a novel technique to “autoseed” implanted vascular stents by capturing endogenous nonmobilized circulating EPCs (Figure 183.1). Stents coated with anti-CD34 antibodies efficiently capture circulating EPCs, which then mature into cells with an endothelial phenotype, completely covering the stent struts and the intrastrut denuded vessel wall (Figure 183.1). The ability of

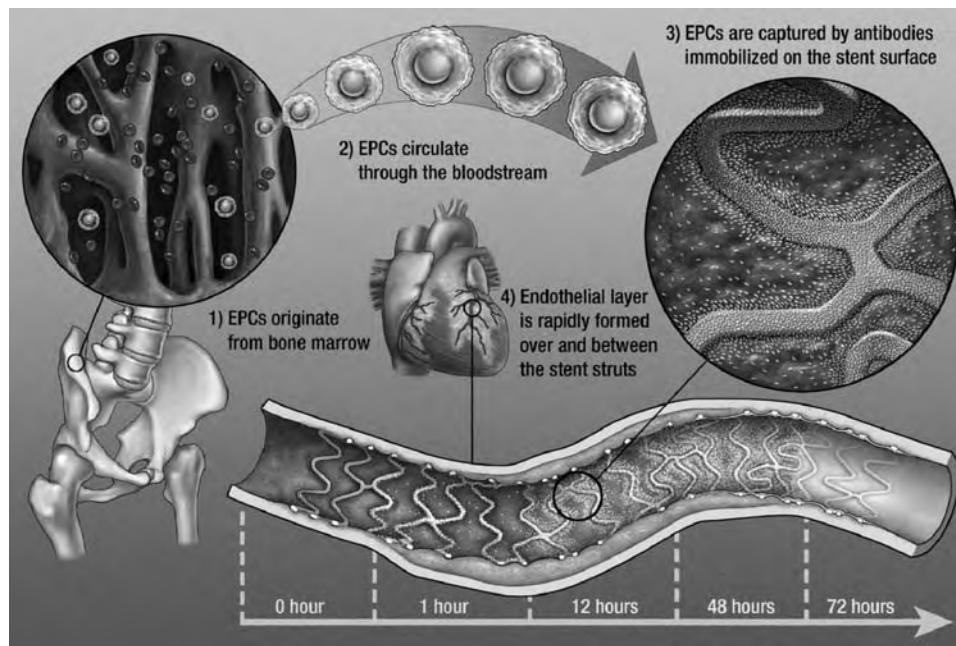

Figure 183.1. EPCs originate in the bone marrow and circulate in the blood. CD34<sup>+</sup> EPCs are captured by anti-CD34 antibodies on the stent surface. The adherent cells proliferate to rapidly cover the stent struts, and subsequently differentiate to re-establish functional endothelium, reducing the chance of stent thrombosis. Accelerated healing post-stent implantation can also result in inhibition of intimal hyperplasia and subsequent in-stent restenosis.

these devices to capture circulating EPCs and, as a consequence, to prevent restenosis and eliminate the risk of stent in situ thrombosis, has been demonstrated in a pig coronary stent model (in press). The clinical safety of these devices has been shown in the HEALING-FIM Trial (33), and the efficacy of this approach to prevent in-stent restenosis is being tested in the HEALING II clinical trial.

### Cell Seeding of Prosthetic Grafts

Apart from a small territory around the anastomotic site, prosthetic grafts do not spontaneously endothelialize in humans (34). It is thought that the lack of surface ECs promotes thrombosis and ultimately leads to the failure of the prosthetic graft. Seeding of the graft lumen with ECs has been used to overcome this problem. Two strategies have been described: single-stage and two-stage seeding (35,36). The single-stage methodology uses freshly harvested ECs either of venous or microvascular origin to immediately line the graft. In two-stage seeding, ECs are extracted and undergo a prolonged period of *ex vivo* cell culture to increase the cell numbers before seeding.

#### *Venous and Arterial Endothelial Cells*

Mansfield and coworkers were the first to describe EC seeding in 1975 (37). They used granulation tissue from the bed of a pedicled skin flap as a cell source to seed a mixture of ECs, fibroblasts, and macrophages onto patches of polyester. In 1978, Herring and colleagues introduced the concept of

single-stage seeding of prosthetic grafts using autologous ECs (35). In dogs, mechanically isolated venous ECs were mixed with blood and used to preclot polyester grafts, which were then implanted as infrarenal abdominal interposition grafts. After 2 to 4 weeks, they demonstrated that the grafts seeded with this method showed extensive lining of endothelium, with a reduction in the area affected by thrombus (38). These initial studies were followed by a series of reports examining cell seeding using both mechanically and enzymatically harvested venous ECs (39–47). It was shown that not only preclotting of polyester grafts with a mixture of ECs and blood, but also seeding of ECs onto the luminal surface of expanded polytetrafluoroethylene (ePTFE), resulted in surface endothelialization in dog models. Herring and coworkers were the first to show that ECs seeded on human arterial prostheses resulted in endothelialization (48). Despite encouraging preclinical results, the results of the initial clinical trials of single-cell seeding using autogenous vein as a source of ECs were variable, but overall disappointing (49–57). The failure of these single-stage seeding trials was thought to be caused by the low seeding density of the ECs. A limited number of ECs can be extracted from veins. In addition, a proportion of seeded cells are lost when exposed to pulsatile blood flow.

Compared with single-stage seeding, two-stage seeding results in superior patency rates in animals (58–62). In two-stage seeding, the ECs are extracted and undergo a period of cell culture and expansion. The superiority of this technique is thought to be due to the high density of seeding and the

retention of a large number of ECs on the surface of the prosthetic material despite cell loss on exposure to pulsatile flow. Zilla and colleagues (63) published the results of the first randomized clinical trial performed with two-stage seeded and nonseeded ePTFE grafts used for femoropopliteal bypasses using ECs isolated from the external jugular vein. Seeded grafts were cultured in vitro for at least 9 days and the total period between EC isolation and graft implantation was 37 days. After 32 months, the actuarial patency rate was 85% for the seeded and 55% for the nonseeded grafts. The persistence of a confluent endothelium was shown in an explanted specimen (64). In 1999, the 9-year follow-up of the initial randomized study by Zilla and coworkers and the 5-year follow-up of the routine clinical endothelialization program were reported (65). The patency rates were significantly higher for the seeded grafts (65%) than for the nonseeded control group (16%). Other clinical trials involving the two-stage endothelialization process have also shown a significantly enhanced clinical performance in small-diameter grafts (65–70). The main disadvantage of the two-stage seeding technique is the labor intensity. A 4- to 5-week delay exists between cell harvest and graft implantation, which prevents its use in emergency situations. The risk of failure of cell culture because of infection of the cells and the inability of the cells to proliferate effectively also limits its clinical applicability.

#### *Microvascular Endothelial Cells*

A shortcoming of the use of venous ECs, either as part of a single- or two-stage seeding process, is the relatively low yield, which has led to the evaluation of other EC sources. A large number of microvascular ECs can be extracted from abdominal, buttock, breast, and omental fat ( $>1 \times 10^6/g$ ). Endothelialization of prosthetic grafts utilizing such a high cell density, single-stage process, has been coined “cell sodding.” Despite favorable patency rates in animal experiments (71–76), the results of clinical studies using microvascular ECs have been disappointing. In a case report, a seeded mesoatrial polyester graft explanted after 9 months showed a vascular endothelium with a substantial subendothelial layer composed of sparse cells and extracellular matrix (77). Meerbaum and associates reported the medium-term results from 34 patients after implantation of ePTFE grafts seeded with subcutaneous fat-derived microvascular ECs for peripheral vascular reconstruction (78). The cumulative patency at 36 months was 19%, similar to studies using nonseeded grafts. Williams published the results of a safety study of 11 patients with significant vascular disease who received microvascular EC-seeded ePTFE peripheral bypasses (79). Of the 11 patients, seven were available for follow-up at 4 years and the patency was 55%. The results of human studies with fat-derived microvascular cells have been less favorable than those of animal studies and of human studies with cultured vein-derived ECs. The inferiority of sodding with microvascular cells may be due to the delay in the formation of a confluent endothelium with this single-stage procedure and the presence of a high percentage of contaminating non-ECs.

#### *Endothelial Progenitor Cells*

EPCs have been shown to contribute to reendothelialization of prosthetic grafts in animals (80). The ability of locally transplanted EPCs to endothelialize vascular bioprostheses has also been demonstrated (29). Using a similar approach, Kaushal and colleagues showed that seeding of EPCs into decellularized porcine iliac vessels implanted as coronary interposition grafts formed a functional endothelial layer and improved vasodilatory function and patency of the grafts (10). An advantage of using EPCs is that they can be obtained by venipuncture rather than surgically. The disadvantages of using EPCs include the risk of infection during ex vivo culture, change of phenotype, and limitations for their use in emergency situations because they require ex vivo expansion.

A novel method of “autoseeding” prosthetic vascular material, developed by our group, has been described by Rotmans and coworkers (81). Anti-CD34 antibodies immobilized on the surface of ePTFE were effective in capturing circulating EPCs and establishing an endothelial layer on the surface of the material when implanted as an arteriovenous shunt. Despite EC coverage of the graft, robust intimal hyperplasia at the outflow anastomotic site remained a problem. Mobilization of EPCs with cytokines has also been shown to be effective in promoting in vivo endothelialization of prosthetic grafts. Both Bhattacharya and colleagues (82) and Shi and associates (83) reported that the mobilization of EPCs from BM by exogenous G-CSF enhances the endothelialization and patency of small-caliber prosthetic grafts.

#### *Genetically Modified Cells*

Several preclinical studies have shown that it is possible to genetically modify ECs ex vivo prior to the seeding of prosthetic material to increase the efficiency of engraftment and to enhance endothelial function (84,85). However, any potential benefits from enhanced endothelial function, proliferative ability, and viability appear to be outweighed by poor retention rates compared with nongenetically modified ECs. Clinical trials using genetically modified ECs have not been initiated because of the poor results in animal studies and ethical questions concerning the role of such therapy.

### **CELL THERAPY AFTER ACUTE MYOCARDIAL INFARCTION**

Due to advanced reperfusion management approaches, survival after myocardial infarction (MI) has improved greatly, but the benefit is critically dependent on the time it takes for patients to present for appropriate treatment. As well, even when revascularization therapy is initiated within the “window of opportunity,” many patients fail to show significant recovery of cardiac function. Therefore, a large number of preclinical and clinical studies have attempted to use cell therapy to restore cardiac function post-MI. For the purpose of this chapter, we will deal only with studies related to the use

of BM-derived or circulating progenitor and stem cells, and the reader is directed to recent reviews that address the use of myocyte or myoblast transplantation (86,87).

### Cell Therapy in Experimental Models

In 2001, Orlic and colleagues first reported regeneration of myocardium by hematopoietic stem cells (HSCs) injected into the infarct border zone of a mouse MI model (88). However, transdifferentiation of HSCs into myocytes has been strongly refuted by several studies that show maintenance of hematopoietic characteristics of transplanted cells despite localizing to the peri-infarct regions (89,90). Despite this controversy, the ability of HSCs (as well as other cell types, such as BM or peripheral blood mononuclear cells [MNCs] and EPCs) to improve cardiac function after acute MI is widely reported (91–93), although the underlying mechanisms are still poorly understood. Recently, EPCs have also been reported to differentiate into cardiomyocytes when cocultured with myocytes (94,95), and Yeh and associates (96) showed that CD34<sup>+</sup> cells transdifferentiated into cardiomyocytes, ECs, and smooth muscle cells (SMCs) in a mouse model of acute MI. BM stromal cells (or mesenchymal stem cells [MSCs]) have also been shown to differentiate into cardiomyocyte-like cells *in vitro* and *in vivo* (97–99), although more typically they differentiate into osteocytes, chondrocytes, and adipocytes. It has also been suggested that MSC transplantation into the injured zone prevents remodeling of peri-infarct regions and improves regional wall motion (98,100).

An alternative strategy for “cell therapy” involves the mobilization of stem and progenitor cells from the BM, thus avoiding the need for cell isolation, processing, and delivery. In mice, G-CSF and stem cell factor (SCF) have been reported to increase bone marrow cell mobilization and stimulate myogenesis and angiogenesis with an improvement in cardiac function after acute MI (101,102). Apart from EPC recruitment, G-CSF has been shown to have direct myocardial effects contributing to improved myocardial function, including the inhibition of cardiomyocyte and endothelial apoptosis (103). It has also been shown that G-CSF can accelerate infarct healing by enhancing macrophage infiltration and matrix metalloproteinase activation (104). Despite the potential advantage of using this technique, it is possible that mobilization of BM cells could aggravate chronic inflammation of atherosclerosis and lead to plaque rupture or other complications (105–108), and thus the safety of this strategy in patients with vascular disease will have to be assessed carefully.

### Clinical Trials

Despite a lack of thorough understanding of the mechanism of cardiac regeneration due to cell therapy, many safety and efficacy trials for acute MI have already been initiated based on encouraging preclinical data. Patients in many of these trials received primary angioplasty with stenting to reperfuse the ischemic myocardium, followed by infusion of cells into the

coronary artery. Most studies used unselected BM cells (i.e., BM MNCs), which include stromal cells, vascular cells, MSCs, and HSCs, and only a few reports used selected (i.e., CD34<sup>+</sup>) cell populations. Results from more than 600 patients from various trials suggest that intracoronary delivery of unselected BMCs is safe when given within several months of MI (109–114). Transplantation of Progenitor Cells and Regeneration Enhancement in Acute Myocardial Infarction (TOPCARE-AMI) also administered EPCs derived from peripheral blood with similar results (112). Cell infusions into the culprit artery after stenting did not appear to result in further damage to the myocardium, nor did this lead to a systemic inflammatory reaction based on analysis of serum troponin and C-reactive protein (CRP) levels. BMC and EPC transfer did not increase the rate of ventricular or supraventricular arrhythmias, as assessed by Holter monitoring and clinical surveillance (109,113), and in most patients, in-stent restenosis was not increased due to cell transfer (110,112,114).

Until recently, trials have not been designed to assess efficacy and, with the exception of the Bone Marrow Transfer to Enhance ST-elevation Infarct Regeneration (BOOST) trial, have not included a randomized control group (114,115). For ethical reasons, even the BOOST trial did not incorporate sham procedures, thus limiting the ability to blind patients and investigators. With these caveats in mind, most trials suggest that intracoronary injection of unselected BMCs or EPCs enhances regional wall motion within the infarct area (109,110,113, 114,116,117). In TOPCARE-AMI and BOOST, regional wall motion was associated with a significantly improved global left ventricular ejection fraction (LVEF) (109,114). In the BOOST trial, there was a 6% increase in LVEF at 6-month follow-up in patients receiving cell therapy compared with controls (114). However, after 18 months there was no significant difference in LVEF between patients receiving placebo and cell therapy, mainly due to an unexpected improvement in control patients.

In the last year, the results of three larger, randomized controlled trials have become available (118–121). The Reinfusion of Enriched Progenitor Cells and Infarct Remodeling in Acute Myocardial Infarction (REPAIR-AMI) (119) clinical trial was the first randomized double-blinded study to show efficacy of BM-MNCs in the post-MI setting (119). This 204-patient study achieved its primary endpoint of improvement in global EF at 4 months, measured by LV angiography, although the actual improvement was rather modest, with only a 2.5% difference between the cell and placebo groups (119). In contrast, two other recent cardiac cell therapy randomized, controlled trials failed to show significant improvement in LV function. The ASTAMI trial was randomized but not blinded and showed no benefit in LVEF measured by MRI (121). However, this trial used cell isolation and processing techniques that have been shown to adversely affect cell viability (122). The Leuven study (Belgium), which involved delivery of cells much earlier (within 24 hours) than the other trials, also failed to achieve its primary endpoint despite improvements in secondary endpoints (i.e., infarct size) (118). Chen and colleagues

(123,124) utilized MSCs injected into the coronary circulation in patients after acute MI and reported no adverse effects, despite evidence in dogs that this approach could accentuate ischemic damage to the myocardium (125). They also showed improved wall motion and global LVEF 6 months after MSC transfer, compared with controls (123,124). In the Magnesium in Cardiac Arrest (MAGIC) trial, peripheral blood MNCs were isolated after mobilization with G-CSF and injected into the infarct-related artery of patients undergoing percutaneous coronary intervention (126). After 6 months, LVEF, regional wall motion, and tissue perfusion were improved in patients receiving cell transplantation compared with matched controls. However, seven of ten patients followed-up at 6 months developed significant in-stent restenosis or complete reocclusion, and two developed a de novo lesion in the infarct-related artery as assessed by quantitative angiography. Whether this was related to the proinflammatory effects of BM mobilization or to an effect of the local delivery of MNCs is uncertain. Although these results raise concerns, the small scale of this trial precludes any definitive interpretations.

### Controversies and Key Issues

It is certainly too early to come to any firm conclusions as to whether cell therapy, in its present form, is sufficiently effective to improve cardiac function substantially after acute MI, and if so, by what mechanisms. As we await the results of larger and more rigorously designed clinical trials, it is important to maintain realistic expectations. As well, it is unlikely that these first trials, which are using simplistic strategies, will reflect the true potential of cell therapy. Even fairly modest improvement, if truly reproducible, would be very encouraging. Moreover, it must be recognized that the use of autologous cells, which will likely be required in the foreseeable future, is associated with several significant limitations. Most patients that require cell therapy will be older, with widespread vascular disease, and multiple risk factors. All these factors will likely have a negative impact on the number and quality of autologous stem and progenitor cells – for example, by reducing their ability to proliferate, migrate, and survive. Already, some preclinical work has been performed to attempt to address some of these issues – for example, by using genetically engineered MSCs, which overexpress the survival factor Akt (98). However, whether genes that interfere with apoptosis can be used clinically is questionable in view of the potential increased risk of cell transformation and neoplastic transformation.

## CELL THERAPY FOR NEOVASCULARIZATION

### Preclinical Experience

A number of the preclinical studies attempting to stimulate neovascularization have been performed with BM- or peripheral blood-derived EPCs. BM transplant experiments have shown that EPCs are mobilized from the marrow in response to tissue ischemia (127,128) and home to, and incor-

porate into, regions of neovascularization (129). In small-animal models of limb ischemia, injection of human blood-derived EPCs improved neovascularization and subsequent limb blood flow (127,130–133). Similarly, using small-animal models of myocardial ischemia or infarction, it has been shown that systemically administered or BM-recruited EPCs stimulate angiogenesis and arteriogenesis, with subsequent improvement in myocardial perfusion (5,92). Kawamoto and colleagues (93) reported that autologous EPCs significantly increased capillary density and collateral development (by angiography) with an associated improvement in LVEF in a pig model of myocardial ischemia.

In a rat ischemic hindlimb model, intramuscular injection of BM MNCs increased the number of visible capillaries (by microangiography), limb flow, and exercise tolerance compared with controls (134). In a rabbit model of hindlimb ischemia, BM MNCs augmented small and larger vessel remodeling, with enhanced collateral development (129). Of note, MNCs cultured under hypoxic conditions had a greater effect on flow recovery than cells grown under normoxic conditions (135), suggesting that these cells are normally responsive to ischemia. In a rat model of cardiac ischemia, BMC implantation induced angiogenesis and improved the perfusion of ischemic myocardium (136). Results from large-animal studies have shown that injection of BMCs improved collateral flow (137,138), augmented capillary density, and reduced contrast echocardiography perfusion defects (91,139).

The use of different disease models, cell types, cell numbers, and species makes the comparison of results between studies very difficult. However, overall functional improvement appears similar whether cell populations are selected using CD34, CD133, or murine Sca-1 determinants or whether unselected MNCs are expanded in differential culture (6,92,127,128,130,140–143). As well, both “early-growth” and “late-growth” EPCs showed comparable *in vivo* neovascularization capacity despite the marked phenotypic differences between these two populations (144). These results seem to suggest that the functional benefit is relatively independent of the type of stem/progenitor cell used. However, some studies have reported that the CD34<sup>+</sup> fractions of BM- or blood-derived MNCs exhibited reduced neovascularization capacity (131,145). In addition, fully differentiated mature ECs have been shown to lack the ability to induce neovascularization (130,144,146). Urbich and Dimmeler (147) have suggested that chemokine- or integrin-receptor-mediated homing is needed for this effect. Certainly in arteriogenesis this may be crucial, as delivery of monocyte chemoattractant protein (MCP)-1 by itself enhanced collateral vessel formation (146), whereas depletion of monocytes has been shown to impair arteriogenesis (149,150).

The ability of EPCs to stimulate neovascularization was initially attributed to their ability to differentiate into ECs. However, studies using BM transplantation of genetically modified cells (with reporter genes such as *GFP* or *LacZ*) have shown greatly varying incorporation rates of genetically labeled, BM-derived cells coexpressing endothelial markers

(0%–90%) (151–155). Some of this variation may be attributable to different levels of tissue injury in the models of ischemia, as injury itself may promote BM mobilization and incorporation (156). The efficiency of engraftment and incorporation also may differ between the types and source of cells as well as the method of delivery. For example, intravenous infusion of ex vivo EPCs leads to a higher incorporation rate than with G-CSF mobilization alone (157,158).

Because the incorporation rate of EPCs is often quite low, it has been suggested that neovascularization may result from paracrine effects (92,159). This is supported by studies showing that these cells have the ability to secrete growth factors such as vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF)-1, hepatocyte growth factor (HGF), and nitric oxide (NO) (147,160,161), which could influence the classical process of angiogenesis (162). In a model of tumor angiogenesis, it was shown that transplanted cells are not integrated in the tumor vessels per se but are found adjacent to the vessels (163). Likely, both the ability to incorporate into the vasculature and to secrete growth factors contributes to the overall neovascular response. In contrast, infusion of macrophages, which did not incorporate into vessels (164), caused only a slight increase in collateral flow after ischemia, suggesting that a combination of paracrine actions of EPCs together with their ability to physically contribute to vessel-like structures may be important for efficient vascular regeneration. Further studies must be conducted to better clarify the mechanisms by which EPCs enhance neovascularization.

### Clinical Trials for Cell-Based Neovascularization

Based on encouraging preclinical results using cell therapy for neovascularization, several clinical trials have already been initiated, not only in the setting of myocardial ischemia, but also for peripheral arterial disease (PAD). In 2002, Tateishi-Yuyama and colleagues (165) published the results from the Therapeutic Angiogenesis by Cell Transplantation (TACT) study, which enrolled 25 patients with unilateral leg ischemia. Patients were treated with BM MNCs in the gastrocnemius muscle of the ischemic leg and with saline in the nonischemic leg. Following the pilot study, 22 patients with bilateral ischemia were randomized to receive BM MNCs in one leg and freshly isolated peripheral blood MNCs in the other leg (158). After 4 weeks, the authors reported a significant improvement in ankle-brachial index (ABI), transcutaneous oxygen pressure (TcO<sub>2</sub>), rest pain, and pain-free walking time after intramuscular injection of BM MNCs compared with peripheral blood MNCs. Based on this limited-scale trial, the authors concluded that administration of BM MNCs could potentially be used to augment neovascularization of the ischemic limb of humans (165). More recently, a similar study was performed using intra-arterial administration of EPCs to rescue critical limb ischemia (CLI) (166). Seven patients were treated with an intra-arterial infusion of autologous EPCs isolated from peripheral blood following G-

CSF mobilization. Twelve weeks after EPC administration, the authors reported an increase in pain-free walking distance, ABI, TcO<sub>2</sub>, flow-dependent vasodilation, flow reserve in response to adenosine, and endothelium-dependent vasodilation. Although these early trials suggest that cell therapy may be useful for inducing neovascularization, larger trials are required to confirm the efficacy of these approaches and their applicability to the treatment of PAD.

### CELL THERAPY FOR PULMONARY VASCULAR DISEASE

Pulmonary arterial hypertension (PAH) is a vascular disease of unknown cause characterized by severe endothelial dysfunction. Although an imbalance between vasodilatory and vasoconstrictive properties in the pulmonary vasculature may contribute to the initial stages in the pathogenesis of PAH, recent studies have suggested that arterial remodeling may predominate, particularly in established disease (167) (see Chapter 129). Recently, loss-of-function mutations in a member of the TGF- $\beta$  family of receptors, bone morphogenetic protein receptor type II, have been found in patients with idiopathic and familial PAH (168), but how these are linked to pathogenesis of this progressive and lethal condition is uncertain. Although many patients with advanced PAH exhibit plexiform lesions characterized by EC and SMC proliferation (167), recent evidence suggests that EC apoptosis, likely as a result of environmental stress and/or genetic predisposition, may be an initiating event in PAH (167). Persistent or repeated bouts of EC apoptosis may lead primarily to microvascular rarefaction, and secondarily to the emergence of hyperproliferative and apoptosis-resistant EC “clones.” Both processes may contribute to the relentless increase in pulmonary vascular resistance that culminates in severe right-heart failure and death. Although there has been considerable progress in the development of new pharmacological treatments for PAH (169), these do not appear to alter the fundamental remodeling processes that drive progression of disease.

### Role of Bone Marrow–Derived Cells in Pulmonary Arterial Hypertension

Our group has conducted studies to determine whether administration of EPCs can rescue the PAH phenotype in a model induced by the injection of the plant alkaloid (170), monocrotaline (MCT) in rats, which results in reproducible and lethal PAH. We also tested the hypothesis that EPCs genetically engineered to overexpress eNOS, the gene responsible for producing NO in ECs, have a greater regenerative capacity and show greater efficacy in rescuing PAH compared to EPCs alone (170). Endothelial dysfunction is characterized by reduced NO bioavailability in ECs (171,172) and notably, NO has been shown to be reduced in severe pulmonary hypertension (173). Previously, it was shown that intrajugular delivery leads to a high percentage of cells retained within the lung

**Table 183-1: Overview of Published Clinical Trials for Acute Myocardial Infarction and Peripheral Arterial Disease**

<i>Study</i>	<i>Pathology</i>	<i>Design</i>	<i>N</i>	<i>Cell Type</i>	<i>Delivery</i>	<i>Outcome</i>
Strauer et al., 2002 (113)	Acute MI	Primarily safety	<i>n</i> = 10	BM MNCs	Intracoronary	Stroke volume↑; wall motion↑; perfusion↑; infarct size↓
TOPCARE-AMI, 2002 (109,112)	Acute MI	Primarily safety	<i>n</i> = 59	BM MNCs, PB EPCs	Intracoronary	EF↑; Infarct size↓; perfusion↑; remodeling↓
Stamm et al., 2003 (116)	Acute MI	Primarily safety	<i>n</i> = 12	BM CD133 <sup>+</sup>	Intramyocardial (during CABG)	Perfusion↑
Fernandez-Aviles, 2004 (110)	Acute MI	Primarily safety	<i>n</i> = 20	BM MNCs	Intracoronary	EF↑; wall motion↑; ESV↓
BOOST, 2004 (114,115)	Acute MI	Randomized, controlled	<i>n</i> = 60	BM MNCs, Saline	Intracoronary	MR: EF↑ (6 months only)
Leuven Trial (118)	Acute MI	Randomized, double-blinded	<i>n</i> = 33	BM-MNCs	Intracoronary	No increase in LV EF; ↓infarct size; ↑ recovery of regional systolic function
REPAIR-AMI (119)	Acute MI	Randomized, double-blinded	<i>n</i> = 102	BM-MNCs	Intracoronary	EF↑; greater benefit in <49% EF and >5 days after MI
ASTAMI (121)	Acute MI	Randomized, non-blinded	<i>n</i> = 50	BM-MNCs	Intracoronary	No benefit
MAGIC, 2004 (126)	Acute MI	Randomized, controlled	<i>n</i> = 20	G-CSF mobilized	Intracoronary	EF↑; perfusion↑; in-stent restenosis↑
TACT, 2002 (165)	Limb ischemia	Randomized, controlled	<i>n</i> = 85	BM MNCs PB MNCs saline	Intramuscular (Gastrocnemius muscle)	ABI↑; walking dist.↑; Tc O <sub>2</sub> pressure↑
Lenk et al., 2005 (166)	Critical limb ischemia	Primarily safety	<i>n</i> = 7	PB MNCs (following G-CSF)	Intra-arterial	ABI↑; walking dist.↑; Tc O <sub>2</sub> pressure↑; vasodilation (flow- and endothelial-dependent)↑; flow reserve↑

PB EPCs, peripheral blood endothelial progenitor cells; ESV, end-systolic volume; PB MNC, peripheral blood mononuclear cells.

immediately after injection (174) and that the majority of these cells transmigrate through the endothelial layer within 24 hours to engraft into the lung (175). Fluorescent microangiography revealed that, in the MCT-injured lung, labeled EPCs engrafted into the endothelium of distal pulmonary arterioles (170), and the administration of EPCs 3 days after MCT, was able to prevent the increase in right ventricle systolic pressure (RVSP) usually seen in this model, whereas fibroblasts had no protective effect. To test the ability of this approach to reverse already established PAH, EPCs were administered 3 weeks following MCT. Compared to the administration of MCT alone, which led to widespread occlusion of precapillary arterioles, EPC administration restored capillary continuity and microvascular architecture. This also was associated with a marked improvement in survival in rats receiving EPCs, with the eNOS-transfected EPCs showing the greatest

effect (170). Moreover, in rats with established PAH, eNOS-transfected cells reduced RVSP to levels that were not different from control animals that did not receive MCT, although EPC administration alone was not sufficient to fully rescue the PAH phenotype in this model (170). Similar results were reported by Nagaya and colleagues using human cord-blood-derived EPCs transfected with adrenomedullin (176).

The results of these experiments show that administration of EPCs can prevent the vascular abnormalities caused by MCT in rats and that gene delivery using EPCs may represent a feasible strategy in regenerating lung microvasculature and treating PAH. Based on this experience, an early-phase dose-ranging trial, the Pulmonary Hypertension: Assessment of Cell Therapy (PHACeT) trial, is about to begin in Toronto, which will be the world's first clinical study combining gene and cell therapy of cardiovascular disease.

## THE FUTURE OF CELL THERAPY

Cell therapy for vascular diseases represents an exciting new avenue that holds tremendous promise for repair and regeneration of blood vessels and possibly even the myocardium. Three main strategies for cell-based therapies are outlined in this chapter: (a) direct delivery of selected or nonselected cells, (b) mobilization of BM stem and progenitor cells, and (c) “autoseeding” of circulating stem or progenitor cells. The suitability of these different strategies for specific applications will vary. For example, autoseeding of stents or other vascular devices using an antibody coating directed at EPCs is ideally suited for the acceleration of endothelialization. In contrast, the direct delivery of regenerative cells into the tissue or into the arterial circulation may be the most efficient strategy for neovascularization of ischemic tissue. In any event, the clinical role of cell therapy for the treatment of vascular diseases has not yet been established in rigorous and adequately designed clinical trials. Although several trials are now under way, it is important to maintain realistic expectations, given our lack of understanding about which cells to use, how they best should be delivered, and perhaps, most important, how to overcome the inherent limitations of autologous cell therapy. Future research needs to be directed at these questions, in particular at ways to enhance the regenerative capacity of autologous cells harvested from generally older individuals with systemic disorders (e.g., hyperlipidemia, diabetes) or genetic factors (e.g., BMP2 mutations) that may reduce the ability of their cells to repair or regenerate the cardiovascular system.

### KEY POINTS

- The use of stem and progenitor cells for the repair or regeneration of the endothelium is a promising strategy for enhancement of the clinical benefits of stents and other vascular prostheses as well as improvement of post-MI myocardial regeneration and neovascularization in ischemic tissues.
- Strategies to promote adhesion of circulating EPCs to stents or other prosthetic vascular devices may enhance the endothelialization of the luminal surface and reduce complications (restenosis and thrombosis).
- The use of various stem and progenitor cells to improve function of damaged myocardium has shown great promise in preclinical studies and has been shown to be safe in several small-scale clinical trials. Currently, double-blinded and randomized trials are being conducted to assess the efficacy of this approach.
- In vascular disorders such as PAH or peripheral arterial disease, the delivery of bone marrow- or peripheral

eral blood-derived endothelial progenitor cells has been shown, through various preclinical studies and limited clinical trials, to improve endothelial dysfunction and promote neovascularization of ischemic tissues.

### Future Goals

- To increase the efficacy of autologous cell therapy and make it a successful clinical therapy, it will be important to reverse the reduced regenerative properties of EPCs derived from subjects with extensive cardiovascular risk factors; this may require genetic or pharmacological enhancement during the ex vivo culture.

## Building Blood Vessels

James B. Hoying and Stuart K. Williams

*BIO5 Collaborative Research Institute, University of Arizona, Tucson*

### BLOOD VESSEL STRUCTURE AND FUNCTION

#### Diffusion, Convection, and the Circulation

Vertebrate cells depend on the molecular diffusion of nutrients for metabolism and function. Single-celled organisms such as bacteria or protists obtain nutrients directly from their respective environments. Here, distances between the medium and cell interiors are small and well within diffusion distance limitations (assuming sufficient local concentrations exist). In contrast, multicellular organisms have cells that are internal to the organism structure, making access to nutrients by simple diffusion from the external environment difficult or improbable. For example, the maximum distance oxygen ( $O_2$ ) can diffuse in mammalian tissues is 20 to 100  $\mu\text{m}$  (due primarily to a relatively low solubility in aqueous environments) (1,2). This limitation is exacerbated for larger nutrient molecules with smaller diffusion coefficients.

Many multicellular organisms overcome this diffusion limitation through two general mechanisms. First, a transport medium is used to contain and even concentrate nutrients. Second, this medium is delivered to the internal cells through some convective means such as active “pumping” of the medium or current-driven permeation through extracellular spaces. In vertebrates, the transport medium is blood, which contains, in addition to a vast array of molecular and cellular components, hemoglobin-carrying red blood cells. Hemoglobin in the blood overcomes the relatively low solubility of  $O_2$  in aqueous environments and creates an “ $O_2$  reservoir” that optimizes  $O_2$  diffusion gradients from blood to tissue cells. In vertebrates, the cardiovascular system serves to move the blood throughout the body, bringing nutrients into close association with tissue cells, where diffusion can then be effective.

The cardiovascular system is a closed-loop distribution system comprising a series of interconnected conduits – blood vessels – that facilitate convective flow initiated by the heart. Although the blood vessel performs a number of critical functions in the body, its primary function is to serve as the conduit for blood flow and nutrient delivery. Consequently, the form

and function of an individual blood vessel are well suited to enable effective transport of a fluid medium (i.e., blood). Considerable effort is being directed toward building vessels (either artificially or naturally) to serve as replacements for a diseased vessel (e.g., sclerotic or aneurysmal arteries) or to provide new avenues for supplemental blood delivery to a tissue (e.g., tissue revascularization). In addition, the ability to build vessels as vascular models enables further study of vascular biology, disease mechanisms, and therapies. In building blood vessels, it is important to consider those critical morphological and functional aspects of a blood vessel in the design and fabrication of the new vessel.

#### The Tube as a Transport Structure

One common feature of convective conduits, whether in the marine sponge wall or in the mammalian circulatory system, is that they are circular in cross-section. In round tubes, radial stresses are evenly applied to all points in the tube wall and surface drag is uniform along the tube’s interior surfaces (3–6). Furthermore, a tubular structure maintains uniform flow patterns and minimizes turbulence, unlike other possible designs such as square or oval (in cross-section) conduits, which would yield differential flow gradients within the conduit. Overall, the tube, with its circular cross-section, makes for a stable and efficient distribution conduit and is the hallmark characteristic of blood vessels.

#### Macrovascular versus Capillaries

To move fluids over greater distances, as must occur in multicellular organisms, conduits must be interconnected to form a distribution system. The wall structure of the sponge is such that tunnels of various calibers are distributed throughout the sponge wall with larger-diameter tunnels branching into smaller tunnels. A similar arrangement occurs in the vertebrate circulatory system. However, because it is a closed loop, the circulatory system is generally arranged as a series of larger caliber vessels branching into smaller caliber vessels which

progress back into larger caliber vessels. This “duality” in the network (small- and large-caliber vessels) resolves two general challenges related to convective transport in large multicellular organisms: (a) bulk flow distribution of blood over relatively long distances to all regions of the body, including the most distal tissues, from a centralized pump (via large-caliber vessels); and (b) diffusion of O<sub>2</sub> and other nutrients into the tissues (via small-caliber vessels). The large-caliber vessels (also termed *conduit vessels* or *macrovessels*) are represented by arteries and veins. The smallest caliber vessels (also termed *exchange vessels*) are represented by capillaries. Large-caliber conduit vessels feed small-caliber capillaries via intermediate-caliber arterioles. Similarly, capillary blood is collected into veins via intermediate-caliber venules. In addition to mediating flow to and from the capillaries, these intermediate vessels serve additional roles. The precapillary arterioles (also termed *resistance vessels*) function to tightly regulate blood flow to the capillaries. The postcapillary venules mediate leukocyte trafficking and permeability changes. Arterioles, capillaries, and venules are collectively referred to as *microvessels*.

Blood moves through the vascular system down a pressure gradient (established by the heart), with the highest pressures occurring in the upstream portions of the vascular network, the arteries, and the lowest pressures in the most downstream portions, the veins. Because the conduit vessels must individually transport the bulk of the blood (e.g., the most upstream vessel, the aorta, must singularly transport all of the blood moving into the systemic circulation), they have large diameters to accommodate larger blood volume flows (flow is proportional to the cross-sectional area). However, the blood pressure will act to push the wall of the vessel outward, resulting in a circumferential stress within the vessel wall. According to Laplace’s Law, higher vessel diameters and internal pressures lead to larger circumferential wall stresses (7). Arteries have thick, muscular walls to normalize circumferential wall stress resulting from the higher intravascular pressures associated with blood pressurization and larger diameters. Veins, on the other hand, have thinner, more compliant walls and are capable of significant stretch and dilation. Even though veins have larger diameters than the corresponding arteries in the vascular tree (e.g., the vena cava has a larger diameter than the aorta), the reduced pressures help to reduce the increased circumferential stresses associated with the relatively larger diameters (7).

In contrast to the macrovessel, which serves primarily as a transport conduit, the capillary provides the necessary interface for diffusion of nutrients from the blood to the tissue cells. For effective exchange, (a) blood flow through the vessel must slow to provide enough time for diffusion from the vascular space to take place, (b) the vessel wall must be thin enough to not be a diffusion barrier, and (c) there must be a sufficiently large surface area for exchange.

The capillaries (as with other microvessels) are uniquely designed to meet these three challenges. Capillary diameters are in the range of approximately 5 to 10 μm. Arterioles, which are immediately upstream of capillaries in the vascular net-

Figure 184.1. Phase micrograph of a microvessel fragment. **A** panel is a low magnification image showing a longitudinal cross-section of a 7–8 micron internal diameter microvessel comprising two cell layers. The dark cells in the lumen are red blood cells packed together. **B** is a higher magnification of the box in the upper panel showing the compact and intimate organization of perivascular cells, with prominent nuclei (*arrows*), and the EC layer. Separating these two layers is only a thin basement membrane. The perivascular layer covers most of the EC tube with only occasional gaps in the coverage (\*). Any design strategy for building a microvessel must address this unique architecture.

work, range in size from approximately 10 to 100 μm in diameter. The small caliber of capillaries and more significantly, the arterioles, help to slow the flow of blood due to the increases in resistance associated with the smaller diameters (resistance to flow is inversely proportional to the fourth power of the radius) (8). The smaller diameter of capillaries also reduces circumferential wall stress, preventing capillary rupture. The wall structure of the capillary comprises the endothelial cell (EC) and the peri-EC (or perivascular cell). The number of perivascular cell layers is few, with the most distal vessel elements containing only one or a partial outer cell layer. The organization of ECs and perivascular cells is tightly structured, with only a basement membrane separating the two layers in the smaller vessel segments (Figure 184.1). In healthy vasculature, the capillary EC body is attenuated and may range in thickness from a few microns (across the nucleus) to submicron dimensions in the thinnest areas. Consequently, vessel diameter (nutrients must diffuse through the blood to reach the capillary wall) and the distance from the capillary wall to the target tissue cells comprise the greatest distance-related

barriers for diffusion (9). Finally, although not specific to vessel structure per se, the high densities of capillaries provides for a very large surface area (as much as 1,200 m<sup>2</sup>) (10) for diffusion and, therefore, effective blood–tissue exchange.

Although vessel caliber and wall thickness are certainly hallmark features of specific vessel types (e.g., arteries are vessels with large diameters and thick, muscular walls), this is a relative description. Vessels of approximately 100  $\mu\text{m}$  in diameter in larger animals are routinely used in studies examining arteriole physiology (11–14). However, the femoral artery of a mouse, clearly a conduit vessel in function, is also approximately 100  $\mu\text{m}$  in diameter. Therefore, when establishing design parameters for a constructed vessel, it is important that the intended function and position of the vessel in the vascular tree are known.

## BUILDING A BLOOD VESSEL

As discussed, macrovessels and capillaries display significant differences in vessel wall structure and composition. Although both macrovessels and capillaries are lined by a single monolayer of ECs, conduit vessels contain numerous circumferential layers of smooth muscle cells and extracellular matrix, whereas capillaries contain considerably less cell mass and extracellular matrix in their walls. Despite these significant differences, both vessel types conform to the shape of a tube. Therefore, in building a blood vessel, the vessel construct must be (a) configured as a tube, and (b) customized to serve the specific functional role of the vessel in the vasculature.

### Building Macrovessels (Conduit Vessels)

The motivation for building large conduit vessels relates to the clinical need to bypass/replace diseased conduit vessels. Arterial occlusive diseases are numerous in Western countries and have a serious impact on human health. The occlusion effectively disrupts the convective delivery of blood to downstream tissues, resulting in tissue ischemia, dysfunction, and/or death. The obvious solution is to re-establish conduit flow either through reopening the occluded vessel or replacing the diseased vessel segment with a new, patent vessel substitute.

#### *Autologous Conduit Vessels*

The development of larger diameter blood vessels for bypassing or replacing diseased arterial segments was based initially on the use of autologous tissue such as a patient's own segment of vein. The redundancy of the venous circulation made it possible to utilize a vein from one region of the body to provide arterial bypass grafting. These procedures showed initial promise and success, and the use of veins for arterial bypass remains a common surgical procedure today. However, it was quickly realized that autologous vein grafting did not permit replacement of large blood vessels such as the aorta. It also has been recognized that veins must adapt to the arterial circulation, and this adaptation often results

in failure of the veins once placed in the arterial position (15–18).

#### *Synthetic Conduit Vessels*

The first use of synthetic materials to build a blood vessel has been credited to Vorhees, Jaretzki, and Blakemore in 1952, with their pioneering work using Vinyon-N fabric to construct a replacement aorta for patients (19). This material was later replaced by Dacron and expanded polytetrafluoroethylene (ePTFE) for use in a wide variety of arterial bypass procedures. Of interest, these earliest studies using Vinyon-N resulted in the spontaneous formation of an EC lining in the midportion of some areas of these grafts. Identifying the source of these luminal ECs has remained a major goal since this early report and has been expanded recently to include the evaluation of circulating ECs and endothelial progenitor cells. Pioneering work by Sauvage and Wesolowski established that tissue ingrowth, including ingrowth of new blood vessels, into these materials following their implantation is critical to their extended patency (20–22). However, it was soon determined that the success of these synthetic arterial conduits was highly dependent on their internal diameter with a critical diameter cutoff of 6 mm. For the last 25 years it has been widely held that synthetic grafts with internal diameters less than 6 mm exhibit clinically unacceptably low patency rates (23). This means that patients needing arterial bypass to smaller vessels – for example, in the lower leg or the coronary circulation – must have a native vessel conduit to assure acceptable patency.

The patient needing a bypass vessel of diameter less than 6 mm who has no acceptable native vessel conduit often faces amputation of a limb or, when the target vessel is a coronary artery, significant morbidity or mortality. Based on extensive research, it is believed that the failure of synthetic grafts in small-diameter positions is related to the lack of a stable, antithrombogenic EC lining on the luminal surface. Implanted synthetic grafts form a pseudointima on the luminal surface, which is composed primarily of fibrin and platelets. These synthetic grafts, regardless of their inner diameter, never spontaneously endothelialize, and grafts explanted from patients after more than 10 years of implantation continue to exhibit a thrombogenic luminal surface. A simple solution to this thrombogenicity, hypothesized over 25 years ago, has been the accelerated formation of a stable EC lining on the blood-contacting surface of synthetic grafts. This simple premise has led to widespread efforts to create a living blood vessel from synthetic and biological components. These studies have progressed through animal studies to multiple human trials.

