interaction between TGF- $\beta$  and syndecan-2 as well as immunoprecipitation of the type III TGF- $\beta$  receptor (betaglycan) suggests participation in the TGF- $\beta$  pathway. A role in ephrin signaling also is suggested by ephrin-Eph signaling-induced clustering of syndecan-2.

- Syndecan-3, although not appearing to play an important role in the vascular system, does have a role in skeletal muscle differentiation, which correlates with its primary expression in neuronal and musculoskeletal tissue. Knockouts of syndecan-3 result in myoblast fusion and accelerated skeletal muscle differentiation as a result of improper expression of myogenin. Indian hedgehog's proper temporal and spatial regulation also appears to depend on syndecan-3 expression.
- Syndecan-4 is expressed almost ubiquitously in all tissues. Through its ability to "tune" FGF2 signaling, syndecan-4 regulates cell migration via cross-talk with  $\beta$ 1 integrin and controls adhesion via cytoskeletal modifications. Initiation of signaling events is prompted by clustering of its extracellular domain via soluble or matrix proteins. Using its intracellular domain, syndecan-4 has been shown to activate PKC $\alpha$ , Src, and Rac1. Although the exact mechanism of syndecan-4 modulation of FGF2 signaling is unknown, it has been demonstrated that syndecan-4 is important in FGF2 endocytosis in ECs by a clathrin- and dynamin-independent process requiring syndecan-4-dependent activation of Rac1. It also has been revealed to interact with CXCR4 and the ERM family of proteins, suggesting roles in angiogenesis and cytoskeletal regulation, respectively.

#### Future Goals

- To further elucidate syndecan-4's role in the FGF2 signaling pathway: Specifically, (how) does endocytosis mediated by syndecan-4 regulate the temporal signaling of the FGF2 pathway? Similarly, is syndecan-4 involved in signaling by other heparin-binding growth factors?
- To explore of the role of syndecan-4 in the activation/inactivation of G-proteins and the actin cytoskeleton: What other proteins are involved in the signaling pathway, and how are they regulated in the context of syndecan-4 mediated migration?
- To examine the role of syndecans as scaffold proteins: What growth factors or morphogens are temporally and spatially localized by syndecans, and how is this process regulated in development?

#### ACKNOWLEDGMENTS

We would like to thank members of the Simons' laboratory and the Angiogenesis Research Center colleagues for helpful discussions and incisive comments. Supported in part by NIH grants HL62289 and HL63609 (MS).

## Sphingolipids and the Endothelium

---

Timothy Hla

*Center for Vascular Biology, University of Connecticut Health Center, Farmington*

Structural diversity in the membrane lipids is essential for proper function of eukaryotic membranes. Sphingolipids, named after the mythical Sphinx due to their enigmatic physicochemical properties, are critical for specialized membrane microdomains such as rafts and caveolae. In higher organisms, sphingolipid metabolites, such as sphingosine, sphingosine 1-phosphate (S1P), and ceramide are utilized in intracellular metabolism, signaling, and extracellular cell–cell communication events. Sphingolipids are particularly important for the mammalian vascular system, in which plasma levels of S1P are several orders of magnitude higher than tissue levels, thereby constituting a vascular S1P gradient. S1P is a major regulator of vital endothelial cell (EC) functions including vascular permeability, vascular stabilization/maturation, angiogenesis, vascular tone control, nitric oxide (NO) synthesis, and survival. The endothelium produces and responds to S1P. Indeed S1P receptors in ECs are dynamically induced and regulated. Thus, sphingolipids (sphingomyelin [SM], sphingosine, ceramide, S1P, as well as numerous glycosphingolipid [GSL] species) constitute a major class of molecules involved in the structure and function of the endothelium (Table 45-1). Further knowledge in this area promises to provide novel therapeutic approaches in the restoration of endothelial health, a vital phenomenon compromised in many human maladies.

### SPHINGOLIPID METABOLISM

Sphingolipids, which are built from the sphingosine base, are major structural components of the biological membranes of all eukaryotes. Both GSLs and SM belong to this class of lipids. Sphingolipids are localized on specialized domains of the membranes (1). For example, SM and GSL are essential constituents of membrane rafts. SM contains the sphingosine backbone, a fatty-acid side chain that is linked via the amide bond, and the amphipathic phosphocholine headgroup. Most SM species contain saturated or *trans*-monounsaturated fatty acids with 16 to 24 carbons. This contrasts with the *cis*-polyunsaturated fatty acids present in the *sn2*

position of glycerol-based phospholipids. In addition, sphingolipids are generally found associated with cholesterol, which is thought to be essential in the formation of plasma membrane microdomains and of the detergent-insoluble domains commonly referred to as *rafts*.