#### *Biohybrid Conduit Vessels*

Malcolm Herring provided the first experience with methods to isolate endothelium from a patient and prepare a synthetic graft with the patient's own cells to accelerate endothelialization (24,25). The term *seeding* was adopted to describe his method of mixing autologous ECs, isolated from the jugular vein by a simple scraping method, with whole blood, and

using this EC-containing blood to preclot the graft (26). The cells and blood were “milked” into the porous structure of the graft wall, followed by graft implantation. These early studies established that the ECs could survive this transplantation, but the efficiency of the cell coverage was poor and no benefit to patency was realized in animal or human studies. Two critical lessons were learned from these studies: (a) the number of cells needed for coverage of the graft was far beyond the number of cells available from a segment of autologous vein (27), and (b) the attachment of the cells to the surface of these grafts was essential to accelerate endothelialization either prior to or following graft implantation (28–33).

Methods to increase the number of ECs available for seeding focused on culture conditions and the use of growth factors to stimulate EC proliferation *in vitro*. The ability to expand human adult ECs in culture prior to placement on a graft was finally achieved using heparin as a co-mitogen in the presence of a crude mixture of EC growth factors (34). With the ability to expand the number of human ECs isolated from a small segment of vein, the possibility to seed large numbers of ECs onto the luminal surface of synthetic grafts was realized. This method has been championed by Peter Zilla and has established the efficacy of using large numbers of autologous ECs to establish monolayers of ECs on the luminal surface of synthetic vascular grafts prior to implantation into small diameter positions (35–39). Nonhuman animal studies established the durability and persistence of these linings and also established the increased patency of synthetic grafts prepared using this culturing system (40). The method involves a significant period of *in vitro* graft development, to allow expansion of ECs and to allow maturation of the EC lining. Nevertheless, these studies established the ability of cell transplantation to improve the patency of synthetic grafts in less than 6-mm applications, attaining the patency observed for autologous saphenous vein (41–43).

The function of these hybrid (cells and synthetic/non-degradable scaffold) tissue-engineered grafts has been assessed extensively in both animal trials and more recently in human trials (44–59). The results of these studies are encouraging and reflect the consistent improvement in techniques to isolate and deposit cells on the surface of grafts. Our expanded understanding of the function of endothelium in vessel homeostasis has resulted in devices that exhibit patency rates approaching those of the saphenous vein. The final proof-of-efficacy for tissue-engineered vascular grafts is the patency of an autologous artery (e.g., internal mammary artery for coronary bypass) when used as a bypass graft, a goal not yet attained but in sight. Initial animal studies established the ability to create EC linings on synthetic grafts and determined that the cells lining these grafts represented the cells originally used to treat the graft at the time of surgical implantation (60,61). This is critical, as it establishes the persistence of the cells transplanted and indicates re-endothelialization is not the result of spontaneous endothelialization through deposition of circulating endothelial progenitor cells. Prior to commencing human clinical trials, it was critical to establish a statistically

significant improvement in the patency of endothelialized as compared to synthetic grafts alone. Of interest, a large number of studies evaluate tissue-engineered neovessel function using grafts of lengths (graft length <10 times the inner graft diameter) (62,63) that are not a critical test of patency. Using grafts of appropriate length and studies with sufficient subjects to provide a statistical assessment, the positive effect of EC treatment on patency has been established in animal studies (64).

### *The Endothelial Cell in Building Macrovasculature*

Several factors led investigators to search for alternative sources of endothelium for cell transplantation. The expansion of ECs using growth factors was reported to cause changes in the karyotype of these cells, with unknown effects on cell function following transplantation (65). The *in vitro* culturing and maturation process involves periods that can extend up to 8 weeks. This timeframe precludes the use of this method for patients needing immediate bypass, and the long culture times increase the cost of the procedure and the susceptibility to infection. An alternative source of cells for graft seeding was identified in human adipose tissue (66–68). This tissue is well vascularized, and methods for the isolation of pure populations of ECs had been previously reported (69). The pellet of cells isolated from adipose tissue following enzymatic dissociation and centrifugal sedimentation was found to be highly enriched in cells that can form a stable EC lining on synthetic grafts (70,71). It was also critical that this method could be accomplished in the operating room at the time of primary bypass (either coronary or peripheral) surgery. A new term, *cell sodding*, was developed to describe the method of EC isolation and immediate cell deposition on a graft to form a monolayer (72). The grafts were implanted immediately into patients. Cells isolated from autologous fat have been used to construct neovessels for use as venous replacements, peripheral arterial grafts, arteriovenous fistula grafts, and coronary artery bypass grafts.

### *Translation*

The translation of this technology for building a blood vessel from cellular components has progressed through careful planning of studies to first assess safety and more recently efficacy. Some investigators have suggested that early successful results reported in animals using EC transplantation, including methods defined as both seeding and sodding, have not been realized in humans. The clinical results are still emerging, but results to date support a more positive outcome and have established the ability to accelerate formation of stable antithrombogenic EC linings on synthetic grafts in humans using autologous cell transplantation. New sources of cells for creating these linings continue to be evaluated, including cells derived from bone marrow and cells circulating in the blood (73–75). The use of degradable scaffolds is also under active evaluation, although serious concerns must be overcome regarding the susceptibility of these grafts to aneurysm formation (76–78).

Recently, the concept of “fallout” endothelialization has reemerged as a possible way to stimulate the formation of an antithrombogenic EC lining on implanted devices. The concept was first suggested in the 1960s, as a way to explain the difference in healing patterns and spontaneous endothelialization observed following implantation of vascular grafts into different species, including man (79). Significant work was performed modifying the internal, luminal surface of synthetic grafts to support spontaneous endothelialization by stimulating the adherence, or “fallout,” of circulating cells that could become endothelium. This concept has been studied most recently using stents modified with proteins or antibodies that have affinity for ECs and/or their progenitor cell types. The results of these studies are highly variable based on the choice of animal models (80), and translation to humans is ongoing. Because these therapies will be most commonly used in the aging population, it will be most interesting to see whether the population of circulating stem cells is present in sufficient quantities in older individuals to support spontaneous endothelialization.

### Building Microvessels

A clinical motivation for building microvessels arises from the need to reestablish or improve blood flow to a compromised or damaged tissue. Often, the introduction of a new conduit vessel, natural or artificial, upstream to an affected tissue reestablishes blood flow and relieves symptoms. However, in those situations where the replacement of an upstream diseased conduit vessel does not resolve the disease condition, it is necessary to regenerate a vascular supply, so-called *therapeutic angiogenesis* (81–83). In therapeutic angiogenesis, the goal is to expand an existing vascular bed, especially the downstream microvasculature, as a means to provide alternate and/or additional avenues for tissue perfusion. Additionally, new advances in tissue engineering are promising to repair or replace the dysfunctional tissues (84–87). Critical to any successful tissue engineering effort is the ability to quickly perfuse the tissue construct when implanted. Any tissue implant greater in dimension than a few millimeters is too big for nutrients to efficiently diffuse to the construct cells. Therefore, the ability to build or grow microvessels is critically important for both in vivo vascular regeneration (i.e., therapeutic angiogenesis) and in vitro tissue construction.

#### *The Endothelial Cell in Building Microvessels*

Clearly, the EC is the central player in establishing, maintaining, and regulating microvessel structure and function. At the core of the microvessel is a tube, constructed from ECs. In the case of the smallest microvessel, the capillary, a single EC wraps around, like a ring, to form a lumen. These “rings” of ECs are connected end-to-end to form the actual microvessel. During development, the first vascular cells to appear and assemble the vessel structure are ECs (or EC precursors) (88). These cells coalesce and align to form tubes organized into a primitive plexus that eventually progresses

to establish the foundation for the subsequent adult vasculature (89). In establishing additional microvessel segments in the adult, again it is the EC, this time already present in the existing microvasculature, that orchestrates the new vessel formation (90).

It is unclear what factors and/or forces are critical in forming a tube from ECs (91). It may be that this ability to form a ring is inherent in the EC. There are many examples in which cultured ECs placed in three-dimensional (3D) matrix environments, even without additional growth factors, spontaneously organize and align into tube or tubelike structures (92). It is unclear what the specific induction cues are in these examples. However, it seems that biophysical forces such as stress and strain within (e.g., along the cytoskeleton) and across ECs (e.g., through cell–matrix interactions), as opposed to solely biochemical signals arising from specific extracellular matrix molecules, may be sufficient given that ECs can form tubes in a variety of 3D matrices regardless of the specific biochemical aspects of the matrices. However, the EC cytoskeleton, in enabling the EC to curve its structure, and cell–cell adhesion molecules for “latching” the EC in place, must be playing significant roles. Clearly, though, the presence of other cues, such as angiogenic factors and cytokines (93–97) or non-vascular tissue cells (89,98), can regulate EC tube formation. In the end, it is likely that these different stimuli and processes work in concert to give rise to an EC tube. In this regard, ECs might spontaneously form a tube in a 3D environment but do so at different rates or lead to varying tube structures, depending on the type of matrix present and the additional varied biochemical signals.

#### *Perivascular Cells*

Recent studies highlight the critical interactions between the ECs of microvessels and the associated perivascular cells (i.e., pericytes, smooth muscle cells) in establishing and stabilizing microvessel structure and function (99). For example, mice lacking platelet-derived growth factor (PDGF)- $\beta$  develop fragile capillaries, due to a failure in recruiting perivascular cells to vessels during development (100,101). Other experiments are revealing that the release of pericytes from a capillary in response to an angiogenic factor is a necessary event for angiogenic sprouting, the natural means by which new microvessels form (102). Related to this, it appears that pericytes act to mature a neovessel and attenuate vascular proliferation. The proliferation of retinal capillaries leading to blindness is associated with the depletion of capillary pericytes in the retina (103). Finally, it is well known that the perivascular cells are an important component in the control of blood flow through the microcirculation, particularly at the precapillary level. This control involves not only indirect endothelial-to-perivascular cell communication (e.g., through soluble mediators such as nitric oxide) but also through direct cell–cell contact between the two cell layers, possibly involving gap junctions (104–109). It is becoming clear that a healthy, functional microvessel must have the appropriate perivascular cells incorporated into the vessel wall

Figure 184.2. Scanning electron micrograph of a sprouting microvessel in a 3D collagen gel matrix. In the preparation, the gels containing growing microvessels were fixed and then peeled apart in layers to expose growing microvessels. Collagen gels were prepared at 3 mg/mL collagen per gel volume. At this concentration, microvessels retain normal architecture but are still able to displace collagen fibrils and grow. Used with permission from Dr. Constance Temm, Indiana University School of Medicine.

with the necessary functional connections between the different vascular cell types.

#### *Tissue Environment in Microvessel Structure*

The nature of conduit macrovessels is such that they can maintain vessel structure (i.e., remain a tube) when removed from the body. This is particularly the case with the large elastic or muscular arteries. In this respect, the extravascular environment, although important in regulating conduit vessel function, is not critical for these vessels to establish and maintain form. In contrast, removal of microvessels from their 3D environments and placing them on two-dimensional (2D) surfaces causes the collapse of the tube architecture and dispersal of the microvessels' cells. Clearly the extravascular environment plays an important role in microvessel assembly and form. Consequently, choices of environments that support microvascular organization are critical to any successful attempt at building microvessels.

One stereotypical environment that is often used to support the building of microvessels is the type I collagen gel matrix. Comprising fibrillar collagen, and representative of a simple interstitial environment, collagen gel matrices provide 3D biophysical constraints and scaffolding for microvascular organization (110,111). These gels are isotropic meshes of randomly arranged collagen fibrils (Figure 184.2) dense enough to provide sufficient structure to constrain vascular cell organization but loose enough to enable rapid diffusion and vessel dynamics. Collagen gels exhibit stereotypical viscoelastic material properties (111,112). When deformed, these gels experience initial relatively high stresses, which then relax over time. The high amount of fluid contained within the gels generates a viscous drag between the gel constituents during

loading (113). Whether viscoelastic behavior is critical for EC tube formation and maintenance of microvessel structure is not clear. Given that other, manmade, scaffolds such as hydrogels share similar biomechanical properties as collagen gels, viscoelastic behavior seems likely to play some role.

Artificial scaffolds are being explored as alternatives to native matrices for use in the engineering of vascular and non-vascular tissues alike (114–119). Made from artificial materials, these scaffolds offer greater flexibility in determining the mechanical strength, compliance, porosity, and ability to degrade of environments for building microvessels (120). A polyglycolic acid-poly-L-lactic acid (PGA/PLLA) composite is one such material used to create artificial scaffolds often employed in assembling microvessels (121). A challenge in using artificial scaffolds concerns the biocompatibility of the materials. Vascular cells and other tissue cells need to interface with these scaffolds in a way that promotes normal cell behavior (e.g., tube formation by EC). One approach to improve biocompatibility is to attach biomolecules, such as matrix molecules, to scaffold materials to create a more biofunctional surface (120,122). The development of new materials and synthesis approaches for making more biocompatible scaffolds that retain design flexibility will greatly expand the ability to build microvascular systems.

#### *Manmade Microvessels*

Common strategies employed to build microvessels in vitro involve a *de novo* approach in which freshly isolated or cultured vascular cells are placed within a scaffolding environment (native or artificial) to form a construct containing microvascular tubes. The simple vascular tubes that subsequently form in these microvascular constructs will then progress to form true microvessels and microvascular networks, but only when implanted into a living host. The most successful approaches in forming in vitro vascular tubes have involved the use of ECs in combination with perivascular cells such as smooth muscle cells, mesenchymal smooth muscle precursors (e.g., 10T1/2 cells), and/or tissue stromal cells (123–125), often cultured separately and combined later with the scaffold. Growth factors/morphogens (e.g., fibroblast growth factor 2 [FGF2]) are often included to induce or accelerate vascular cell organization into a microvascular network (126,127). Interestingly, ECs, when used alone, will form tubes but will not effectively progress into a stable microvasculature when implanted without additional manipulation. For example, microvessel formation and survival in constructs prepared from human ECs in collagen gels or polylactic acid sponges were considerably enhanced when the ECs were engineered to overexpress the antiapoptotic protein Bcl-2 (128,129). An alternate strategy uses isolated, intact microvessel segments instead of cultured vascular cells (110). The microvessel segments retain the intimate microvessel structure, including endothelial and perivascular cells. When embedded in a 3D collagen matrix, the isolated microvessel fragments undergo angiogenesis and are capable of progressing into a mature, functional microcirculation when implanted in vivo (130). In

this approach, no further manipulation or addition of factors is necessary to produce the new microvasculature.

The findings in the above example studies point to two key concepts in the establishment of a healthy microvessel structure: (a) perivascular cells are important in microvessel formation and structure, and (b) the *in vivo* environment provides a key stimulus in building a mature microvasculature. When cultured perivascular or perivascular precursor cells were included with pure EC cultures or as part of the vascular structure to begin with (as in the isolated microvessel fragments), no special manipulation (e.g., genetic engineering) of the system was required (125,130). Interestingly, in those examples in which Bcl-2 overexpression in cultured ECs was used, increased perivascular cell recruitment from host tissues correlated with the increased microvascular stability (129). The findings that mature, specified (i.e., arteriole, capillary, venule specification) microvessels formed only when microvascular constructs were implanted indicate that some aspect(s) of the *in vivo* environment, absent *in vitro*, is critical to the ultimate formation of a mature microvessel. Although there may be a variety of *in vivo*-related stimuli involved (such as blood-borne or tissue-derived molecular factors), it seems likely that blood flow, and the associated pressures and shear stresses, is the primary stimulus, *in vivo*, leading to microvessel maturation. It is well established that hemodynamics contribute greatly to the maturation and remodeling of preexisting macro- and microvessels (7,131,132). Presumably, similar mechanisms are at play concerning the maturation of EC tubes.

A growing effort to build microvessels has involved traditional microchip fabrication techniques. Technologies such as soft lithography (133) or micro-electricomechanical system (MEMS) (134) fabrication methods are being used to create channels of microvascular dimensions to serve as a template for microvessel construction. Typically, grooves or channels are fabricated on a silicon wafer surface with appropriate dimensions. These channels are then coated with extracellular matrix molecules to facilitate EC adhesion to the channel walls to create vascular cell-lined channels (Figure 184.3) (135,136).

Figure 184.3. Schematics of three different soft lithography-based approaches for microvessel fabrication. **A** and **B** involve fabricating channels using dimensions that reflect the microvessel structure. The walls of the channels serve as the walls of the microvessel. **C**: The channel serves only to contain a 3D matrix within which a microvessel is allowed to form. Channel dimensions in **A** and **B** may be on the order of 8 to 20 microns, whereas the channel shown in **C** may be as large as 100 microns.

An alternative strategy would involve creating microvessels within a scaffold matrix placed within the microfabricated channels (Figure 184.3). In this approach, microvessels would form as they do in 3D matrices and are therefore not limited by channel dimensions. The channels, in this case, serve only to constrain the pattern of microvessels formed into a desired network topology (i.e., the channels do not directly determine microvessel structure).

### Naturally Made Microvessels

**ANGIOGENESIS.** In the adult, new microvessels are built from preexisting vessels via angiogenesis. Although angiogenesis will not be discussed in detail here, it is useful to consider aspects of angiogenesis in the context of forming a new microvessel element and structure. The classic conceptual model of angiogenesis involves the signaled focal relaxation of the parent microvessel structure followed by the sprouting of an EC at the relaxed site (137). This sprout appears as a spear-like cell projection from the microvessel wall that extends out into the extravascular space (110,138). Interestingly, it does not appear that formation of the new microvessel segment involves complete dissolution of either the parent microvessel or the growing neovessel (139). In studies involving intact microvessel elements, elongated neovessels comprised ECs contiguous with the tip EC of the sprout (110,130). There was no clear evidence from these studies that ECs leave the vessel and then reassociate during neovessel growth. In this regard, the formation of a new vessel element by angiogenesis differs from the *de novo* approaches used *in vitro* to fabricate microvessels from cultured cells. *In vitro*, individual cells coalesce to form the prevessel tube. In sprouting angiogenesis *in vivo*, the “prevessel” is an extension of a preexisting vessel structure, which continues to elongate and finally mature. However, growing evidence supporting a role for circulating endothelial progenitor cells in building neovessels during angiogenesis suggests that individual vascular cells separate from the vessel structure do add to the neovessel wall (140,141). Perhaps the *in vitro* approaches model this process.

An interesting question concerning the mechanism of vessel formation during angiogenesis is whether a lumen is maintained in the sprouting neovessel or is instead reestablished as the angiogenesis event is resolved. It appears that the lumen of the neovessel forms in the elongating region behind the tip cell of the sprout (142). This suggests that the EC is capable of forming a ring soon after or even during a proliferative event. An understanding of how the EC is organized within the sprouting segment and how the sprout is integrated with the parent vessel might provide insight leading toward more effective strategies for assembling microvessels *in vitro*.

During sprouting, it is thought that the perivascular cells are not associated with the growing neovessel. This was directly demonstrated in a model of vascularization (130) in which  $\alpha$ -actin-positive cells were seen to leave the angiogenic vasculature and not associate with the new sprouting neovessels. However, once angiogenesis stopped and vessel maturation began,  $\alpha$ -actin-positive cells reassociated with the

microvasculature, which correlated with reestablishment of blood flow within the newly formed network (130). These observations are consistent with findings that perivascular cells are important in establishing mature microvessels (143).

Clinically, angiogenesis can be used therapeutically to create new vasculature within a tissue. The general approach has been to deliver angiogenic factors, either as a native molecule (e.g., a peptide) or as a transgene encoding the factor (83,144). Vascular endothelial growth factor (VEGF) and FGF2 are two factors that have been actively explored as agents for therapeutic angiogenesis (145–148). Clinical trials with these agents have produced mixed results (144). Although perfusion-related evidence indicates an increase in vasculature within treated tissues (typically heart or skeletal muscle) relatively early after treatment, long-term benefits of the therapy were not realized. These findings suggest that early vessel growth occurred, but long-term stability of the new vessels (and resulting new vasculature) was compromised; either the new vasculature regressed, or it is not functioning normally with respect to perfusion capacity. Consistent with this interpretation is that, in the context of tissue vascularization (such as in therapeutic angiogenesis), simply providing new microvessel segments (i.e., angiogenesis) is ineffective at expanding the perfusion capacity of the microvasculature in the absence of the necessary postangiogenic events. These events include vessel redifferentiation, artery side–vein side specification, structural adaptation, and network remodeling. More information is needed concerning the biology driving postangiogenesis events before an effective angiogenesis-dependent therapy can be developed.

**ARTERIOGENESIS.** One vascular process related to postangiogenesis maturation that is being actively investigated involves the development of feed vessels from microvessels. Called *arteriogenesis*, this process results in the increase in diameter and vessel wall mass of an existing capillary or arterioles (149–153). Typically the increase in mass involves the addition of both cells (often perivascular cells) and matrix to the vessel wall. Presumably there is an analogous process for forming venules/veins (*venogenesis*) and capillaries (*capillarygenesis*) as neovessels formed by angiogenesis are integrated into the perfusion network. The term *arteriogenesis* generally is used when describing the formation of a new feed artery to a local vascular network. This is often visualized clinically by angiography as an appearance of collateral vessels in a tissue. Active research into the formation of collateral arteries has identified numerous possible biochemical regulators of arteriogenesis, including growth factors, inflammatory cytokines, and vasoactive mediators (154–157). Furthermore, changes in endothelial shear stress and circumferential stress can lead to compensatory changes in wall characteristics leading to arteriogenesis (158–160). In the case of arteriogenesis, an increase in shear (due to an increase in flow) will result in dilation of the vessel segment. As the vessel dilates, the wall will experience greater circumferential stress, leading to a compensatory thickening of the vessel wall to normal-

ize this stress. Regardless of the mechanism, arteriogenesis is thought to occur in response to a chronic need to provide additional blood flow to the downstream vasculature such as would happen following the formation of new vessel elements via angiogenesis.

### *The Microvascular Network*

Whether microvessels are built naturally or in the laboratory, the final intent is actually the formation of a microvascular network. Rarely, if at all, is the outcome the fabrication of a single, stand-alone microvessel. This may reflect, perhaps, significant technical challenges related to fabricating a single, small-caliber vessel that can be practically used. However, a single capillary brings blood into close proximity to an area that is a few cell layers thick. Only through a network of capillaries and other microvessels will there be sufficient exchange to support an entire tissue bed (161). Therefore, unlike with conduit vessels where a single vessel meets the primary purpose (i.e., bulk transport of blood), it is the microvessel network that fully meets the tissue needs. In addition, it is likely that proper neovessel maturation and adaptation depends on network hemodynamics and communication (131). Consequently, one might argue that successful strategies to build microvessels should include network-related considerations.

### *The Capillary as a Specialized Tissue–Blood Interface*

As discussed earlier, the primary role of the capillaries within the cardiovascular system is to provide an effective means by which nutrients are delivered to tissue cells and serve as specialized interfaces between tissues and the blood. Consequently, the capillary is structured such that diffusive exchange between the blood and tissue is optimized. Furthermore, the endothelium of capillaries exhibit a variety of specialized structures and functions associated with specific tissue activities. For example, in tissues requiring relatively large exchange capacities, such as the kidney or an endocrine organ, the endothelium of the capillaries is fenestrated. Currently, strategies/approaches to build capillaries are focused on creating small-caliber perfusion elements and not necessarily attempting to impart additional specialization to the fabricated vessels. Certainly, most, if not all, of the studies involving the fabrication of microvessels have not evaluated the structural and functional aspects of the microvessels with respect to tissue-specific functions; emphasis is placed on the ability of the new microvasculature to carry blood. There is growing evidence that tissue cells contribute to the specialization of endothelium within the microvasculature of that tissue. For example, the presence of astrocytes can lead to the formation of tighter cell–cell junctions in EC monolayers (162,163), cardiac cells can regulate cardiac-specific gene expression in EC (164), and kidney podocytes can stimulate the formation of fenestrae in cultured ECs (165,166). It is likely that as methodologies to build microvessels improve, strategies to impart microvessel specificity in these methodologies will be explored.

## KEY POINTS

- The primary function of blood vessels is to act as conduits for the transport of blood to within close proximity of tissues, thereby enabling effective nutrient delivery to tissue cells.
- The tubular nature of vessels is optimal for efficient fluid transport and vessel stability and is the hallmark structural feature of all vessels.
- The functional requirements of the vessel, be it bulk transport of blood or efficient exchange of nutrients, determine key structural features of vessels.
- The wall characteristics must be customized to serve the specific functional role of that vessel.

## Future Goals

- To define the molecular, cellular, and biophysical rules that govern tube and lumen formation by the EC
- To determine how the cells of the vessel wall integrate to establish wall structure and vessel architecture. This pertains to both native vessels and biohybrid designs incorporating artificial biomaterials
- To define the relationships between the microvessel and the extravascular environment in determining microvessel structure and function

## ACKNOWLEDGMENTS

We thank the members of the University of Arizona Vascular Research Group for their useful discussions and input. This work was supported in part by National Institutes of Health grants HL63732, HL63873, HL67067, HL077683, and HL60450.

## Gene Transfer and Expression in the Vascular Endothelium

---

Michael J. Passineau and David T. Curiel

*The Gene Therapy Center, University of Alabama at Birmingham*

Gene transfer to the endothelium represents a potentially powerful approach to research and therapy. Interest in gene transfer and expression has grown apace with the evolving understanding of the importance of the endothelium in many biological and pathological processes, as detailed elsewhere in this volume. The technological advances that have made efficient gene transfer to living cells possible are relatively recent, and therefore gene transfer to the endothelium is still a somewhat immature field with substantial technical challenges still unresolved. This is particularly true with regard to *in vivo* gene transfer to the vascular endothelium of an intact organism.

Transfer and expression of foreign DNA to a living cell requires two components: (a) a vector to carry, protect, and traffic the foreign DNA, and (b) a DNA sequence which, once inside the host cell, is capable of interacting with the host cell's translational machinery. In nature, this process can occur in single-cell organisms by means of transformation, but it occurs in mammalian cells efficiently only by viruses. Therefore, the advent of recombinant viruses, produced by means of molecular engineering, brought gene transfer into the scientific mainstream.

As an intact organ, the endothelium has greater access to the vascular compartment than any other cell or tissue type. Therefore, the endothelium is the first point of contact between a gene-delivery vector administered to the vascular compartment and the host. For this reason, it presents an accessible target of opportunity for systemically administered gene-delivery vectors. Conversely, the intimate relationship between the endothelium and the intravascular compartment mandates careful consideration of unintended consequences of the interaction between the endothelium and a systemically administered gene-delivery vector.

The history of attempts to transfer genetic payloads to the endothelium has clearly been technology-limited. In this regard, a troublesome disconnect persists between the considerable progress that has been made in unraveling endothelial

physiology and the gene-transfer technology needed to translate these insights into robust *in vivo* transgene expression in the intact endothelium of a living mammal. Gene transfer to endothelial cells (ECs) *ex vivo* is an established and powerful research tool that has contributed to many advances in endothelial biology. Nevertheless, gene transfer to isolated, *ex vivo* systems has limited value as it does not take into account the organ complexity of the intact endothelium. In addition, therapeutic modification of gene expression in disease states of the endothelium will require a vector capable of effecting gene transfer following systemic infusion into the vascular space.

Meeting the technical challenge of bridging the gap between *ex vivo* and practicable *in vivo* gene transfer to the endothelium represents a key step in advancing the field of endothelial biomedicine. The following brief overview of gene transfer to the endothelium will illuminate the technical hurdles restricting progress and how recent technological developments suggest that these restrictions might soon be obviated in the research context. Finally, an experimental model will be described that makes efficient vector-mediated endothelial gene transfer possible in an intact animal.

### HISTORY OF VASCULAR ENDOTHELIAL GENE EXPRESSION AND VECTOR DEVELOPMENT

The history of gene transfer to the endothelium has evolved concurrently with the development of both gene transfer and vectorology as scientific disciplines. Although gene transfer technology has generally been developed along strict demarcations between *ex vivo* and *in vivo* potential, the branching nature of the vascular tree makes possible the anatomical sequestration of a vector infused *in vivo* with simple surgical techniques such as clamping of vascular segments. Owing to this unique capacity for vector compartmentalization, gene

transfer to the endothelium has occupied a middle ground between the in vivo and ex vivo experimental paradigms.

The key factor in the early development of gene transfer in ECs was the emergence of recombinant retroviruses as gene-transfer vectors and the optimization of such systems for endothelial expression (1). Gene transfer to ECs was first shown to be feasible in a practicable way in 1989 by Zwiebel and colleagues at the National Institutes of Health (NIH), who transduced rabbit ECs with retroviruses (2). This same group, a short time later, extended these findings to human ECs (3), and later replaced the reporter gene with a relevant “therapeutic” gene, *tissue-type plasminogen activator (t-PA)* (4,5).

Several laboratories reported direct gene transfer to endothelium by infusion of retroviral vectors into a surgically isolated vascular space (6,7). However, owing to the limitations of the available retroviral systems, most notably their relatively inefficient transduction rates, the in vivo potential of these systems has not yet been demonstrated. At present, retroviruses are mainly conceptualized as an ex vivo gene-transfer system (8,9) whereby target cells are extracted and purified prior to gene transfer and then reimplanted into the host. Notably, this ex vivo approach has been successfully implemented, recently forming the treatment basis of the first gene therapy “cure” for a genetic disorder, severe combined immune deficiency (SCID) (10). This clinical trial in SCID has highlighted an additional safety concern with retroviral vectors – namely, the oncogenic potential of these vectors due to the potential for insertional mutagenesis (11).

In 1995, von der Leyen and colleagues demonstrated the potential to apply previously established in vivo endothelial gene delivery to treat various diseases (12). However, the limitations imposed by poor in vivo expression with retroviral or liposome systems delayed the clinical implementation of these gene-therapy strategies. Attempts to improve the in vivo expression efficiency of these vector systems have been largely unsuccessful thus far, confining their present usefulness to the aforementioned ex vivo schema. These considerations limit the usefulness of retroviral vectors for applications in endothelial gene delivery.

Recently, lentiviral vector systems have received a great deal of attention as gene-transfer vectors. In contrast to many other Retroviridae, lentiviruses are capable of gene transfer to quiescent or slowly dividing cells. This property is particularly relevant in the central nervous system, including brain (13) and retina (14). Lentiviral vectors administered via a systemic vascular route show low but measurable gene transfer to the endothelium (15). Various strategies are being tested to improve the production efficiency, in vivo expression and targeting of lentiviral vectors (16).

As an alternative to retroviral systems, adenovirus (Ad) was proposed (17), with the expectation that the robust in vivo expression provided by this vector system would allow for direct in vivo expression (18) of therapeutic transgenes, in this case  $\alpha$ -1 antitrypsin, and obviate the need for ex vivo systems. These studies by Lemarchand and coworkers demonstrated that Ad vectors can achieve high levels of gene expression,

consistent with replacement levels of  $\alpha$ -1 antitrypsin levels, in the intact vascular endothelium.

Lemarchand’s work also highlighted the two of the main shortfalls of Ad vectors for in vivo gene transfer: (a) expression was variable and transient, peaking at 7 days and becoming extinct by 28 days, and (b) anatomical sequestration of the vector by occlusion of the vascular segment for more than 15 minutes was necessary for the achievement of significant endothelial expression. Although modern surgical techniques make this type of transient anatomical sequestration possible, many endothelial populations of clinical interest exist in vascular segments that cannot be occluded without significant risk (e.g., pulmonary and cardiac endothelium). Despite the drawbacks of the Ad system, these studies powerfully demonstrated the utility of recombinant Ad systems as a tool to achieve gene transfer to the endothelium. Based on these findings, subsequent studies examined different methodologies for selective delivery of Ad vectors to the vessel wall (19).

Additional studies have confirmed the finding that robust in vivo expression can be achieved following systemic injection of an Ad vector, but that this expression is low in endothelium. The innate hepatotropism of this vector system effectively sequesters systemically administered Ad to the liver, with resultant toxicity to the host. The relatively low affinity of Ad vectors for ECs, particularly when compared to the strong affinity of Ad vectors for the liver, constitutes the primary limitation to achieving Ad-mediated gene transfer to the vascular endothelium. On this basis, it has become clear that in order to achieve meaningful in vivo gene transfer to the vascular endothelium, retargeting of Ad vectors is mandated.

Finally, the use of adeno-associated viruses (AAVs) as gene-transfer vector systems for endothelium has recently gained widespread attention, beginning with a series of studies in 1997 (20–23) using AAV serotype 2. Potential advantages of AAVs over Ad include increased duration of transgene expression (months versus days in many models), relatively less immunogenicity in the host, and substantially diminished hepatotropism and toxicity. Difficulties with producing high-titer preparations of AAVs, combined with low levels of in vivo expression (relative to Ad), have thus far limited the clinical utility of AAVs. In addition, the relatively small genome of AAVs creates a technological limitation when considering various endothelial-specific promoters or large transgenes (as described in more detail in this chapter). Improvements in AAV technology aimed at overcoming these limitations are ongoing (Table 185-1).

It should be noted that the endothelium forms a barrier that is essentially impenetrable to viral vectors, with the exception of fenestrated endothelium in such sites as the liver and spleen. Indeed, Cefai and coworkers (15) have directly compared lentiviral vectors to Ad vectors and shown that these vectors do not penetrate beyond the endothelial layer of the arterial wall in vivo, although an inflammatory response to Ad was observed in the smooth muscle cell layer. In contrast, one of the more intriguing utilities of AAVs is an apparent ability of some serotypes to traverse the EC layer (24).

**Table 185-1: Vector Systems for Endothelial Gene Transfer – Advantages and Disadvantages**

<i>Vector System</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Applications</i>
Retrovirus	Genome integration, long-term expression	Relatively weak in vivo expression	Ex vivo gene transfer for transplantation/reimplantation
Liposomes	Ease of manufacture, low immunogenicity, large capacity	Extremely low expression of genetic payload	Research
Adenovirus (Ad)	Strong expression in vivo	Strongly immunogenic, transient expression	Gene transfer in many contexts, including in vivo
Adeno-associated virus (AAV)	Some genome integration, long-term expression, low immunogenicity	Small genome size, difficult to produce in high titer	Ex vivo gene transfer

### ADENOVIRUS RETARGETING TO ACHIEVE IN VIVO ENDOTHELIAL GENE TRANSFER

In the in vivo context, restricting Ad vector-mediated gene expression to a particular cell type (endothelium) requires both increasing the affinity of the vector for the target cell (targeting) and simultaneously reducing ectopic expression (untargeting), particularly in the liver. With the notable exception of the liver, kidney, and spleen, the endothelial barrier tightly regulates transfer of substances from blood to extravascular compartments and thus restricts access of a systemically administered Ad vector to non-ECs. Successful endothelial “retargeting” is therefore achieved once the threshold is reached at which the affinity of the Ad gene transfer vector for the target EC exceeds its affinity for the liver (and to a lesser extent spleen and kidney). The degree to which this threshold can be exceeded by the retargeting strategy dictates the therapeutic relevance of the retargeting strategy.

To date, two general approaches to retargeting Ad have been developed and successfully validated. First, vectors may be retargeted on the *transductional* level by means of modifying the viral capsid in a manner which alters its ability to bind to cellular surfaces. Second and independent from transductional retargeting, the vector’s expression cassette can be modified in such a way as to embody target cell-specific expression, termed *transcriptional* targeting. The combination of these two retargeting strategies in a single Ad vector system has been shown to be synergistic (25). This concept of transcriptional targeting, and its specific relevance to endothelial gene transfer, will be detailed later in the chapter.

#### Transductional Targeting

Transductional targeting has been accomplished by modifying the viral capsid’s cell surface tropism in two ways: either with bispecific “adapter molecules” or by means of genetic capsid modification (Figure 185.1). The first instance of transductional retargeting to ECs (26,27) was accomplished using

bispecific antibodies. In this schema, antibodies to a surface epitope on the EC target (such as  $\alpha v$  integrins) are chemically conjugated to antibodies specific for an epitope on the viral capsid. Later studies embodying the same technique were shown to accomplish EC transductional retargeting in vivo (28). Of note, the adapter molecule approach to transductional retargeting can achieve, to some extent, the objective of liver untargeting when the portion of the bispecific adapter molecule that recognizes the viral capsid thereby blocks a liver-binding epitope normally displayed on the virus capsid (most notably the fiber knob that recognizes the coxsackie-adenovirus receptor, CAR). This general adapter molecule strategy has since been slightly modified to create single-molecule bispecific fusion proteins (29) (fusions of single chain antibodies, soluble CAR receptors, CD40 ligand) rather than chemical conjugates of two antibodies (Table 185-2).

Direct genetic modification of the viral capsid proteins responsible for cell tropism (namely those in the fiber and penton base) has been proposed as an alternative strategy to adapter molecules. One of the primary advantages of this approach with respect to potential for clinical translation is the “single agent” nature of a genetically modified vector, as opposed to a vector/adaptor molecule system. The genetic retargeting strategy may be as simple as introducing an alternate Ad serotype (Ad3, Ad35, etc., as opposed to the most commonly used Ad5). Furthermore, the capsid protein genes can be selectively modified on the genomic level, yielding capsid proteins that, when assembled into virions, confer an alternate tropism (30). Such an approach can modify or ablate native tropism, generating a genetically distinct vector species with the capacity to be propagated perpetually in permissive cell lines (31).

To date, the primary technological limitation hindering the usefulness of the genetic capsid modification strategy is the relative intolerance of the fiber and penton base proteins to large additions, deletions, or modifications. Attempts to insert targeting ligands into the fiber protein have resulted in vector species that are nonviable. Similarly, penton base

Figure 185.1. Transductional targeting approaches. (A) Fiber replacement strategy. The Ad5 fiber shaft sequence is replaced with the sequence for phage T4 fibrin. Fibrin forms trimers similar to those of the Ad5 shaft but is more permissive of C-terminal ligand incorporation. This example illustrates the replacement of Ad5 knob with a c-terminal 6His tag in the fiber–fibrin chimera. (B) Adapter molecule strategy. An adapter molecule, with motifs that recognize and bind the Ad knob and a target receptor (such as ACE) partially ablates the vector's native tropism while allowing the vector to recognize and bind an alternate receptor.

modification has been primarily restricted to deletion of the RGD motif exposed on the surface of the mature protein.

Insertion of small peptide sequences into the knob region of Ad fiber is possible, and modest retargeting has been accomplished using this approach *in vitro* (32–35) and *in vivo* (36). More recently, Nicklin and coworkers (37) have applied this principle to achieve EC transduction. However, this approach is severely limited with regard to both the size of the ligand (published upper limit of 30 amino acids) (38,39) and the potential for post-translational processing needed to produce viable ligand function (e.g., S–S bonds). Finally, incorporation of small peptide sequences into the fiber protein has

**Table 185-2: Illustrative Studies Documenting Transductional Targeting of Vectors to Endothelium *In Vivo***

Vector	Technique	References

Adenovirus	Adapter molecule, hCAR model	28, 45
AAV	Small peptide insertion in viral capsid	47

not been shown to effectively ablate the native tropism of the vector.

In light of these considerations, replacement of the entire fiber protein has been proposed (40). Using the phage T4 fibrin protein as a substitute for Ad5 fiber, Belousova and coworkers (41) successfully incorporated a physiological targeting ligand, CD40 ligand (CD154), into an artificial fiber and demonstrated binding to the cognate receptor, CD40. To date, this approach represents the only viable approach to genetic ligand incorporation into the Ad fiber.

One difficulty associated with this retargeting strategy is that the genetic incorporation of targeting ligands is limited by the failure of Ad fiber proteins to pass through the Golgi apparatus prior to assembly, thus limiting the post-translational modification of the proteins. The fibrin–CD40L virus constructed by Belousova and coworkers exploited the lack of disulfide bonds in the mature CD40L protein, thus avoiding the post-translational limitations imposed by the Ad lifecycle (41). However, nearly all targeting ligands of medical relevance are not amenable to such an approach due to the requirement for disulfide bond formation for proper ligand function.

Both of the retargeting approaches described – adapter molecule retargeting and genetic incorporation of targeting ligands – are constrained by the availability of relevant genetically encoded targeting ligands. In the field of endothelial biomedicine, target definition has made considerable progress, and more progress is expected, particularly with regard to vascular bed–specific expression of endothelial surface markers. Nevertheless, it must be considered that only a subset of these markers will interact with a known genetically encoded ligand. In this regard, single-chain antibodies (scFv's) have been proposed as an alternative to the more stringent receptor–ligand schema. An additional advantage of scFv's is the lack of a requirement for post-translational modification to form the mature protein. Although promising, scFv's have yet to prove their full potential *in vivo*.

### Transcriptional Targeting

As scientists continue to unravel the complex physiology and function of the endothelium, it has become clear that the endothelium is not homogeneous throughout the vascular tree (42). Rather, ECs differ in their specific cellular programs from

Figure 185.2. Transcriptional targeting in vivo. Transcriptional control of Ad-mediated gene transfer to the liver. Immunohistochemistry of liver from wild-type or hCAR mice 24 hours after systemic administration of a vector encoding CEA (as a reporter gene) under the control of either *CMV* or *FLT-1* promoters. The *FLT-1* promoter leads to dramatic reduction of expression in the liver. For color reproduction, see Color Plate 185.2.

one vascular bed to another. The molecular characterization of this heterogeneity is far from complete, but the implications for vascular bed-specific control of gene transfer are already significant.

Gene transfer to the endothelium, or to any cell type, can be accomplished by any number of vectors, viral or nonviral, as previously discussed. Once the transgene has been delivered, however, expression is uniformly accomplished by interaction of the target cell's transcriptional machinery with a promoter sequence. Thus, in their most minimal form, transgenes are composed of a promoter region and a coding region.

Historically, gene transfer has been undertaken using promoters with a uniformly strong activity profile in multiple cell types. Most famous among these promoters is the *cytomegalovirus* (*CMV*) promoter, which has been used in literally thousands of viral and nonviral constructs. More recently, alternative promoters have been explored that show a more tissue/organ or cell-specific activity profile. Control of transgene expression with promoters whose activity profiles differ from one vascular bed to another – e.g., the *von Willebrand Factor* (*vWF*) or *FLT-1* promoters (43) – is a reasonable strategy for achieving targeted gene expression (Figure 185.2; for color reproduction, see Color Plate 185.2).

It must be noted that any transcriptional targeting strategy, although a powerful research tool, ignores the major technological obstacles that must be overcome before endothelial gene transfer can expand beyond laboratory research to

become a practicable clinical intervention. Specifically, transcriptional targeting controls only the expression profile of the vector, without affecting its biodistribution. In other words, toxicities and other complications known to result from viral vectors are not primarily dependent on the expression profile of the transgenic construct, but rather the host immune response, both preexisting and adaptive. Toxicities could therefore still result in tissues where little or no transgene expression occurs.

### A Transgenic “Shortcut”

On the basis of the aforementioned considerations, it is clear that vectors that achieve robust endothelial gene expression while minimizing ectopic expression in the systemic context are not yet available. Although this technological limitation severely limits the clinical implications of gene transfer to the vascular endothelium, the research community has a broader array of options. The development of artificial systems capable of directing gene expression to the vascular endothelium in an intact animal model represents a significant research priority in the field of endothelial biomedicine.

Tallone and coworkers (44) have developed a simple transgenic mouse model which effectively enables robust endothelial gene transfer with Ad vectors. This transgenic animal expresses a truncated, nonsignaling version of human CAR (hCAR), the native receptor for Ad5, ubiquitously throughout

Figure 185.3. Transductional retargeting in the hCAR model. Ad-mediated gene transfer to ECs in the hCAR mouse. Strong endothelial expression of the reporter gene (CEA) is observed in lung sections from hCAR mice. Lung expression is essentially absent in the wild-type mouse. For color reproduction, see Color Plate 185.3.

all tissues. In this system, all cell and tissue types have a similar and high susceptibility to Ad5 infection. Hence, the tissue distribution of an administered Ad vector becomes dependent on tissue access rather than tissue tropism.

An Ad vector administered systemically to this “hCAR” mouse will be predicted to achieve robust transduction of the vascular endothelium. Further, the impermeability of the vascular endothelium to viral vectors restricts a systemically administered vector’s access to cells that have direct contact with the vascular compartment, limiting spread of the vector beyond the endothelium. In this schema, efficient endothelial gene transfer in the intact animal should be achieved (Figure 185.3; for color reproduction, see Color Plate 185.3).

The concept that transcriptional targeting using the *FLT-1* promoter can achieve selective gene expression *in vivo* has been previously established (23). The availability of the hCAR transgenic mouse gives investigators the opportunity to study gains accruing to transcriptional targeting strategies exclusive of transductional considerations. In order to establish the validity of this system, Everts and coworkers (45) tested the *FLT-1* Ad vector constructs used previously in Reynolds’s (28) study in the hCAR transgenic model, finding that lung-specific expression could be achieved in the hCAR mouse model by replacing the *CMV* promoter with the *FLT-1* promoter. Further, this expression was found to be localized exclusively to ECs.

The results of this study validated two concepts: (a) the hCAR mouse model allows robust transduction of ECs with Ad vectors, and (b) transcriptional control alone, in the absence of tropism modification, achieves selective gene transfer to specific vascular beds. This system, therefore, represents a high-throughput experimental model in which to study gene transfer to the endothelium. Of note, various studies have illuminated the activity of human promoters in mouse endothelium, establishing the principle that the mouse system is a useful *in vivo* model for studying the activity of human promoters in the endothelium of different vascular beds. This cross-species relevance of the hCAR system greatly expedites efforts to screen the ever-increasing array of promoters relevant to the endothelium. The Ad vector technology allowing facile and efficient swapping of promoters in Ad constructs is currently available, establishing the hCAR system as a powerful advancement in the study of gene transfer to the endothelium.

The relevance of the hCAR system to promoter screening is apparent. However, applications of this system that go beyond simply reporter gene transfer to the endothelium must be interpreted with caution. For example Ad vector-mediated transfer of a gene of interest to the vascular endothelium with the intent of studying the resulting biological effects of the expression of such a gene must take into account a number of complicating factors. First, Ad vector expression, although robust, is transient and varies over days and weeks. In general,

the time course and peak of gene expression in this system is known. However, great care must be taken to normalize doses and experimental time points before any conclusions are drawn. Further, Ad vectors are extremely immunogenic, particularly in the dose levels needed to achieve robust *in vivo* gene transfer and expression. This consideration is emphasized in an experimental schema that utilizes promoters other than *CMV*, particularly vascular-bed-specific promoters. The low native activities of many promoters of particular relevance to the vascular endothelium require that larger doses of vector be administered in order to reach detectable expression levels.

As previously noted, transcriptional targeting strategies that minimize ectopic expression by gene transfer vectors in nontarget tissues do not thereby minimize ectopic toxicities in those same nontarget tissues. In the case of the hCAR mouse system, it is clear that substitution of the conventional *CMV* promoter with the partially lung-specific *FLT-1* promoter does effectively redirect transgene expression to the pulmonary endothelium, at the same time dramatically reducing expression in the liver. However, the sequestration and accumulation of vector in the liver is only slightly reduced in the hCAR system relative to the wild-type mouse.

## CONCLUSION

Gene transfer to EC culture or explants has been effectively employed within the research community for over a decade, and studies employing this technique have contributed to the evolving understanding of the endothelium as a dynamic organ. With the development of small interfering RNA (siRNA) technology, and its demonstrated utility in viral vectors, investigators have the capability to rapidly over-express or eliminate expression of a gene of interest to study the biological sequelae in ECs. Combined with microarray technology, gene transfer provides a powerful scientific tool.

*Ex vivo* gene transfer to the endothelium has been well established and is less technology limited than *in vivo* gene transfer. Applications of *ex vivo* gene transfer include not only myriad research strategies but also select clinical interventions. For example, autologous ECs modified to overexpress cytokines or growth factors, then seeded into vascular stents, have been proposed as a strategy to reduce inflammation and rejection. At present, the clinical applications of *ex vivo* gene transfer to ECs is principally limited not by the available vector technology but rather by the difficulty of obtaining and expanding ECs for autologous transplantation.

With regard to *in vivo* gene transfer, it is clear that research tools are now emerging that will allow scientists to solve one half of the endothelial gene expression puzzle, namely the transcriptional targeting approach for targeted gene expression. However, it is equally clear that transductional targeting approaches, by far the more important consideration in contemplating clinical implications, are still lacking. The hCAR mouse model explained herein obviates the transductional issues as they relate to the endothelium, making efficient

endothelial gene transfer *in vivo* a practicable reality. This transgenic “shortcut” offers a powerful new research tool. Nevertheless, transductional targeting issues must be addressed if *in vivo* gene transfer is ever to transition from bench to bedside.

It is important to note that the biological effects of viral infection in ECs, irrespective of the particular genetic payload, are mostly unknown. Various microarray studies have indicated that Ad vector infection provokes dramatic changes in the cellular expression of thousands of genes (46,47). In this milieu of cellular responses, deciphering the physiological changes due solely to the expression of a transgene of interest seems a daunting task. These issues become even more complex in conceptualizing medical applications of endothelial gene transfer.

At present, Ad vectors have yet to be usurped as the vector of choice for *in vivo* gene transfer. However, the disadvantages of Ad vectors including transient and variable gene expression, immunogenicity, and toxicity make Ad an imperfect vector upon which to advance endothelial gene transfer as a therapeutic strategy. Until a substitute for Ad vectors is devised that accomplishes the level of expression needed for research and medical applications, gene transfer to the endothelium will continue to be significantly complicated by ectopic gene expression and the complex postinfection physiology of the Ad vector itself. It is expected that improvements in alternative vector systems, as well as refinement of retargeted Ad vectors, will continue to emerge.

## KEY POINTS

- To date, gene transfer to the endothelium has been largely confined to *in vitro* or *ex vivo* systems.
- Available vector systems, with the exception of Adenovirus, fail to achieve *in vivo* expression levels desired for research and clinical applications.
- Improvements in Adenoviral targeting along with improvement in other viral systems, particularly AAV and lentiviruses, are progressing.
- An artificial animal model (hCAR mouse) has been designed which facilitates robust *in vivo* gene transfer to the endothelium.

## ACKNOWLEDGMENT

This work was supported by 5PO1HL076540 and 5T32CA75930 from the National Institutes of Health.

## Drug Targeting to Endothelium

---

Vladimir R. Muzykantov

*University of Pennsylvania School of Medicine, Philadelphia*

Endothelial tissue represents both a key target for therapeutic intervention and a barrier to successful extravascular drug delivery. Alas, most drugs have no natural affinity to any therapeutic sites, including endothelial cells (ECs). Thus, only a minute fraction of injected therapeutics actually binds to the endothelium, despite its immediate accessibility to circulation. The goal of endothelial targeting is to promote the specific and safe delivery of a drug to, into, or across ECs, to localize its effects in the lumen, desired intracellular endothelial compartment, or subendothelial space. Ideally, targeting would direct drug accumulation to a desired vascular domain.

The successful pursuit of this goal depends on several parallel lines of research, including the design of drug carriers and the identification of target endothelial determinants. To date, the majority of studies have focused on cell culture systems and animal models, with few published reports in human subjects. In this chapter, we briefly review research efforts in this field and describe basic principles that are important for endothelial targeting in specific disease states. More details on this topic can be found in recent reviews (1–10) as well as in other chapters in this volume.

The pharmacokinetics of most drugs do not favor their delivery to or/and across endothelium due to their: (a) inactivation in vivo and elimination from blood by the reticuloendothelial system (RES), a problem hampering delivery of labile, large (>50 kD) biotherapeutics including proteins and nucleic acids; (b) renal excretion, a problem especially acute for small (<10 kD) drugs; and (c) lack of affinity to ECs, which is characteristic of both classes of drugs.

Based on these considerations, several goals exist for optimizing the pharmacokinetics and thus delivery of drugs: (a) protection of drugs from inactivation en route; (b) provision of sufficient circulation time to permit accumulation in the target; and (c) reduction of interaction with nontarget cells and general toxicity (11–13). These aims can be achieved by using natural (e.g., cells or proteins) or artificial (e.g., liposomes or polymer particles) drug carriers conjugated with targeting moieties that selectively bind to determinants on the cells of interest (Table 186-1).

### CARRIERS FOR DRUG DELIVERY TO ENDOTHELIAL CELLS

Liposomes are bilayer submicron vesicles (~50–200 nm is the most popular size range) composed of either natural or synthetic phospholipids. They provide versatile carriers for either hydrophobic drugs that intercalate into liposomal membranes or hydrophilic drugs that can be loaded into an aqueous inner space (14–16). Cationic liposomes condense DNA, protecting it from inactivation and facilitating intracellular delivery via endocytic mechanisms and lipid fusion with the plasma membrane. Liposomes have been intensively studied for the targeting of drugs and genetic material into ECs in cell cultures and animal studies (17–23).

Most drugs and carriers, including liposomes, are rapidly cleared from the blood by renal filtration and by macrophages in the RES, which eliminate foreign, denatured, and senescent proteins and cells from circulation. Macrophages in the hepatic sinuses (termed *Kupffer cells*) have unlimited access to circulating drugs and carriers. Fixation of antibodies or complement (opsonization) by carriers greatly enhances their RES uptake. Some drugs, carriers, and targeting moieties (e.g., immunoglobulin [Ig]G antibodies) may cause adverse effects by activating host defenses, including blood coagulation, complement, cytokines, and kinins. Small antigen-binding domains of targeting antibodies lacking Fc-fragment (Fab and scFv fragments) do not activate complement, vascular cells, or phagocytes and therefore are safer for intravascular administration.

Conjugation of polyethylene glycol (PEG, a hydrophilic linear polymer) to proteins, liposomes, polymer carriers, and viral particles creates a “PEG brush” on their surface that forms a water shell that prevents their aggregation and interactions with antibodies, complement, phagocytes, and vascular cells. This “stealth technology” prolongs the circulation of drugs and drug-carrier complexes and minimizes immune reactions and side effects associated with recognition by host defense systems (16,24). Several types of PEG proteins and PEG liposomes are approved for clinical use.

**Table 186-1: Advanced Drug Delivery Means**

<i>Cargoes</i>	<i>Carriers</i>	<i>Masking Moieties</i>	<i>Affinity Moieties</i>
Drugs	Liposomes	PEG	IgG
Enzymes	Polymer particles	Glycolipids	Multivalent IgG
Toxins	Polymer chains	SACCH	Fab fragments
Isotopes	Cells		scFv:
MRI contrasts	Viruses		– Monovalent
Imaging probes	Phages		– Multimeric
Genes	Proteins		Carbohydrates
Oligonucleotides	Antibodies		Lectins
	Carbohydrates		Hormones
			Nutrients (folate)

Left column provides examples of therapeutic and imaging agents that can be loaded to, encapsulated by, intercalated into, or conjugated with carriers shown in the second column. In addition to polyethylene glycol (PEG), natural molecules including glycolipids (e.g., some gangliosides) and sialic acid-containing carbohydrates (SACCH) have been tested as potential masking moieties for coating liposomes and other carriers to achieve “stealth” features. Based on the bioconjugation format, antibodies (IgG) may serve as both carriers and affinity moieties (direct conjugation of cargoes to IgG) or as affinity moieties (e.g., IgG coupling to drug-loaded liposome). IgG, Fab, or scFv fragments can be used in either monomolecular or multivalent format, attained by either chemical conjugation or using recombinant techniques (scFv). Coupling multiple copies of affinity moieties to a carrier also converts them to multivalent format.

This stealth effect increases proportionally with the number of PEG molecules attached to a protein, DNA, or liposome; the denser the PEG brush, the more profound the stealth effect. However, conjugation of multiple PEG chains inactivates sensitive proteins and DNA, and PEG grafting of more than 5% to 10% of phospholipids destroys liposomes. To solve the problem, stable carriers consisting of biocompatible, biodegradable synthetic polymers (e.g., polylactic acid or polyglycolic acid) chemically conjugated with PEG have been designed for drug delivery (25–28). Such polymer carriers are considerably more stable and circulate for a longer time compared with PEG-coated liposomes (29). Drugs can be coupled to polymer chains (either natural, such as sugars, or synthetic), intercalated into polymer or encapsulated into the inner space. Encapsulation into a polymer shell protects drugs from inactivation and enables controlled drug release regulated by environmental factors, for example low pH in lysosomes (30).

Polymersomes synthesized from PEG-conjugated biocompatible copolymers, such as polylactic-co-glycolic acid (PLGA), are polymer analogs of liposomes with a large internal aqueous domain that can be loaded with drugs (31). The membrane bilayer of polymersomes is much thicker than that

of liposomes (~8 nm compared with ~3 nm), resulting in a more durable carrier with a greatly enhanced circulation half-life. Diverse hydrophilic and hydrophobic drugs can be encapsulated into polymersomes. The efficiency of encapsulation generally decreases with the increasing molecular size of a drug. Loading of active proteins is challenging due to harsh encapsulation conditions.

In summary, drug delivery systems consist of: (a) a drug encapsulated into the inner volume of a carrier, intercalated into or coupled to the shell; (b) the carrier proper (e.g., a liposome); and, (c) masking moieties, such as PEG conjugated to the carrier surface. Some delivery means, such as protein conjugates and recombinant fusion protein constructs, do not utilize drug carriers, but instead combine drugs directly with targeting moieties (32). Ideally, a drug delivery system also includes a targeting moiety coupled to the carrier surface (preferably to ends of the masking PEG chains), which provides specific binding to endothelial surface determinants, a topic discussed in the next section.

## DRUG TARGETING TO ENDOTHELIAL BINDING SITES

Diverse ligands that bind to selected determinants, including hormones, sugars, nutrients, lectin, and peptides can serve as targeting moieties, directing the binding of drugs and drug carriers to selected cells (see Table 186-1). Monoclonal antibodies (mAb) and their antigen-binding fragments represent the most popular modular class of such ligands. Humanization, the recombinant grafting of antigen-binding sites of a mouse IgG into human IgG scaffold, minimizes immune reactions. Recombinant methods also permit deimmunization (replacement of immunogenic amino acids), maturation (enhancement of binding affinity by point-directed mutagenesis of antigen recognizing sites), and production of diverse forms of antigen-binding fragments including single-chain variable fragments (scFv), which are the minimal full-affinity antigen-binding unit of IgG that combine the first hypervariable domains of light and heavy chains of IgG, connected by a peptide linker (33,34).

Bioconjugation means for coupling drugs or drug carriers with antibodies include chemical bifunctional reagents, streptavidin-biotin pairs, and construction of recombinant fusion proteins, for example, by combining an active part of a therapeutic enzyme with scFv via a flexible peptide linker. For example, biotin-streptavidin cross-linking pairs can be used to couple antibodies (or drugs) to carriers or synthesize protein conjugates characterized by high drug incorporation efficiency; a wide range of sizes and valency governed by the degree of biotinylation and molar ratios of the components; and a relatively rigid and biodegradable structure (32,35). When compared to chemical conjugation, genetically fused recombinant constructs afford even higher degrees of purity, homogeneity, and reproducibility (33,36).

For targeting to reach its full potential, endothelial determinants must meet several criteria. Accessibility, specificity, and safety are obligatory criteria for all targeting means, whereas selectivity and precision are highly desirable and, in fact, obligatory for the targeting of many therapeutic and diagnostic agents.

### Accessibility

Surface density and the accessibility of target sites must suffice to accommodate therapeutic amounts of carriers ranging in size from small fusion proteins to submicron particles. Pathological factors may cause shedding, masking, or suppression of expression of some target molecules (37). On the other hand, altered ECs expose abnormal surface markers and cellular components. Such pathological endothelial determinants represent very attractive targets.

### Specificity

Target counterparts in blood or non-ECs accessible to blood should be below levels at which they compromise delivery or induce side effects. For example, P-selectin, a surface marker of pathologically activated ECs also is expressed on activated platelets; hence, targeting P-selectin may direct drug delivery to platelets. Yet, absolute specificity is not necessary if competing determinants are inaccessible to blood.

### Safety

Targeting should have minimal, if any, adverse side effects in endothelium. Engagement and cross-linking by carriers may inhibit or activate target molecules, induce signaling, endothelial activation, shedding, and/or endocytosis. Some of these potential side effects may be detrimental and must be rigorously tested for. Ideally, binding to a target molecule should cause therapeutically beneficial secondary effects, such as the inhibition of the target molecule's function.

### Selectivity

Even indiscriminate delivery to ECs in the vasculature will improve the therapeutic effects of many drugs. Yet, ideally, targeting should direct drugs to selected vascular areas (e.g., pulmonary, cerebral, or tumor), blood vessel types (e.g., arterioles, capillaries, or veins), or domains within the EC body (e.g., caveolae, fenestrae, or intercellular junctions) to enhance specificity and effectiveness of action. Site-selective delivery is necessary for many diagnostic strategies and for the delivery of harmful therapeutics, such as antitumor agents.

### Precision

Docking to a target should direct a drug to the desired subcellular site, such as the luminal surface proper, or the intracellular or subcellular compartments. In some cases, the constitutive

turnover of a target molecule guides the subcellular trafficking of drugs. For example, noninternalizable adhesion molecules are ideal for anchoring drugs that are designed to exert their effect in the lumen (38), whereas caveolar antigens facilitate intracellular delivery (39,40). Valency and carrier size control the rates of their internalization and intracellular traffic. For example, the multivalent engagement of certain noninternalizable target determinants induces endothelial endocytosis and intracellular drug delivery.

## QUEST FOR TARGETS: PAN-ENDOTHELIAL, SITE-SPECIFIC, CONSTITUTIVE, AND INDUCIBLE ENDOTHELIAL SURFACE DETERMINANTS

Most drugs and carriers have no specific affinity to endothelium. Thus, an important goal is to achieve EC-specific binding. Ideally, such binding should be localized to the desired vascular areas. However, site specificity may not be necessary for those drugs providing protective effects (e.g., antioxidant, antithrombotic, anti-inflammatory agents), as well as for certain systemic interventions (e.g., enzyme replacement and gene therapies). These drug delivery systems can be directed to pan-endothelial determinants indiscriminately distributed throughout the vasculature.

Pan-endothelial ligands can be directed to specific vascular beds using vascular catheters inserted into conduit arteries (18,41). Further "organ-specific" endothelial targeting using pan-endothelial determinants can be achieved in transplantation settings, in which a graft is perfused with the targeted drugs prior to or after the harvest, thus precluding recipient exposure to the agent (42).

The pulmonary vasculature is a privileged target for pan-endothelial delivery systems. It represents approximately 30% of the total endothelial surface in the body and receives the entire cardiac output of mixed venous blood; hence, carriers targeted to pan-endothelial determinants accumulate in the lungs after intravascular injections (8,10,43,44).

Although pan-endothelial drug delivery may provide therapeutic gain, targeting to specific populations of ECs in diverse types of blood vessels, organs, and tissues, either normal or pathologically altered, is considered the "Holy Grail" of vascular targeting. Site-selective targeting also may facilitate drug delivery to extravascular compartments in desired organs or tissues.

Genetic and local environmental factors dictate specific EC phenotypes, including surface expression of unique marker molecules (45–47). ECs located in different organs, blood vessel types, and regions of the same vessel (e.g., bifurcations versus straight segments of arteries) may express stable or inducible markers potentially useful for targeting these specific vascular domains. The distribution of these markers may differ in health and disease. Constitutively expressed determinants can be used for either prophylactic or therapeutic drug delivery. Inducible determinants are ideal for diagnostics

**Table 186-2: Tentative Endothelial Determinants for Drug Targeting**

	<i>Pan-EC</i>	<i>Relative Vascular Specificity</i>	<i>Function</i>	<i>Constitutive or Inducible</i>	<i>Internalization</i>
PECAM-1	Yes	No	WBC transmigration	C	Only induced by anti-CAM multimers (CAM-mediated endocytosis)
TM	+/-	No	Anti-thrombotic	C	Constitutive, stimulated by monomolecular ligands
ACE	+/-	Lung	Ang-II production, Bradykinin decay	C	Constitutive
AP	No	Lung	Bradykinin decay	C	Not known
ICAM-1	+/-	No	WBC adhesion	C/I	CAM-mediated endocytosis (multimers)
P-selectin	+/-	Postcapillary venules	WBC rolling	I	Constitutive via clathrin-coated pits
E-selectin	+/-	Postcapillary venules	WBC rolling	I	Constitutive via clathrin-coated pits
VCAM-1	-/+	Postcapillary venules	WBC adhesion	I	Constitutive via clathrin-coated pits
GP-60	?	Unknown	Albumin uptake	C	Constitutive via caveolae
GP-90	?	Lung	Unknown	C	Constitutive via caveolae
GP-85	No	Alveolar capillaries (AVZ) and heart	Unknown	C	No
Tf-R	+/-	BBB, liver	Iron transport		Constitutive via clathrin-coated pits
AN	No	Tumors	Peptides decay	Unknown	Unknown

TM, thrombomodulin; AP, aminopeptidase-P; AN, aminopeptidase-N; Tf-R, transferrin receptor; GP, glycoproteins of indicated molecular weight; AVZ, avascular zone; WBC, white blood cell.

and therapeutics, but not for prophylactic drug delivery. Table 186-2 provides several examples of tentative endothelial determinants that can be used for drug targeting; some of these determinants will be discussed in detail in the next sections.

Even within one cell, the endothelial plasma membrane contains diverse domains, including those that are relatively static (e.g., intercellular junctions) and those that are dynamic (e.g., caveolae and intracellular fenestrae). Recent studies identified several EC markers enriched in these specific domains. For example, glycoprotein GP85 is localized in a thin part of EC body that lacks main organelles and separates alveolar and vascular space in lung capillaries ("avesicular zone") (48,49). GP85 antibodies accumulate in rat pulmonary vasculature without internalization and deliver conjugated cargoes into the pulmonary vasculature (50). In theory, such an antigen could be an interesting candidate for drug delivery to the surface of alveolar capillaries.

Targeting caveolae, which are cholesterol-rich invaginations in endothelial plasmalemma (6,51,52), may afford intracellular and, perhaps, transcellular drug delivery in the vasculature (2,40) (see Chapter 73). Caveolar-mediated endocytosis and transcytosis play an important role in endothelial transport functions (6,53,54). Figure 186.1 provides an abridged overview of principal endocytic and intracellular trafficking pathways in ECs. Ligands, including antibodies, may promote clustering of receptors within caveolae, leading to their endocytosis and transcytosis (54–56). In rats, the intravenous injection of ligands with an affinity for caveolar determinants (e.g.,

glycoprotein GP90) results in their accumulation in the pulmonary vasculature, followed by endothelial endocytosis and transcytosis (39,40). The functions of GP90 and effects of its alteration by targeting remain to be defined, yet this and other caveolar determinants are candidates for drug delivery to and across the endothelium.

#### QUEST FOR ENDOTHELIAL TARGETS: STRATEGIES FOR IDENTIFICATION OF MARKER DETERMINANTS

Staining of cells and tissues by antibodies, followed by studies of the biodistribution of these injected labeled antibodies, helps to identify candidate determinants. This relatively low-throughput hypothesis-driven strategy sets a framework for targeting in a given biomedical context, taking into account the distribution, functions, and regulation of the identified target molecules, but it is not designed to discover unknown and/or rare markers. New high-throughput discovery-driven strategies such as functional genomics, proteomics of the endothelial plasma membrane, and phage-display library selection provide a basis for vascular mapping and identification of determinants specific for defined areas of vasculature or endothelial domains.

Functional genomics of ECs obtained from normal or pathological vascular areas characterizes the relative abundance of messages for practically unlimited numbers of proteins (57). Analysis of proteins and peptide digests using

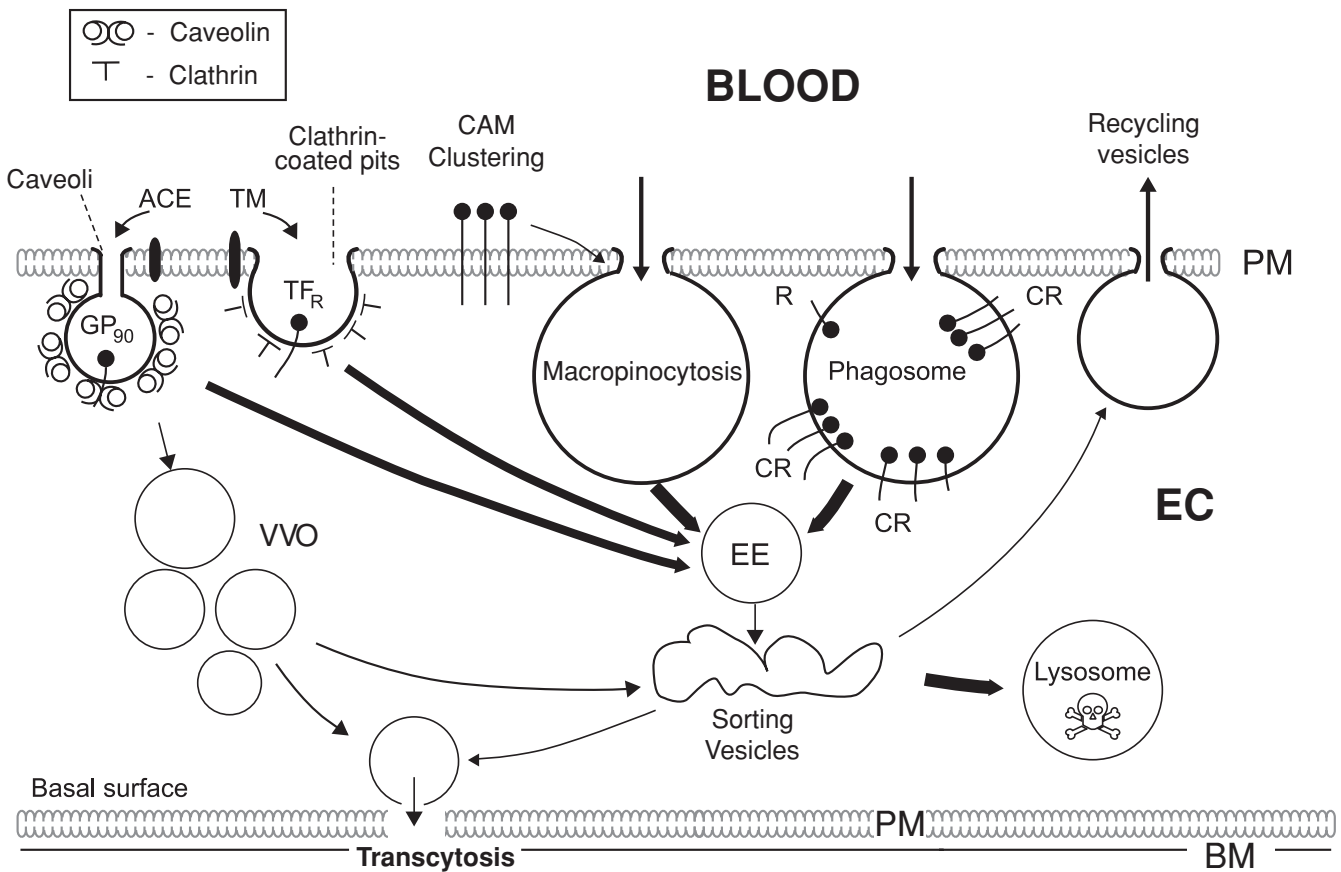

Figure 186.1. Physiological pathways for intracellular and transcellular drug delivery in ECs. Circulating cargoes can access the EC interior from blood lumen via fluid-phase uptake mechanism (pinocytosis and macropinocytosis), or via receptor-mediated endocytic (*left*) and phagocytic (*right*) pathways. Clustering of target determinants such as receptors (*R*) into cross-linked clusters (*CR*) by affinity carriers usually stimulates these pathways. Caveolae and clathrin-coated pits serve for endocytosis via specific receptors enriched in these plasma membrane (*PM*) domains, such as GP90 and transferring receptor (*TFR*). Constitutively internalized endothelial determinants such as ACE and thrombomodulin (*TM*) undergo endocytosis via either caveolar or clathrin-dependent pathways. Clustering of PECAM-1 and ICAM-1 (i.e., CAMs that are not constitutively internalized), induces endocytic pathway similar to, yet distinct from macropinocytosis. The formation of endocytic vesicles brings cargoes into the cell traffic in the cytosol and merges with vesicular organelles including early endosomes (*EE*), sorting vesicles, and the vesiculo-vacuolar organelle (*VVO*) compartment (the latter trafficking direction is more typical for caveolar uptake). From the sorting compartment, cargoes can traffic to lysosomes (a dominant pathway), where acidic hydrolases destroy them, or recycle to the plasma membrane via recycling vesicles. The caveolar pathway favors the transfer of some cargoes through the EC (transcytosis), although most likely other endocytic pathways also can provide transcytosis. Bold arrows show the typical destination of materials entering ECs via indicated endocytic pathways.

mass-spectrography and two-dimensional electrophoresis provides information about relative levels of proteins in the ECs of these tissues (58,59). The laser capture microdissection and analysis of ultra-small samples permit a delineation of differential gene expression in ECs from adjacent vascular areas that are subject to distinct environmental factors (60).

Further, methods used to isolate endothelial plasma membrane from different vascular beds and from specific microdomains (including caveolae [52,61]) provide a means for characterizing the surface topography of the endothelium. Such strategies yield novel site-specific determinants that may be leveraged for vascular bed-selective targeting (62,63).

Screening of phage display libraries in cell cultures helps to identify diverse epitopes potentially useful for endothelial delivery (64,65). The testing of phage display *in vivo* is a high-throughput method to find site-specific binding sites in selected normal or pathological vascular areas (66,67). This method is based on repetitive cycles of intravenous injections of phages encoding stochastic peptides, which may bind to sites accessible to circulation, followed by the identification of specific phages homing into selected tissues, and the eventual isolation of the homing determinants (68–70). The restriction to accessible targets – a built-in feature of this selection strategy – is an advantage in terms of drug delivery.

## TARGETING CONSTITUTIVE PAN-ENDOTHELIAL CELL ADHESION MOLECULES

The endothelial adhesion molecules platelet-endothelial cell adhesion molecule (PECAM)-1/CD31 and intercellular adhesion molecule (ICAM)-1/CD54, which are transmembrane glycoproteins of the Ig superfamily, are relatively evenly distributed in ECs throughout the vasculature (71,72). PECAM-1, predominantly localized in intercellular borders, is stably and abundantly (millions of copies/cell) expressed in ECs, permitting robust targeting to normal or pathologically altered vasculature in prophylactic or therapeutic settings (10,43). ICAM-1 is expressed normally on the apical endothelial surface at levels of  $2 \times 10^4$  to  $2 \times 10^5$  surface copies per cell (73). Other cell types also express ICAM-1, yet the blood-accessible endothelial ICAM-1 binds most of anti-ICAM-1 after intravascular injection.

Reporter compounds, therapeutic enzymes, genetic materials, and drug carriers conjugated with anti-PECAM-1 or anti-ICAM-1 accumulate and display their functional activity in the pulmonary endothelium as soon as 10 minutes after intravenous injection in mice, rats, and pigs (21,35,38,41,74–76). Protein conjugates (32,43), liposomes (19), or polymer carriers (76) carrying multivalent anti-PECAM-1 and anti-ICAM-1 display high endothelial affinity and targeting.

Pathological stimuli including oxidants, cytokines, thrombin, and abnormal shear stress enhance the surface density of ICAM-1 on ECs (77,78); hence, inflammation and oxidative stress facilitate ICAM-1 targeting (38,74,79). Therefore, ICAM-1 is an attractive target for the endothelial delivery of diagnostic (80,81), prophylactic, and therapeutic agents (10,38).

ECs bind anti-PECAM-1 and anti-ICAM-1 without internalization, but internalize multimeric 0.1- to 0.5-micron anti-cell adhesion molecule (CAM) complexes (9,35,43,82,83). This feature permits the use of anti-CAM as affinity moieties to target drugs either to the endothelial surface (e.g., utilizing monomolecular conjugates and scFv constructs) (38) or intracellularly (e.g., utilizing multimeric anti-CAM complexes) (10,76,84). It is tempting to speculate that anti-CAM targeting can also facilitate drug delivery across endothelium.

ECs internalize anti-ICAM-1 and anti-PECAM conjugates via a novel endocytic pathway (see Figure 186.1), namely CAM-mediated endocytosis (9,82,84). ICAM-1 dissociates from anti-ICAM-1 conjugates early after internalization, recycles to the plasma membrane, and participates in multiple cycles of intracellular delivery (76). The pace of PECAM-1- and ICAM-1-mediated trafficking and the destination of its cargo may be modulated by auxiliary drugs. For example, chloroquine (a weak base) decelerates the degradation of proteolysis-susceptible cargoes, while disruption of microtubules blocks lysosomal traffic and dramatically prolongs the duration of therapeutic activity of internalized drugs (84).

Potential therapeutic applications of PECAM-1 or ICAM-1 targeting include local and systemic delivery of pro-

TECTIVE DRUGS. For example, targeting antioxidants conjugated with anti-PECAM-1 and anti-ICAM-1 protects ECs against oxidative stress in cell cultures (32,43,84,85), perfused organs (42,86), and in mice and rats (42,87). Targeting plasminogen activators to the endothelial surface using monomolecular, non-cross-linking anti-CAM (which minimizes internalization) facilitates fibrinolysis in the pulmonary vasculature (34,38).

ICAM-1 supports the firm adhesion of activated leukocytes to ECs, whereas PECAM-1 supports cellular recognition, adhesion, and transendothelial migration of leukocytes (71,72,88,89). Blocking these molecules attenuates inflammation and injury in animal models and clinical pathological settings associated with acute inflammation, ischemia-reperfusion, and oxidative stress (90–94). This aspect of endothelial drug delivery has been discussed in a more general context in the earlier Safety section. Targeting CAMs may offer secondary benefits in conditions associated with inflammation, oxidative stress, and thrombosis.

In summary, antibodies to PECAM-1 and ICAM-1 represent potentially practical and useful means for drug targeting to and into the ECs.

## TARGETING SELECTED VASCULAR AREAS

Targeting pan-endothelial determinants will optimize the effects of many drugs by enhancing their effectiveness (dose percentage that actually acts in target cells may be increased), safety (general dose may be decreased), and specificity (the drug may be delivered to an appropriate subcellular compartment). It could be especially useful in those settings in which systemic endothelial effects are welcome or local administration of targeting is feasible (e.g., infusions via vascular catheters or application in organ transplantation). Yet, specific accumulation of drugs in selected vascular areas after systemic administration promises even greater advantages. Vascular selectivity provides a critical means for reducing the side effects of highly toxic drugs. This section provides selected examples of constitutive and inducible endothelial determinants potentially useful for site-selective drug delivery to and across ECs in several specific vascular areas.

### Pulmonary Vasculature

The pulmonary compartment is a preferable site for the action of wide classes of noninjurious agents including antithrombotic, anti-inflammatory, and antioxidant drugs, as well as for enzyme replacement therapies, such as those used to alleviate genetic defects. As discussed earlier, the pulmonary vasculature represents a preferential accumulation site of drug delivery systems targeted to pan-endothelial determinants.

Endothelial determinants which are enriched in the pulmonary vasculature and potentially useful for lung-specific drug delivery, have been identified. This strategy may be useful

for the treatment of pulmonary diseases, including pulmonary hypertension, edema, hyperplasia, tumor growth, and other maladies involving this predominantly vascular area.

One example of such a determinant is angiotensin-converting enzyme (ACE), a luminal endothelial transmembrane glycoprotein that converts angiotensin (Ang)-I into the vasoconstricting and proinflammatory peptide, Ang-II (95). Some ACE antibodies block its active site and facilitate ACE shedding from the endothelium (96,97), which may be beneficial in the management of hypertension and inflammation. Pulmonary vasculature is rich in ACE: approximately 100% of alveolar capillaries are ACE-positive versus less than 15% of extrapulmonary capillaries (44).

ACE is a good candidate for pulmonary endothelium targeting for diagnostic, prophylactic and, perhaps, therapeutic means. Reporter probes and drugs conjugated with anti-ACE accumulate in the lungs after intravenous injection in animals and humans (1,44,98,99). Because ECs constitutively internalize monomolecular anti-ACE (100), intracellular drug delivery is possible (albeit the endocytic pathway of anti-ACE and its regulation are not yet characterized). Antioxidant enzymes conjugated with anti-ACE accumulate in rat lungs *in vivo* and protect perfused rat lungs against hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) damage (86,101). Anti-ACE does not cause acute harmful reactions in animals and humans (1,96). Recently, anti-ACE has been used successfully for the retargeting of viruses to pulmonary endothelium in rats (102,103). Targeting of genetic materials into ECs is a rapidly developing field (70,104).

Using endothelial plasma membrane proteomics and *in vivo* phage display, new markers in the pulmonary vasculature have been identified in animals. For example, the injection of radiolabeled antibody to aminopeptidase-P, identified in the pulmonary endothelium using subtractive proteomics, allows the  $\gamma$ -camera visualization of lung blood vessels in rats and the detection of vascular abnormalities associated with pulmonary pathologies (62,63). These data, as well as similar results obtained with radiolabeled anti-ACE in animals and humans (1), imply that targeting of constitutive endothelial markers may have a diagnostic utility.

Interestingly, many pulmonary-specific endothelial markers are ecto-peptidases. This fact presumably reflects a key role of the pulmonary vasculature in metabolizing vasoactive peptides, and emphasizes the importance of understanding the potential consequences of inhibiting target molecule function. For example, ACE and aminopeptidase-P play a part in important physiological roles, such as bradykinin degradation (105); hence, the unintended inhibition of their functions by blocking antibodies may cause potentially harmful effects, such as vascular edema.

The issue of adverse side effects inflicted by inhibition of target molecules is nicely illustrated by studies that target thrombomodulin, an endothelial surface glycoprotein that converts thrombin into an antithrombotic enzyme that inactivates coagulation factors (106). This affinity moiety has been extensively used in the model targeting of liposomes, genetic materials, and injurious agents to the pulmonary endothe-

lium in laboratory animals (17,107,108). However, thrombomodulin inhibition may increase the risk for thrombosis, which is illustrated in animal studies using antithrombomodulin conjugates (108–110). One potential application of thrombomodulin targeting is in animal models of human vascular pathologies localized in the pulmonary vasculature (87,108).

### Sites of Inflammation

Diagnostic visualization and drug targeting to sites of vascular inflammation represent an enormously important biomedical goal (81). Some basic principles of inflammatory site targeting, including the secondary benefit of inhibiting the target *per se*, have been discussed in the context of targeting pan-endothelial determinants ICAM-1 and PECAM-1. In fact, these determinants appear to be excellent candidates for the delivery of anti-inflammatory therapies. Moreover, because inflammatory mediators result in the local induction of ICAM-1 expression on ECs, targeting this molecule will facilitate site-specific delivery of drugs to foci of inflammation.

At sites of inflammation, the endothelium displays many other phenotypic changes (111). Inflammatory mediators (e.g., cytokines, activated complement), oxidants, and proteases cause endothelial exposure of P-selectin, normally stored intracellularly and mobilized rapidly to the surface, and E-selectin, which is newly synthesized by activated endothelium (77,88). An Ig-superfamily CAM, vascular cell adhesion molecule (VCAM)-1, also is exposed on the surface of activated ECs (72). Selectins and VCAM-1 facilitate adhesive interaction of activated white blood cells with ECs (71). In theory, selectins and VCAM-1, transiently exposed on the surface of activated ECs, are attractive determinants for therapeutic (but not prophylactic) drug delivery to pathologically activated endothelium, with a potential secondary benefit of leukocyte adhesion attenuation (10,93).

Diverse carriers include polymer particles ranging from 0.1 to 0.5 microns which carry antibodies against EC adhesion molecules (e.g., P- and E-selectin, VCAM-1, and ICAM-1) adhesion molecules. These bind to cytokine-activated ECs in cultures (76,112,113). Experiments in cell cultures (19,20,114,115) and animal studies (36,115–117) showed that antibodies to selectins may permit the targeting of liposomes and drugs to cytokine-activated endothelium. It should be noted, however, that affinity carriers directed to P-selectin can target not only ECs but also – and, in many cases of vascular pathologies, predominantly – platelets (36,81).

ECs constitutively internalize E- and P-selectins and VCAM-1 (in contrast to ICAM-1 and PECAM-1) via clathrin-coated pits (118,119). This enables the intracellular delivery of liposomes (22,120), anti-inflammatory drugs (121), and genetic materials (115) targeted to these determinants. However, the rapid uptake of cell-bound drugs targeted to selectins and VCAM-1, which restricts their effects in the lumen, makes these targets unsuitable for delivery of certain drugs such as antithrombotic agents.

Targeting VCAM-1, a marker that is expressed in ECs early in the course of atherosclerosis, may eventually provide diagnostic and drug-delivery tools for site-specific containment of atherosclerosis (122,123). High-affinity antibody fragments selected by phage-display library techniques and identified as anti-VCAM-1 peptides currently are being tested in cell cultures and in animal models of atherosclerosis (65,124). ICAM-1, a hallmark of atherosclerotic lesions, is also a plausible target for the delivery of anti-inflammatory drugs in this disease condition (125,126).

The kinetics and persistence of selectin exposure on endothelial activation are difficult to follow even in animal models in which conditions are tightly controlled. Furthermore, even at their activation peak, selectins are exposed at relatively low surface densities; hence, targeting robustness may be suboptimal for therapeutic interventions requiring the delivery of large drug doses. Yet, targeting selectins is an attractive avenue for the diagnostic visualization of activated endothelium in inflammation foci by delivery of conjugated isotopes (116) or ultrasound contrasts (81).

### Cerebral Vasculature

The blood-brain barrier (BBB) represents a specific, challenging, and extremely important therapeutic target. Cerebral endothelium is enriched in surface markers, including receptors for transferrin, insulin, putrescine, and some growth factors. Animal studies have demonstrated the delivery of reporter compounds and genes into the brain using antibodies and peptides binding to these determinants (127–129).

Importantly, some of these endothelial receptors apparently permit transcellular drug delivery across the BBB into the brain cells (129,130). The transferrin receptor represents one of the most extensively studied (131). Phage-display promises to guide the selection of new targeting peptides that bind to and transcytose across cerebral ECs (132).

The expression of CAMs, including ICAM-1, is elevated in cerebral endothelium in ischemia and inflammation (133). It is tempting to speculate that targeting therapeutic cargoes to ICAM-1 can improve treatment of stroke and cerebral infections, via both the delivery of cargoes and blocking ICAM-1. Moreover, blocking blood cell adhesion to ECs may provide therapeutic benefit in stroke, brain trauma and, likely, neurodegenerative diseases. More details on targeting of cerebral endothelium and means to permeate the BBB can be found in reviews (134–136).

### Tumor Vasculature

ECs in solid tumors represent a key target for the delivery of agents designed to visualize tumors, inhibit angiogenesis, and/or kill malignant cells (4,137,138). Tumor vasculature is characterized by numerous functional (e.g., acidosis and hypoxia) and morphological (e.g., irregular shape and orientation of blood vessel) abnormalities (139,140). It has been suspected for decades that the ECs in tumor vasculature

express abnormal determinants. Indeed, functional genomic and proteomic approaches have identified a spectrum of genes and proteins characteristic of tumor endothelium (57). Screening techniques utilized since the early 1990s, including plasma membrane proteomics and phage-display libraries *in vivo*, have identified several promising candidate determinants. For example, ECs in tumor vessels expose abnormal determinants including selectins, specific integrins, markers of apoptosis, and receptors for growth factors; targeting these determinants augments the accumulation of drugs in solid tumors in animal models (7,141–144). High-throughput plasma membrane proteomics and phage-display libraries *in vivo* have identified several promising candidate determinants characteristic of certain solid tumors, including aminopeptidase-N (143,145) and annexin-A1 (63).

Targeting endothelial determinants in tumors helps to accomplish many goals: (a) tumor localization; (b) thrombosis of tumor vessels with infarction and starvation of malignant cells; and, (c) delivery of antitumor agents to the target malignant cells (62,63,143,146–148). The latter approach involves permeation of the endothelial barrier, mostly due to enhanced vascular permeability and decelerated lymphatic drainage in solid tumors (enhanced permeability and retention, EPR) (149). However, targeting those integrins overexpressed on tumor endothelium and caveolar antigens can provide endothelial transcytosis (150). Targeting tumor endothelium is an area of very active research; for recent reviews on the identification of surface determinants characteristic of tumor vasculature see Refs. 4, 7, and 151.

### KEY POINTS

- Diverse drug delivery systems such as stealth liposomes, polymers, and polypeptide carriers designed for a wide range of drug delivery applications can be utilized to target drugs and diagnostic probes to the endothelial tissue that represents both a prime therapeutic target and a barrier for drug delivery.
- The targeting is achieved by coupling drugs or drug carriers to affinity ligands of endothelial surface determinants. These agents must meet several criteria, including accessibility to circulating agents, endothelial specificity, safety of targeting effects, selectivity of addressing within the vasculature, and precision of addressing to proper cellular compartments.
- Pan-endothelial targeting, for example, directed to PECAM-1 and ICAM-1, optimizes the effectiveness, safety, and specificity of many therapeutic means aimed at the protection or correction of endothelial function and interventions within the circulation. Surface determinants expressed predominantly

in certain types of endothelia, such as in specific vascular areas or pathologies, offer site-selective delivery and greater specificity of interventions.

- Constitutive endothelial targets, such as PECAM-1 and ICAM-1, as well as ecto-peptidases (e.g., ACE, aminopeptidase-P) can be utilized for both prophylactic and therapeutic drug delivery. They may also be used as diagnostics based on the suppression of their endothelial expression in pathologies. Inducible determinants in pathologically altered endothelium (fairly common for inflammation, tumor growth, and ischemia) are ideal for diagnostics and, if the time window and surface density of their exposure suffice, therapeutic targeting.
- Hypothesis-driven strategies for the selection of endothelial targets allow a target to be tested in terms of optimal subcellular addressing and secondary effects beneficial in the context a particular pathological process. However, these strategies are low-throughput and not inclusive. High-throughput, discovery-driven strategies offer a wealth of knowledge on endothelial surface topography, yet offer rather limited, if any, insight into the functions and metabolism of newly identified determinants. A combination of these complementary strategies will guide the design of safe and effective systems for drug delivery to, into, and across selected populations of ECs.