In addition to their structural role, sphingolipids are metabolized to intermediates that are utilized as intracellular regulatory lipids, metabolic intermediates and extracellular mediators and receptors. For example, sphingosine and ceramide are studied extensively as intracellular regulatory lipids (2). Hexadecanal and phosphoethanolamine, which are products of the S1P lyase enzyme, are utilized as intermediates in the phospholipid biosynthetic pathway (3). S1P is recognized as an extracellular mediator that activates cell surface G-protein–coupled receptors (4), and GSLs are recognized as ligand–receptor pairs that are involved in extracellular cell–cell recognition (5).

The metabolic pathway of sphingolipid metabolism in mammals is shown in Figure 45.1. The *de novo* pathway is present in all cells and produces SM. Many of the pathway's enzymes have been characterized molecularly from the yeast *Saccharomyces cerevisiae* (6). The biosynthesis of SM takes place in the intracellular membranes, such as the Golgi complex. Once formed, SM is shuttled between specific membrane compartments. The transport systems of sphingolipids is not well understood, even though specific transport proteins, such as the ceramide transporter, have been described. SM also is degraded in the sphingomyelinase (SMase) pathway. The sequential action of SMase, ceramidase, and sphingosine kinase (Sphk) results in the formation of S1P. The formation of S1P occurs at several locations in the cell, such as the cytosol, the intracellular face of the plasma membrane, and the extracellular compartment. S1P is degraded by the S1P phosphatase or the S1P lyase, which are found on the endoplasmic reticulum (ER) membrane (7). The subcellular topology, localization, and transport of various sphingolipid mediators, as well as the metabolic enzymes, are poorly understood at present. It is likely that site-specific formation of sphingolipid mediators is important to their bioactivity and is coupled tightly to the respective effector systems in cells.

**Table 45-1: S1P Receptors and Endothelial Cell Expression**

Receptor	Expression in ECs	EC Phenotype	Induction	Expression in VSMCs	VSMC Phenotype	—/—
S1P <sub>1</sub> (also known as EDG-1)	YES	Induces migration, proliferation, cell–cell adhesion; tube formation (S1P3 needed as well); inhibits permeability; enhances survival and angiogenesis; induces NO	Shear stress, phorbol esters, and angiogenic growth factors; increased in tumor endothelium	Induced (activated, proliferative VSMCs)	Promotes cell migration	Embryonic lethal at E12.5–14.5; hemorrhage and vascular leak
S1P <sub>2</sub> (also known as EDG-5)	+/-	Inhibits migration and proliferation	Not known	YES (quiescent, synthetic VSMCs)	Inhibits cell migration; promotes contraction	Viable, but cooperates with S1P <sub>1</sub> in vascular development
S1P <sub>3</sub> (also known as EDG-3)	YES	Functions with S1P <sub>1</sub>	TNF- $\alpha$	YES (quiescent, synthetic VSMCs)	Promotes contraction	Viable; impaired endothelium-dependent vasorelaxation

The vascular endothelium is enriched in sphingolipids and participates actively in sphingolipid metabolism and signaling. The strategic anatomic position of the endothelium enables access to the abundant sphingolipids present in plasma, blood-

borne cells, and lipoproteins. Indeed, S1P and sphingomyelin are abundant in plasma. In addition, ECs express S1P receptors and therefore respond to S1P (8). Moreover, expression of Sphk isoenzymes as well as ceramidase and SMase by ECs