#### ACKNOWLEDGMENTS

This work was supported by NHLBI RO1 grants HL71175, HL078785, and HL73940; Department of Defense Grant (PR 012262); ITMAT award; and Pennsylvania Nanotechnology Institute core project. I express my gratitude and appreciation to Drs. S. Muro and T. Dziubla (University of Pennsylvania) for productive collaboration, exciting discussions, and invaluable help in preparing this chapter.

# Complexity

## Introductory Essay

### Complexity and the Endothelium

---

Ary L. Goldberger

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

This medical textbook is unusual in that it includes a section devoted to the endothelium and “complex systems.” What may at first appear an editorial eccentricity will, upon further inspection, hopefully be seen as a useful addition and perhaps even as a template for future texts in other clinical fields. Indeed, the endothelium presents a compelling case study of the wide and deep potential interconnections between biomedicine and the contemporary study of complexity (1).

What makes a system complex, and not just complicated? The endothelium exemplifies two key features of complex systems (2). First, such systems function over a broad range of time and space scales (3,4) ranging from picoseconds to minutes, months, and longer, and from the quantum to the cellular to the organismic and even up to the level of social networks. Second, such multiscale systems display dynamics that are *nonstationary* and *nonlinear* and, therefore, defy analysis using traditional tools used by biostatisticians (1). Nonstationarity refers to the finding that the statistical properties (e.g., the mean and the variance) of fluctuations generated by a system change over time. Nonlinearity means that the components interact in nonadditive ways, so that the output will not be consistently proportional to the input. Indeed, in nonlinear systems, small changes can have huge or anomalous consequences, a phenomenon sometimes referred to as the *butterfly effect*.

Nonlinear systems cannot be understood by the traditional reductionist strategy of dissecting out their components, studying them in isolation, and then “recompiling” the system. Instead, the nonlinear interactions can lead to qualitatively novel structures and dynamics, so-called *emergent properties*. Thus, nonlinear systems cannot be characterized using a “modular” type of approach. Not only are the components at different scales interdependent, but global behaviors may arise as emergent properties of more local interactions. The failure of reductionist models to fully understand a system is a useful test of whether one is dealing with a truly complex system (e.g., an organ system) versus one that is merely complicated (e.g., most man-made machines). From a practical

point of view, the presence of nonlinear interactions may foil attempts to engineer safe and effective pharmacologic interventions based on linear (“domino-like”) cause–effect mechanisms with fixed targets. In a nonlinear system, the targets may not only be “moving” but also “morphing,” a consideration that accounts for some of the unintended consequences induced by well-intended but deadly pharmacologic interventions.

The implications of complex systems for physiology and clinical medicine have only begun to be explored in the last decade or so (2–6). The rigorous underpinnings for these analyses have come primarily from the interrelated fields of nonlinear dynamics, applied mathematics, statistical physics, and chaos theory, including the study of fractals (scale-free objects and processes) (7,8). At the same time, the challenges posed by the study of living systems is stretching the envelope of concepts and models developed to study the most complex processes known in the physical world, such as turbulent flows. The preeminent cosmologist, Stephen Hawking, has predicted that this era will be the “century of complexity,” an apt moniker likely to be borne out by explorations at the emerging and unexpected interfaces of biology, engineering, mathematics, and physics.

One of the most exciting discoveries in complexity science that will help propel such interdisciplinary studies is the principle of *universality* (5). Surprisingly, nonlinear systems that appear to be very different in their specific details may exhibit certain common patterns of response or architecture. For example, nonlinear systems may change in a sudden, discontinuous fashion. One important and universal class of abrupt, nonlinear transitions is called a *bifurcation*. This term describes situations in which a very small increase or decrease in the value of some parameter controlling the system causes it to change abruptly from one type of behavior to another. The output of the same system may suddenly go from being very irregular to a highly periodic, or vice versa. Another example of the principle of universality is related to the concept of *fractals* (7,8). Classical geometric forms are smooth and regular

and have integer dimensions. In contrast, fractals are highly irregular objects that have noninteger, or fractional, dimensions. Fractals are composed of subunits and these, in turn, of sub-subunits, and so on, that resemble the larger scale structure. A wide variety of natural shapes share this self-similarity property, including branching vascular trees and coral formations, crenellated coastlines, and ragged mountain ranges. The concept of self-similarity (scale-invariance) also can be applied to complex processes that lack a characteristic scale and to certain types of scale-free networks described in this section. Loss of complexity, including the breakdown of fractal organization, appears to be a widespread, if not universal, theme in pathophysiology and aging (3,4,8).

Of interest within the community of complexity scientists already investigating biologic process is a useful tension between those who embrace stochastic mechanisms related to purely random effects and those emphasizing deterministic (rule-based) mechanisms. Common sense and analysis of actual data suggest a necessary compromise based on mixed models that include both stochastic and deterministic elements (9). In some cases, the same “phenotype,” for example a fractal-type tree, can be generated either by stochastic models or by deterministic ones. It is possible, from an evolutionary perspective, that complex novel behaviors or structures initially arising by purely stochastic means but conveying some adaptive advantage could become encoded as part of the subsequent deterministic blueprint of the organism. (Nonlinear mechanisms such as emergence and bifurcations appear to toss a monkey wrench into the machinery of those challenging Darwinian theory, because these well-established phenomena already provide a rigorous foundation for the discontinuous appearance of novelty and complexity in the absence of an intelligent designer. Further, extravagantly complex structures and dynamics can arise from even simple-appearing nonlinear systems [10,11]. For example, the Mandelbrot set [7], among the most complex objects in mathematics, is generated by iteration of one of the simplest-in-form nonlinear equations.)

The chapters in this section present a wide-ranging, but by no means exhaustive, sampling of state-of-the-art work linking complex systems with the study of endothelium.

Classical mathematical modeling attempts to describe the rate of changes in a system. The most powerful models not only have explanatory capacity – the ability to account for observed behaviors – but also are predictive of experimentally testable changes. Clermont, Vodovotz, and Rubin concisely overview the use of differential equations (ordinary and partial) to model such changes, the classical approach to understanding the temporal and spatial properties of dynamical systems (Chapter 191). The extraordinary challenges posed by the complexity of multiscale biologic systems such as the endothelium also have generated complementary approaches, including so-called *agent (individual or entity-based) based-models* introduced in the chapter by An (Chapter 188). Such simulations attempt to capture features of the global behavior of a system based on the rules governing the interactions of its individual components. As an example, Athale and Deisboeck

present an agent-based computational approach to modeling the effects of angiogenesis on multiscale tumor growth dynamics (Chapter 193). Huang considers endothelial cell fates (different phenotypes) in terms of the nonlinear conceptual framework of *attractors* and *multistability* (Chapter 190). The basic idea is that the genome-wide gene regulatory network that controls cell behavior imposes constraints on the global dynamics such that only relatively few stable network states can arise. High-dimensional “attractor states” in the gene expression state space represent these discrete phenotypic cell fates. Almaas and Barabási describe new approaches to modeling complex networks that lack a characteristic scale (Chapter 189). Such scale-free (fractal-like) networks, which are intimately associated with ubiquitous power-law distributions, have universal properties that promise to link the study of endothelium with a wide range of other networks in nature. Finally, Ingber explores the delicate and essential interplay of mechanical forces and biochemical changes in cellular biology (Chapter 192). This chapter describes how a particular form of architecture known as *tensegrity* stabilizes the shape of the constituent cells, the extracellular matrix, and the intracellular cytoskeleton. Among its far-reaching implications, this work emphasizes the physical context of multicomponent networks and underscores the inherent limitations of contemporary analytic approaches focused primarily at the gene-molecule level.

These discussions of complementary approaches to modeling will hopefully provoke new “out-of-the-box” ways of thinking and rethinking endothelial structure–function relationships and stimulate previously unplanned basic and clinical experiments and therapeutic approaches (1). The ways in which models fail to account for the complexity of real-world dynamics is as important as their successes and an essential guide in the dynamic and evolving interplay of theory and experiment. To paraphrase a remark attributed to the English astronomer, Sir Arthur Eddington: The physiologic universe is likely to be not only stranger than we imagine, but stranger than we can imagine.

## Agent-Based Modeling and Applications to Endothelial Biomedicine

---

Gary An

*Northwestern University, Feinberg School of Medicine, Chicago, Illinois*

The chapters in this volume have thus far primarily described the properties of individual endothelial cells (ECs) as well as the behavior of the endothelium as a whole organ. But how is that transition from individual cellular function to organ-level behavior made? Merely extrapolating the behavior of individual ECs is insufficient; the internal heterogeneity of the endothelial organ precludes linear summation of individual EC function. Rather, it is necessary to place the behavior of the ECs in the context of their local environment, be that in various tissue beds in a baseline state of health or in pathological regional disruptions associated with injury or infection. What is required is a means of formalizing the process by which the laboratory-derived data about individual ECs can be translated into the richness of behavior that is seen at the level of an organism. Systems biology and mathematical modeling can provide a mechanism for this translation, and this chapter will introduce one of these techniques, agent-based modeling (ABM), and give an example of an ABM that includes endothelial function.

### WHAT IS AGENT-BASED MODELING?

ABM is a type of mathematical modeling that is dynamic (evolving over time), discrete-event (stepwise progression of time and action), and mechanistic (dependent upon rules). ABM is completely deterministic, meaning that, for a specific set of initial conditions, the model will run exactly the same for each simulation run. However, stochasticity built into the model at multiple levels (through the use of random-number generators) allows for variation in the models' dynamics. The emphasis with ABM is on the individual components of a dynamic system and the rules that govern them. A dynamic system is viewed as an aggregate of the behaviors of its constituent components, with the recognition that the components function based on an internal rule system. The components of the system are grouped into classes of "agents" by virtue of shared mechanisms, which are derived from

experimental and observational data. The mechanisms can be expressed as a series of conditional ("if-then") statements, and computer programs are written to describe the rules of behavior. Agents are treated as finite-state machines that respond to inputs and outputs based on their class rules. A specific series of rules defines a particular class of agent. Another important aspect of ABM is that agent inputs are locally constrained. Thus, an agent acts based on limited knowledge of what is going on in the system as a whole. The boundary of agent knowledge is determined by the structure of the model. For example, the knowledge boundary can be spatial (as in grid-based ABMs) or a restricted group of links (as in a network ABM).

In addition to creating populations of agents, ABM defines a particular "virtual world" in which the agents carry out their functions. The structure and parameters of the virtual world depend on the system being modeled and the type of ABM being created. For instance, in spatial ABM, the virtual world is often represented as a grid. Variables representing the characteristics of the reference system are placed in the grid, and the agents move and interact over the grid. Heterogeneous distribution of "environmental" parameters/variables in the virtual world allows for divergent behavior of agents from within the same class (i.e., those agents having the same rules). As the agents execute their internal algorithms in a stepwise, parallel fashion (to simulate simultaneous behavior), they respond to these heterogeneously distributed local inputs, resulting in multiple paths/trajectories of individual agent behavior within the population of an agent class. The dynamics of the system emerges from the multiple differential interactions between the agents over time and the resulting aggregate distribution of characteristics of their populations.

Agents ideally should have well-identified, simple rules. A wide range of abstraction is used in developing the parameters of agents and their world, extending from simple two-dimensional (2D) cellular automata, to weighted nodes in a neural network, to more sophisticated nodes in a small-worlds network, all the way to extended algorithms of conditional statements (such as experimentally derived cellular/molecular

mechanisms) in a multidimensional, mobile cellular automata. This last type of ABM is possible because, although the agents themselves may be complex constructs, their complexity can be managed by drawing a boundary at which well-documented responses occur to external inputs and outputs. Applying stochasticity to their algorithms through the use of random-number generators introduces the “uncertainty” that can accompany the behavior of complex systems. It should be noted, however, that this places a limit on how finely grained the analysis of model behavior can be; the probabilistic components in the model therefore represent “black boxes” in terms of analysis and intervention.

ABM can be thought of as essentially a formalized means of concurrently expressing multiple hypotheses of multiple mechanisms. By focusing on a system’s components and their behavior, ABM is often fairly intuitive to nonmathematicians who may find it easier to think in terms of conditional statements than equations. As a result, ABM is well suited to translating multiple experimental conclusions into a dynamic, synthetic, analytical framework.

#### APPLICATIONS OF AGENT-BASED MODELS

Complex systems are often defined as those systems in which the overall behavior of the system cannot be directly inferred or predicted by knowing the characteristics of the individual components of the system (1). Implicit in this description is a nonlinear and noncontinuous relationship between component behavior and overall system behavior. This particular characterization of complex systems is well suited to the capabilities of ABM. Therefore, it is not surprising that ABM has found most of its applications in complex systems described in this way. The classic examples are that of bird flocking, fish schooling, and insect colony behavior (2). Other systems and processes that fall into this category and that have been investigated using ABM include economics (3), political science (4), social science (5), ecology (6), and evolution (7). Human physiology and pathophysiology are generally recognized as behaving as a complex system, and relatively recently there has been interest in the use of ABM to study these processes (8–11). One such ABM (9), which specifically includes EC function, is described briefly later. This model will be used as an example of the considerations that go into the process of developing ABM, will focus discussion of validation strategies for ABM, and will give examples of how such ABM can be used. Another example of ABM in the medical field is the tumor angiogenesis model of Deisboeck found in Chapter 193.

#### AGENT-BASED MODELING OF THE ACUTE INFLAMMATORY RESPONSE

The ABM described herein uses cells as the primary agent level and focuses on the interactions that occur at the interface between ECs and blood-borne inflammatory cells. (A more

extensive description of this ABM, as well as the web site at which the model is posted, is available [9]). Cells were selected as the agent level because they can be readily subgrouped into classes based on common behavioral rules, and the responses of single types of cells to various mediators has been extensively characterized in the basic science literature. The focus is on the endothelial–blood interface because I believe that activation of endothelial surfaces (be it from injury or infection) is the initiating point at which inflammation has consequence to tissue beds, and that the interaction between the endothelium and blood-borne inflammatory cells is responsible for the propagation and regulation of the inflammatory process. The endothelial surface is therefore treated as a physiological membrane that has barrier, transport, and communication functions.

The ABM reflects this particular concept by its basic configuration as a 2D grid (Fig. 188.1A; for color reproduction, see Color Plate 188.1). The edges of the grid “wrap,” meaning that agents moving off the right edge of the screen appear on the left edge, and vice versa. This is also true for the upper and lower edges of the screen, with an end result that the topological surface of the ABM is a torus. This configuration is also topologically equivalent to an aggregate of all the capillary beds in the body. On each “square” of the grid resides an agent of the EC class. As mentioned earlier, all these agents have the same rules and algorithms and, although ECs do not move, their discreteness in space allows them to manifest different trajectories of behavior. The knowledge boundary for each agent is the immediately surrounding eight grid spaces (called a *Moore neighborhood* in the terminology of cellular automata; for more information about cellular automata see Ref. 12). This neighborhood corresponds to the immediate extracellular space in which the cell interacts via its membrane. The ECs change their state depending on the variables within this space, with the end result being that the EC component of the ABM functions as a cellular automata.

A mobile component to the ABM is also present, made up of the inflammatory cell agents (ICAs). The classes of ICAs include neutrophils (polymorphonuclear cells, PMNs), circulating mononuclear cells, and T-cell subspecies. As opposed to the EC agents, which are imbedded in the grid, ICAs move freely over the surface of the EC matrix. Although no directional flow is present, the baseline random movement of these agents reflects the fact that there is localization and limitation with respect to how far a particular cell can move between capillary beds. Even though they are mobile, ICAs have the same knowledge boundary as ECs (a Moore neighborhood) that moves with them as they move. Variables that correspond to chemotactic mediators will affect the pattern of ICA movement, variables that correspond to adhesion factors will affect the rate of ICA movement, and other variables that correspond to pro- and anti-inflammatory cytokines will initiate ICA algorithms that correspond to cytokine production/secretion, respiratory burst, and apoptosis, among other cellular functions. Again, it should be noted that each individual agent runs its algorithms based on the input from its Moore neighborhood,

Figure 188.1. These panels are screen shots of the ABM (8) described in the text. The space is made up of  $101 \times 101$  cells, in each of which is an EC agent, shown as gray background. The other colored squares represent ICA agents: PMNs are white, monocytes are light gray, T-cell species are black. (A) A nonperturbed system with only the EC/ICA agents present. (B) A system perturbed with a simulated infection. The initial insult is given in a roughly circular distribution of simulated infectious vectors (representing gram-negative bacteria) represented by gray squares. The effect of the simulated infection is to damage and kill EC agents, represented as patches of black and shades of black. The lighter patches in B represent activated PMNs that have responded to the insult and are exercising their algorithmic rules systems. The screen shot in B was taken at approximately 48 hours simulated time. Note the relative paucity of infectious vectors compared to the size of the area of damaged ECs. This denotes the efficacy of bacterial killing by the ICAs, but also the degree of “collateral damage” generated by the proinflammatory component of the inflammatory response. For color reproduction, see Color Plate 188.1.

and that the agents execute their rules in an emulated parallel fashion to simulate simultaneous behavior. In the course of a simulation, all the agents execute their algorithms in a stepwise fashion that is calibrated to the relative amount of “real time” it takes for the process to occur. In a nonperturbed situation, the behavior of the model is “stable,” meaning that the general overall parameters of the model remain relatively constant. The model can persist in this state indefinitely. However, interesting dynamics occur when the system is perturbed. This is accomplished with a spatial distribution of damage to the underlying EC matrix. This damage can take the form of simply “killing” a set number and pattern of EC agents, or introducing simulated infectious vectors that will not only damage ECs but also replicate and spread. In either case, the introduction of the perturbation changes the state conditions of the affected agents, with subsequent consequences on the other agents in the area. The spatial distribution of the initial insult is variable even given a set value/level of the initial insult. This heterogeneity of initial conditions plays a role in the subsequent divergent behavior of the system as a whole. The dynamics of the ABM now can follow different trajectories reflecting different behaviors and outcomes that can be evaluated against what we see in the real world. An example of the ABM in the process of dealing with a simulated infection can be seen in Figure 188.1B.

Therefore, the end result is the creation of a “virtual organism” that is essentially a giant EC culture that includes active inflammatory cells. It combines the knowledge gleaned from individual EC function and individual ICA function into an interactive framework that would be difficult, if not impossible, to replicate in a basic science lab without significant artifacts. This “virtual organism” can now be subjected to *in silico* experiments of a type that would parallel experiments carried out in a wet lab. Because the ABM is based on mechanistic rules, any rule programmed into the ABM can be manipulated in a potential experiment. Before “new” experiments can be considered, however, it is necessary to validate the ABM.

#### VALIDATION AND IN-SILICO EXPERIMENTS

The validity of any model is a measure of how well the model matches the behavior of the reference system it is intended to emulate. It determines the applicability and usefulness of the model. Validation is therefore a critical step in the development of any model, be it *in silico*, *in vitro*, or *in vivo*. With respect to ABM, validation provides both challenges and opportunities. Validation strategies can be divided into two general categories: validation of assumptions and validation of behavior.

The validity of the assumptions of a model is a perpetual sticking point with respect to all mathematical models. This is popularly expressed with the acronym “GIGO,” or “Garbage In, Garbage Out.” This is especially true with mathematical models, in which the lack of intrinsic constraints (such as the laws of physics or chemistry) can lead to nonsensical results. However, there is a readily available solution: transparency. Transparency means making explicit the process by which the architecture and rules of the model are chosen and implemented. This is important, because all models represent some degree of abstraction that is at the discretion of the modeler. Making the initial modeling assumptions (as expressed in the architecture and rules of the model) explicit allows anyone examining the model and its behavior to determine for themselves to what degree they agree with the structure of the model and the results gathered from it. The potential limitations of the model are therefore apparent from the outset, and the expectations of what can be gleaned from the model are placed in an appropriate context. This is consistent with the concept of modeling as an iterative process of hypothesis generation and testing, with each model sufficient to an acknowledged point of failure, but through its failure constantly advancing the boundary of understanding of the system being examined.

The other general category of validation is that of the behavior of the model. This can be approached through a series of strategies. All of them, to some degree, consist of comparing the behavior of the model to some real-world data set of expected behavior. When the behavior of the model matches the real world data set, then the model is deemed valid for that particular test. If the model does not match, then the model is reexamined and either the basic structure of the model is reconfigured, or specific variables and relationships are fine-tuned. This latter process is called *calibration*. It should be evident by this last statement that one potential significant pitfall exists – namely, When is the problem one of calibration, and when is it one of basic structure? There is no easy answer to this, other than to make the basic structure transparent, and rely on feedback from the community at large.

Validation of ABM behavior can be accomplished at three levels: at the level of individual response (*individual dynamic*), at the level of the behavior of a population with respect to intrinsic variables (*population dynamic*), and finally with the behavior of the population with respect to an intervention (*population response*). For example, in the EC/ICA ABM described earlier, the individual dynamic behavior is the reproduction of the four possible dynamics associated with injury/infection: containment and healing, a hyperinflammatory forward feedback response, an anti-inflammatory negative feedback response, and overwhelming initial insult (9). The population dynamic is reproduced by mean patterns of pro- and anti-inflammatory cytokines generated in simulated populations that match those seen in equivalent clinical populations (9). Finally, the population response is validated by simulating existing mediator-directed therapies and performing in silico trials in simulated populations matched to those

reported in the clinical trials. Up to this point, all the validation strategies are dealing with a model that reflects the baseline, unmodified functions of the reference system. No manipulation of the baseline agent rules or state variables has been done; the initial perturbation is the only intervention to the steady-state model. However, with the third level of validation, the population response, we move into the realm of in silico experiments. As mentioned before, any rule or variable in the model can be targeted for intervention, and populations of simulated runs can be generated for both the baseline ABM (the “control group”) and for the modified ABM (the “intervention group”). Again, the structure of an ABM and its reliance on mechanistic rules makes this transition very intuitive, and it is not hard to imagine treating the ABMs just like any other wet lab/clinical population. In the particular case of the EC/ICA ABM, the reference system interventions are previously published clinical trials of mediator-directed therapies against sepsis, and the resulting ABM experiments are in silico simulations of those trials. In these situations, the addition of anti-tumor necrosis factor (TNF), anti-interleukin (IL)-1, and granulocyte colony stimulating factor (G-CSF) all failed to produce a statistically significant improvement in mortality, results that were seen in the clinical trials (9). Unfortunately, at this time, the single successful trial of mediator-directed therapy, activated protein C, has not been simulated, and the strength of the validation would be greatly enhanced by replication of a positive result (this is currently in development). However, despite the reliance on validation by negative outcome, the behavior of the model is significant in that the model reflects the summation of beliefs and hypotheses that existed and fomented the development of those failed trials, and is a further example of the utility of ABM as a means of hypothesis testing.

This can be carried to the next logical step by simulating hypothetical, as yet untried interventions. In the case of the EC/ICA ABM, this was done by trying two different treatment strategies. The first was a modification of the dose and duration of anti-TNF and anti-IL-1, with the idea of using lower doses and longer durations to “dampen out” the inflammatory response (this hypothesis has its basis in the trend of “supplementation therapies,” such as low-dose “replacement” corticosteroids and vasopressin). The second was to use multiple drugs to attack the redundancies in the inflammatory response, specifically anti-TNF with anti-IL-1. Neither of these strategies has been implemented (yet), so these in silico experiments were truly prospective. Unfortunately, both strategies proved ineffective in the in silico experiments (9). It must be noted that, because the ABM in which these experiments were carried out is a very abstract model, one should not come away with the idea that these approaches are doomed to failure. However, one should also note that the philosophies underpinning both these strategies are currently prevalent in the critical care community. Perhaps the finding that these strategies do not work when they are implemented in a synthetic, analytical framework should be cause for some reexamination of the underlying hypotheses.

## LIMITATIONS

ABM is a modeling technique that is just beginning to progress out of its infancy. In the scope of more traditional, equation-based modeling, ABM can seem imprecise. Conditional statements that constitute most agent rules do not have the same degree of mathematical precision as equations. ABM cannot be “solved” in a formal sense and, for them to be mathematically analyzed, they must be transformed into equations (if possible). The calibration of ABM can be very difficult. Because the agents are treated as “black box” input-output devices, generating their rule systems requires very extensive reductionist mechanistic data from the wet lab. Since the dynamics of the model arise through multiple agent interactions with a stochastic component, it can be very difficult to determine the effect of a single rule change (in fact, this property is precisely why certain systems are modeled using ABM). This precludes the curve fitting that can be done with coefficient modification, as in equation-based models. These characteristics of ABM make it suited primarily as a research tool, not a clinical/bedside application.

There is a paradox, however (as is the nature of complex systems!) with the limitations of ABM. The paradox is that the limitations listed here derive from the characteristics that make ABM a desirable and beneficial modeling tool. Agent rules expressed as algorithms of conditional statements are often more intuitive than deriving ordinary or partial differential equations. Furthermore, experimental conclusions are usually expressed as conditional statements, making ABM well suited as a translational, synthetic tool. The need for extensive mechanistic wet lab data integrates ABM development with ongoing scientific investigation, potentially emphasizing gaps in knowledge and directing future experiments. Often the systems under study are too complex for intuitive determination of cause-and-effect of a single rule change; this is why mathematical modeling, and ABM in particular, is being applied to the particular problem – if people could have figured it out without having to resort to computational methods, they quite likely would have done this already.

This carries us back to a point that has been revisited multiple times in this chapter: that mathematical modeling such as ABM represents a formalized way of expressing and testing hypotheses. The process that goes into developing ABM is an integral component of what every good scientist already does intuitively. However, we recognized that in some systems and problems, intuition breaks down; in those circumstances, tools like ABM have their place. As with any tool, its useful application is tied to understanding and working within its known limitations.

## FUTURE DIRECTIONS FOR AGENT-BASED MODELING AND ENDOTHELIAL BIOMEDICINE

With this in mind, it is possible to place ABM in its appropriate context with respect to its applications to the emerging field of

endothelial biomedicine. As with nearly all biological systems, system-level endothelial function is a complex system (13). As with all complex systems, there is a nonlinear, nonintuitive relationship between the underlying mechanisms of the system’s components and the system’s behavior. This is the point of breakdown with the traditional analytic-synthetic paradigm of Newtonian science. We have the analytical capabilities, the product of 500 years of the Scientific Method; what is lacking are the appropriate synthetic tools for integrating the information we obtain through analysis and placing it into a context that reflects the phenomena we observe in the real world. The mechanisms and tools of systems science, and ABM in particular, can provide the appropriate synthetic framework to form the necessary adjunct to the study of a complex system like the endothelium. More specifically, the intrinsic spatial characteristics of ABM make it well suited to handle the heterogeneity of endothelial behavior, and the flexible, modular nature of ABM can foster the collaborative integration of disparate lines of study. Toward this end, work is being done on creating a universal modeling “grammar” for the simulation of acute inflammation (14). Given the use of classes and class rules in ABM, the goal is to create a robust and flexible grammar through which the cellular and molecular data generated from basic science laboratories can be translated into a community-wide, open source ABM. It is hoped that this platform will provide the requisite transparency needed for evaluating mathematical models, and also a potential common frame of reference through which controversies can be discussed and compared. This goal will hopefully parallel the evolution of endotheliology as a discipline, because many of the same issues of integration and synthesis lie at the heart of both endeavors.

### KEY POINTS

- ABM, a form of mathematical modeling, can be a useful tool in the study of complex systems, such as the endothelium.
- ABM is essentially a formalized means of hypothesis expression and testing.
- By its nature as a mechanistic, rules-driven type of modeling, ABM is well suited as a translational, synthetic adjunct to traditional research paradigms.
- ABM may be able to provide a community-wide framework for integrating collaborative approaches to studying a system as wide-ranging and extensively distributed as the endothelium.

#### LIMITED GLOSSARY OF MODELING TERMS

**Cellular Automata (CA):** Initially described by Stanislaw Ulam and John Von Neumann, cellular automata are discrete dynamic systems. Each point in a regular spatial lattice, called a *cell*, can have

any one of a finite number of states. The states of the cells in the lattice are updated according to a local rule, relying only on its own state one time step previously, and the states of its nearby neighbors at the previous time step. All cells on the lattice are updated synchronously. Thus, the state of the entire lattice advances in discrete time steps.

**Class Rules:** A set of rules for behavior, usually expressed as conditional (“if/then”) statements, that is common to a particular group of agents (an “agent class”).

**Finite State Machine:** An object in which the number of its conditions or “states” can be expressed using a finite number. This implies that each of those states can be linked to a distinct time step.

**Population Dynamic:** The dynamics of the behavior of a population as a whole.

**Population Response:** The subsequent population dynamic following a perturbation to a population.

**Random-Number Generator (RNG):** A mathematical algorithm that, when implemented in a computer, produces a string of “random” numbers. In truth, since they are generated via an algorithm, the numbers are “pseudorandom.” However, with most available RNGs, the cycle of the algorithm is so great as to effectively be “random.”

**Reference System:** The real world system that is the subject of modeling/simulation. Example: The reference system for a model of human acute inflammation is the human acute inflammatory system.

**Simulation:** A real, implemented, or instantiated model, or a situated or embedded model, or a set of actions such that, when executed, affect the environment. The use of the term *simulation* carries implications about a similarity relationship between the simulator and the simulation. There is an implication that the similarity is somewhat analytic, meaning that, if the reference system is decomposable, the simulation is decomposable, and the similarity extends down to the components. However, simulations are all abstractions, and this similarity is always incomplete.

**Virtual World:** An environment that is an informational construct and not physically manifest in the real world. The most common popular description is “cyberspace.”

## Scale-Free Networks in Cell Biology

Eivind Almaas and Albert-László Barabási

*University of Notre Dame, Indiana*

The last century brought with it unprecedented technological and scientific progress, rooted in the success of the reductionist approach. For many current scientific problems, however, it is not possible to predict the behavior of a system from an understanding of its (often identical) elementary constituents and their individual interactions. For these systems, we need to develop new methods to gain insight into their properties and dynamics. During the last few years, network approaches have shown great promise in this direction, offering new tools to analyze and understand a host of complex systems (1–4). A much studied example of the network approach concerns communication systems like the Internet and the World Wide Web, which are modeled as networks with nodes being routers (5) or web pages (6) and the links being the physical wires or URLs. The network approach also lends itself to the analysis of societies, with people as nodes and the connections between the nodes representing friendships (7), collaborations (8,9), sexual contacts (10), or coauthorship of scientific papers (11), to name a few possibilities. It seems that the more we scrutinize the world surrounding us, the more we realize that we are inextricably entangled in myriad interacting webs; to describe them we need to understand the architecture of these various networks that nature and technology offers to us.

Biological systems ranging from food webs in ecology to biochemical interactions in molecular biology can benefit greatly from being analyzed as networks. In particular, in the cell, the variety of interactions between genes, proteins, and metabolites are well captured by network representations, especially with the availability of veritable mountains of interaction data from genomics approaches. In this chapter, we discuss recent results and developments in the study and characterization of the structure and utilization of biological networks, and their relevance for the endothelium.

### CHARACTERIZING NETWORK TOPOLOGY

Many tools are available to study the structure of complex networks. Here, we discuss two methods that have received

the most attention: degree distribution and node clustering. Additionally, it is customary to investigate the *betweenness-centrality* (BC) of both nodes and links, and the network *assortativity*. The BC is related to the number of shortest paths going through either a node or a link; hence, a large BC value indicates that the node or link acts as a bridge by connecting different parts of the network. The assortativity describes the propensity of a node to be directly connected to other nodes of similar degree.

### Degree Distribution

The representation of various complex systems as networks has revealed surprising similarities, many of which are intimately tied to power laws. The simplest network measure is the average number of nearest neighbors of a node, or the average degree  $\langle k \rangle$ . However, this is a rather crude property, and to gain further insight into the topological organization of real networks, we need to determine the variation in the nearest neighbors, given by the degree distribution  $P(k)$ . For a surprisingly large number of networks, this degree distribution is best characterized by the power law functional form (12) (Fig. 189.1A),

$$P(k) \sim k^{-\alpha} \quad (\text{Equation 1})$$

Important examples include the metabolic network of 43 organisms (13), the protein interaction network of *Saccharomyces cerevisiae* (14), and various food webs (15). If the degree distribution instead was single-peaked (e.g., Poisson or Gaussian), as in Figure 189.1B, the majority of the nodes would be well described by the average degree, and we could with reason talk about a “typical” node of the network. This is very different for networks with a power-law degree distribution; the majority of the nodes only have a few neighbors, while many nodes have hundreds and some even thousands of neighbors. Although average node degree values can be calculated for these networks because their size is finite, these values are not representative of a typical node. For this reason, these networks are often referred to as “scale-free.”

Figure 189.1. Characterizing degree distributions. For the power-law degree distribution (A), there exists no typical node, whereas for single-peaked distributions (B), most nodes are well represented by the average (typical) node with degree  $\langle k \rangle$ .

### Clustering Coefficient

A measure that gives insight into the local structure of a network is the so-called *clustering of a node*: the degree to which the neighborhood of a node resembles a complete subgraph (16). For a node  $i$  with degree  $k_i$  the clustering is defined as

$$C_i = \frac{2n_i}{k_i(k_i - 1)} \quad (\text{Equation 2})$$

representing the ratio of the number of actual connections between the neighbors of node  $i$  to the number of possible connections. For a node that is part of a fully interlinked cluster  $C_i = 1$ , while  $C_i = 0$  for a node where none of its neighbors are interconnected. Accordingly, the overall clustering coefficient of a network with  $N$  nodes is given by  $\langle C \rangle = \sum C_i / N$ , quantifying a network's potential modularity. By studying the average clustering of nodes with a given degree  $k$ , information about the actual modular organization of a network can be extracted (17–20): For all metabolic networks available, the average clustering follows a power-law form as

$$C(k) \sim k^{-\delta} \quad (\text{Equation 3})$$

suggesting the existence of a hierarchy of nodes with different degrees of modularity (as measured by the clustering coefficient) overlapping in an iterative manner (17). In summary, we have seen strong evidence that biological networks are both scale-free (13,14) and hierarchical (17).

### NETWORK MODELS

As we have just seen, many biological networks are dominated by a scale-free distribution of nearest neighbors. Why is this power-law behavior so pervasive? To understand the cause of the scale-free degree distribution and the hierarchical network structure, we describe three models that serve as network paradigms. These models build on very different princi-

ples and, to varying degrees, are able to explain the observed network features.

### Random Network Model

In discussing the origin of the observed power-law behavior, we must first understand the properties of the simplest available network model. Although graph theory initially focused on regular graphs, since the 1950s, large networks with no apparent design principles were described as *random graphs* (21), proposed as the simplest and most straightforward realization of a complex network. According to this Erdos-Renyi (ER) model of random networks (22), we start with  $N$  nodes and connect every pair of nodes with probability  $p$ . This creates a graph with approximately  $pN(N - 1)/2$  randomly distributed edges (Fig. 189.2A,D; for color reproduction, see Color Plate 189.2). The distribution of nearest neighbors follows a Poisson distribution (Fig. 189.3A; for color reproduction, see Color Plate 189.3) and, consequently, the average degree  $\langle k \rangle$  of the network describes the properties of a typical node. Furthermore, for this “democratic” network model, the clustering is independent of the node degree  $k$  (Fig. 189.3D). The ER model, although simple and appealing, captures neither the properties of the degree distribution nor the clustering coefficient observed in biological networks.

### Scale-Free Network Model

In the network model of Barabási and Albert (BA), two key mechanisms, which both are absent from the classical random network model, are responsible for the emergence of a power-law degree distribution (12). First, networks grow through the addition of new nodes linking to nodes already present in the system. Second, a higher probability exists to link to a node with a large number of connections, a property called *preferential attachment*. These two principles are implemented as follows: Starting from a small core graph consisting of  $m_0$  nodes, a new node with  $m$  links is added at each time step and connected to the already existing nodes (Fig. 189.2B,E). Each of the  $m$  new links are then preferentially attached to a node  $i$  (with  $k_i$  neighbors), which is chosen according to the probability

$$\Pi_i = k_i / \sum_j k_j \quad (\text{Equation 4})$$

The simultaneous combination of these two network growth rules gives rise to the observed power-law degree distribution (Fig. 189.3B). In Figure 189.2B, we illustrate the growth process of the scale-free model by displaying a network at time  $t$  (green links) and then at time  $(t + 1)$ , when we have added a new node (red links) using the preferential attachment probability. Compared to random networks, the probability that a node is highly connected is statistically significant in scale-free networks. Consequently, many network properties are determined by a relatively small number of highly connected

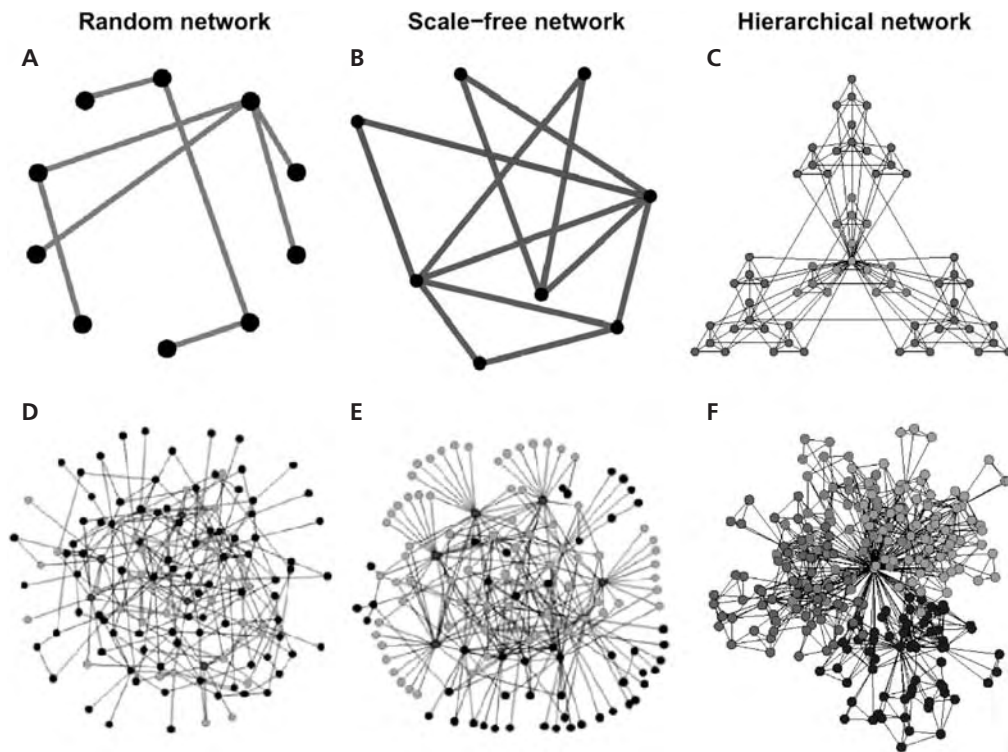

Figure 189.2. Graphical representation of three network models: (A, D) The ER (random) model; (B, E) the BA (scale-free) model; and (C, F) the hierarchical model. The random network model is constructed by starting from  $N$  nodes before the possible node-pairs are connected with probability  $p$ . Panel A shows a particular realization of the ER model with 10 nodes and connection probability  $p = 0.2$ . In panel B, we show the scale-free model at time  $t$  and at time  $(t + 1)$  when we have added a new node using the preferential attachment probability (see Equation 4). Panel C demonstrates the iterative construction of a hierarchical network, starting from a fully connected cluster of four nodes. This cluster is then copied three times while connecting the peripheral nodes of the replicas to the central node of the starting cluster. By once more repeating this replication and connection process, we end up with a 64-node scale-free hierarchical network. In panel D, we display a larger version of the random network, and it is evident that most nodes have approximately the same number of links. For the scale-free model (E), the network is clearly inhomogeneous: Although the majority of nodes have one or two links, a few nodes have a large number of links. Whereas in the random network only 27% of the nodes are reached by the five most connected nodes, we reach more than 60% of the nodes in the scale-free network, demonstrating the key role played by the hubs. Note that the networks in D and E consist of the same number of nodes and links. Panel F demonstrates that the standard clustering algorithms are not that successful in uncovering the modular structure of a scale-free hierarchical network. For color reproduction, see Color Plate 189.2.

nodes, often called *hubs*. To make the effect of the hubs on the network structure visible, we have colored the five nodes with largest degrees red in Fig. 189.2D and 189.2E and their nearest neighbors green. While in the ER network only 27% of the nodes are reached by the five most connected ones, we reach more than 60% of the nodes in the scale-free network, demonstrating the key role played by the hubs. Another consequence of the hub's dominance of the network topology is that scale-free networks are highly tolerant of random failures (perturbations) while being extremely sensitive to targeted attacks (23). Comparing the properties of the BA network model with those of the ER model, we note that the clustering of the BA network is larger; however,  $C(k)$  is approximately

constant (Fig. 189.3E), indicating the absence of a hierarchical structure.

### Hierarchical Network Model

Many real networks are expected to be fundamentally modular, meaning that the network can be seamlessly partitioned into a collection of modules in which each module performs an identifiable task, separable from the function(s) of other modules (24–27). In biology, most of these networks have a scale-free degree distribution, which initially seems at odds with the notion of modularity, given that the hubs with their many links connect to a significant fraction of nodes, making it difficult to

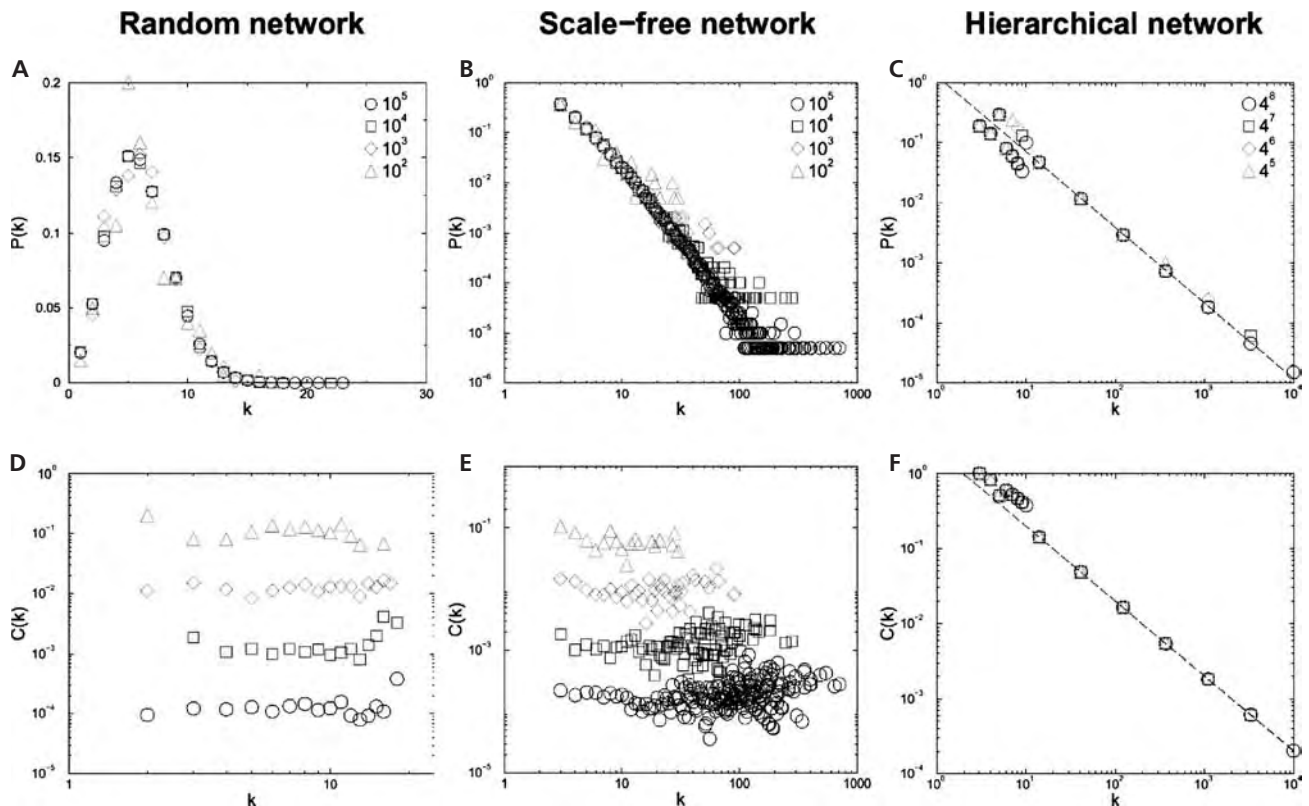

Figure 189.3. Properties of the three network models. (A) The ER model gives rise to a Poisson degree distribution  $P(k)$  (the probability that a randomly selected node has exactly  $k$  links), which is strongly peaked at the average degree  $\langle k \rangle$ . The degree distributions for the scale-free (B) and the hierarchical (C) network models do not have a peak; they instead decay according to  $P(k) \sim k^{-\gamma}$ . The average clustering coefficient for nodes with exactly  $k$  neighbors,  $C(k)$ , is independent of  $k$  for both the ER (D) and the scale-free (E) network model. (F) In contrast,  $C(k) \sim k^{-1}$  for the hierarchical network model. For color reproduction, see Color Plate 189.3.

have relatively separated modules. Therefore, we must reconcile the scale-free property with that of potential modularity. To account for the modularity as reflected in the power-law behavior of  $C(k)$  and a simultaneous scale-free degree distribution, we have to assume that clusters combine in an iterative manner, generating a hierarchical network (17,20). Such a network emerges from a repeated duplication and integration process of clustered nodes (17), which in principle can be repeated indefinitely. This process is depicted in Figure 189.2C, in which we start from a small cluster of four densely linked nodes (blue). We next generate three replicas of this hypothetical initial module (green) and connect the three external nodes of the replicated clusters to the central node of the old cluster, thus obtaining a large 16-node module. Subsequently, we again generate three replicas of this 16-node module (red), and connect the 16 peripheral nodes to the central node of the old module, obtaining a new module of 64 nodes. This hierarchical network model seamlessly integrates a scale-free topology with an inherent modular structure by generating a network that has a power-law degree distribution (Fig. 189.3C) with degree exponent  $\gamma = 1 + \ln 4 / \ln 3 \approx 2.26$  and a clustering coefficient  $C(k)$ , which proves to be dependent on  $k^{-1}$

(Fig. 189.3F). However, note that modularity does not imply clear-cut subnetworks linked in well-defined ways (17,28). In fact, the boundaries of modules are often blurred considerably (see, for example, Fig. 189.2F). Finally, note that we know examples of scale-free networks, such as the router-level Internet map or the Barabási-Albert model, that are scale-free but not hierarchical. Thus, hierarchy is an additional important property of real networks, characterizing modularity, and it is not a simple consequence of a network's scale-free nature.

## NETWORK UTILIZATION

Despite their impressive successes, purely topological approaches have important intrinsic limitations. For example, the activity of the various metabolic reactions or regulatory interactions differs widely, some being highly active under most growth conditions, whereas others are switched on only for some rare environmental circumstances. Therefore, an ultimate description of cellular networks requires us to consider the intensity (i.e., strength), the direction (when applicable), and the temporal aspects of the interactions. Although, so

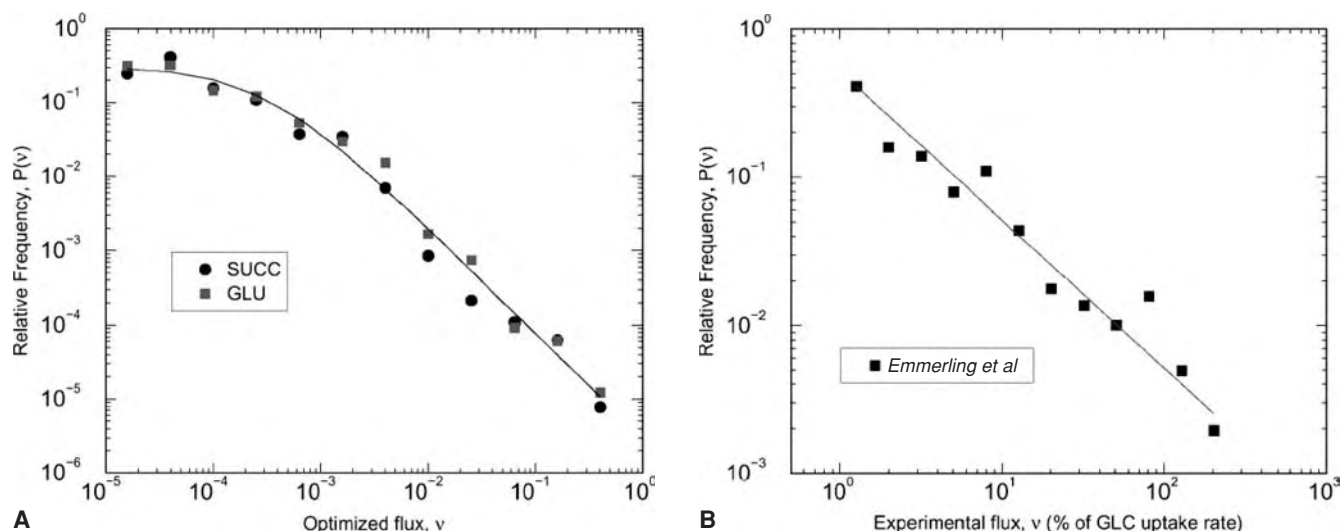

Figure 189.4. Flux distribution for the metabolism of *E. coli*. (A) Flux distribution for optimized biomass production on succinate- (black) and glutamate- (gray) rich uptake substrates. The solid line corresponds to the power law fit  $P(v) \sim (v + v_0)^{-\alpha}$  with  $v_0 = 0.0003$  and  $\alpha = 1.5$ . (B) The distribution of experimentally determined fluxes (36) from the central metabolism of *E. coli* also displays power-law behavior with a best fit to  $P(v) \sim v^{-\alpha}$  with  $\alpha = 1$ .

far, we know little about the temporal aspects of the various cellular interactions, recent results have shed light on how the strength of the interactions is organized in metabolic and genetic-regulatory networks (29–31) and how the local network structure is correlated with these link strengths.

### Flux Utilization

In metabolic networks, the flux of a given metabolic reaction, representing the amount of substrate being converted to a product within unit time, offers the best measure of interaction strength. Recent advances in metabolic flux-balance approaches (FBA) (32–35) allow us to calculate the flux for each reaction, and they have significantly improved our ability to generate quantitative predictions on the relative importance of the various reactions, thus leading to experimentally testable hypotheses. The FBA approaches can be described as follows: Starting from a stoichiometric matrix model of an organism, for example, one for *Escherichia coli* containing 537 metabolites and 739 reactions (32–34), the steady-state concentrations of all metabolites must satisfy

$$\frac{d}{dt}[A_i] = \sum_j S_{ij}v_j = 0 \quad (\text{Equation 5})$$

where  $S_{ij}$  is the stoichiometric coefficient of metabolite  $A_i$  in reaction  $j$ , and  $v_j$  is the flux of reaction  $j$ . We use the convention that if metabolite  $A_i$  is a substrate (product) in reaction  $j$ ,  $S_{ij} < 0$  ( $S_{ij} > 0$ ), and we constrain all fluxes to be positive by dividing each reversible reaction into two “forward” reactions with positive fluxes. Any vector of positive fluxes  $\{v_j\}$  that satisfies Equation 5 corresponds to a state of the metabolic network, and hence, a potential state of operation of the cell.

Assuming that the cellular metabolism is in a steady state and optimized for the maximal growth rate (33,34), FBA allows us to calculate the flux for each reaction using linear optimization, providing a measure of each reaction’s relative activity (29). A striking feature of the resulting flux distribution from such modeling of *Helicobacter pylori*, *E. coli*, and *S. cerevisiae* is its overall inhomogeneity: Reactions with fluxes spanning several orders of magnitude coexist under the same conditions (Fig. 189.4A). This is captured by the flux distribution for *E. coli*, which follows a power law in which the probability that a reaction has flux  $v$  is given by  $P(v) \sim (v + v_0)^{-\alpha}$ . This flux exponent is predicted to be  $\alpha = 1.5$  by FBA methods (29). In a recent experiment (36), the strength of the various fluxes of the *E. coli* central metabolism was measured, revealing (29) the power-law flux dependence  $P(v) \sim v^{-\alpha}$  with  $\alpha \cong 1$  (Fig. 189.4B). This power-law behavior indicates that the vast majority of reactions have quite small fluxes, while coexisting with a few reactions with extremely large flux values.

The observed flux distribution is compatible with two quite different potential local flux structures (29). A homogeneous local organization would imply that all reactions producing (consuming) a given metabolite have comparable fluxes. On the other hand, a more delocalized “hot backbone” is expected if the local flux organization is heterogeneous, such that each metabolite has a dominant source (consuming) reaction. To distinguish between these two scenarios for each metabolite  $i$  produced (consumed) by  $k$  reactions, we define the measure (37,38)

$$Y(k, i) = \sum_{j=1}^k \left( \frac{\hat{v}_{ij}}{\sum_{l=1}^k \hat{v}_{il}} \right)^2 \quad (\text{Equation 6})$$

where  $\hat{v}_{ij}$  is the mass carried by reaction  $j$ , which produces (consumes) metabolite  $i$ . If all reactions producing (consuming) metabolite  $i$  have comparable  $\hat{v}_{ij}$  values,  $Y(k, i)$  scales as  $1/k$ . If, however, a single reaction's activity dominates Equation 6, we expect  $Y(k, i) \sim 1$ ; that is,  $Y(k, i)$  is independent of  $k$ . For the *E. coli* metabolism optimized for succinate and glucose uptake, we find that both the *in* and *out* degrees follow the power law  $Y(k, i) \sim k^{-0.27}$ , representing an intermediate behavior between the two extreme cases (29). This suggests that the large-scale inhomogeneity observed in the overall flux distribution is increasingly valid at the level of the individual metabolites as well: For most metabolites, a single reaction carries the majority of the flux. Hence, the majority of the metabolic flux is carried along linear pathways instead of branching pathways. We call the set of such linear pathways the metabolic high flux backbone (HFB) (29).

### Gene Interactions

One can also investigate the strength of the various genetic regulatory interactions provided by microarray data sets. Assigning each pair of genes a correlation coefficient that captures the degree to which they are coexpressed, one finds that the distribution of these pair-wise correlation coefficients follows a power law (30,31). That is, while the majority of gene pairs have only weak correlations, a few gene pairs display a significant correlation coefficient. These highly correlated pairs likely correspond to direct regulatory and protein interactions. This hypothesis is supported by the finding that the correlations are larger along the links of the protein interaction network and between proteins occurring in the same complex, than they are for pairs of proteins that are not known to interact directly (39–42).

Taken together, these results indicate that the biochemical activity in both the metabolic and genetic networks is dominated by several “hot links” that represent a few high-activity interactions embedded into a web of less active interactions. This attribute does not seem to be a unique feature of biological systems: Hot links appear in a wide range of nonbiological networks in which the activity of the links follows a wide distribution (43,44). The origin of this seemingly universal property is, again, likely rooted in the network topology. Indeed, it seems that the metabolic fluxes and the weights of the links in some nonbiological system (43,44) are uniquely determined by the scale-free nature of the network. A more general principle that could explain the correlation distribution data is currently lacking.

### CONCLUSION

Power laws are abundant in nature, affecting both the construction and utilization of real networks. The power-law degree distribution has become the trademark of scale-free networks and can be explained by invoking the principles of network growth and preferential attachment. However, many

biological networks are inherently modular, a fact which at first seems to be at odds with the properties of scale-free networks. However, these two concepts can coexist in hierarchical scale-free networks. In the utilization of complex networks, most links represent disparate connection strengths or transportation thresholds. For the metabolic network of *E. coli*, we can implement a flux-balance approach and calculate the distribution of link weights (fluxes), which (reflecting the scale-free network topology) displays a robust power law, independent of exocellular perturbations. Furthermore, this global inhomogeneity in link strengths is also present at the local level, resulting in a connected “hot-spot” backbone of the metabolism. Similar features also are observed in the strength of various genetic regulatory interactions.

The endothelium, consisting of cells interacting through a network with a highly complex topology, readily lends itself to a network description on multiple levels. On the level of the individual cell, the utilization and structure of the regulatory and metabolic networks is dynamically adjusting to changes in the local environment. These networks represent the topic of this chapter. Yet, the cells do not exist in isolation, but constantly integrate cellular signals from their neighborhoods to produce coherent responses at the level of multiple cells, thus creating intercellular communication networks. At this point, much less is known about the structure of these networks. We can continue this network description all the way up to the organism level. Because the endothelium is part of a fractal-like vascular architecture, we must take into account the constraints imposed by this physical layout and develop new models that properly incorporate the three-dimensional embedding. To develop realistic network models of the endothelium, it is necessary to further develop our understanding of how different networks dynamically interact and integrate information. Despite the significant advances witnessed during the last few years, network biology is still in its infancy, with future advances most notably expected from the development of theoretical tools, development of new interactive databases, and increased insights into the interplay between biological function and topology.

### KEY POINTS

- Important insights into the structure and function of complex systems can be gained by using a network description.
- The degree distribution of many biological networks, most notably the protein interactions and metabolism, is scale-free.
- The structure of biological networks strongly influences how they are being used: The metabolic fluxes follow a power law, and the mass predominantly flows along linear pathways.

## Cell Fates as Attractors

### Stability and Flexibility of Cellular Phenotypes

---

Sui Huang

*Children's Hospital, Harvard Medical School, Boston, Massachusetts*

The vascular endothelial cell (EC) is one of perhaps thousands of “cell types” in the body of higher vertebrates for which a definition as a distinct type is fairly straightforward. A vascular EC is naturally defined by its distinct anatomical and physiological attributes as the cell lining the blood vessels and in contact with circulating blood. In general, we do not yet have a handle for a precise, systematic, and comprehensive taxonomy for all the cell types in the body. Nevertheless, in molecular terms, it appears that a cell type can be characterized by its distinct transcriptome and proteome – that is, by a genome-scale combinatorial code of the expression status of tens of thousands of genes, akin to a very long bar code. Currently, DNA microarray-based gene expression profiling at the level of mRNA abundance and subsequent cluster analysis of the high-dimensional set of molecular attributes reveal highly robust expression profiles that can readily be grouped into similarity “clusters” that correspond to the individual tissues or cell types as defined by physiology and histology (1,2).

Morphologically and at the molecular level, the EC cell type consists of an entire class of distinct subtypes defined by their location in the hierarchy of the vasculature (arteries, arterioles, capillaries, venules, and veins) as well as by tissue bed (e.g., brain versus dermal capillary ECs). In addition to this apparently static variation that is manifest as the stable subtypes, gene expression patterns in an EC also vary with the dynamics of functional states, such as the switching from a quiescent to “activated” state during inflammation, or to the proliferating and migrating state during angiogenesis. Importantly, the heterogeneity of the EC phenotype also is reflected in characteristic similarity clusters of gene expression profiles, suggesting the existence of distinct subtypes that represent phenotypic entities (3–5).

Of the 25,000 or so genes in the human genome, perhaps 10,000 are expressed in a given cell type. Only a fraction of them are unique – that is, specific for a given cell type. In the case of ECs, roughly 100 to 400 genes can be called “EC-specific” based on expression at the mRNA level (5). (These numbers are to be taken *cum grano salis*, since they depend

on measurement sensitivity and threshold definition.) The subtype identity is in part reflected in the relative expression of these EC specific genes – but also in the expression patterns of nonendothelial genes (4,5). Despite the considerable overlap of gene expression profiles *between* and the spatiotemporal heterogeneity *within* one cell type, each phenotypically identifiable cell type nevertheless forms a recognizable cluster of similarity with respect to the high-dimensional set of variables provided by gene expression profiles (1,2). Hence, the heterogeneity of gene expression within a cell type is due to variability at a hierarchically finer scale, so that one could postulate a taxonomical hierarchy that extends over multiple ontological levels.

How can we describe this intra-cell type heterogeneity within the framework of stable cell types? The static variability of a cellular phenotype may correspond to the “nature” aspect of a cell phenotype, to use the terminology proposed by William Aird (6), and to its associated gene expression profile, since it is “epigenetically fixed.” In contrast, the dynamic variability may reflect the “nurture” aspect, since changes in the microenvironment in part account for additional variation in the transcriptome. However, it is important to note that this terminological distinction is not a black-and-white scheme, but depends on the height of the “epigenetic barriers”: To what extent can an epigenetically fixed phenotype change? The most extreme case of “jumping” epigenetic barriers is the rare event of transdifferentiation between quite unrelated types, best epitomized in the epithelial–mesenchymal transition under highly specific conditions.

This question leads us back to the more fundamental question: What is a cell type? Because it is ultimately defined by a particular, characteristic gene expression profile, and because (virtually) all cells in the body harbor the same set of genes, why then don't we see a continuum of gene expression profiles in the vast “universe” of all combinatorially possible expression profiles, much as a bar code can encode any item of a given inventory? In other words, why can cells not smoothly “morph” into any phenotype by gradually changing

the expression of individual genes so as to match any desired expression pattern? Instead, we find discrete groups of cell types that form clearly separable entities. Shifts of expression profiles do in fact happen – but mostly within some epigenetic barriers that ensure that the cell maintains its type identity. This confined variability of gene expression profiles produces the *within* cell type–heterogeneity. Concretely, despite the heterogeneity of ECs reflected in the variations of gene expression profiles caused by environmental influences (“nurture”), the EC’s very “nature” is usually not challenged by these external perturbations: An EC remains recognizable as such under a wide variety of conditions, including cell culture.

Thus, an operationally appropriate question is: What is the very nature of the “epigenetic barriers” that separate the combinatorially possible expression profiles into classes of distinct, discrete, and robust cell phenotypes, and hence, define the “nature” as opposed to “nurture” in controlling the gene expression patterns? The purpose of this chapter is to help formalize this question in more precise terms by presenting a conceptual framework in which cell types represent “attractors” that can be imagined as valleys in the landscape of all possible gene expression profiles. Specifically, we will discuss concepts derived from system dynamics that explain how the gene regulatory network imposes constraints on the dynamics of gene expression profiles as a whole, so as to govern whole-cell behavior and produce the stable, yet flexible molecular definitions of cell types. But first, in the next section, we will discuss three philosophical problems of biological explanation that rely on the conventional paradigm of molecular pathways.

## CELL FATE DYNAMICS AND THE PROBLEM OF MOLECULAR EXPLANATION

### Molecular Chains of Causality: Who Controls the Controller?

Over the past decades, the focus on individual molecular pathways as a scheme to explain a particular cellular process has shifted the attention away from the actual system-level dynamics of cell-fate regulation. At this level of whole-cell behavior, a given cell in the body is limited to occupy a finite and relatively small number of accessible cell fates, such as proliferation, apoptosis, senescence, quiescence, or differentiation into a particular cell type (Figure 190.1A). The latter, of course, is the cell-fate decision faced by multipotential progenitor or stem cells. The embryologist Conrad H. Waddington recognized this particular dynamic in the 1940s, and proposed the “epigenetic landscape” (Figure 190.1B) as an intuitive metaphor to explain the natural discreteness of cell phenotypes, the switch-like fate transitions and the instability of “intermediate types” (for other modern metaphors of the endothelium, see Chapters 24–26). In this metaphor, the valleys represent stable cell fates. A prosaic manifestation of discreteness that is often taken for granted is the ease with which we detect distinct subpopulations of cells when monitoring the expression of a cell-fate marker, for example, a protein  $X$ , in a cell population using flow

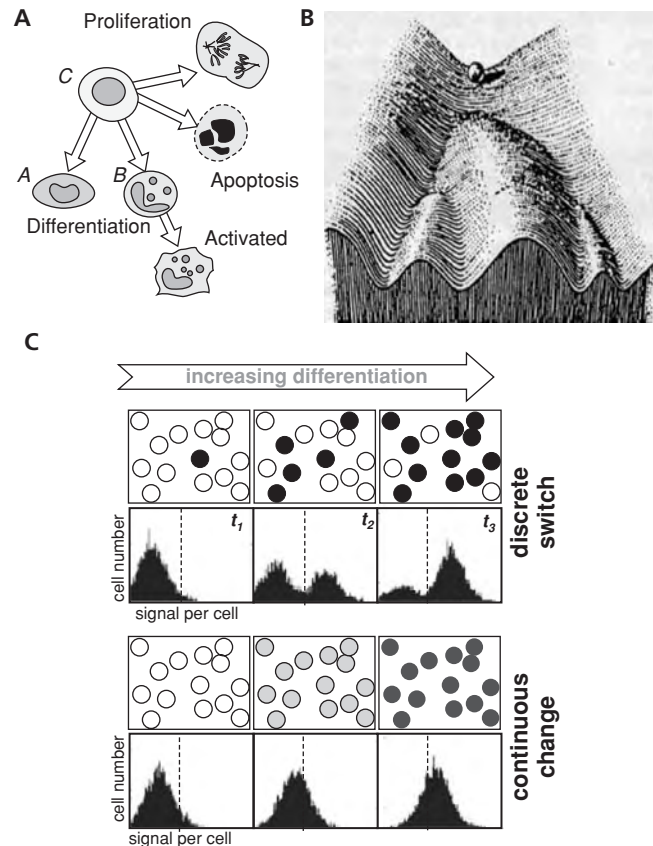

Figure 190.1. Dynamics of cell fate behavior. (A) Schematic example of cell-fate options and transitions available to a cell. Note the “discreteness” of alternative fates. (B) Waddington’s “epigenetic landscape,” a metaphor proposed to capture the discreteness of cell-fate regulation. (Reprinted with permission from Waddington CF. *The Strategy of Genes*. New York: Allen & Unwin, 1957.) (C) Schematic illustration for two fundamentally different ways of how a cell population apparently gradually increases the expression of a differentiation marker over time: discrete switching or gradual expression at single cell level. Circles represent cells, color of cell represent expression level of the differentiation marker. Computer-simulated flow cytometry histograms are shown. Note the bimodal distribution in the case of discrete switching – this is more frequently observed.

cytometry (Figure 190.1C). As cells differentiate, a *bimodal* distribution of expression of the differentiation marker  $X$  indicates that a differentiating cell population consists of two distinct subpopulations,  $X^{low}$  and  $X^{high}$  cells, representing undifferentiated and differentiated cells. The general experience of monitoring differentiation markers in flow cytometry is that individual cells “jump” from one subpopulation to another when cells differentiate, as manifested by the shift in the size of the two subpopulations or peaks in the bimodal distribution of the flow cytometry histogram (Figure 190.1C). The alternative mode of change would be a gradual increase of expression level of  $X$ , which would be presented as a shift of one single (*unimodal*) population from one position to another (bottom of Figure 190.1C). However, such gradual change is almost never observed. (Note that biochemical methods for measuring the

expression of  $X$ , such as immunoblots, measure population averages, and will suggest a gradual response due to noise). Later in this chapter we will explain the discrete behavior of cell-fate switching based on the dynamics of gene networks.

Decades of a pathway-centered view in molecular biology have produced a particular scheme of explanation, which is based on cascades of molecular events and to which we have become so habituated that it remains unquestioned. Thus, a liver cell-specific gene is thought to be expressed in the liver because it is regulated by organ-specific transcription factors that are present in the liver, such as hepatocyte nuclear factors (HNFs) (7). Such “master genes” control the expression of genes that are considered to be part of the liver-specific “genetic program.” But who controls the controller? Why are the HNFs expressed in the liver? Obviously, because of another transcription factor acting further upstream of it. This scheme of so-called *proximal explanation* only shifts the true *causa rerum* out of sight, out of mind. Well-studied examples of such “key regulators” include MyoD for muscle cells, peroxisome proliferator-activated receptor (PPAR) $\gamma$  for adipocytes, GATA-1 for the erythroid cells, or PU.1 for myeloid cells. These gene products appear to play a role both in the actual dynamics of cell-fate switching as well as in controlling the activation of downstream effector genes that execute the functions of the differentiated state, for example, hemoglobin gene expression driven by the transcription factor GATA-1. In the case of ECs, no such master gene has been unambiguously identified to date. Perhaps the difficulty in identifying specific master control switches in certain cell types is due to “distributed control” of gene expression, in that a network of multiple genes jointly control a particular gene expression pattern, as will be discussed below using a two-gene network.

A similarly unsatisfactory explanation is that the stability of gene expression programs associated with a cell type – the “memory” of lineage identity – is maintained by covalent chromatin modification, such as acetylation or methylation of histones and by direct methylation of DNA (7–9). These modifications regulate chromatin remodeling and hence accessibility of genomic DNA for the transcriptional machinery, thus controlling gene expression. Although the general notion is that these covalent modifications, commonly referred to by molecular biologists as *epigenetic mechanisms*, are capable of maintaining cell type-specific gene expression programs, this explanation does not stand rigorous epistemological scrutiny: There is nothing particularly enduring about covalent bonds in biology because they are subjected to both enzymatic formation and breakage, which makes the thermodynamic stability of covalent bonds irrelevant. Indeed, the histone-modifying enzymes are part of a highly dynamic system consisting of a sophisticated balance between reactions in both directions: histone acetyltransferases versus deacetylases, or methyltransferases versus dimethylases, and so on (10). Moreover, these enzymes act in tight association with the locus-specific transcription factors to control differentiation (11,12). So, if all is dynamic, where does the stability of cell type-specific programs of gene expression come from? To theoretical biologists,

the term *epigenetic* has a much broader meaning than merely covalent modification of chromatin or DNA: It encompasses all the dynamic principles that can store information based on gene interactions, as we will see in the next section.

Taken together, what is needed is a closed loop, self-consistent explanation that involves the genome-wide, complex networks of genes that regulate each other. Such an integrating concept should help us understand the governing principles underlying the global dynamics of gene expression profiles and would explain why cells get “stuck” in stable profiles that define the phenotypic cell types.

### How Do Signal Transduction Pathways Coordinate Global Expression Changes?

A second problem of explanation is that our knowledge of the very fundamental organizing principles that govern the transition between cell fates, such as a switch from a proliferative state (e.g., progenitor cell) to the terminally differentiated state, is fairly limited. The current pathway-centered approach focuses on specific factors as inputs that trigger such transitions. These inputs may be such agents as growth factors or cytokines, which bind to their cognate cellular receptors and elicit signaling cascades that end in the nucleus to regulate the expression of genes to implement the output. Although this explanatory scheme has promoted the elucidation of many useful mechanistic details of signal transduction cascades, it faces multiple challenges when placed in the broader context of complex molecular networks: It does not explain how cells seamlessly compute all the pleiotropic changes triggered by the fanning-out signaling cascades, yet still maintain signal specificity that allows the cell to switch to a new cell fate by inducing the concerted changes in the activity of thousands of genes, precisely so as to produce the new gene expression profile associated with the new fate. In other words – to use the metaphor discussed in Chapter 24 – we still don’t know how the input is mapped to the output of coherent cell behavior.

The challenge is even greater if we consider the larger picture of cell-fate dynamics: Despite the astronomical number of theoretically possible gene activation configurations in the universe of expression profiles, cells are able to robustly integrate multiple simultaneous, noisy, and often conflicting signals to which they are exposed and which affect scores of genes across the genome. Their response is then the unambiguous adoption of one of just a few alternative cell fates. As a consequence of this limited number of fate choices, the very same cell fate can be triggered by a broad variety of unrelated, often noisy signals, including those lacking molecular specificity, such as mechanical forces, as discussed later (13,14). Conversely, the very same signal can induce different, even opposite cell fates (such as proliferation versus apoptosis), depending on the biochemical or physical state of the cell (15). The mapping of an input to a coherent, whole-cell behavior as the output will require the coordination of thousands of parallel molecular events, in a kind of “distributed information processing.” This

processing is not easily accommodated by the traditional picture of individual signaling pathways, which are thought to embody a point-to-point chain of causation.

The distributed cellular information processing is well illustrated in the finding that in ECs (and probably other cells) the shape of the cell, a physical signal devoid of molecular specificity, acts as a particular input. Specifically, the state of cell spreading is a critical regulator of cell fates, in addition to the classical inputs, such as soluble growth factors and the extracellular matrix (ECM) (16). It makes sense that cell spreading is a necessary condition for entry into the cell division cycle: During angiogenesis, a cell at the sprouting tip of capillaries spreads on newly formed ECM. This cell shape change, which occurs only in cells that can extend to the new matrix, stimulates cell proliferation, whereas immediately adjacent cells in the densely packed monolayer of the vessel wall will remain quiescent despite receiving the same inputs in terms of soluble angiogenic factors. On the other hand, if a cell is spatially compressed to a small area, then, despite the presence of growth factors, it will undergo apoptosis (16,17). This regulatory mechanism that permits an individual cell to survive and divide only if it can stretch out implements an organizing principle that is known from automaton models: The behavior of a single cell as an “agent” is determined only by its local neighborhood and some rules. But when implemented by every cell of a population, a collective behavior arises, such as tissue homeostasis, which, in this case, is the maintenance of an intact endothelial layer.

Molecularly, it is assumed that, during cell spreading, the distortion of the actin cytoskeleton, which forms a mechanically continuous, force-bearing system between cell and ECM through focal adhesions, will cause rearrangements in these adhesions. Because the latter provide the scaffold for orienting arrays of signaling complexes, they could simultaneously modulate the signal transduction of multiple pathways. Again, somehow, the distributed signals are coordinated such as to produce a coherent, mitogenic stimulus to the cell. In other words, the complex apparatus of cell-fate regulation has evolved to harness the forces exerted by a physical input that lacks molecular specificity and to use it as a signal for switching between cell fates. The concept of attractors (presented later in this chapter) provides an explanation for how distributed signals are spontaneously channeled through a complex molecular machinery to produce a specific cell-fate program.

### The Numerical Problem: A Huge Universe of Expression Profiles

The third problem of explanation is more abstract and fundamental. To demonstrate and understand elementary principles, it is often necessary to make (temporarily) simplifying assumptions. Hence, let us assume here that each of the biologically observable “macroscopic” cell fates is characterized by a distinct profile of gene expression, and that each gene locus has a “micro-state” that can either be active – that is, the gene

is expressed (status ON = 1) or silenced (status OFF = 0). Also, let us for now assume a genome consisting of only of  $N = 2$  genes, labeled  $X$  and  $Y$ . Hence, we would have  $2^2 = 4$  gene activation configurations, or “macro-states”  $S = (X, Y)$ , each defined by the combination of micro-states of  $X$  and  $Y$ : (0,0), (1,0), (0,1), and (1,1). All four gene expression profile  $S = (X, Y)$  could be mapped as one point into a two-dimensional (2D) *state space*, spanned by the axes  $X$  and  $Y$ . The state space hence represents the aforementioned “universe” of all thinkable states of the cell as defined by gene expression profiles. In this case, it contains only four states or gene expression profiles. In reality, the human genome has  $N = 25,000$  genes, according to the last count (18). Hence, assuming again ON–OFF genes, we would have  $2^{25000} = 10^{7520}$  possible genome-wide configurations of gene activation (macro-states) in a state space that now has  $N$  dimensions – one axis for each gene. Despite our simplification, which omits gradual activation levels, post-transcriptional, post-translational modifications, and the like, the number of  $10^{7520}$  possible gene expression profiles is hyperastronomic: There are approximately  $10^{80}$  protons in the universe, and there are approximately  $10^{17}$  cells in our body. Assuming that each expression profile encodes a particular phenotypic cell fate, we would have an almost endless, quasicontinuous universe of cell phenotypes if all these gene activation configurations would be realizable. As discussed in the introduction, the cell could move in the  $N$  dimensional state space and *gradually* morph from one phenotype to another. Many cell types would be very similar to each other; for example, two expression profiles that differ by only the gene expression micro-state of one of  $N$  genes. The biological reality is that we have *discrete* cell phenotypes, with almost discontinuous switches between them (Figure 190.1B–C). In other words, most of the state space of expression profiles goes unused.

The obvious explanation is that not all combinatorial gene activation configurations of the genome are logically possible because of gene regulatory interactions: Genes do not change their activation status independently. Take the above two-gene example: If gene  $X$  inhibits gene  $Y$ , then the state  $(X, Y) = (1, 1)$  would not be “logically” allowed. It is physically unstable and will transition into the state  $(X, Y) = (1, 0)$  that complies with the regulatory interactions. The cell is said to “move” in state space along a *trajectory* from state (1,1) to state (1,0). This is still a hand-waving explanation, but a step toward a formal concept: A network of gene regulatory interactions enforces some dynamics upon the global gene expression profile, so that the cell (gene network) cannot occupy any point in the state space, but rather is forced to move along trajectories to resolve the conflicts arising from the regulatory interactions.

In this section we have discussed three problems that challenge current molecular biology thinking. In the next section we will show, using a two-gene circuitry, that abstraction and conceptualization are helpful and could explain in a more formal way how one system can produce multiple, in this case two or three, stable network states that correspond to discrete cell fates.

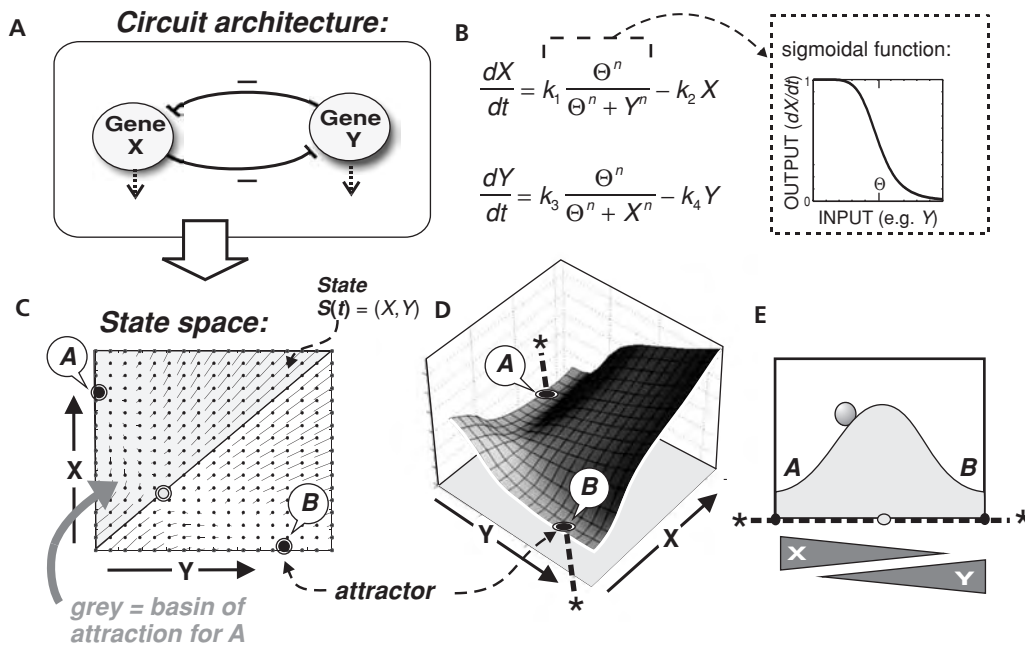

Figure 190.2. Bistability in two-gene circuit of mutual inhibition. (A) The circuit architecture of two-gene circuit as a didactical example, with mutual inhibition of the two genes/proteins, X and Y; both are also subjected to first-order inactivation (dashed arrow). (B) Set of ordinary differential equations for the activity level of the variables X and Y. *Inset:* Inverse sigmoidal curve illustrating the “INPUT–OUTPUT” relationship, as expressed in the first term of the equation, determining how the input Y affects the output  $dX/dt$ . The higher the activity Y, the smaller is the synthesis rate of X,  $dX/dt$ . (C) Two-dimensional state space (phase plane) for X, Y. Each point in the XY plane is a state  $S(t) = [X(t), Y(t)]$ . The “ticks” emanating from each dot (representing initial states) illustrate a fragment of the trajectory that the respective state would travel during  $\Delta t$ , collectively giving rise to a “vector field.” The two large black dots, A and B, are the attractor states. The gray dot represents an unstable stationary state. The *basin of attraction* for attractor state A is shown as the gray triangular region of the phase plane. (D) Schematic representation of the state space as a landscape. The vertical axes represent some “potential function” reflecting the “flow” in the vector field (see text for details). (E) Another schematic view of the state space, projected as a simple “hill” corresponding to the cross-section of the state space in D through the dashed line. The horizontal axis reflects the relative activity of X and Y.

## MULTISTABILITY AND ATTRACTORS IN GENE REGULATORY NETWORKS

### A Two-Gene Circuit as Toy Example

The goal of this section is to explain how a simple system can capture the essential macroscopic dynamics of cell-fate transitions; specifically, how a progenitor cell C can differentiate into either one of two distinct cell types, A and B. This behavior captures the general features of cell-fate dynamics with discrete, mutually exclusive fate decisions and all-or-none transitions between these discrete cell phenotypes. Figure 190.2A shows a circuitry consisting of two genes, X and Y, a mini-network so to speak. The circuitry consists of the following interactions: The two genes inhibit each other’s basal activity (e.g., gene expression or protein synthesis). Moreover, each gene spontaneously loses activity (e.g., due to decay of the protein). Unlike the example discussed earlier, the genes now can continuously change their values of activation (e.g., expression level) over time  $t$ . We define again the *state variables*

$X(t)$  and  $Y(t)$ . Then, as used earlier, the dynamics of the system can be mathematically described by the *state vector*  $S(t)$ , which defines a position in the *state space* spanned by the two axes X and Y for each time point:  $S(t) = [X(t), Y(t)]$ , and hence represents a *system state* S at time  $t$ . To mathematically describe the continuous movement of S in this state space driven by the gene regulatory interactions, one describes the *change* of X and Y over time; that is, the rates  $dX/dt$  and  $dY/dt$ . The *differential*  $dX$  is the infinitesimally small difference in X by which X changes in the infinitesimally small time window  $dt$ .

Mathematical modeling here is all about how to describe the rate of changes in the state variables X and Y – that is,  $dX/dt$  and  $dY/dt$  – by an expressions that involves  $X(t)$  and  $Y(t)$  themselves, since obviously, their values influence the changes as laid out in the circuit diagram. The resulting system equations of our two-gene system represent a set of so-called *nonlinear differentiation equations*, as shown in Figure 190.2B. Such modeling, based on differential equations describing the continuous changes of variables, is discussed in detail in

Chapter 191. The goal of solving these differential equations is to find out the behavior of  $S$  in the state space – how  $X(t)$  and  $Y(t)$  change over time, since  $S(t) = [X(t), Y(t)]$ , and to evaluate the long-term behavior.

So, how can we model the regulatory influence exerted by the current level of gene expression,  $X(t)$  or  $Y(t)$ , on the rates  $dY/dt$  or  $dX/dt$ , respectively? An essential point in establishing the differential equations for such gene regulatory systems is to model the regulatory influences as a sigmoidal input/output (stimulus/response) relationship (see inset in Figure 190.2B, right), which for example, can be written as:  $dX/dt = 1/(\Theta^n + Y^n)$  for the influence of  $Y$  on the change of  $X$ . This equation captures the inverse sigmoidal relationship, in that increasing levels of  $Y$  (the input) would decrease the activation rate of  $X$ ,  $dX/dt$  (the output).  $\Theta$  and  $n$  are constants –  $\Theta$  represents the threshold  $Y$  value in the sigmoidal curve, and  $n$  its steepness (Hill coefficient). Such sigmoidal “transfer functions” reflect *sensitivity amplification* (19), which is warranted, even in the absence of cooperativity (the best known cause of such sigmoidality), on grounds of the particular physicochemical conditions of the intracellular milieu that departs from that of ideal, well-stirred macroscopic solutions (20–22). The sigmoidality of this regulatory influence introduces the “non-linearity” aspect and is crucial for the generation of discrete behavior.

For the spontaneous decay term, each gene (or its encoded protein) is modeled as being subjected to a *first-order* inactivation (degradation), in that the inactivation rate is proportional (linear) to the current amount of  $X(t)$  or  $Y(t)$ , respectively, that is present. Thus, the term  $-kX$  in the equation describes the inactivation of  $X$  at a rate proportional to the level of  $X(t)$ .

The circuit architecture of the type shown in Figure 190.2A with mutual, nonlinear regulation, either reciprocal inhibition or activation, is in fact very common among transcription factors critically involved in cell-fate decisions (23–28). In ECs, Id and Egr-1 appear to form such a feedback loop of mutual activation (29). We now discuss the solution of the equations – the dynamic behavior of this system,  $S(t) = [X(t), Y(t)]$  – without going into the detailed mathematics.

### The Dynamic Behavior: Multistability and Attractors

In our example, the two genes,  $X$  and  $Y$ , inhibit each other (Figure 190.2A). Thus, with the experience of our ON–OFF system discussed earlier, one would intuitively expect two possible stable *steady-states*, in which either  $X$  dominates (state  $A$  with  $X \gg Y$ ) or  $Y$  dominates (state  $B$ , with  $Y \gg X$ ). Because of the interaction in our example, not every state  $S$ , defined by a pair of values for  $X$  and  $Y$ ,  $S = (X, Y)$ , is stationary and stable: Due to mutual (symmetrical) inhibition, if there is just slightly more  $Y$  than  $X$ , then  $Y$  would suppress  $X$  (more than  $X$  suppresses  $Y$ ) and  $Y$  will increase until it reaches an equilibrium with its own decay that scales with the higher values of  $Y$  because of the first-order kinetics of decay.  $X$  similarly would decrease to an equilibrium between its activation and deactivation rate. Mathematically, to find the steady states of

the system – the states in which  $X$  and  $Y$  do not change – one sets  $dX/dt = \text{rate of change} = 0$  and  $dY/dt = 0$  and solves the equations algebraically for  $X$  and  $Y$ . Doing so will find three *stationary* states,  $A = (X_A, Y_A)$ ,  $B = (X_B, Y_B)$ , and  $C = (X_C, Y_C)$ .

The stationary states  $A$ ,  $B$ , and  $C$  are shown as circles in the 2D state space spanned by  $X$  and  $Y$  in Figure 190.2C, which represents the 2D state space, or *XY-phase plane*, in which each point represent a state  $S(t) = [X(t), Y(t)]$ . We can now pick any state  $S$  around the steady-states and, using the differential equations, calculate how these arbitrary states will “move” by a small step  $\Delta X$  and  $\Delta Y$  in both state space dimensions during a short time period  $\Delta t$  along a trajectory. This movement of  $S$  is driven by the interactions of the circuitry captured in the differential equations. Similar to a night photograph snapshot of cars moving on a road, in which the traces of the headlights represent the motion of cars during the exposure time  $\Delta t$ , we can draw trajectory fragments in the state space for various points  $S$  to obtain a “vector field” indicating where the states would move in  $\Delta t$ . As shown in Figure 190.2C, we see that the two points  $A$  and  $B$  in fact “attract” trajectories from starting points in a certain region in their neighborhood, confirming that these steady states are stable. Stability of a state thus means that, upon small perturbations that displace that state to a spot within its neighborhood in state space, the displaced state will fall back to that original state. In our case, the system has two stable states,  $A$  and  $B$ , and is said to exhibit *bistability* or, in general terms, *multistability*. In contrast, the steady state  $C$  is not stable: It is a “mountain pass” between  $A$  and  $B$  that attracts some trajectories along one direction (diagonal), but repels them toward the “valleys”  $A$  or  $B$  along the other direction. Thus, the two states  $A = (X_A, Y_A)$  and  $B = (X_B, Y_B)$  are the “attractors” of the system. The region in the state-space neighborhood around the attractor  $A$  in which all the starting states  $S(t = 0)$  (so-called *initial states*) would “flow” to the attractor  $A$  represents the *basin of attraction* of attractor  $A$  (gray zone in the state space in Figure 190.2C).

The concepts of attractors and basins of attraction are fundamental ideas in the field of system dynamics and are central to the understanding of the robustness of cell-fate regulation. The vector field in Figure 190.2C suggests some natural movement like that of a marble rolling down to the attractors; hence, it can be regarded as a topographic *landscape*, as shown in Figure 190.2D. The tendency with which a given state  $S(t)$  moves to the attractor states is captured in the vertical dimension to emphasize the *potential character* of the attractors. (This is not a true potential because the functions on the right-hand side of the equations in Figure 190.2B are nonintegrable.) Figure 190.2E is a simplified, schematic cross-section of the state space along the dashed line through the attractor states  $A$  and  $B$ . In this intuitive picture, the valleys represent the attractors, separated by a hill, which can be viewed as the epigenetic barrier that we alluded to at the beginning of the chapter. This attractor landscape may be what Waddington had in mind in the 1940s, when he proposed the “epigenetic landscape”

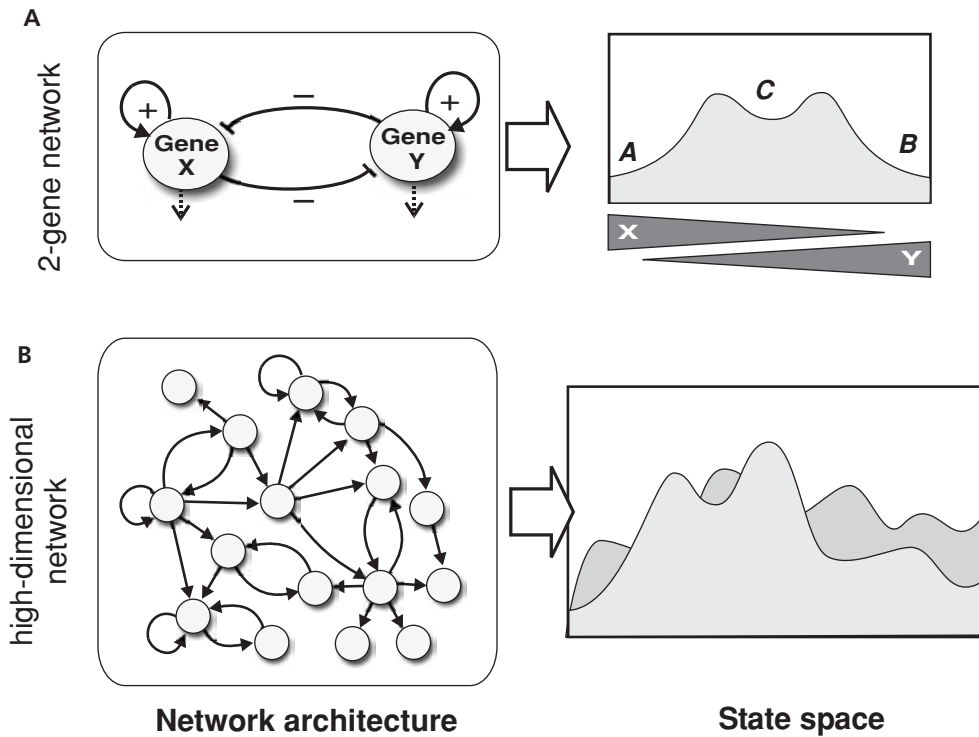

Figure 190.3. State space for more complex networks. (A) Two-gene network as in Figure 190.2, but each gene is now autoregulatory, promoting its own expression. Note that this leads to converting the unstable stationary state of Figure 190.2 into a local attractor  $C$ , corresponding to a progenitor cell that expresses both  $X$  and  $Y$  (“promiscuous expression”) and can be tipped into either cell fate (attractor)  $A$ , expressing  $X$ , or  $B$ , expressing  $Y$ . (B) A large (“complex”) network. Schematic cartoon of a high-dimensional state space with attractors, projected into an intuitive landscape image.

(Figure 190.1B) – without the notion of genes and regulatory interactions!

Although we have explained the case of mutual inhibition, it can be easily shown that a similar circuit with mutual *activation* will result also in two stable states  $A$  ( $X_A = Y_B = 0$ ) and  $B$  ( $X_A = Y_B = \text{high}$ ). Now let us make the circuitry of Figure 190.2A slightly more complicated: Assume now that the genes  $X$  and  $Y$  also activate themselves via an autoregulatory loop (Figure 190.3A). Such a circuit structure, in which a transcription factor stimulates its own expression, is very often encountered in key factors that regulate cell-fate transitions: For example, GATA-1, GATA-2, MyoD, and E2F-1 are all autoregulatory factors. If we build such autoregulatory feedback loops into our two-gene system, the dynamics will be changed qualitatively, as can easily be shown by numerical solution of the differential equations. The stationary but unstable “hill top” state  $C = (X_C, Y_C)$  becomes locally stable (compare Figures 190.2E and A): It has a basin of attraction between that of  $A$  and  $B$ , and is defined by intermediate-low, equal levels of  $X$  and  $Y$ . We will return to this later in this chapter when we discuss multipotential progenitor cells.

In summary, the mathematical treatment of the simple mutual regulatory circuit shows that one system (our two-gene network) can produce a system behavior that encompasses multiple stable states (attractors) given a particular “wiring”

of the interactions of its parts (the genes). It can be shown that the discussed behavior exists for a large range of parameter values ( $k, \Theta, n$ , where  $n > 2$ ) that shall not be further discussed here. Which attractor the network (the cell) “occupies” at equilibrium depends on where it started from, the so-called “initial states” or the position of  $S(t = 0)$  in the state space.

## CELL FATES AS ATTRACTORS

It is now natural to view an attractor as a state representing a cell fate: Both are discrete, mutually exclusive entities defined by a stable gene activation configuration that arises from the dynamics of the gene regulatory network. In other words, the state space is the formal framework that helps us translate the static gene regulatory network architecture into the dynamics of whole-cell behavior. Even if the gene expression profiles overlap (e.g., state  $C$  in Figure 190.3A shares genes  $X$  and  $Y$  with states  $A$  or  $B$ , respectively), a given system (cell) can only occupy one of a set of alternative states at a time – the attractors are mutually exclusive, and the cell appears to make discrete “decisions” between distinct, genome-wide (typically overlapping) gene activation patterns. The attractors are stable to small perturbations. Larger changes in  $X$  or  $Y$ , however,

can cause a system, which for instance is in state  $A$ , to move to state  $B$ , if the perturbation changed the  $X$  and  $Y$  values so much as to place the system state  $S = (X, Y)$  into the basin of attraction of the attractor  $B$ . Such an attractor transition would correspond to a cell-fate switch in response to external signals. Importantly, the attractor model suggests that a cell-fate switch can take multiple trajectories; that is, multiple differentiation paths exist leading from  $A$  to  $B$ , provided the cell reaches the basin of attraction of  $B$ .

If cell fates correspond to attractor states, then the developmental potential of a cell is represented by the neighboring attractors that a cell can access. Of special biological interest in our more complicated example (Figure 190.3A) is the attractor state  $C$  which – because of its position between the other two – can be “kicked” out into either attractor  $A$  or  $B$ . Thus,  $C$  represents a multipotential precursor cell poised to (almost irreversibly) commit to the  $A$  or  $B$  cell fate by promoting expression of either  $X$  over  $Y$ , or vice versa. Interestingly, this multipotent cell  $C$  is characterized by a gene expression configuration in which both  $X$  and  $Y$  (the cell type-specific markers for  $A$  and  $B$ , respectively) are active at low levels. This property of promiscuous gene expression of multipotent progenitor cells in fact recapitulates experimental observations, notably in the hematopoietic system, in which progenitor cells have been shown to exhibit a promiscuous gene expression pattern that contains concomitantly the genes that are expressed uniquely in either of the successor cell lineages (30–33). From this example we also learn that a biological quality, such as multipotency or “stemness” need not be reduced to a particular molecule (as manifest in the current quest for the “stemness genes”) (34), but can be simply and naturally explained by the dynamics of the underlying circuitry.

Multistability explains the existence of multiple alternative, nongenetic traits and their enduring nature (35) within one single genetic system. This property is at the very core of the emergence of differentiation into multiple cell types in multicellular organisms, because all cells in the body have the same genome. Because an attractor state is robust to perturbations, after cell division and random partitioning of cellular proteins into the daughter cells, the gene activation pattern of the attractor reestablishes itself from a slightly perturbed state, thereby providing nongenetic inheritance of a particular cellular phenotype. A material basis, such as a covalent modification of chromatin, is in principle not necessary to explain the “memory” of stable gene expression configurations. In 1948, Max Delbrück proposed bistability as a general principle to explain how discontinuous transitions between two stable states arise in biochemical reaction systems and how they could explain differentiation. Since then, this central theme with variations has been discussed by many investigators, mostly applied to single-cell organisms (36). The architectural requirement in a system for the emergence of multiple, distinct, stable states is that the circuit contains feedback loops (37,38). Low-dimensional systems consisting of one or two genes that exhibit multistability and can be described by a

set of differential equations that assume sigmoidal regulation characteristics have recently seen a renaissance in the spirit of “systems biology,” both in theory (39,40) and experiments (41–44).

With the concepts of “attractor” or “epigenetic landscape” (Figure 190.1B, Figure 190.2D,E; Figure 190.3), we also naturally introduce the aforementioned notion of the epigenetic barriers, an almost tangible metaphor but defined purely by abstract dynamics. The landscapes can become structurally quite sophisticated for systems with more than just two genes, exhibiting multiple pits, valley, planes, notches, and hills. The essence is that the epigenetic barriers separate the valleys (basins of attraction) and thus, the individual cell fates and associated “genetic programs.” The epigenetic barriers account for the observation that many different input signals can produce the same output – if they displace the cell state to different positions in the state space, but within the same basin of attraction. Conversely, multistability implies that, given the same genome, a cell can occupy different stable states, and hence respond differently to the same input because of different accessibility to neighboring basins. Thus, the epigenetic barriers can be related to the “set-points” proposed by Aird (6) and would account for the “nature” aspect of EC heterogeneity.

## GENERALIZATION TO LARGER NETWORKS: HIGH-DIMENSIONAL ATTRACTORS

### The Concept of Contraction of State Space

We have so far only discussed how attractor states, which explain much of the cell-fate dynamics, arise in a two-gene circuit. The reality is that gene regulation is not organized in the isolated modules of few genes, but is embedded in an almost genome-wide network. In fact, emerging functional genomics data for a bacterium (*Escherichia coli*), a yeast (*Saccharomyces cerevisiae*), a nematode (*Caenorhabditis elegans*), and a fruit fly (*Drosophila melanogaster*) show that certainly protein–protein interaction networks (and hence, probably also gene regulatory networks) form genome-wide connected networks that encompass almost the entire genome (45). Graph theoretical principles of how networks evolved by the addition of new genes that then connected to the rest of the network also suggest that most probably the members of the network will form a large, connected component rather than consist of fully isolated, small subnetworks (46). So, what are the dynamics of such huge complex networks? Do they also produce “ordered” behavior with attractors?

We are now dealing with networks of  $N =$  tens of thousands of elements, not just two, and the defining requirement for an attractor state is much higher: An attractor state must be stable (attracting) with respect to changes not in two but in thousands of genes. Thus, a state that we described earlier as  $S(t) = [X(t), Y(t)]$  is now defined as  $S(t) = [x_1(t), x_2(t), \dots, x_N(t)]$ , where  $x_i(t)$  is the expression level of gene  $i$ , with  $i = 1, 2, \dots, N$ . With  $N$  genes, the state space now has  $N$  dimensions

and – as discussed earlier, an unfathomable number of possible states or gene expression profiles. We do not know the architecture (“wiring diagram”) of the gene interactions in the genome-wide regulatory network. However, studies during the 1960s by Stuart Kauffman, in which the dynamics of statistical ensembles of randomly wired, simplified model networks consisting of several thousands of binary genes were simulated (47,48), showed that in fact, a complex, apparently irregularly wired network of thousands of genes can, if the “wiring” of the interactions exhibits certain architectural properties, give rise to stable attractors rather than behave “chaotically.” (A behavior that is “chaotic,” in conjunction with high-dimensional systems, would mean that the network state  $S(t)$  would wander aimlessly in state space and eventually visit the entire universe of possible states.) Based on the intriguing finding that complex networks can exhibit stable attractor behavior, Kaufmann proposed that cell types in the body are attractor states (48). For high-dimensional systems, we can define an attractor in a more general way: It is the property that a  $N$ -dimensional volume of initial states  $S_i$  in the  $N$ -dimensional state space (as shown by the triangle in Figure 190.2C for the 2D case) will “contract,” as the trajectories of their dynamics are followed for some time, to a state space volume that is much smaller than the initial volume. (Technically, the attractor can be a point attractor, consisting of one stable, stationary state, or  $S(t)$  can oscillate periodically or chaotically, but in doing so, cover a small volume that is tiny compared to the volume of the initial states that represent its basin of attraction. Thus, in high-dimensional systems the relevant scale of observation emphasizes the contraction of state space volume rather than the actual shape of the attractor.)

Systems in which a volume of initial states collapses to a smaller volume and stays there are called *dissipative systems*. The existence of multiple such *attracting regions* would compartmentalize the huge universe of combinatorially possible expression profiles, the  $N$ -dimensional state space, into subregions that represent basins of attraction of a small number (relative to  $2^N$ ) of attractor states. These in turn would map into the phenotypic cell fates and their associated expression profiles. Thus, because of gene regulatory interactions, the hyperastronomical number of possible gene activation configurations collapses to a countable number (thousands?) of stable attractor regions. Relatively nonspecific perturbations that place a cell from state  $A$  to somewhere in the basin of attraction of another new attractor  $A'$  would result in the cell “automatically” assuming the highly specific expression profile of the new attractor states. Thus, even sloppy signals, if they perturb a certain set of genes, can induce cell phenotypes that are defined by distinct expression profiles. This is the basis for robustness, yet flexibility, of cell fates in multicellular organisms.<sup>1</sup>

1 Note that *robustness*, in terms of dynamics in state space, as used here, is conceptually distinct from robustness in terms of connectivity (communication between the nodes = genes) of a network that depends on the particular topology.

### Experimental Data: Existence of High-Dimensional Attractors

The larger view of cell regulation with its system-level dynamic features, including the mutual exclusivity and discreteness of stable cell fates and the ability of nonspecific stimuli to trigger a switch between distinct programs, already lends support to the idea of attractor states in the complex gene regulatory network of real cells. As mentioned earlier, the ability of physical perturbations, such as the distortion of a cell, to regulate the switch of cell fates in ECs (14,16) also points to the existence of attractors that would relax the biochemical constraints for an input signal to induce a particular program. The ability of non-selective stimuli that affect the expression level of hundreds to thousands of signaling proteins and genes, such as kinase inhibitors, solvents, and modifiers of chromatin structure and methylation, to trigger a distinct cell-fate transition also supports the idea that cell fates are high-dimensional attractor states of the molecular regulatory network (22).

But are real genomic networks, with their complex network architecture, also wired in a way that such compartmentalization into alternative, globally defined stable states really occurs? Most randomly wired, complex networks would behave chaotically, without compact attracting regions. Finding the relevant architectural features of the network that can produce ordered behavior with compact attractors has been the objective of intense research activities by computational biologists. Properties that have been shown so far to increase the likelihood for generating ordered rather than chaotic behavior with few compact attractors include: (a) sparseness of interactions in the network, in that a gene on average interacts with a relatively low number  $k$  of other genes compared to  $N$ , that is,  $k \ll N$  (48); (b) preferential use of a certain subset of logical functions that describe the “promoter logics” through which gene transcription is regulated by multiple upstream factors (48,49); and (c) a “scale-free” topology, as discussed in Chapter 189 (50,51). These architectural properties have indeed been found in real protein-interaction networks (45). In addition, a bias in the occurrence of regulatory functions also has been observed for a set of selected, well-characterized promoters (52).

Direct evidence at the molecular level for the existence of attractor states in the mammalian genome and the notion that they represent cell fates has recently been obtained using DNA microarray-based dynamic gene expression profiling of in vitro differentiating neutrophils in a promyeloid cell lines (53,54). By monitoring two different state space trajectories that were defined by  $N = 2,800$  genes and represented two differentiation processes triggered by two different agents, it was shown that the state  $S$  of the undifferentiated cells could be displaced to two different regions of the state space. Then, as cells differentiate into neutrophils, the two trajectories would converge from different directions of the state space to a very similar expression profile, corresponding to that of differentiated neutrophils. Although only two trajectories were monitored, their convergence with respect to thousands of state-space

dimensions is in agreement with the contraction of a state-space volume. Concretely, at the level of individual genes, it was found that some genes that have a characteristic expression level in neutrophils arrived at that level through initially different if not disparate time courses (e.g., temporary down- versus upregulation in response to the two triggering agents) before they were “attracted” to the final expression level. Such behavior, observed for thousands of genes, is in line with the existence of alternative, converging high-dimensional trajectories. This behavior of genes also defies the signal transduction paradigm of a unique and specific molecular pathway that is dedicated to mediating differentiation.

### ATTRACTORS AND HETEROGENEITY WITHIN A CELL TYPE

If a particular cell fate, or a cell type, such as a differentiated EC, is an attractor state, then how do we explain the heterogeneity of cell phenotypes within the “organ” endothelium? First, as discussed in the beginning of this chapter, the very heterogeneity itself comes in different ontological flavors: We can operationally distinguish at least between *stable* (enduring) and *dynamic* (temporary) heterogeneity. The former is realized by the variety of subtypes of cells, such as the location-dependent diversification of ECs into morphological and biochemical subtypes. Temporary heterogeneity can act on top of static heterogeneity and modify the gene expression profile to accommodate the various functional states of the endothelium induced by external signals.

How does this relate to the concept of gene expression profile dynamics in the high-dimensional state space with attractors? As discussed in another section, an attractor is unlikely to be a simple point attractor, as we have seen for the 2D pedagogical case in Figure 190.2. In contrast, the  $N$ -dimensional attractor landscape has a complex structure, with valleys representing the attractor regions. Importantly, such attractors are not dimensionless points in state space, but have some dimensionality that can still grant the system some *degrees of freedom* with respect to selected dimensions. These state-space dimensions may represent “marginal” genes that are loosely connected to the core regulatory network of feedback interactions that establishes the attracting property. Thus, such attracting *regions* can be metaphorically thought of as a plane (in a subset of directions) at the bottom of a valley in a high-dimensional space.

The notion of degrees of freedom is now central for understanding how microenvironmental inputs (“nurture”) can cause a heterogeneity of EC states. The degree of freedom with respect to some genes permits temporary changes of their expression level in response to short-term environmental signals that will shift the state  $S$  within a constrained volume of the attractor region (since affecting only a tiny fraction of the  $N$  dimensions), without overcoming the epigenetic barriers of the attractor that define the (sub)type. Therefore, despite these adaptive responses to temporary environmental inputs,

the cell will stay in the attractor and not switch its type identity or “nature.” Such free movements in dimensions that are virtually independent of the attracting directions of the state space, and hence, would not violate gene interaction rules, are the basis for *local epigenetic plasticity*. For example, in an inflammatory response, skin capillary ECs may be brought to various “activated states” in response to various input signals that target such genes in the nonattracting dimensions. These states are thus located within the flat bottom of the attractor region. Alternatively, temporary “nurture” signals may also be viewed as perturbations that “kick” a state up the steep walls of the basins of attraction (but without reaching the top of the epigenetic barriers) because of conflicting gene expression changes. This would correspond to activated states that will slowly relax back to the basal attractor states once the perturbation disappears – a central mechanism of homeostasis.<sup>2</sup>

A useful metaphor for the dynamic heterogeneity of a cell population of ECs is the following: If the expression profile of each individual cell were to be projected to a point  $S$  in the state space, the population would appear like a swarm of flies, each point (cell) moving individually, yet staying together as a whole, forming a cloud that covers a compact subvolume in state space, and thus, collectively representing a relatively stable EC subtype.

On the other hand, the *stable* heterogeneity of subtypes, such as brain versus skin capillary ECs, may be deterministically defined by the gene network and manifest in the distinct “subattractors” (again, with respect to a subset of state-space dimensions) that exist within the larger “EC attractor.” The attractor property and associated epigenetic barriers would ensure that, despite changes in the gene expression profile caused by alterations in the expression of genes in response to changes in “nurture,” the “nature” of the cell is maintained: For example, in the larger picture, a skin capillary EC remains a skin capillary EC even in an injured vasculature. In fact, the EC-specific transcriptome of scleroderma tissue still clusters very closely with that of the endothelium of normal skin (4).

As cautioned earlier, a gray zone exists between nature and nurture, because ontologically an entire hierarchy of heterogeneity can exist. Thus, although some subtype-specific features, such as genes expressed in high endothelial venules, are epigenetically maintained – that is, they belong to the attracting dimensions of the state space – others require the continuous input of environmental factors (6). Attractors and, accordingly, the expression of associated cellular phenotypes whose persistence requires the chronic contribution of an external input to maintain epigenetic barriers, have previously been termed *pseudoattractors* (53). On the other hand, a truly

2 Technically, the *dynamic* component of heterogeneity in expression profiles may also be due to oscillatory or “strange” attractors (chaos in the classical sense), where  $S(t)$  is not stationary but deterministically “dances” in a small state-space volume that in high-dimensional systems may be tiny compared to the scale of the basin of attraction traversed by transients in biologically relevant time scales. Furthermore, nonsynchronized, random fluctuations in gene expression due to molecular noise also may become manifest as cell population heterogeneity and contribute to the dispersion of occupied states within the attractor region.

epigenetically “fixed” phenotype also can be lost: Strong and persistent perturbations can cause major displacements of the state  $S$  to jump beyond epigenetic barriers that define EC subtypes and bring the cell into a new, stable, and persisting phenotype. A classical example for such a local transdifferentiation between subtypes is the observation that venous ECs, when exposed to the pulsatile mechanical inputs normally encountered in arteries, will adopt an arterial cell phenotype. The irreversible loss of an EC’s natural features which, when isolated and kept in cell culture, subsequently converge to a typical, stable culture phenotype may be due to similar processes.

In summary, the structure of attractors in a high-dimensional system can be complex enough to permit local variations of the expression profile within a small, attracting region in state space without having global effects on the cell type-defining aspects of (attracting) gene expression profiles. Such local variations represent the observed heterogeneity of gene expression profile *within* a cell type. Because the height of epigenetic barriers may vary over a broad range, the relative contribution of nature and nurture also varies. This results in a broad hierarchy of phenotypic heterogeneity that may blur the ontological notions of “cell type” and “subtype.”

## CONCLUSION

In this chapter, we have presented a conceptual framework for understanding cell-fate regulation based on the treatment of complex networks as high-dimensional dynamical systems. Relying largely on qualitative reasoning, we have explained the emergence of high-dimensional attractors and presented the idea that stable cell phenotypes, or cell fates, including cell types and subtypes, represent attractors in the high-dimensional gene expression state space. Observed cell-fate behavior, the architecture of gene regulatory networks found so far, and genome-scale dynamic gene expression analysis supports this idea.

The gene expression state space, compartmentalized into potential-like attractors and their basins within a complex landscape, establishes a formal basis for Waddington’s intuitive metaphor of an “epigenetic landscape.” The attractor landscape provides a stage on which cell behavior takes place, governed by the constraints of the regulatory network (nature) that is embodied by the deterministic landscape substructure, but susceptible to influence from environmental inputs and stochastic variability (nurture). With the reduction of the landscape metaphor to mathematical principles, we can now more comfortably use it to articulate subtle questions, such as those about phenotypic heterogeneity of cell types. Similarly, old concepts expressed in intuitive metaphors, such as epigenetic barriers, nature versus nurture, input/output, plasticity, and the like all can be formally addressed using the principles of high-dimensional state space and attractor.

Although current efforts in biology are focused around the elucidation of the details of the wiring diagram of the gene regulatory network, the ultimate goal for understanding cell

behavior as an emerging property is to map out the actual structure of the “epigenetic landscape” and to correlate it with observed cell behavior. This not only requires knowledge of the wiring diagram, but must involve systematic perturbations and dynamic gene expression profiling to measure the constrained temporal evolution of transcriptomes and proteomes, coupled with phenotypic observation. Ideally, this should be achieved in single cells within the tissue context to capture the microenvironmental inputs and to identify stochastic variability as one source of heterogeneity. With a clear and concrete conceptual framework in mind, as the one presented here, there should be enough motivation to drive our multidisciplinary effort to surmount these formidable technical challenges in the near future.

## KEY POINTS

- Cell fates, including cell types and stable subtypes, represent discrete cell behavior programs that correspond to high-dimensional attractor states in the dynamics of the underlying complex gene regulatory networks.
- The “attractor landscape” is a mathematical formulation of Waddington’s “epigenetic landscape,” and explains why cells are forced to undergo almost all-or-none transitions between a small number of discrete cell fates.
- The model naturally explains many observed phenomena that remain unexplained by the traditional pathway paradigm, such as discreteness of cell fate; limited accessibility to neighboring phenotypes (including multipotential capability and “stemness” of progenitor cells); epigenetic inheritance of phenotype; regulation by nonspecific, noninstructive signals; and the coexistence of robustness and flexibility.

## Future Goals

- To begin, in addition to characterizing in detail the wiring diagram (regulatory pathways) of the genome, to map out the structure of the “epigenetic landscape” (state space with attractors) through systematic measurements of the evolution over time of genome-wide profiles of the activity of cellular molecules
- To distinguish between epigenetically fixed, environmentally induced, and stochastically varying phenotypes, using single-cell analysis in the context of the tissue

# Equation-Based Models of Dynamic Biological Systems

Gilles Clermont, Yoram Vodovotz, and Jonathan Rubin

*University of Pittsburgh, Pennsylvania*

The endothelium serves barrier, synthetic and catalytic functions and is a site of complex interacting processes involving a large number of biological components. Mathematical modeling might provide valuable insight into the global integration of those interactions into tissue function. The purpose of this chapter is to provide a nontechnical review of a well-established modeling platform, namely differential equations, that harnesses the powerful tools of calculus to analyze the time-dependent behavior of dynamical systems. Differential equations have been abundantly used by modelers. Yet, this framework is largely unknown to basic and clinical scientists. We will briefly describe this framework, provide examples that relate to endothelium modeling, and discuss its strengths and weaknesses (Figure 191.1).

## DYNAMICAL SYSTEMS

A dynamical system is an amalgam of interacting components together with a set of rules for how the states of the components evolve in time, and so the notion of time evolution is key when thinking about such a system. Many primary or calculated useful physiological quantities, such as cardiac output and vascular resistance, are related in a static fashion. In other words, one can relate these quantities by means of algebraic equations of varying complexity. The equations resulting from drawing an analogy between electrical circuits and the circulation have led to additional appealing concepts, such as peripheral vascular resistance and vascular capacitance. However, the clinician is clearly aware that these quantities change over time as the “system” adapts to changing external and internal conditions such as fluid administration, local concentration of effectors, or drug dose. The previous chapters have described the concept of predicting the time evolution of complex systems and the implementation of rules that will dictate, given the state of a system now, the state of the system at some future time. These rules can be represented through several mathemati-

cal formalisms. This chapter will concentrate on differential equations, a powerful mathematical framework with a long and fruitful track record in helping physicists and biologists describe and predict the behavior of simple and complex systems.

## DIFFERENCE AND DIFFERENTIAL EQUATIONS

### Ordinary Differential Equations

Given a system described by variables, taking values  $x(t) = \{x_1(t), x_2(t), \dots, x_n(t)\}$  at time  $t$ , a difference equation is a rule specifying how to use  $x(t)$  to calculate  $x(t + 1)$ , the value of the same variable at the next time step. The “biology” of the system is embodied in the difference equation. For example,  $x(t + 1) = 2gx(t)$  represents the geometrical growth of dividing cells or bacteria, where the time step is taken to be 1 in some unit of time. This approach is similar to the cellular automata or agent-based models described previously, in which the rules of the biology are included in the mapping (1). There is no obstacle to including several interacting variables, or even values from multiple different time steps, within a difference equation. Although the principle is simple, the resulting simulations are often not intuitive, giving rise to interesting emergent behaviors. The natural extension of difference equations is to consider the case where the time steps become infinitely small. In this limit, the left hand side of the prediction equation consists of not the value of a variable at the next time step, but rather the velocity with which the variable is evolving. This formulation is a differential equation.

Many of the best known computational models for biological processes that evolve continuously in time are expressed as ordinary differential equations (ODEs). ODE models consist of sets of coupled differential equations of the form  $dx_i/dt = h(x_1, \dots, x_n)$ , where  $h$  is a function of some subset of the variables in the model. The function  $h$  encodes some simplified version of the biology of the system being modeled.

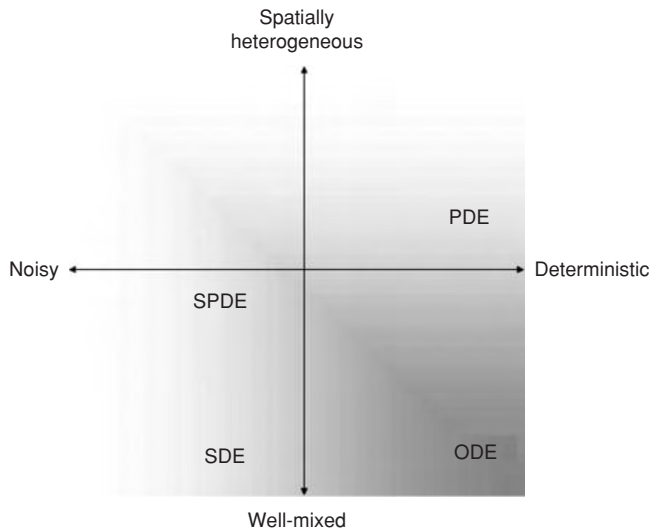

Figure 191.1. Equation-based models are particularly applicable to systems that contain large numbers of components, that evolve continuously in time, and that are not too spatially heterogeneous. The choice between ordinary differential equations (ODEs) or partial differential equations (PDEs) depends on whether precise spatial information is essential to describing the behavior of the biological system. Incorporating uncertainty generated by noise and incomplete information into differential equations will lead to stochastic ordinary differential equations (SODEs), or partial differential equations (SPDEs). The darker the shading in the figure, the more natural is the fit between the biological system and a description using differential equation-based models.

For example, this typically includes information with regard to the presence of specific interactions between components of the system and the relative strength of those interactions, quantified by model parameters. These models are based on the premise that the system involved is “well-mixed” and that there are sufficiently many components (e.g., proteins, cells, small molecules) that their numbers can be regarded as continuous quantities. Although many of these assumptions are not strictly true within an individual cell, ODE models have been found to provide a great deal of insight into the behavior of complex interacting systems. Numerical methods for the solutions to ODEs are mature, very reliable, freely available, and easily implemented on personal computers. Furthermore, ODE models are amenable to formal mathematical analysis. Although it may not be possible to write down formulas expressing the solutions to differential equations as explicit functions of time, this mathematical framework allows one to determine the possible qualitative behaviors that the system can support, depending on particular choices of initial conditions and model parameter values.

Qualitative behaviors of ODE systems may include convergence to equilibrium points, which are states at which all variables remain constant, and periodic oscillations, as well as many more complicated time courses. For a fixed parameter

set, a system of ODEs may have more than one possible equilibria, each of which may be stable (in a variety of precise ways) or unstable. To every stable equilibrium, there corresponds a basin of attraction, which refers to the set of initial conditions that will ultimately evolve to this equilibrium. These basins can change with changes in parameters; indeed, equilibria and other interesting solutions can be born or cease to exist as parameters vary. Correspondingly, one can segment parameter space a priori into regions with qualitatively different equilibrium structures.

When spatial structure plays an important role in the behavior of a system, ODEs may still provide a useful modeling tool, if the system can be considered as a collection of well-mixed compartments. In this case, a key aspect of the modeling process is the characterization of the transfer of information from one compartment to the next, such as occurs via molecular diffusion or cellular trafficking. As long as inter-compartmental exchange can be reasonably modeled as being driven by differences in relative abundances of a quantity, or relative strengths of a physical force such as pressure, across adjacent compartments, ODEs remain a viable, relatively simple option for characterizing spatially structured systems.

### Partial Differential Equations

There are situations where the particular geometry of a system is crucial in dictating behavior. Whether this is true or not may depend on the type of information one seeks through modeling. For example, the geometry of the axon need not be considered for an approximate analysis of action potential propagation, but it is key in determining the precise influence of gradual changes in axon width on propagation characteristics. Similarly, cellular motion along chemoattracting gradients, the physical plugging of an endothelial tear by aggregating platelets, and the thickening of lung tissue with the accumulation of interstitial edema are also exquisitely dependent upon the spatial characteristics of the biological system. When continuous aspects of geometry are important or the “well-mixed” assumption is obviously at odds with the nature of the system at hand, ODEs are insufficient to capture the underlying physical processes, and spatial dependence must be explicitly introduced into model equations. The resulting formalism is that of partial differential equations (PDEs). PDEs and ODEs are often complementary modeling tools and may coexist in analyses of the same system, especially when one is attempting to include several scales of description. PDEs are considerably more demanding computationally than ODEs, often requiring a larger computing platform than personal computers. As with ODEs, formal mathematical theory has been developed for many types of PDEs. Unfortunately, this theory is more complicated, and often further removed from insights about the dynamic structure of the underlying system, than is the theory for ODEs, and many of the PDEs relevant to detailed biological modeling are too complex for analytical

treatment. However, mathematical theory may be useful in selecting appropriate numerical simulation methods to apply, even when it cannot give any direct information about possible model behavior.

In some cases, biological systems may be so fragmented that PDEs may be impractical. For example, the dissemination of an infectious disease in a city, where health care service points, schools, restaurants, and churches all represent privileged areas of disease transmission, would be difficult to simulate with equation-based models. Realistic simulations must take into account individual behavior and the precise geographic location of each of those areas. In such situations, agent-based models certainly represent a more practical simulation platform than PDEs.

### Noise and Differential Equations

Traditional ODEs and PDEs are deterministic models. A given set of initial and/or boundary conditions will always lead to the same outcome in these models. However, there is some degree of randomness, or stochasticity, due to temperature fluctuation, variability in molecular interactions, and a wide variety of other factors, in all physical systems. Although some dynamic phenomena, such as convergence to globally attracting equilibria, are highly robust to noise, others are not. In addition to the types of dynamics generated by a system, the number of cells or molecules involved in the system also contributes to the importance of stochastic effects in sculpting its behaviors. The smaller the scale of description, the greater the potential impact of noise. In situations where the inclusion of noise in a model is appropriate, and where the nature of this noise is reasonably well understood, stochastic differential equations (SDEs) provide a mathematical framework for doing so. Due to the importance of stochasticity in the outcomes of many cellular processes, there has been a great deal of interest in applying stochastic simulation methods in this setting (2–4). Most of these methods rely on the Gillespie algorithm (5), which yields an exact simulation of a stochastic reaction process. There are extensions of the original algorithm, which provide the core for a number of recent simulation tools (6). Wolkenhauer and colleagues review the advantages and disadvantages of the Gillespie method of stochastic simulation relative to the standard ODE approach outlined above (7).

The difficulty with the Gillespie method occurs when a model includes many reactions and interactions and a large number of molecules and biological species. In this case the net reaction rate becomes very big, so that the time between events is exceedingly small and millions of steps must be taken to advance a significant amount in time. One way around this difficulty is to derive an approximation called the chemical Langevin equation, consisting of a classical SDE, to the overall system of reactions (8). Depending on whether spatial elements are included or upon the complexity of the system, solving such a stochastic equation may be computationally challenging. The practical tools available for analyzing the characteristics of such systems also may be quite limited.

### EXAMPLE OF EQUATION-BASED MODELS

The biomedical literature contains a rich repertoire of differential equation-based models. Yet relatively few of those models relate to endothelial function. A considerable body of work, recently reviewed by Chaplain and colleagues (9,10), has addressed the growth of networks of blood vessels in the context of cancer-related angiogenesis. These models are both of the ODE and PDE types and have been used to predict the geometry of neovascular growth, the relationship between neovascularization and tumor blood flow (11), the onset and sustained stimulation of neocapillarization (12,13) and the prediction of possibly effective interventions in curtailing angiogenesis. Other models have investigated the role of the local cellular environment in stimulating blood vessel growth (14).

Other investigators used PDEs to examine the interdependence of nitric oxide (NO) and of oxygen in the microcirculation. All NO synthase isoforms (endothelial [eNOS], neuronal [nNOS], and inducible [iNOS]) require oxygen to produce NO, yet tissue oxygen consumption is reversibly inhibited by NO (15). Interestingly, the blood flow “steal” phenomenon, in which decreased vascular resistance in specific regions of the circulatory bed results in excessive flow (compared to metabolic demand) to those regions while other regions become underperfused, is an emergent behavior of these simulations.

There exist several models of intercellular communication through tight junctions, although most of these address renal or gastrointestinal epithelial tight junctions. To our knowledge, there are only two published mathematical models for endothelial permeability (16,17). Several authors have examined the dynamics of coagulation and the role of the endothelium in clot growth and propagation (18–23).

Of particular significance is the absence of published equation-based models, or any other type of simulations, of the interactions among inflammation, coagulation, and the endothelium, a significant knowledge gap because these processes are key to a number of high impact acute and chronic illnesses. Our group is currently involved in such an effort, in which we have created a mathematical model that describes the dynamics of acute inflammation in the settings of sepsis and trauma (24–27). The inflammation model was calibrated using data from mice that were subjected to endotoxemia at various doses, surgical trauma, and surgical trauma combined with endotoxemia. We have initiated a preliminary calibration of the coagulation equations, which resulted in defining initial values of all rate constants in those equations, in the setting of endotoxemia. This calibration involved an initial description of the changes over time in the concentrations of various components of coagulation (tissue factor; prothrombin; thrombin; protein C; activated protein C; protein S; factors VIIa, IX, IXa, X and Xa; and plasminogen activator inhibitor [PAI]-1), specifically as they relate to the changes in other components of the innate response previously calibrated in animal experiments. Of relevance to endothelial biology, our model

contains interactions in which proinflammatory stimuli first suppress eNOS expression and later induce iNOS expression, in line both with our data and with the literature (28–31).

### STRENGTHS AND PITFALLS OF EQUATION-BASED MODELS

Differential equations, as a modeling approach, have enormous appeal. They (a) provide an intuitive means to translate mechanistic concepts into a mathematical framework, (b) can be analyzed using a large body of existing techniques, (c) can be numerically simulated easily and inexpensively on a desktop computer, (d) provide *both* qualitative and quantitative predictions, and (e) allow for the systematic incorporation of higher levels of complexity. Critics are entirely justified in pointing out that equation-based models usually depend on a large number of parameters that quantify biological interaction, and that specifying these parameters is a difficult task. However, unlike in other approaches, these parameters are explicit in differential equation models. Therefore, knowledge gaps are readily identified. Further, the speed of computation with differential equation-based models allows for massive experimentation with parameters that may not be cleanly manipulable experimentally, leading to the development of hypotheses on the roles of individual parameters that can drive subsequent experimental investigations.

### VALIDATION OF EQUATION-BASED MODELS

Several issues relate to the validation of complex models. At the simplest level, a model is deemed valid if the predictions furnished correspond to empirical data. The problem of assessing the validity of an equation-based model is somewhat more involved. Such a model must first be structurally valid. In other words, the biology embodied in the equations of the model must be rooted in empirical evidence. This entails the inclusion in the model of specific biological processes and their quantification. The level of detail included in such models depends entirely on the scale of description for which a particular model is intended. Interestingly enough, less detailed models might be more difficult to specify, because individual molecular or cellular species may be replaced by more abstract physiological functions, which may be difficult to associate with quantitative empirical evidence. Quantifying biological processes and interactions is clearly a formidable challenge to modelers, even when there exists good empirical evidence. For example, models commonly necessitate the quantification of molecular or cellular half-lives. Empirical data describing an observed half-life in the circulation may be inaccurate in describing the duration of the biological effect of a particular component. A model describing the proinflammatory effect of lipopolysaccharide on vascular endothelium should use a serum half-life, provided that provision is made for recirculation and the processes triggered by endotoxin binding are

themselves modeled. However, if the downstream effects of the interaction of a molecule with a target cell receptor are not specifically included in the model, then the modeler must include an appropriate estimate of the biological half-life of this molecule.

This simple example should illustrate the great care that must be taken in ascribing values to parameters, irrespective of the modeling framework adopted. At best, these parameter values should serve as a starting point to further fitting of the model to empirical data, or to known qualitative behaviors in the absence of empirical data. A number of very sophisticated algorithms have been proposed and are commonly used to adjust parameters to produce optimal fits to empirical data. Unfortunately, the process differs fundamentally from statistical fits, where there are clear prescriptions as to how to achieve model fits and unique solutions typically exist. Because mechanistic models often include many parameters with unclear biological values, the problem of fitting models to empirical data is high dimensional, computationally intensive, and may produce nonunique solutions. Therefore, modelers have typically not produced quantitative model validation, except for restricted, highly simplified systems. Those models are therefore of limited usefulness. A clear research objective resides in the production of new theoretical and computational methods to conduct quantitative fits, together with the congruent development of experimental paradigms that will provide optimal data streams to accomplish this task. Indeed, the range of predictions of a mechanistic model extends well beyond highly controlled sets of initial conditions (experimental or clinical conditions under which empirical data was obtained). This situation is in sharp contrast to statistical models, which cannot offer predictions beyond the observed set of associations between initial conditions or lead to conclusions about temporal dynamics.

### MULTISCALE MODELS

Multiscale models combine components relating to different scales of description of a biological system, such as molecules and tissues, tissues and organs, and the like (32). It appears inevitable that serious models of endothelial biology, for example, will have to relate NO to vascular resistance and blood pressure on one hand, requiring modeling at the level of global cardiovascular dynamics, and capillary permeability on the other hand, necessitating a link to local cellular and gaseous diffusion and blood flow and in turn affecting local and systemic energy supply. Differential equations can be used to describe several aspects of this system or subsystems, and could be combined with other modeling platforms if these were determined to be more suitable for certain aspects within particular multiscale models. Considerable work has been published on theoretical and practical aspects of merging modeling platforms describing different aspects of a multiscale model (33). Such expertise will be crucial to large-scale simulations of endothelial processes and their systemic repercussions.

## CONCLUSION

Early in the twenty-first century, the scientific community is marshalling an unprecedented effort to encourage, support, fund, and implement interdisciplinary, systems-based science. Attempts at this dialogue are not new, but never has the need been so great. There is a remarkable divide in the peer-reviewed literature between the modeling community and the clinical and basic sciences communities. This divide originates from a critical lack of collaborative efforts, a shortfall within past modeling efforts in the creation of standards that would appeal to other communities, a lack of understanding by experimentalists of the type of data required for modeling, and a lack of demonstrable incremental utility of the modeling exercise in general. Recent initiatives by funding and regulatory agencies such as the National Institutes of Health (NIH Roadmap Initiative) (34) and the Food and Drug Administration (35) to bridge this gap and reward serious interdisciplinary work are both necessary and commendable. A similar step from industry is long overdue. The repeated failures in registering promising inflammation modulation drugs in late-phase clinical trials and postmarketing discoveries of disastrous side-effects may promote the emergence of modeling as a useful discovery and design tool.

Any effort at producing insightful models depends exquisitely on the availability of high quality empirical data. Therefore, hypothesis-driven, reductionist investigations that examine and quantify biological processes in highly controlled environments, remain the key foundation of any effort at gaining insight into complex biology through modeling. Computational neuroscience has a longer tradition of association between modeling, physiology and clinical medicine than other theaters where computational tools are currently applied, and therefore valuable lessons can be drawn from this literature (36). Yet, the full potential of reductionist science remains unexplored from lack of interdisciplinary effort. As a result, in the absence of such efforts, more data may fail to translate to new knowledge. Conversely, modelers should be exquisitely aware of the importance of producing relevant results and should interact with basic researchers to help identify critical data gaps and to structure experimental work to fill those gaps.

Equation-based modeling offers distinct practical advantages as a modeling platform, including its potential for inclusion of biological detail, suitability for simulation, and ease of parameter manipulation for predictive purposes, but it is not the preferred approach for simulating the stochastic interactions of small numbers of agents or the dynamics of highly fragmented systems. This modeling platform is one of several tools that will be solicited by interdisciplinary teams of expert modelers, basic scientists, and clinicians, with sufficient funding and fair access to peer-reviewed literature. The expected output of this work will be an improved translation of basic knowledge into clinical care and prevention approaches, as well as the design of new therapies. Modeling efforts that relate to an integrated understanding of endothelial function have

been sparse, a frustrating state of fact for an emerging science where integrated knowledge appears to be so central.

## KEY POINTS

- Equation-based models remain widely used in the mathematical description of dynamical biological systems.
- Equation-based modeling is a powerful, mature mathematical discipline well-suited to a vast array of biological problems that can shed light into mechanism, provide predictions, and lead to new hypotheses.
- The usefulness of equation-based models for specific applications is best determined by a multidisciplinary team.

## Future Goals

- To develop a close collaboration between bioscientists and modelers in the use of models that translate empirical data into new knowledge, with the hypotheses to be examined and the specific data to be gathered rooted in this collaboration

## Vascular Control through Tensegrity-Based Integration of Mechanics and Chemistry

---

Donald E. Ingber

*Children's Hospital, Harvard Medical School, Boston, Massachusetts*

The vascular endothelium paves the entire inner surface of the blood vessels that permeate every organ of our bodies. It is essentially the “Grand Canal” through which oxygen, nutrients, and other chemical stimuli travel to reach the cells that comprise our tissues. Although originally viewed as a passive boundary layer that interfaces with blood, the endothelium is now known to be a key integrator in human physiology, and to play a central role in control of thrombosis and the inflammatory response. The growth of new blood vessels by microvascular endothelium through angiogenesis and vasculogenesis also is critical for the development of all normal organs, in addition to contributing to the etiology of many diseases, including cancer, atherosclerosis, arthritis, and macular degeneration. Thus, understanding of vascular control can have a fundamental impact on biology and medicine.

Because biology has been dominated by a focus on genomics and molecular biochemistry over the past 50 years, there has been an enormous increase in our understanding of the molecules and genes that contribute to control of endothelial cell (EC) function. Cogent descriptions of these molecules and the important roles they play can be found in other chapters in this volume. However, in addition to being a conduit for transfer of chemical factors, the endothelium is also constantly exposed to mechanical stresses that influence its form and function. In particular, physical forces associated with changes in blood pressure, wall tension, and fluid shear stresses have been found to regulate various signal transduction pathways, change cytoskeletal structure, and alter gene expression in ECs, as well as modulate the angiogenic response (1–3). Moreover, these stress-dependent changes in cell behavior occur even in the presence of constant levels of soluble regulatory factors. Pathological changes of the vasculature that characterize some of the biggest killers of man, including atherosclerosis and hypertension, also are associated with local changes in cell or tissue mechanics (3). The challenge is therefore to understand how physical forces interplay with soluble factors and adhesive cues to regulate endothelial form and function.

The question of how living cells sense multiple simultaneous chemical and mechanical inputs, integrate this information, and produce a single concerted response (e.g., growth versus differentiation or apoptosis) cannot be addressed by classic reductionist approaches in which the goal is to identify a single critical gene or signaling molecule. To effectively attack this problem, it is necessary to understand how the whole cell and tissue process these different types of information and orchestrate complex cellular responses through collective interactions among thousands of different molecular components. But understanding cell regulation by mechanical forces involves more than information flow; we also must incorporate “physicality” into the cellular regulatory network.

This brief chapter reviews work from our laboratory carried out over the past two decades that has focused on this question of how physics and biochemistry are integrated in living tissues, and particularly in vascular ECs.

These studies have revealed that the ability of cells to coordinate their form and function, and to integrate mechanics and chemistry, is based on how they are structured architecturally at the molecular level. Specifically, we have found that living tissues use a particular form of architecture known as *tensegrity* to stabilize the shape of their constituent cells and extracellular matrix (ECM), as well as the form of the intracellular cytoskeleton (4–6). This latter observation is critical because many of the molecules and enzymes that mediate cell metabolism and signal transduction normally function when physically immobilized on insoluble cytoskeletal scaffolds (7). Because of this architectural arrangement, mechanical stresses transmitted across the surface membrane via adhesion receptors that connect the ECM to the cytoskeleton, such as integrins, are channeled through the cytoskeleton, and focused on multiple cytoskeletal-associated sensory molecules located throughout the cell and nucleus. Mechanical forces may thereby influence cellular biochemistry and signal transduction as a result of associated stress-dependent changes in molecular shape that alter chemical potentials, and hence change biochemical activities (1).

Thus, the challenge for the future is to understand molecular biochemistry in the physical context of living cells and tissues, and to develop quantitative descriptions of these processes. Only this way, will we be able to develop computational models, nanotechnologies, and engineered tissue replacements that will revolutionize how endothelial biology and vascular medicine are carried out in the future.

### CONTROL OF VASCULAR MORPHOGENESIS: SOMETIMES FUNCTION FOLLOWS FORM

The old adage that “form follows function” is based on the idea that if an object performs a particular task, it must be designed to best support that function. Although this concept comes from the world of design, it also is often assumed to govern the natural world given the exquisite coupling between form and function observed in all living systems. However, in part because of this simple phrase, most people assume that the shape of a tissue is governed by the functions it must carry out. In fact, this is true in the case of the vasculature. Increases in blood pressure or hemodynamic shear stresses result in remodeling of the vascular wall, including changes in wall thickness and vessel diameter (2). But what is less well recognized is that the opposite is true as well: The form of a tissue also may govern its function.

The three dimensional (3D) shape of any structure – whether a building or a blood vessel – is determined through a dynamic balance of physical forces, and thus, every architectural form will be characterized by its own distinct pattern of internal forces. The stability of the vascular endothelium, for example, requires that tensional stresses generated in the cytoskeleton of each cell be balanced by its points of anchorage to the underlying ECM and to neighboring cells. Every position in a physical structure will therefore experience distinct architectural stresses – tension, compression, shear – which are characteristic of that point in the structural assembly. Hence, over 20 years ago, we raised the possibility that tissue shape may itself provide a physical form of positional information that could be equally important for control of tissue morphogenesis as gradients of soluble mitogens or growth factors (4,5,8).

Macroscale mechanical forces have been long known to regulate tissue form and function; the effects of compression on bone, tension on muscle, and shear on blood vessels are just a few examples. Thus, the novel point here is that *microscale* forces internal to tissues, and characteristic of their particular forms, may feed back to control cell growth and function. In particular, we suggested that because the ECM (e.g., basement membrane) is stiffer than the cell, then local changes in ECM thickness or mechanical compliance (flexibility) may feed back to alter cell shape. This is because as cells exert cytoskeletal traction forces on their ECM anchors and cell–cell adhesions, they will spontaneously remodel their internal cytoskeletal structure to minimize local stresses and strains, and this response will differ depending on the cell’s position.

During angiogenesis, the endothelial basement membrane thins locally as a result of increased degradative activity at sites where new capillary sprouts will subsequently form (9). Vascular endothelial tissues are “prestressed” (i.e., exist in a state of isometric tension) as a result of the action of different cell types (e.g., adventitial fibroblasts, ECs) generating opposing forces and exerting them on a common basement membrane. Thus, we proposed that a local weak spot in the basement membrane might stretch out more than surrounding regions, and hence physically distort adherent ECs in these particular areas. EC shape and cytoskeletal structure are tightly coupled to cell growth, with more highly spread cells exhibiting enhanced growth in response to soluble mitogens (10). Changes in the mechanical force balance within small regions of the vascular tissue may therefore feed back to spatially constrain cell spreading and proliferation, and thereby drive branching morphogenesis during angiogenesis (4,5,8). These changes in physical forces might alter cellular biochemistry as a result of their transmission over discrete cytoskeletal filaments that orient much of the cellular metabolic machinery (7). Hence, to explain how these architectural forces could influence cell and tissue morphogenesis, it is first necessary to understand how cells and tissues structure themselves at the nanometer scale.

### TENSEGRITY IN CELLS AND TISSUES

We based our vision of tissue form governing tissue function on a theoretical model of cell and tissue structure in which cells use a form of tensile architecture known as tensegrity (short for “tensional integrity”) to maintain their shape stability (1,4–6). Tensegrity networks are composed of opposing tension and compression elements that balance each other and thereby create an internal prestress (resting isometric tension) that stabilizes the entire structure (Figure 192.1A). Tensegrity can be seen in the way pulling forces generated in muscles and resisted by bones stabilize the shape of our bodies. In tensegrities, a local stress is borne by multiple prestressed elements that rearrange at multiple size scales, rather than deform and yield locally, when a mechanical load is applied (Figure 192.1B). These rearrangements occur without compromising structural integrity, and they cause the entire network to physically strengthen when mechanically stressed (11). Because tensegrities are composed of discrete support elements, they also provide a way to transmit mechanical forces along specific paths, and to focus or concentrate stresses on distant sites and at different size scales.

Analysis of living organisms reveals the use of structural hierarchies (systems within systems) that span multiple size scales and are composed of tensed networks of muscles, bones, ECMs, cells, and cytoskeletal filaments (1,6). Moreover, the level of prestress (isometric tension) within this network tunes the whole system and governs how it will respond to external mechanical loads. This use of structural hierarchies and tensile prestress for mechanical stability and integrated

Figure 192.1. Tensegrity architecture. (A) A prestressed tensegrity framework composed of steel bars and tension cables. Note that the compression struts resist the inward pull of the surrounding tensed cables and thereby maintain a stabilizing prestress throughout the entire structure. (B) A hierarchical tensegrity structure that contains both a smaller spherical structure at its center (analogous to a nucleus in a cell) as well as elements that are themselves composed of tensegrity networks at smaller and smaller size scales. Note, as shown at the bottom, that when external tension is applied at one point on the surface of this network, all of the interconnected elements reorient to bear that load.

system-wide control is a hallmark of tensegrity architecture. In fact, blood vessels are known to be prestressed under physiological conditions (e.g., exhibit “residual strain”), and they increase their stiffness in direct proportion to the applied mechanical stress, just like living cells and tensegrity structures (11,12). As described earlier, this prestress results from a balance between contractile forces generated within the cytoskeletons of ECs and resisting forces exerted by other contractile cells (e.g., adventitial cells), by stiffened ECMs (e.g., tensed basement membranes, cross-linked collagen bundles), and by macroscale forces acting in the tissue microenvironment (e.g., hemodynamic forces in the cardiovascular system).

When a whole blood vessel is physically stressed, the ECMs (e.g., basement membranes, interstitial matrix) that hold the cells together become mechanically strained. These tensed ECMs adapt to the stress by rearranging on multiple size scales like a tensegrity structure (Figure 192.1B) and becoming stiffer. Cells sense distortion of the ECM or an increase in its rigidity as a tug on integrins or other transmembrane receptors that link the ECM to the contractile cytoskeleton (11). Integrins mechanically couple to the cytoskeleton by clustering together and recruiting a multitude of proteins (e.g., talin, vinculin, paxillin, zyxin,  $\alpha$ -actinin) that self-assemble within focal adhesion anchoring structures to form a molecular bridge to the actin cytoskeleton. Similar force transfer occurs at cell–cell junctions through other transmembrane adhesion proteins, such as cadherins (13).

The cytoskeleton responds mechanically to forces transferred over the ECM and channeled through integrins by rear-

ranging interlinked cytoskeletal filaments on an even smaller scale, thereby strengthening the cell against the potential injurious effects of mechanical distortion. Studies using confocal microscopy, birefringence microscopy or intracellular stress tomography of living cells expressing green fluorescent protein (GFP)-labeled molecules confirm that forces applied to the EC surface and transmitted to cytoskeletal scaffolds (i.e., microfilaments, intermediate filaments, and microtubules) result in localized stress concentrations deep in the cytoplasm and nucleus, as well as within basal focal adhesions where cells are physically anchored to the ECM (14–16). These forces also can produce stress-dependent changes in intracellular signal transduction and gene transcription (17). In contrast, these effects are not observed when similar forces are applied to other transmembrane molecules on the cell surface (e.g., metabolic receptors, growth factor receptors). Moreover, this long distance force transfer can be prevented by dissipating cytoskeletal prestress (15), the key stabilizing feature of tensegrity architecture. This “action at a distance” may explain how mitochondria that associate with microtubules may sense mechanical strain in ECs and release reactive oxygen species that are required for activation of nuclear factor (NF)- $\kappa$ B and induction of vascular cell adhesion molecule (VCAM)-1 gene expression (18). Conversely, increases in cytoskeletal tension inside the cell may feed back to promote structural changes in the surrounding ECM, such as unfolding of fibronectin molecules that promote ECM fibril assembly (19), and thereby add strength to the tissue at a higher systems level.

In tensegrity structures, tensional forces in the cables are balanced by compression struts and by external tethers to

stiffened components that are part of larger tensegrity systems (see Figure 192.1). In cells, tensional forces that are generated within contractile microfilaments and transmitted over intermediate filaments and membranes are balanced by internal microtubules and cross-linked cytoskeletal filament bundles (e.g., microfilaments within filopodia and stereocilia, microtubules in the primary cilium), as well as by extracellular adhesions to the ECM and to other cells at the tissue level (1,6). This allows cells to shift compressive forces back and forth between microtubules and ECM adhesions, such that microtubules bear the majority of the prestress in poorly adherent cells, whereas the ECM bears most of the load in highly spread cells (20). The existence of this complementary force balance explains how forces applied at the cell surface can change the critical concentration of tubulin and control microtubule polymerization in various cells, as well as why cytoskeletal tension and ECM adhesions contribute to this response (6). Tensegrity-based mechanical interactions between microfilaments and microtubules also control the shape and mechanical stiffness of cells, as well as spatial regulation of microtubule turnover during directional cell migration (6). In addition, shifts in this cytoskeletal force balance may control activation of Rho as well as translocation of Rho and Rac to the membrane where these small guanine triphosphate (GTP)ases can influence focal adhesion assembly (21,22). In fact, both disruption of microtubules, which shifts mechanical loads onto ECM adhesions via a tensegrity force balance, and direct physical distortion of these adhesions activate Rho and stimulate focal adhesion formation.

This ability to channel mechanical forces over discrete molecular paths to sites deep inside hierarchical tensegrity structures can explain how cell distortion or mechanical stress application to cell surface integrins produces changes in nuclear shape and induces molecular realignment within nucleoli on progressively smaller size scales (14). These long-range effects are mediated largely by intermediate filaments, and to a lesser degree by the actin cytoskeleton (14–16). Importantly, focused stress transfer through the cytoskeleton and to the nucleus can activate stress-sensitive ion channels on the nuclear membrane and thereby impact gene transcription (23); it also could potentially alter chromatin folding, torsional strain within DNA, or access of key proteins (e.g., transcription factors, steroid hormones) to gene regulatory sites (1). The importance of this mechanical connectedness between the surface, cytoskeleton, and nucleus may explain why disruption, mutations, or deletions of intermediate filament proteins or nuclear lamins results in decreased mechanical stiffness of the whole cell and cell injury in response to mechanical stress, as well as reduced mechanical activation of gene transcription in the cardiovascular system (24).

In summary, if cells are hierarchical tensegrity systems, then mechanochemical conversion does not have to take place only at the cell membrane because forces applied at the surface can be transmitted to structural elements deep inside these prestressed networks. Perhaps even more importantly, stresses applied at the macroscale that mechanically strain ECMs and

deform cells and their internal cytoskeleton may be able to trickle down to smaller size scales, be focused on specific molecular components, and produce structural rearrangements within these molecules that change their biochemical activities. In this context, it is interesting to note that individual proteins may be viewed and modeled computationally as tensegrity structures that globally reorient their local stiffened domains (e.g.,  $\alpha$ -chains,  $\beta$ -strands) when mechanically stressed (6). The tension exerted on these molecules through their prestressed cytoskeletal linkages may allow cells to sense signals in the cytoplasm in the presence of background thermal noise and to maintain optimum mechanosensitivity, not unlike the amplification scheme used by the tensed hair cells of the inner ear. Thus, the process of cellular mechanotransduction may be a manifestation of this fundamental tensegrity design principle that governs biological architecture, rather than being due to the action of any single molecular component (1).

Importantly, a mathematical formulation of the tensegrity model predicts both qualitative and quantitative results from experimental studies with various cultured cells (6,12). Recent studies also confirm that cytoskeletal prestress is critical for cell shape stability, and that microtubules bear compression in the cytoskeleton of living cells – the key hallmarks of the cellular tensegrity theory (6,25,26). Experiments using microfabricated substrates to control the shape of EC monolayers have directly confirmed that the architectural form of a tissue can feed back to control cell growth patterns as a result of local variations of internal mechanical stresses that are distributed through the cytoskeleton and resisted by cell–cell and cell–ECM adhesions (27). Cell distortion–dependent changes in cytoskeletal structure that feed back to regulate the Rho signaling pathway are key to this architectural form of growth control (28). Endothelial cell–cell adhesion molecules (e.g., vascular endothelial [VE]-cadherin) also influence cytoskeletal organization and cell proliferation by feeding into this same signaling pathway (29). Thus, tissue shape may feed back to control cell proliferation by concentrating stresses at particular sites and physically restructuring the cytoskeleton inside cells within these regions, thereby changing Rho signaling. Importantly, we recently showed that this mechanical control mechanism also operates *in vivo*: The local gradients of cell proliferation that drive epithelial budding during embryonic lung morphogenesis as well as endothelial branching during angiogenesis can be enhanced or inhibited by altering cytoskeletal tension using Rho signaling modulators (30). Thus, tissue development appears to be controlled through a mechanochemical mechanism, as we previously proposed (4–8).

#### CELLULAR COMPLEXITY: INTEGRATION BETWEEN STRUCTURAL AND INFORMATIONAL NETWORKS

The vascular endothelium is an outstanding example of a complex adaptive system in which system-level behaviors

emerge through collective interactions among numerous components. The field of “Complexity” attempts to explain the behavior of systems that contain multiple interdependent sub-components by focusing on information flow within dynamic regulatory networks. For example, it has been proposed based on study of theoretical networks that different cell types (e.g., lung versus liver) represent different “attractor” states, or “default” states, in the state space of the genome-wide gene regulatory network (31). In this model, stable high-dimensional attractor states arise at the *whole system level* as a consequence of particular regulatory interactions between the network components that impose constraints on the global dynamics of the network. As a result of these regulatory constraints, the cell cannot occupy any arbitrary network state, and tends to be attracted to only a handful of stable attractor states. This hypothesis is consistent with the observation that cells undergo all-or-none, phase transition-like switches between different fates during embryological development.

We have shown that ECs similarly switch between growth, differentiation, and apoptosis in an all-or-none manner when their physical shape is varied by being spatially constrained on microfabricated ECM islands (10,32). This finding that the cell-fate transitions normally induced by specific high affinity growth factors also can be triggered by unrelated signals that apparently lack molecular specificity (e.g., cell shape distortion) is consistent with the concept that these stable cell phenotypes represent high dimensional attractors (33,34). Importantly, we recently experimentally confirmed that cell fates represent high dimensional attractor states that self-organize within the genome-wide gene regulatory network of human cells (35; see Chapter 190 for more details).

The existence of attractors in cell regulatory networks that confer stability with respect to thousands of dimensions (e.g., gene expression levels) is important because it explains how cells can simultaneously sense multiple chemical, adhesive, and mechanical inputs and yet only switch on one of a limited number of specific, reproducible behavioral responses. But because it lacks physicality, this information flow-based theory of cell regulation cannot explain how specific 3D structures or tissue patterns come into existence. Interestingly, a key feature of the attractor model is that multiple regulatory elements (e.g., ensembles of genes and signaling proteins) must alter their values at the same time to produce an attractor switch. Given that mechanical forces and cell shape distortion simultaneously impact many cytoskeletal-associated signaling molecules, this may in part explain how mechanical forces and associated stress-dependent changes in cell shape are able to control cell-fate switching.

## CONCLUSION

My laboratory has pursued both conventional and nonconventional areas of research in our pursuit of how blood vessels form and function. We have published many reports describing particular molecules and signaling components that

mediate control of EC growth, differentiation, apoptosis, and directional motility, as well as contractility of vascular smooth muscle cells. But the most important insights have come from our analysis of how cells sense mechanical cues in their local microenvironment, and integrate them with chemical signals to control cell function and tissue development, as summarized above.

In simplest terms, there are two key fundamental insights relating to biological control that have emerged from our work. The first is the discovery of the critical need to bring pushes and pulls into balance to create the stability necessary for meaningful growth and development in living systems. This is true whether we are considering a single EC, a capillary network, a large blood vessel, or the entire cardiovascular system. Most investigators are aware of the importance of hemodynamic forces and other mechanical stresses for development of the vasculature. The surprising insight here is the key role that isometric tension and hidden structural forces play in vascular control.

The second theme is the importance of context: whether genes, molecules, cells, tissues or organs, all living things are context-dependent. This perspective emphasizes the importance of structural context when considering the function of multicomponent *networks*, such as where a cell is located within a tissue, where a particular molecule is positioned inside a cell, or the physical stresses these components experience at these sites. But the implications are much larger because once one understands the importance of physical context, one then realizes the innate limitations of current gene- and molecule-focused analytical approaches.

The use of tensegrity and its link to dynamic information processing networks offers potential new avenues of exploration in physiology, pharmacology, and bioengineering of the vasculature. For example, tensegrity can explain how molecular filaments (e.g., microtubules, intermediate filaments) and subcellular components (e.g., integrins, nuclear lamins) that are not contractile can contribute to the impaired whole cell contractile response that characterizes many vascular and cardiovascular diseases. Because changes in the mechanical properties of the whole cell can contribute greatly to development of vascular diseases (e.g., hypertension), it may be possible to screen for drugs that alter global changes in the integrated mechanical behavior of the cytoskeleton that will prove effective regardless of the particular molecular defect or defects that lead to development of the disease. Analyzing their effects on whole-cell mechanics also may minimize the unwanted side effects of drugs that are designed to target single molecules. Finally, because this work has uncovered fundamental design criteria that govern how nature builds and controls on the nanometer scale, this knowledge may be harnessed to create entirely new types of nanotechnology-based materials, microdevices, and control technologies for medicine in the future. Examples include self-assembling mechanochemical scaffolds for tissue engineering that respond to local mechanical cues by elaborating growth factors and altering vascular tone, or therapeutic control technologies that use dynamical

inputs (chemical, mechanical, or electrical) to switch capillary cells from growth to apoptosis, and thereby shrink tumors, as well as atherosclerotic plaques.

Thus, the challenge for the future is to develop quantitative descriptions of both physical and information processing networks, and eventually to analyze how they are seamlessly integrated so as to produce vascular tissues in which structure and function can never be dissociated. With this understanding in hand, it will be possible to engineer artificial blood vessels, and to build biologically inspired materials and cellular reprogramming technologies for clinical care that meld naturally with our own bodies and provide a new handle on physiological control.

### KEY POINTS

- ECs use tensegrity architecture to channel mechanical forces through the cytoskeleton and to influence cellular biochemistry so that their growth and function are optimally adapted to their physical and chemical microenvironment.
- Mechanical forces are critical regulators of cellular biochemistry and gene expression as well as tissue development.
- The cytoskeletal scaffolds that physically interconnect with extracellular matrices through cell surface integrin receptors provide a mechanism for ECs to integrate mechanical and chemical signals.

### Future Goals

- To develop quantitative descriptions and computational models of how physical networks and information processing networks are integrated within living cells
- To use these models of cellular information integration to develop new therapeutic modalities and biologically inspired control technologies for clinical care

### ACKNOWLEDGMENTS

This work was supported by grants from NIH, NASA, DOD, DARPA, ARO, NSF, and the Keck Foundation.

# Simulating the Impact of Angiogenesis on Multiscale Tumor Growth Dynamics Using an Agent-Based Model

Chaitanya A. Athale and Thomas S. Deisboeck

*Complex Biosystems Modeling Laboratory, Harvard-MIT (HST) Athinoula A. Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Charlestown, Massachusetts*

The growth of solid tumors and metastases beyond a certain size limit of 1.4 to 2.5 mm in diameter (1) is enabled by the tumor-induced sprouting of blood vessels, a process termed *angiogenesis*. Folkman and colleagues (2) first identified a soluble growth-factor referred to as tumor-angiogenesis factor (TAF) produced by tumors that could induce the growth of such new capillaries. This in turn led to the concept of anti-angiogenesis as tumor therapy (3). Experimental verification of this mechanism in a rabbit model (4), research discovering details of the cellular processes of tumor angiogenesis (5), and *in vivo* inhibition of tumor-induced angiogenesis (6) form the basis of most of the work that followed.

In parallel to the experimental work, attempts were being made early on to mathematically model the endothelial cell (EC) sprouting, the interconnection and looping of blood vessels, and their growth toward the tumor induced by TAFs (7). Meanwhile, a model of the extravascular transport of reporter molecules in tumor and normal tissue showed a good fit to one-dimensional diffusion. Furthermore, real tumors were found to provide fewer hindrances to macromolecular transport by diffusion than were surrounding tissue (8). Modeling work that compared experimentally measured TAF profiles predicted that this factor could be secreted outside the neoplasm only after the tumor exceeds a threshold size (9). Patterns of angiogenesis have been examined subsequently using reaction diffusion simulations that focused (for example) on TAF diffusion (10). Furthermore, work by Byrne and Chaplain (11) examined the role of the migration rate of newly sprouted capillaries and its consequences on brush borders and the parameters contributing to successful vascularization of tumors. Another study concentrated on the role of EC proliferation and migration and showed good comparison to experimental data (12). In addition, detailed biochemistry, molecular transport models, and EC chemotaxis has been used to produce good fits with experimental data on the onset of

vascularization and the rate of migration of the growing capillary tip (13). Recent work has attempted to use numerical simulations that explicitly include molecular interactions as a way to test various angiogenesis-directed chemotherapeutic approaches (14).

Work in our laboratory has examined the emergent properties of brain tumor growth using, for example, quantitative experimental measurements (15), agent-based simulations (16), and a theoretical chemotaxis model that demonstrates homotypic attraction as critical for the branch formation of invasive cells (17). Further work using our agent-based model showed a correlation between the tumor's surface fractality (the scale-invariant "self-similar" nature of the tumor surface indicated by a noninteger value of the dimension of the surface) and its expansion rate (18), and has been augmented to include a two-gene network that tests the predictive value of the gene expression values (19). Experimental observations of gliomas have shown evidence that migrating cells do not proliferate and, conversely, proliferating ones do not migrate, which in turn led Giese and colleagues (20) to propose the concept of "dichotomy" in glioma. Because both *in vitro* and *in vivo* data have implicated the epidermal growth factor receptor (EGFR) pathway in proliferative as well as migratory responses (21) and phospholipase C  $\gamma$  (PLC $\gamma$ ) in the "dichotomy" (22,23), we have recently adapted our agent-based simulation to model an EGFR gene-protein interaction-based molecular "decision" network that predicts subcellular, single cell, and multicellular patterns within the growing tumor (24). Here we continue that line of work by integrating an angiogenesis response to a TAF into our multiscale *agent-based* brain tumor modeling platform. Each cell in this particular modeling framework (see Chapter 188) is simulated as an autonomous "agent" that uses local information to make decisions about its "fate"; that is, depending on its internal gene-protein interaction network state, each tumor cell proliferates,

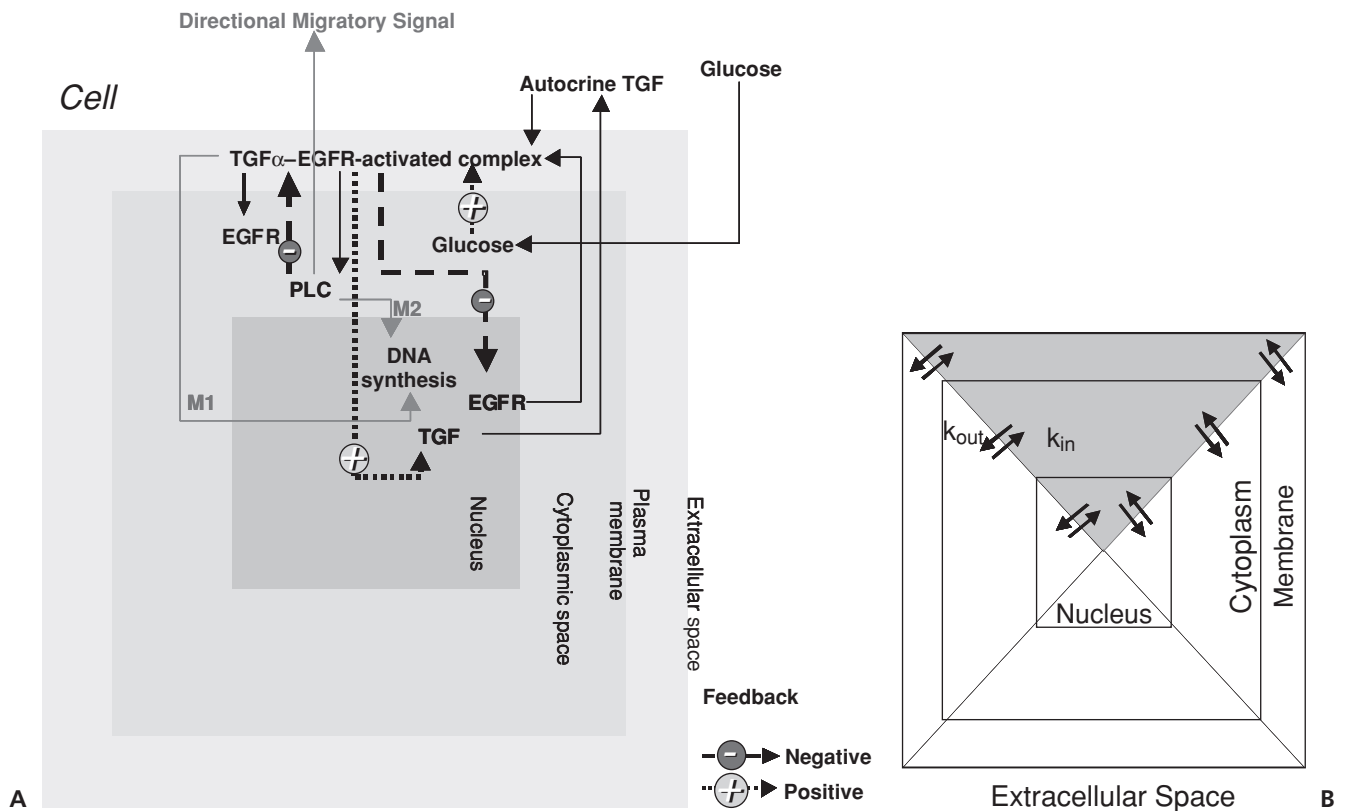

Figure 193.1. (A) Shown is the interaction network involving genes and proteins of the simplified EGFR pathway. The arrows indicate interactions and those with a plus or minus sign represent positive or negative feedbacks, respectively. The components of the network are restricted to specific subcellular compartments. (B) The directional geometry of each cellular subcompartment is displayed and mass exchange between spatially oriented subcompartments due to diffusion is demonstrated for one region. The solid arrows represent the in ( $k_{in}$ ) and out ( $k_{out}$ ) rates of mass exchange.

migrates, or remains stationary at a particular point in time. The dynamics of the multicellular tumor system thus emerge from the collective behavior of these autonomous cells.

## METHODS

Our computational model consists of the following three *modules*: (a) the tumor growth module, (b) the extracellular grid module, and (c) the angiogenesis module.

### Tumor Module

We model the tumor as a collection of cells in which the smallest unit is a molecular species. The model focuses on a simplified EGFR *gene–protein interaction network* involved in phenotypic – migration – proliferation – decision making. The molecules are localized in one of three compartments, either the cell membrane, cytoplasm, or nucleus (Figure 193.1A).

Specifically, the cell-surface EGFR protein can reversibly bind to extracellular transforming growth factor (TGF)- $\alpha$ . This complex dimerizes and can undergo autophosphorylation. In turn, this phosphorylated complex is capable of signaling to the mitotic pathway and phosphorylating PLC $\gamma$ . PLC $\gamma$

is then bound to the membrane-anchored TGF- $\alpha$ /EGFR-activated complex and downregulates the complex (negative feedback). The ligand–receptor (LR) active complex upregulates the gene expression of TGF- $\alpha$  (positive feedback) and downregulates that of EGFR (negative feedback), both in the nucleus. The RNA transcribed from the two genes, TGF- $\alpha$  and EGFR, is transported to the cytoplasm and translated into protein at a constant rate. In addition to synthesis, the cytoplasmic pool of EGFR and TGF- $\alpha$  is altered by internalization and dissociation of the LR complex. Due to receptor recycling, EGFR enters the membrane from the cytoplasmic pool at a constant rate and internalizes in the reverse direction. Similarly, TGF- $\alpha$  protein is secreted from the cytoplasm into the extracellular space. It is this interaction network, modeled as a set of coupled mass balance equations, that determines the exchange of material between compartments and within them. The mass balance scheme is of the generic form,

$$\frac{dX_i}{dt} = s \cdot X_i - r \cdot X_i \quad (\text{Equation 1})$$

where  $X_i$  is the concentration of the molecule,  $s$  is the rate at which this molecule is synthesized, and  $r$  is its rate of degradation. Coupling with other molecules occurs when the  $s$  or

$r$  values change due to other molecular components of the network.

The subcellular compartments of the cell (plasma membrane, cytoplasm, and nucleus) are all divided into four spatial regions in the four cardinal directions North (N), South (S), East (E), and West (W), and each subcompartment is connected to two other spatially adjacent ones (Figure 193.1B). The flux of molecular concentrations between different regions (N, S, E, and W) also is governed by a mass balance kinetic scheme, based on the values of diffusion rates of each molecular species. Thus, subcellular localization is determined by the following equation:

$$\frac{dX_{i,j}}{dt} = k_{in} \cdot [X_{i,j-1} + X_{i,j+1}] - 2 \cdot k_{out} \cdot X_{i,j} \quad (\text{Equation 2})$$

where  $X_{i,j}$  is the concentration of the molecule  $X_i$  in a given compartment  $j$ , while  $X_{i,j-1}$  refers to the neighboring compartment before  $X_{i,j}$  and  $X_{i,j+1}$  to the compartment after  $X_{i,j}$ . Here,  $j$  (1 to 4) is the compartment number and  $k_{in}$  and  $k_{out}$  are the flux rate constants into and out of the compartment, respectively.

Behavior of single cells in our model is based on converting the status of the interaction network into a particular cellular *phenotype*. Presently, we consider the following phenotypic states: cell quiescence, proliferation, or migration. Dittmar and colleagues (25) could show in breast cancer cells that PLC $\gamma$  is activated transiently and to a greater extent during migration and more gradually in the proliferative “mode.” Hypothesizing that such a mechanism also operates in gliomas, we adopt a simple threshold,  $\sigma_{PLC}$ , to decide whether the cell should undergo migration or not. Thus, the *potential to migrate* is assessed by a cell evaluating the following function:

$$M_n [(PLC\gamma)] = \left[ \frac{d(PLC\gamma)}{dt} \right]_n \quad (\text{Equation 3})$$

where  $d(PLC\gamma)/dt$  is the change in concentration of PLC $\gamma$  over time ( $t$ ) and  $n$  is the cell number. If  $M_n > \sigma_{PLC}$ , the cell becomes eligible to migrate, otherwise it could proliferate or become quiescent (i.e., it neither proliferates nor migrates, yet remains viable). If the cell decides to migrate, the direction of migration is expressed in terms of a local valuation function for each neighboring lattice point  $j$  in the *von Neumann* neighborhood as follows:

$$L_j [(PLC\gamma), n_j] = (1 - n_j) \cdot [(PLC\gamma)]_j - \arg \max_{j \leq m} [(PLC\gamma)]_j \cdot \Psi_{PLC} \quad (\text{Equation 4})$$

where  $L_j$  is the value of a grid point in the neighborhood of the cell; the neighboring grid locations and compartments are numbered as  $j$  (1 to 4). In a given subcellular compartment  $j$ ,  $(PLC\gamma)$  is the concentration of activated PLC $\gamma$ ,  $n$  is the number of cells at that location in the neighborhood, and  $m$  is the

total number of compartments (here:  $m = 4$ ).  $\Psi_{PLC} \in [0, 1]$  denotes the so-called *search-precision* parameter, representing the biological equivalent of a receptor-driven, nonerroneous evaluation of the permissibility of the microenvironment, as discussed in detail in our previous work (24,26,27). For example, when the search precision parameter  $\Psi_{PLC} = 0$ , the cell performs a pure random walk, and when  $\Psi_{PLC} = 1$  the cell never commits chemotactic “mistakes” and always migrates fully biased to the most permissive location with the highest level of PLC $\gamma$  (based on Equation 4).

If the change in concentration of active PLC $\gamma$  is below the migration-threshold,  $\sigma_{PLC}$ , yet above a set noise threshold,  $\sigma_n$ , then the cell evaluates the *proliferative potential*  $P_{prolif} \geq 0$ . This potential is calculated using Equation 5,

$$P_{prolif} [(LR)] = (LR) - \sigma_{EGFR} \quad (\text{Equation 5})$$

where  $(LR)$  is the concentration of ligand-bound phosphorylated TGF $\alpha$ -EGFR complex in a cell and  $\sigma_{EGFR}$  is the LR concentration threshold (24). This function is derived from experimental observations citing cell proliferation in relation to an EGF-receptor threshold (28) and an experimentally validated model that relates receptor occupancy to percent maximal proliferation (29). Again, if neither the conditions for migration nor proliferation are met, the cell turns quiescent. Cell death is currently not considered in our model here.

## Extracellular Module

The simulation is run in two dimensions (2D) and initialized with 100 tumor cells in the center of the grid (at  $[X, Y = 100, 100]$ ), in itself a rectangular section of a toroidal lattice with one side ( $R$ ) of length  $R = 200$ . The grid represents the extracellular space, and the edges of the grid behave as a perfect sink. In the North East (NE) quadrant, we model a circular source of nutrients, which is representative of a cross-section of a blood vessel (as discussed later) from which the “example” nutrient (i.e., glucose) constantly diffuses down a concentration gradient. The boundary of the grid functions as a sink, and the blood vessel as a replenished source. The concentration of glucose at any point  $s$  on the grid changes based on,

$$J_s = -D_g \cdot \nabla C_g \quad (\text{Equation 6})$$

where  $D_g$  stands for the extracellular glucose diffusion constant, taken to be  $6.7 \times 10^{-7}$  cm<sup>2</sup>/s from previous work (30), and  $\nabla C_g$  is the glucose concentration gradient in one dimension (1D). Glucose enters the lattice or virtual tissue system through the blood vessel walls and this flux is represented by,

$$J_w = q_g (C_s - C_g|_{wall}) \quad (\text{Equation 7})$$

where vessel permeability to glucose  $q_g$  is taken to be  $3 \times 10^{-5}$  cm/s from Gatenby (31) and the serum concentration of glucose  $C_s \approx 5$  mM. The diffusion of glucose from the vessel edge occurs in an orthogonal manner. At the same time, each

**Table 193-1: Values of Parameters and Their Definitions as Used in the Angiogenesis Part of the Simulation, Based on Literature Sources Where Available**

Parameter	Value	Description	References
$D_g$	$6.7 \times 10^{-7} \text{ cm}^2/\text{s}$	Diffusion coefficient of glucose	30
$D_c$	$10^{-8} \text{ cm}^2/\text{s}$	Diffusion coefficient of TAF	30
$q_g$	$3 \times 10^{-5} \text{ cm/s}$	Blood vessel permeability to glucose	30
$C_s$	5 mM	Serum concentration of glucose	30
$\lambda_c$	$0.1 \text{ min}^{-1}$	Decay rate of TAF	11
$\alpha_c$	0.1 mM/min	Production rate of TAF	11
$\mu$	$2 \times 10^{-9}$ to $2 \times 10^{-8} \text{ cm}^2/\text{s} \cdot \text{M}$	Coefficient of random motility of expanding blood vessel	11
$\chi$	$2.6 \times 10^3 \text{ cm}^2/\text{s} \cdot \text{M}$	Coefficient of chemotaxis of expanding blood vessel	11

viable tumor cell (regardless of its phenotype) produces TAF molecules at a constant rate, and they also diffuse through the extracellular matrix down a concentration gradient, as in Equation 6, with the grid edges serving as a sink and the individual viable tumor cells as a source. The TAF gradient formation is based on the Byrne and Chaplain model (11) as follows,

$$\frac{\partial c}{\partial t} = D_c \cdot \frac{\partial^2 c}{\partial x^2} - \lambda_c \cdot c + \alpha_c \cdot m \quad (\text{Equation 8})$$

where  $c$  is the concentration of TAF,  $D_c$  its diffusion constant ( $10^{-8} \text{ cm}^2/\text{s}$  estimated by Byrne and Chaplain [11]),  $\lambda_c$  its natural decay rate, and  $\alpha_c$  the rate of production. The number of cells is denoted by  $m$  and indicates that, in the absence of tumor cells, no TAF production occurs.

### Angiogenesis Module

The blood vessel in the NE quadrant (at  $[X,Y = 150,50]$ ) is modeled as a 2D cross-section with an expanding radius, accounting for the effect of angiogenesis. Specifically, the vessel's advancing tips are implicit in its increasing radius; that is, the radius of the cross-sectional blood vessel is a continuum with many small vessels that sprout and grow. Modifying the 1D model of Bryne and Chaplain (11) we model this change in vessel radius ( $\rho$ ) as,

$$\frac{\partial \rho}{\partial t} = v - d \quad (\text{Equation 9})$$

where  $v$  is the speed of expansion due to blood vessel tips and  $d$  is the death rate of the capillaries in units of capillary length per unit area per unit time. This is further resolved by,

$$d = \gamma \cdot \rho \quad (\text{Equation 10})$$

where  $\gamma$  is the rate of length reduction in cm/min. Note that, in the absence of experimentally measured values, we set  $\gamma = 0$ .

The velocity of blood vessel sprouts in angiogenesis ( $v(x,t)$ ) is a combination of random and chemotactic tip motion. The constants that determine this are referred to as *coefficients of random motility* ( $\mu$ ) and *chemotaxis* ( $\chi$ ) and the tip extension rate is,

$$v = \mu \cdot \frac{\partial n}{\partial x} + \chi \cdot \frac{\partial c}{\partial x} \quad (\text{Equation 11})$$

In vitro experiments measuring motility response of ECs to fibroblast growth factor (FGF) gradients (in the order of magnitude of  $10^{-10} \text{ M}$ ) provide values of  $\chi = 2.6 \times 10^3 \text{ cm}^2 \text{ s}^{-1} \text{ M}^{-1}$  from previous works (32–34). The TAF concentration is represented by  $c$  and evolves according to Equation 8. The variable  $n$ , which is the tip density of capillaries, has been modeled in previous work (11) to change over space, yet as a first approximation here, we consider it to be constant within the region of the blood vessel:  $\partial n / \partial x = 0$ .

### PRELIMINARY RESULTS

Employing the aforementioned algorithm, implemented in Java and using the agent-based modeling toolkit Repast (<http://repast.sourceforge.net/>), the model is integrated using finite time stepping. The simulation is terminated when the first cancer cell enters the edge of the expanding blood vessel. A single run with the parameters listed in Table 193-1 here (revised from our earlier work [24]) took 2 hours with visualization on a single 2.40-GHz Xeon processor workstation running WinXP. The human U87 glioma cell line served as the “virtual” cell line with  $2.1 \times 10^5$  EGFR molecules per cell (35).

2D snapshots of the expanding tumor system at consecutive time points (Figure 193.2; for color reproduction, see Color Plate 193.2) confirm that both the tumor system and blood vessel grow *toward each other* as a direct consequence of the dynamic feedback between tumor cells and ECs, mediated by TAF.

Figure 193.2. Depicted is a single-run, 2D visualization of the growing tumor at consecutive (scaled) time points  $t = 50$  and  $200$  min, respectively. The key to the color coding (right) is as follows: (1) migrating, (2) proliferating and (3) quiescent tumor cells, (4) the extracellular matrix, (5) blood vessel outline and (6) glucose. Note the spatio-temporal expansion of the tumor toward the nutrient that diffuses from an expanding blood vessel located in the NE quadrant. For color reproduction, see Color Plate 193.2.

We also have studied the subcellular localization of the PLC $\gamma$  protein in several tumor cells at the end-point (data not shown). These preliminary results indicate that PLC $\gamma$  is *heterogeneously* distributed in its cytosolic localization.

## CONCLUSION

As described in a recent review by Mantzaris and colleagues (36), tumor nourishment is generally believed to consist of two components, the initial diffusion of nutrients, typically termed as *avascular tumor growth state*, and the *vascular growth phase*, which involves the formation of blood vessels or angiogenesis. We have added such a glucose diffusion–yielding neovascularization module to our multiscale agent-based brain tumor model. This model allows us to study the microenvironmental impact on subcellular, microscopic, and macroscopic tumor growth patterns. Building on our previous gene–protein interaction network model (24), the present simulation combines in a sense both phases of cancer growth, avascular and vascular. We found that:

- Initially, the virtual tumor grows primarily based on autocrine and paracrine stimuli, here represented solely through TGF- $\alpha$ .
- However, once extracellular glucose reaches the tumor, diffusing from the distant blood vessel, the effects of tumor cellular uptake, changes in intracellular phosphorylation state and phenotypic alterations predominate. Typically, at this point cells at the periphery of the tumor then tend to regain their migratory phenotype in response to the strong chemotactic stimulus (Figure 193.2, left panel).
- The diffusion of TAF, which is typically 10 times slower than glucose (see diffusion constant values of glucose ( $D_g$ ) and TAF ( $D_c$ ) in Table 193-1), eventually reaches the edge of the blood vessel, which in turn leads the vessel diameter to expand (Figure 193.2, right panel).

We then conclude for the pilot simulation experiment that:

- Driven by the *feedback* mechanism between tumor-secreted TAF and capillary growth, angiogenesis appears to affect tumor growth *across* various scales of interest.
- In particular, the subcellular localization patterns of the PLC $\gamma$  protein concentration should have an impact on the cells' phenotypic decision between proliferation and migration, and therefore ultimately alter the tumor's overall spatio-temporal growth dynamics.

Future work will have to include not only more simulation runs and detailed numerical analyses, but will also need to investigate, for example, the level of robustness of the tumor growth patterns with regards to dynamical changes of nutrient supply. Relating the tumor cells' distinct PLC $\gamma$  polarization patterns and resulting phenotypic behavior to the vessel's growth dynamics is another area of interest. This may also spur *in vitro* and *in vivo* experiments aimed at comparing the dynamics of molecular profiles of proteins such as phospho-PLC $\gamma$  and TGF- $\alpha$  in both the avascular and vascular tumor growth stages.

Necessarily, in this first approximation, the intricate processes involved in tumor angiogenesis had to be simplified to make the results tractable. However, this approach will allow us to add further complexity in future iterations, geared toward investigating the inherent nonlinearity of these biological processes in more detail. Therefore, although still at its beginning, we argue that multiscale cancer models such as this one represent a promising step toward a new set of research tools to simulate the impact of the microenvironment on subcellular signaling pathways, its phenotypic consequences, and the multicellular patterns this may trigger. This line of work generates testable hypotheses and thus contributes to our understanding about cancer biology.

## ACKNOWLEDGMENTS

This work has been supported in part by NIH grants CA 085139 and CA 113004 and by the Harvard-MIT (HST) Athinoula A. Martinos Center for Biomedical Imaging and the Department of Radiology at

Massachusetts General Hospital. We thank Dr. Le Zhang (Complex Biosystems Modeling Laboratory, MGH) for critical review of the manuscript.

## New Educational Tools for Understanding Complexity in Medical Science

Grace Huang\*, Michael J. Parker\*, and James Gordon†

\*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts;

†Harvard Medical School and Massachusetts General Hospital, Boston, Massachusetts

The factors that have caused the endothelium to be an under-recognized and underemphasized organ system are the same reasons that make it a challenging topic for students and teachers alike. The endothelial cell (EC) is hidden from view, seen only by microscopy rather than at the gross anatomical level. Because it participates in all vascular structures, it is often regarded as part of other organs, rather than as a distinct entity. Its distribution throughout the body results in interactions that are multiple and complex, which means that it cannot be discussed without a prior understanding of other organ systems. The endothelium is not readily evaluated by specific diagnostic tests, and at the cognitive level, the endothelium may not evoke a specific mental image as would the heart, for instance. To fully understand the complexity of endothelial biomedicine, new educational tools may be useful in complementing traditional teaching approaches.

Technological advances in the past few decades have had dramatic consequences on how the biomedical sciences are being taught. Educators can now harness the power of technology to manage enormous amounts of information and to deliver content in a manner that promotes high-level, experiential learning. Medical simulation is one area that is revolutionizing medical education. Broadly defined, medical simulation refers to the controlled reproduction of physiologic or clinical environments. For our purposes, we will consider it to be “a model of some phenomenon or activity that users learn about through interaction with the simulation” (1). In the most effective educational simulations, learner-driven exploration and experience lead to enhanced understanding of complex phenomena. Although “standardized patients” played by patient-actors can provide such a platform, in this chapter we will instead concentrate on three types of technology-enhanced medical simulation:

- **Concept simulation:** Computer-based animations that model scientific phenomena for the purpose of understanding complex physiology or pathophysiology

- **Virtual patient simulation:** Interactive computer-based programs that mimic real-life clinical scenarios to allow the user to interview, examine, diagnose, and treat a patient
- **High-fidelity patient simulation:** The use of realistic robot-mannequins to replicate the clinical encounter in its entirety

Used together, these forms of medical simulation can animate the entire range of biomedical processes, from molecular mechanisms to the actual delivery of health care (Figure 194.1). In a learning environment that employs all three modalities, for instance, a student can see not only how derangement at the level of the EC leads to tissue abnormalities, organ dysfunction, and systemic illness, but also how these concepts affect the patient’s overall experience and course of care. Table 194-1 summarizes the advantages and relative disadvantages of the different types of medical simulation.

### CONCEPT SIMULATION

One of the ways adults learn is through the development of mental models – imagined representations that can be “run” in working memory to understand, solve problems, and predict outcomes (2). Such models are critical to understanding complex phenomena or systems (3). Because the structure and function of the EC are complex, particularly when considered at multiple levels of organization (cell, vessel, organ, whole body), there is a tendency for learners to oversimplify concepts. One method of helping learners develop more complete mental models is to provide them with “conceptual” models.

Whereas a mental model is a construct in a learner’s mind, a conceptual model is an instructional tool that facilitates the process of creating the mental model. Conceptual models may come in different forms, including images, animations, videos, computer diagrams, or other simulations. For example, a computer animation that illustrates how blood flows through

**Table 194-1: Advantages and Disadvantages of the Different Types of Medical Simulation**

<i>Type</i>	<i>Advantages</i>	<i>Disadvantages</i>
Concept simulation	Useful for visualization and understanding of pathology and pathophysiology Capable of allowing independent exploration of complex phenomena Ease of access Relatively low-cost for production	Limited physical interactivity Limited fidelity
Virtual patient simulation	Able to encompass multiple aspects of clinical encounter Useful for incorporating lessons about longitudinal and multidisciplinary care Ease of access Readily customizable	Limited physical interactivity Limited fidelity
High-fidelity patient simulation	Immersive, active experience Takes advantage of emotional and sensory components of learning Fosters critical thought and communication Animates basic science within the context of clinical reality	Cost and space requirements Access inherently limited by the number of simulators and staff Reliance on human teachers/operators Engineering limitations

Concept simulation, virtual patient simulation, and high-fidelity patient simulation have distinct advantages and disadvantages compared to one another, which are important considerations in curriculum development.

the heart can vividly portray aspects of anatomy and physiology that are typically described only through words and static images. Multimedia technology and simulations are well suited to help learners construct useful mental models of complex phenomena.

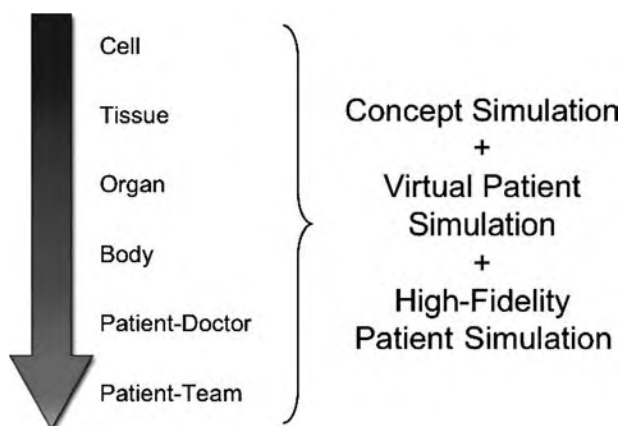

Figure 194.1. The spectrum of medical simulation. The spectrum of biomedical science from molecular processes to human-system interactions can be depicted using the various forms of medical simulation in concert.

Concept simulation refers to computer-based interactive diagrams that model phenomena for the purpose of understanding the underlying physiology or pathophysiology. “Interactivity” can range from animations in which the learner controls the pace to dynamic simulations whereby the learner influences the output by adjusting parameters. The strengths of concept simulation include its abilities to illustrate processes that are difficult to visualize, help form correlations and connections between ideas, make complex topics easier to conceptualize, and allow interactive exploration of topics. Concept simulation promotes integration of basic with clinical science by bringing molecular processes within easy reach of learners, simulating empiric methods of research.

How can we take advantage of these strengths in teaching about the endothelium? The EC can be difficult to visualize in terms of structure and function. Useful concept simulations include three-dimensional modeling of complex structures and animations of time-dependent phenomena. Three-dimensional graphic models can be developed of the endothelium at the level of the cell, vessel, organ, and whole body. A concept simulation could tie these together, allowing the learner to shift between levels, first examining the structure at the whole body level, then zooming in to individual organs, vessels, and cells. Such a construct would allow for

comparisons between organs, individual vessels, or even cells, thereby emphasizing the heterogeneity of the endothelial processes.

The three-dimensional model discussed earlier need not be static. Animation at each level of organization can illustrate important concepts. Some have proposed the metaphor of endothelium as a circuit board, with ECs as input-output devices. This can be visually reinforced and clarified by animations that show how various cells are switched on or off or variably activated (e.g., the spectrum of activation states could be shown as changing shades on a color gradient). At the level of individual cells, an array of inputs and outputs can be animated along with the known signal transduction mechanisms.

Concept simulations need not be restricted to animation alone; graphical user interfaces combined with sophisticated underlying models allow a high degree of interactivity. Imagine a situation where a learner could interact with a computer-based simulation by “trying out” various hypothetical inputs to a cell; resulting signal transduction and output could be instantaneously displayed and evaluated. Such a model could be further used to illustrate how the same inputs may produce different outputs for individual ECs and even for the same EC at different times. This type of interactive exploration engages the learner and encourages active construction of knowledge (4).

Similarly, interactive concept simulations can help learners understand the idea of the endothelium as part of a network, with linkages and communication between nodes that include ECs, circulating cells, and soluble mediators. A computer model may show the learner a dynamic representation of this network and allow pathophysiology to be introduced, with resulting changes in both number and nature of nodes and links.

The possibilities for potential concept simulations are numerous. How would these be used in the spectrum of medical simulation to teach about the EC? We offer a hypothetical teaching scenario using severe sepsis as the endothelium-related topic. In this scenario, a full body simulator or virtual patient simulation could be used to introduce learners to a patient with an infection that leads to a systemic inflammatory response. In the course of interacting with the patient, students would observe signs and symptoms of this illness and other evidence of altered perfusion and organ system dysfunction. They would examine the patient for possible sites of infection, order lab tests, and administer therapeutic agents as appropriate.

Both during and after the case, the role of the endothelium could be highlighted through the use of explanatory concept simulations. As the patient’s blood pressure drops, learners can view a conceptual model of the mediators involved, their signaling mechanisms, and their effects on the endothelium. As the team considers using novel therapeutic agents, they can use the computer to run a simulation illustrating how the drug affects targets in the endothelial network. The effects of changes in vascular tone and permeability on cardiac output

and differential distribution of blood flow could also be shown in the same way. Other parameters, such as body temperature and heart rate, can be incorporated into a concept simulation depending on the desired level of realism.

As we discuss simulations, it is important to note that the level of complexity of a model or scenario should be appropriately adjusted to the level of the learner and to the desired learning objectives – a senior medical student or resident might be able to attend to and understand a greater level of detail than a first-year medical student. Providing too complex a model or scenario for a learner’s level may result in decreased initial learning and transfer of knowledge (with transfer being defined as ability to apply the knowledge in related situations) (5,6).

## VIRTUAL PATIENT SIMULATION

A medical student taking basic science classes may understand the structure and function of the endothelial cell. She may be able to identify it against the backdrop of other cell types. She might also recognize the specific cytokines and cell–cell interactions that result in striking changes in vascular permeability. In essence, the traditional student learning from lectures is equipped with skills at the basest level of clinical competence as depicted by Miller’s triangle (i.e., “knows”) (7) (Figure 194.2; for color reproduction, see Color Plate 194.2.). The next logical step is to assess how our hypothetical student applies her medical knowledge in the cognitive domain (i.e., “knows how”). Virtual patient simulation can be helpful in tracking such development.

Virtual patients are defined as “interactive computer programs that simulate real-life clinical scenarios in which the learner acts as a health care professional obtaining a history and physical examination and making diagnostic and therapeutic decisions” (8). The original impetus for the

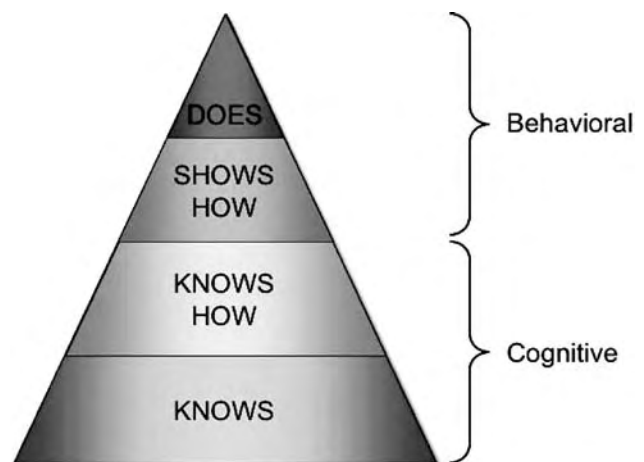

Figure 194.2. Miller’s Pyramid of Clinical Competence. This framework for clinical competence depicts a hierarchy for assessing skills in order of increasing relevance. For color reproduction, see Color Plate 194.2.

development of virtual patients was the failure of the traditional undergraduate medical school curriculum to keep pace with changes in health care delivery. Economic forces have caused medical management to shift into the outpatient setting. As a consequence, medical students have diminished contact with patients in the hospital, where the bulk of clinical training still takes place. The cases encountered by students in the hospital are increasingly severe and complex and therefore less representative of the disease spectrum seen by many physicians in typical practice.

Our index disease, sepsis, would obviously be managed in the hospital, but many other disorders of the vascular endothelium, such as atherosclerosis, thrombosis, and hypertension, are chronic and therefore handled in the ambulatory arena. In addition, faculty members face constant pressure to increase clinical volume and to be productive researchers. The cumulative result is that students have less exposure to the two core elements of their training: they lose the opportunity to build relationships with patients and to learn about disease in a psychosocial context, and they lack physician role models and mentors.

Virtual patient simulation addresses these deficiencies by giving students access to both patients and faculty. A student using the virtual patient gets the opportunity to manage a multitude of diseases and to practice the skills of clinical decision-making. The patient encounters can span many “virtual years,”

allowing the student to gain the experience of longitudinal care in a matter of hours. He may also see events and procedures he would not ordinarily witness while on a short clinical rotation, which permits knowledge acquisition at an accelerated pace. Furthermore, virtual patient cases give specific and ongoing feedback, as would a faculty member, and they may feature videos that model exemplary behavior in physician–patient interactions.

Consider the following hypothetical virtual patient case developed to teach about the endothelium. A middle-aged male patient presents to a virtual emergency room complaining of malaise and cough. By typing questions into the computer program, the student obtains relevant data through a focused interview; she elicits symptoms of fevers, chills and dizziness and a distant history of splenectomy. A virtual faculty member reminds her to ask about recent travel or sick contacts, to elucidate the spectrum of possible organisms causing the fever. A simulated examination (Figure 194.3) combines user input with audiovisual elements and allows the student to check vital signs, to listen to the heart and lungs, and to form a general impression of the disease severity. Here, the student hears abnormal lung sounds, measures a low blood pressure, and recognizes that the patient is acutely ill. The program confirms the accuracy of her assessment.

As the clinical encounter progresses, the computer program asks her to draw up a list of possible diagnoses, and she

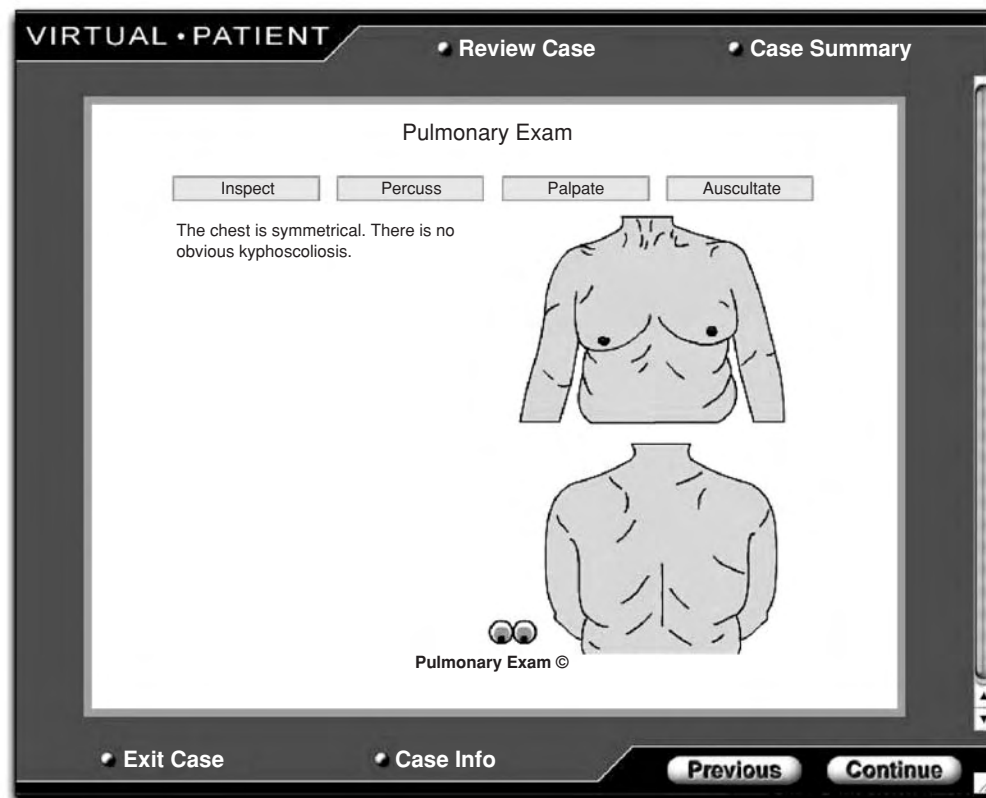

Figure 194.3. Physical examination simulation. This figure is an example of screen-based simulation of the physical examination. (Reproduced with permission from the Carl J. Shapiro Institute for Education and Research at Harvard Medical School and Beth Israel Deaconess Medical Center.)

includes bacterial pneumonia as the most likely cause of the patient's symptoms. This clinical impression will inform her choice of diagnostic tests, which includes a complete blood count and an urgent chest radiograph. Due to the acuity of the clinical presentation, the question of "where" to treat the patient is as equally pressing as "how" to treat the patient. The student astutely decides to hospitalize the patient in the intensive care unit (ICU) for presumed septic shock, rather than putting him in a hospital ward, where monitoring would occur less frequently. In the ICU, the student needs to demonstrate her understanding of the endothelium through her actions. She therefore treats sepsis by addressing the endothelial defect; she counteracts abnormal systemic vascular permeability and loss of arterial perfusion through the use of isotonic intravenous fluid and vasopressors. She must also manage the underlying etiology that is responsible; she decides to broaden the antibiotic coverage. Every action on the part of the student leads to a clinical event, whether it is an arrhythmia, a lab abnormality, an adverse drug reaction, or multi-organ failure. The final outcome, that is, survival, depends on the user's choices, including the timing and sequence of those decisions.

On the other hand, imagine that the student did not realize the severity of the patient's presentation from the beginning, and she discharged him with oral antibiotics. The virtual patient simulation might have resulted in a respiratory arrest in the patient's home. Herein lies the critical benefit of simulated learning environments: virtual patient simulation permits discovery and enforces the consequences of poor decision-making, without harm to the live patient. The richness of the experience derives from witnessing a multitude of cause-effect relationships, with the ability to rehearse the same actions or, alternatively, to experiment with another path. The complexity of clinical outcomes for virtual patients can mirror the intricacies of real patient care.

In addition, virtual patient simulation addresses the needs of adult learners. Teaching students how to take care of a virtual patient with sepsis provides both context and relevance. Adult learners are goal-oriented and therefore benefit from problem-centered education. They are also motivated by their own objectives, and in the case of medical students, their professional goals likely include the ability to manage an illness that is the common endpoint of severe infections.

Virtual patient simulation takes the benefits of case-based learning and delivers the content using a technology that is ubiquitous, interactive, and multimedia-enriched. The end result is a tool that gives a student insight into the actual management of sepsis, tailored to the individual's actions. Ultimately, virtual patient simulation provides a medium to practice critical decision-making in a learning environment that is not only safe to students but also safe to patients.

### HIGH-FIDELITY PATIENT SIMULATION

High-fidelity patient simulation refers to the use of sophisticated human models, and encompasses both full-body simu-

lation (robot-mannequins) and procedural simulation (task-specific trainers for invasive procedures). Full-body patient simulators, first popularized for anesthesia training in the early 1990s (9), can breathe, blink, talk, move, and respond like actual patients, allowing doctors to experience realistic patient care in a protected environment (10). At face value, they have remarkable appeal for health care providers, who can now practice with patient simulators like pilots can practice on flight simulators. In the case of high-fidelity patient simulation, a single immersive scenario can be as useful for the novice as for the expert when the learning objectives are tailored to the individual (i.e., the "good teaching case" can be instructive at multiple levels).

Consider the power of experience for a new intern who "floats" her first pulmonary artery catheter on a hypotensive patient in the ICU; based on the readings, the preliminary diagnosis of cardiogenic shock is changed to septic shock, completely redirecting the therapeutic rationale and plan. This level of intimate participation in real clinical care – the actual experience of doctoring – fosters a level of cognitive and emotional integration that is critical to the development of expertise (11). Through experience, the novice will learn more about the differential presentation of septic shock than ever possible through books or lectures. The question is, can high-fidelity patient simulation replicate the power of experiential learning in an artificial environment, thus enhancing the acquisition of expertise without risk? Can realistic simulation promote the progression from "knows" and "knows how" all the way up to "shows how" and "does" on the pyramid of clinical competence?

Students who participate in such scenarios think so (12,13), but research in this area has just begun. While there is an entire field of procedural simulation (and a corresponding literature of outcomes research) (14), full-body medical simulation typically concentrates on establishing a level of emotional involvement and experience that fosters complex thought (15). Students who "float" a pulmonary artery catheter in the immersive simulator lab, for example, not only practice the procedure, but also comment on the level of critical thought and communication required for optimal patient care. In most scenarios, the radio-transmitted "voice" of the simulator is critical to establishing the proper learning environment, transforming the experience from a passive or technical algorithm to an emotionally charged clinical encounter.

One of the true benefits of high-fidelity patient simulation lies in its capacity to unify multiple teaching approaches in a self-contained learning space. A classroom that contains a patient simulator, a conference table, and a large-screen computer display, for example, could allow students to seamlessly transition from a high-tech tutorial discussion to realistic bedside teaching (16). Students studying septic shock could use the display screen to work through interactive computer diagrams (i.e., concept simulation of endothelial effects), and to explore virtual patient resources, including virtual microscopy of endothelial structures. Then they could turn to the patient simulator as a force for contextualizing core

concepts, using the emotionality of a simulated patient encounter as a catalyst for advanced understanding of complex material (17).

### KEY POINTS

- Medical simulation is a novel approach that promises to harness the power of experiential learning as a unifying intellectual force.
- Combined effectively, the types of medical simulation can help fundamentally integrate basic and clinical science throughout the learning process.
- Medical simulation is an innovative interdisciplinary educational method that promotes contextual learning, allows practice without risk to real patients, and may accelerate development of expertise.
- Concept simulation refers to computer-based animations and models of physiologic processes.
- Virtual patient simulation refers to computer-based programs that allow the learner to play the role of a health care provider in the care of a patient.
- High-fidelity patient simulation refers to the use of realistic robot-mannequins to replicate clinical scenarios.
- Used together, these three types of medical simulation permit robust integration of basic science and clinical science as a unified whole.

### Future Goals

- To better understand how medical simulation can foster the development of researchers and clinicians who are more flexible in incorporating new information, more adaptable in applying knowledge outside the classic paradigm, and more likely to conceive of new diagnostics or therapeutics based on a deeper understanding of biomedical science

# Endothelial Biomedicine

## The Public Health Challenges and Opportunities

---

George A. Mensah

*National Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control and Prevention, Atlanta, Georgia*

Recent advances in endothelial biomedicine and vascular biology have provided renewed hope that strategies for health promotion and the prevention and control of diseases can be improved substantially. These advances hold promise for the detection, evaluation, prevention, treatment, and control of chronic diseases in general and cardiovascular diseases (CVDs) in particular. However, translating these scientific advances into effective clinical practices poses unique challenges (1–3), and translating them into effective public health practices at the community or population level is even more daunting.

This final translational step is crucial, especially for scientific advances related to chronic noncommunicable diseases and their risk factors, which constitute some of the major public health challenges of the twenty-first century. The World Health Organization has estimated that 35 million people died from chronic diseases in 2005 alone and that heart diseases, stroke, cancer, chronic respiratory diseases, and diabetes accounted for the bulk of these deaths (4). These chronic diseases and their risk factors are major epidemics that are not likely to be conquered at the bedside by using individual patient strategies. However, a combination of individual and population-based strategies built on a sound foundation of biomedical science holds tremendous promise for success.

This chapter presents a review of the major advances in vascular biology likely to provide the bases for successful public health policy, practice, and research initiatives in chronic disease prevention and control. It describes clinicians' frequent failure to recognize the endothelium as a spatially distributed organ system, addresses the relevance for continuing medical education and translational research, and discusses the practical implications for health promotion and the prevention and control of chronic diseases. It also presents specific examples

of steps that can be taken immediately to apply endothelial research findings in efforts to improve population health and proposes that members of the public health workforce receive appropriate training about the importance of the endothelium in efforts to prevent or control chronic diseases. Most importantly, this chapter emphasizes the need for increased collaboration among vascular biology centers, basic scientists, clinician-investigators, and public health practitioners.

### PUBLIC HEALTH IN THE TWENTY-FIRST CENTURY

As pointed out by the Institute of Medicine, "*public health is what we, as a society, do collectively to assure the conditions for people to be healthy*" (5). Being healthy in this regard means more than just being free from disease but also having the physical, mental, social, and psychological wellbeing necessary to lead long, satisfying lives. The primary challenge to public health practitioners attempting to promote this broad concept of health is to address the leading causes of morbidity, death, and poor quality of life at the population level and to reduce or eliminate health disparities between subgroups of the population.

At the turn of the twentieth century, communicable diseases and perinatal conditions accounted for most of the deaths and cases of disability in the United States (6,7). In fact, in 1900, the three leading causes of death were pneumonia, tuberculosis, and diarrhea and enteritis (7). Together with diphtheria, these infectious diseases caused one-third of all deaths (7). Today, however, chronic noncommunicable diseases constitute the leading causes of death and disability in the United States and worldwide (8–12).

In 2002, the World Health Organization estimated that chronic diseases were responsible for 59% of global deaths (33.1 million)(11) and 47% of the global burden of disease, and projected that they would account for 73% and 60%,

Disclaimer: The findings and conclusions this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

respectively, by 2020. In addition to their toll in human suffering, these diseases are also financially costly. In the United States, nearly 75% of the estimated \$1.9 trillion in annual health care spending goes to chronic diseases (13,14). Cardiovascular diseases, including stroke and all diseases of the heart, cause almost one-third of global deaths (11). The four leading chronic diseases (cardiovascular diseases, cancer, chronic lung disease, and diabetes) caused 29 million deaths in 2002 (10). Seven of the ten leading causes of death in the United States are chronic diseases, which together accounted for nearly 70% of all U.S. deaths in 2003 (15). Furthermore, the number of diabetes cases worldwide is projected to double in the next 25 years (10).

These chronic diseases are also leading causes of disability, poor quality of life, and health disparities (16–20) and constitute some of the most serious public health challenges of the twenty-first century. Addressing these challenges will require appropriate recognition of the role of endothelial biomedicine in health promotion and disease prevention programs; its successful integration into basic, clinical, and population science research; and the translation of basic endothelial biomedical science findings into clinical and public health practices.

### CHALLENGES AND OPPORTUNITIES

In many ways, the endothelium is to individual health what public health activities are to the health of society. Like public health, the endothelium is hidden and very much underappreciated. When the endothelium functions normally and organ function is maintained and disease is prevented, society rarely takes notice. The endothelium is also like public health in that relatively inexpensive strategies that preserve function (such as increasing one's physical activity, avoiding tobacco smoke, getting proper nutrition, and obtaining essential preventive services) are often less supported than more expensive interventions such as drug therapy after function has already been compromised. These are important programmatic and practical challenges faced by those attempting to translate endothelial biomedical advances into public health practice.

Several factors further compound these challenges. First, basic scientists and clinician-investigators who work in the field of endothelial biomedicine focus on endothelial cells (ECs), and discrete organ systems, while public health practitioners in chronic disease prevention focus mostly on individual persons, families, and populations, rarely on organ systems, and almost never on cells. Thus interactions between members of these two groups are rare. Second, most clinician-scientists who work in endothelial biomedicine view endothelial function in the limited context of large artery vasomotion and its implications for ischemic cardiovascular disease. Third, clinician-scientists seldom fully appreciate the vast spatial distribution, complexity, and heterogeneity of ECs. Finally, people in traditional public health practice and research rarely

consider the diagnostic and therapeutic potential of endothelial biomedicine for health promotion and disease prevention. However, before addressing the challenges of translating endothelial research findings into effective public health practices, we must begin with a review of recent advances in endothelial biomedicine.

### ADVANCES IN ENDOTHELIAL BIOMEDICINE: PUBLIC HEALTH RELEVANCE

Enormous advances have been made in our understanding of the structure and function of the endothelium (21–23). The most important advances regarding the structure of the endothelium include insights into its vast spatial distribution, its heterogeneity in the different vascular beds, its complexity, and its remarkable ability to adapt to a wide variety of conditions. Similarly important advances in how we understand the function of the endothelium have shown that the endothelium does more than provide a barrier between the luminal contents of the blood vessel and the underlying vascular wall structures. The endothelium also plays a key role in cell growth, cell migration, cell survival, the release of endocrine and paracrine hormone factors, the control of vasomotor tone, leukocyte trafficking, inflammation, and hemostasis (21,24). These functions have tremendous implications for several major chronic diseases, including heart disease, stroke, cancer, diabetes, and chronic lung disease.

For example, in a recent review, Vogel (25) described four key ways in which endothelial research findings may be relevant to the prevention of coronary heart disease. First, endothelial vasodilator dysfunction has been associated with all the established coronary risk factors both among asymptomatic subjects in the general population and among patients with coronary heart disease. Second, the degree of vasodilator dysfunction has been shown to correlate with the number and severity of coronary risk factors. Third, this vasodilator dysfunction has been shown to precede the development of even the earliest anatomic atherosclerotic lesions (26). And fourth, effective treatment of controllable risk factors has been associated with a demonstrable reversal of endothelial vasodilator dysfunction (25). Taken together, these findings indicate that endothelial dysfunction is a reliable marker of atherogenic risk (as defined by conventionally determined coronary risk factor status) and that reversal of this dysfunction during the treatment of risk factors is desirable.

Another form of endothelial dysfunction, caused by oxidative damage and the presence of oxidized low-density lipoprotein (LDL)-cholesterol, results in destruction of nitric oxide, increased platelet aggregation, thrombosis, inflammation, plaque formation, proteolysis, plaque fissure, and rupture (22,27). Specific evidence that endothelial dysfunction is associated with major coronary risk factors such as age, male sex (22,28–30), hypercholesterolemia (31), cigarette smoking (32,33), diabetes (34–39), physical inactivity (40,41), and high

**Table 195-1: The Relative Extent to Which Researchers Recognize the Endothelium’s Role in Various Endothelial-Based Disease, and the Estimated Direct and Indirect Costs of Each Disease in the United States**

<i>Endothelial-Based Disease or Condition</i>	<i>Relative Recognition of Endothelium’s Role</i>			<i>Direct and Indirect Costs in Billions of Dollars, USA (Year) (Refs.)</i>

Pulmonary Hypertension	+++	++	None	*
Sickle Cell Disease	++++	+++	+/-	*
Preeclampsia	+++	+/-	None	*
Cancer	+++	++	+/-	189.8 (2004)(79)

Key: Subjective relative recognition is designated on a continuum where “None” is relatively no recognition, “+/-” is very little recognition, and “++++” is very substantial recognition; \*, data not available.

saturated fat intake all add to the public health relevance of the endothelium.

As a result of the endothelium’s role as both a source and target of chronic disease mediators and because of its vast spatial distribution throughout most organ systems, studies of the endothelium and the scientific underpinnings of its activation and dysfunction could play a major role in public health research in chronic diseases and also provide novel avenues for public health programs and policies. However, as shown in Table 195-1, the endothelium’s role in most chronic diseases is relatively unrecognized by clinicians and public health practitioners at the clinical and population/community levels.

**ENDOTHELIAL FUNCTION AND DYSFUNCTION IN CHRONIC DISEASES**

Although the potential effects of EC dysfunction are manifold, most clinicians and public health practitioners largely

view endothelial dysfunction within the narrow confines of its effect on large artery vasomotor tone. They also generally fail to appreciate the heterogeneity and phenotypic variation of ECs and the implications of these variations in the role that endothelial dysfunction plays in chronic diseases (24).

Why is the endothelium so important in chronic diseases? First, because the endothelium is both victim and perpetrator (both a source and target of the mediators of chronic diseases and their risk factors), it plays an important role in the initiation, progression, and development of chronic disease complications. Second, because the endothelium is spatially distributed throughout the body, it establishes a dialogue with every tissue cell in the body. Third, because the endothelium is highly plastic, it is affected by many disease processes and their risk factors (endothelium as victim). Fourth, because the endothelium is highly active, it contributes to many disease processes (endothelium as perpetrator). The plasticity and accessibility of the endothelium make it a potentially powerful platform for diagnostic as well as therapeutic interventions (24).

## ENDOTHELIUM IN SCREENING AND DIAGNOSTIC EVALUATION

Screening and early detection of disease is a crucial component of the public health strategy for disease prevention and control. The strategic position of the endothelium within the vascular tree makes it ideal for the early detection of disease before clinical manifestations appear and also for the diagnostic evaluation of established diseases. Until recently, however, the emphasis in most clinical cardiovascular research has predominantly been on the noninvasive assessment of flow-mediated dilation of large arteries as a marker of atherosclerosis in children and young adults at risk for coronary artery disease (42,43) and in adult patients with established atherosclerosis (44,45). From a public health perspective, however, the endothelium holds promise as a marker for a lot more.

For example, circulating endothelial growth factors could prove useful as early markers for cancer (46,47), just as circulating endothelium-related biomarkers may serve as novel risk markers for atherogenesis and for plaque rupture leading to acute unstable syndromes and sudden cardiac death. In fact, circulating ECs and endothelial progenitor cells have shown potential value as markers for the diagnostic evaluation of a wide variety of chronic diseases, including erectile dysfunction, rheumatoid arthritis, diabetes, stroke, cancer, systemic sclerosis, pulmonary hypertension, and end-stage kidney disease (48–53). Werner and colleagues (54) recently showed that increased levels of bone marrow–derived endothelial progenitor cells were associated with a reduced risk of death from cardiovascular causes, a first major cardiovascular event, coronary revascularization, and hospitalization even after adjustment for age and other major cardiovascular risk factors. Thus, endothelial progenitor cell levels may also have prognostic value.

## ENDOTHELIUM IN DISEASE PREVENTION AND TREATMENT

Health promotion strategies and the entire spectrum of disease prevention approaches (55) – primordial, primary, and secondary prevention – all stand to gain from the appropriate translation of endothelial biomedical findings into public health practice. Health-promoting strategies such as increasing one's level of physical activity, eating a diet rich in fruits and vegetables and low in saturated fats and calorie-dense starches, not smoking, and avoiding environmental tobacco smoke have also been shown to promote endothelial health and reverse endothelial dysfunction (56–64), whereas unhealthful behavioral and lifestyle practices have been shown to impair endothelial function (65–68). These study results suggest that the scientific underpinnings of endothelial function, activation, and dysfunction could play a major role in public health research into chronic diseases and also provide novel avenues for public health programs and policies.

## STRATEGIC INITIATIVES FOR ACTION

The advances made in the basic science of endothelial biomedicine need to be translated into clinical practice and into public health strategies for improving population health, including more innovative public health research. Increased collaborations among vascular biology centers, basic and clinical researchers, and the public health community can help facilitate this translation. In addition, because clinical and public health practitioners should recognize that the endothelium is a spatially distributed organ system with tremendous potential to influence the function of all organs, endothelial biomedicine should be part of continuing medical education for all practitioners.

The development of a common lexicon to describe endothelial function, activation, and dysfunction in terms appropriate for basic, clinical, and population science research and for clinical and public health practice would be an important first step towards increased research collaboration. Endothelial biomedical scientists, clinician-investigators, practicing clinicians, and public health professionals also need to integrate their scientific activities and promote an increased awareness of the diagnostic and therapeutic potential of the endothelium. Most importantly, patients, physicians, and the general public need to be educated about the importance of endothelial biomedicine and the promise it holds for health promotion and disease prevention and encouraged to support endothelial-related public health research and the translation of basic endothelial research findings into effective clinical and public health practices.

## PRACTICAL STEPS FOR IMPROVING INDIVIDUAL AND POPULATION HEALTH

As a first practical step, all lifestyle interventions that enhance normal endothelial function should be encouraged as a means of overall health promotion and as a means of addressing risk factors for chronic disease. Such interventions include the adoption of diets low in saturated fats and total cholesterol but rich in antioxidants, smoking cessation or avoidance, increased regular physical activity, and maintenance of ideal body weight. People should also be encouraged to adopt healthful habits beginning in youth and adolescence so that they do not develop major risk factors for chronic disease such as dyslipidemia, obesity, and hypertension. Appropriate intervention strategies should also be designed for people who already have one or more risk factors for CVD (primary prevention) and for those with existing CVD (secondary prevention).

Pharmacologic interventions are also important means of preserving or improving endothelial function. Angiotensin-converting enzyme (ACE) inhibitors and statins have been shown to help reverse endothelial vasodilator dysfunction in patients with a variety of chronic diseases (65–68) through their effects on the renin-angiotensin-aldosterone system,

amelioration of dyslipidemia, and a variety of pleiotropic effects. These two drug classes are also important in the primary and secondary prevention of chronic diseases, especially heart disease and stroke. The effectiveness of other pharmacologic interventions with agents such as aspirin, supplemental antioxidants, vitamins, L-arginine,  $\omega$ 3 fatty acids, and glycemic control interventions have been reviewed elsewhere (69), but in general they have been examined mostly in the context of reversing endothelial vasomotor dysfunction. Future therapeutic strategies need to address other realms of endothelial dysfunction in their appropriate spatial and temporal context (24).

**UNANSWERED QUESTIONS AND FUTURE IMPLICATIONS**

Much work needs to be done and many questions have to be answered for the full potential benefits of endothelial biomedicine to be tapped. For example, how can the diversity of endothelial function and dysfunction be reliably assessed and used for population research and program development? To what extent does the reversibility of endothelial dysfunction in patients with chronic diseases translate into lives saved or quality-of-life improvements? Are there endothelial biomarkers that characterize the transition of patients from preclinical states to manifest disease states or the conversion of tumors from benign, to premalignant, to malignant states? What insights from endothelial research can be applied to the development of new preventative strategies? What does biomedical research concerning endothelial function in the pulmonary vascular bed teach us about the huge burden of morbidity and death associated with chronic lung diseases and what, beyond smoking cessation, would work to reduce this burden? Can changes in endothelial factors and function help identify women at risk for eclampsia months before the clinical disease (70,71)? What role does the endothelium play in the interaction among monocytes, fat cells, and macrophages that leads to the increased secretion of proinflammatory cytokines/chemokines, adipokines, and angiogenic factors and thus to obesity and its complications (72)? Does the endothelium provide clues for the development of interventions to combat the burgeoning obesity epidemic? How can endothelial biomedicine facilitate investigation of the type, dose, and frequency of lifestyle-related interventions that promote a healthy endothelium, prevent disease, and permit people to lead long, satisfying, healthy lives? What are the appropriate genomic and proteomic applications of endothelial biomedical research (73,74) for disease prevention, health promotion, and healthy aging?

**CONCLUSION**

Despite the many unanswered questions about the potential benefits of endothelial biomedical research in the prevention

and control of chronic diseases, what has thus far been discovered is already cause for at least cautious optimism and perhaps even excitement. Nevertheless, it must be emphasized that a major problem with chronic disease prevention efforts today is the underutilization of interventions known to be effective, principally smoking cessation, proper nutrition, moderate levels of physical activity on most days of the week, and adherence to clinical and community-level guidelines for the provision of essential preventive services. So even if we do translate the findings of basic endothelial research into effective clinical practices and public health interventions, we then must ensure that these practices and interventions are widely adopted.

Endothelial biomedicine may lead to innovative new methods of addressing many unanswered questions about chronic disease. However, the successful implementation of these methods will depend in part on clinicians and public health practitioners recognizing the unique attributes of the endothelium and the implication of endothelium dysfunction in chronic diseases. To ensure that findings from basic endothelial research are translated into effective clinical treatments and public health interventions, we must have greater collaboration among vascular biology centers, basic scientists, clinician-investigators, and public health practitioners; more continuing education about the role of endothelial biomedicine in clinical treatment and public health; and a genuine commitment to close the gap between basic endothelial research and clinical and public health practice.

**KEY POINTS**

- Advances in endothelial biomedicine hold great promise for chronic disease prevention, detection, treatment, and control; however, translation of the science into clinical and public health practice remains a daunting challenge.
- Traditional public health practitioners rarely consider the diagnostic and therapeutic potential of ECs for health promotion and disease prevention.
- The role of the endothelium in most chronic diseases is relatively unrecognized by clinicians and public health practitioners at the clinical and population/community levels.
- As both a source and target of the mediators of chronic diseases and their risk factors, the endothelium plays an important role in the initiation, progression, and development of chronic disease complications.
- The plasticity, accessibility, and vast spatial distribution of the endothelium make it a potentially powerful platform for diagnostic as well as therapeutic interventions.

- Evidence of this potential already exist for many chronic diseases such as coronary heart disease, cancer, high blood pressure, stroke, diabetes, and pulmonary hypertension.

#### Future Goals

- To seek greater collaboration among vascular biology centers, basic scientists, clinician-investigators, and public health practitioners
- To explore the diagnostic potential of EC dysfunction beyond the narrow confines of large artery vasomotor tone in the evaluation of chronic diseases
- To emphasize the heterogeneity, complexity, and phenotypic variation of ECs and their implications for chronic disease prevention and control
- To support the development of a common vocabulary to describe endothelial function, activation, and dysfunction in terms appropriate for basic, clinical, and population science research and for clinical and public health practice

†Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts

Here, by Chapter 196 of a volume exploring the endothelium in medicine, it has become clear that this is an astonishingly diverse and far-reaching subject. Identified for the first time only at the end of the nineteenth century, the once seemingly simple and passive cell layer is now understood to represent a dynamic system that reflects and determines much about health and function for humans and other vertebrate species. This collection of chapters shows how far we have come in our understanding, and also how rich the opportunities are for further study and more effective translation of our understanding into clinical practice.

There is great virtue in bringing together all these topics that would normally reside in the archives of separate disciplines. We have gained many different perspectives of what the endothelium is and how endothelial cells (ECs) come together as a functioning system. By reflecting on the way the endothelium develops and by comparing phenotypes across different species, we gain insights into the alternatives available and what any particular developmental pathway means for the organism. This helps us understand the endothelium as a highly evolved, integrated system. The system is by no means perfect. Rather it is an interlocking “bundle of adaptations,” some of which were born of trade-offs that are no longer applicable. Indeed, the extreme path-dependence of evolutionary change has undoubtedly engendered design flaws that render the modern-day human endothelium highly vulnerable to disease.

The use of metaphors to conceptualize the endothelium is a powerful tool for understanding an otherwise hidden and under-appreciated entity. We hope that the reader will agree that the analogies between endothelium and weather, landscape, and urban design are at the same time provocative and illuminating. While the metaphor of the EC as an input-output device has obvious limitations, not least of which is the risk of overlooking what are often considered to be “emergent properties,” it has nonetheless provided an important organizing theme for the book. Moreover, the use of the input-output device metaphor illuminates how our biological knowledge might be carried into clinical practice. For example, if we

consider the remarkable capacity of the endothelium to sense and respond to its extracellular environment it is not a leap to assume that *every* drug we administer systemically to patients will alter EC phenotypes, for better or for worse. On one hand, such capacity to be modulated may be leveraged to develop novel agents targeted against the endothelium. On the other hand, the exquisite sensitivity of ECs to the extracellular environment may contribute to the adverse effects of many drugs.

When considered collectively, the chapters on endothelium in health and disease provide a clear message: as diverse as the endothelium is in structure and function, it is nevertheless a highly integrated system. The more we learn about the endothelium *across* the vasculature, the more successful we will be in identifying common or core properties, and the better poised we will be to understand the wider consequences of endothelial-based disease.

The collection of perspectives brings many, many new questions and new directions for research. That is clear. New knowledge together with new ways of knowing will bring richer research results, and we have opportunities to translate those results into clinical practice. But we will not do so without changes in the medical curriculum. In that spirit, it is incumbent upon us to train our physicians, starting in undergraduate programs and medical schools, to think of the endothelium not simply as a collection of cells that passively separate circulating blood from underlying tissue, but rather as an active, interactive, dynamic and directive organ system.

Based on the collective writings in this volume, we conclude that the endothelium is a powerful organizing principle in health and disease. Indeed, endothelial biomedicine is a field that warrants recognition in its own right – at all levels of training and research. In addition, the current book calls for reconceptualizing biological structure and function more generally and extending the same questions and approaches to other biological systems. And it calls for new ways of working, not in isolated and separated specialized disciplinary laboratories, but interactively and collaboratively. Perhaps through our own efforts, we can set an example on how to apply

integrated research strategies to complex systems. Systems biology continues to be inspired for the most part by high-throughput genomic and proteomic approaches. However, as emphasized throughout this volume, complexity is “encoded” not so much in the component parts, but rather in the links or interactions between genes, proteins and cells. Moreover, systems biology is heavily rooted in evolution and development. Hence, an understanding of the phylogeny and ontogeny of complex systems, such as the endothelium, provides invaluable insights into the role of these systems in health and disease.

Finally, we hope to have made a case for the importance of conceptual innovation and clarification for structuring available information in such a way that new perspectives can emerge. History teaches us how the endothelium was conceptualized within certain domineering paradigms and how our ideas about the endothelium have changed in light of new developments. Today, however, this relationship might well be reversed and the focus on endothelium as an integrated complex system might lead to a reconceptualization of other areas of biomedicine.