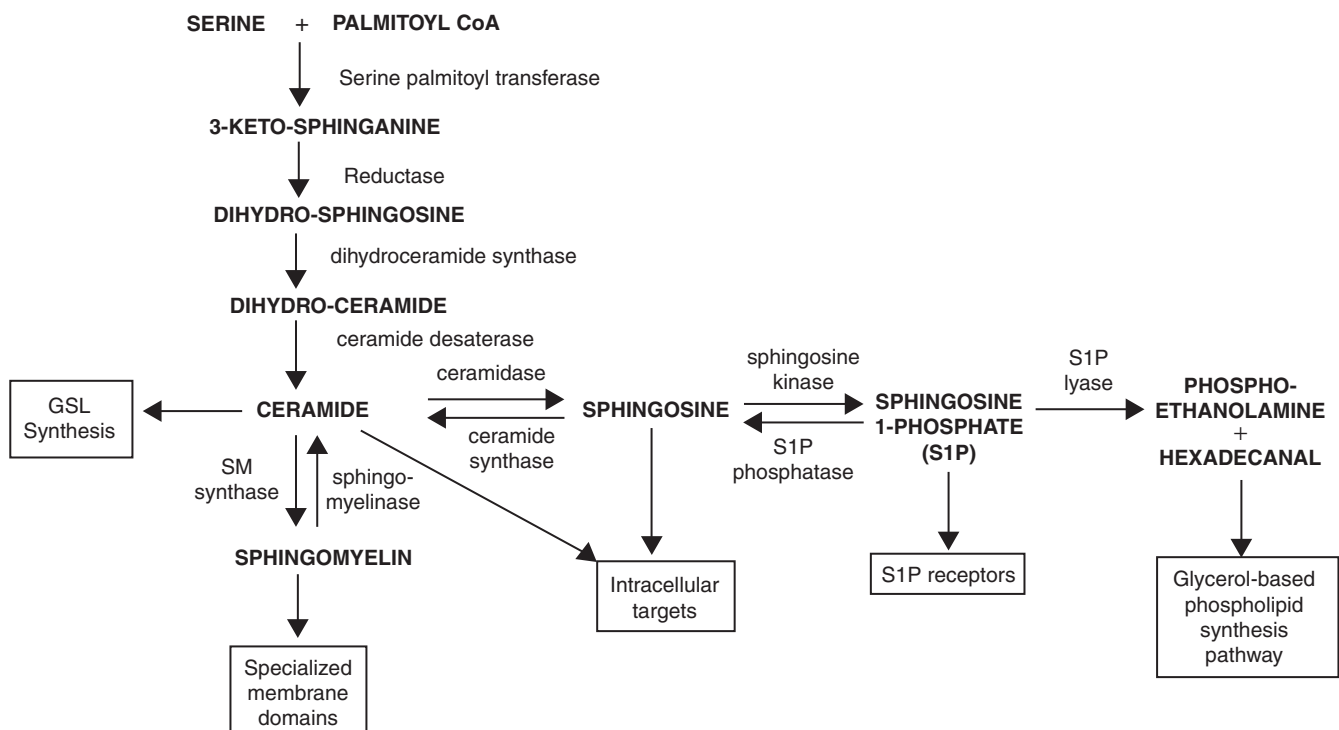

Figure 45.1. Sphingolipid metabolism in signaling.

makes this cell type a contributor of S1P in plasma (9). In this chapter, we discuss the role of sphingolipid metabolism in vascular biology, especially as it pertains to EC functions.

### STRUCTURAL ROLES OF SPHINGOLIPIDS

Although much controversy surrounds the concept of membrane lipid rafts, it is clear that sphingolipids are critical for the formation and function of these membrane microdomains. The structural properties of SM and GSL enable this family of lipids to associate with cholesterol and thus possess differential lateral mobility within the plasma membrane (10). Rafts are enriched in sphingolipids and cholesterol as well as phosphatidyl inositol-linked proteins. In ECs, caveolae or flask-shaped endocytotic vesicles, are common and are observed by transmission electron microscopy methods. In some cases, such vesicles, referred to as vesiculo-vacuolar organelles (VVOs), exist as transcytotic channels (11). They have been implicated in the transcellular transport of plasma proteins and plasma. In addition, caveolae are well known to cluster signaling proteins such as kinases, NO synthase (NOS), and G-proteins. Sphingolipids may be essential for the structure and function of caveolae and VVOs. Important transmembrane proteins such as platelet-endothelial cell adhesion molecule (PECAM)-1/CD31 is found on vesicular membrane invaginations that resemble bunches of grapes (12). These represent the plasma membrane reserve pool that allows leukocyte trafficking through the endothelial monolayer. In addition, discontinuous endothelium in secretory organs contains specialized membrane patches called *fenestrae*, which are essential for the secretion of fluid from plasma into these tissues and the secretion of hormones from tissue into plasma. The role of sphingolipids in the formation and maintenance of complex membrane domains is not well understood and must be defined.

### SPHINGOLIPID MEDIATORS AND THE ENDOTHELIUM

Recent work has clearly established S1P as a bona fide lipid mediator that acts via G-protein-coupled receptors (4). In contrast, sphingosine and ceramide, even though they were considered previously as intracellular signaling lipids, act in a poorly defined manner (13). Much of the work in the literature involves treatment of cells with nonphysiological lipids such as C2-ceramide, which may have nonspecific effects on the membranes. However, modulation of enzymes involved in ceramide and sphingosine metabolism in unicellular and multicellular organisms using genetic approaches have clearly shown that sphingosine, S1P, and ceramide all have intracellular effects, suggesting that they are utilized in intracellular signaling pathways (1). The challenge at hand is to sort out generalized effects on membranes from specific receptor-mediated effects.

S1P, like lysophosphatidic acid (LPA), acts on plasma membrane G-protein-coupled receptors of the endothelial differentiation gene (EDG) family, and it regulates intracellular signaling events in a wide variety of cells (4). As discussed in the next section, S1P action on ECs is of critical importance to the normal development and physiological function of the vascular system. In addition, dysregulated S1P signaling may be important in several disease states.

### THE VASCULAR S1P GRADIENT

S1P is found generally associated with carrier proteins or membrane lipids. Although comprehensive knowledge of S1P binding proteins is not known, it is found in association with albumin and high-density lipoprotein fractions in plasma (14). Indeed, total serum concentration of S1P is very high, estimated to be in the range of 0.4 to 2  $\mu\text{M}$  in mammals. However, plasma concentration is somewhat lower (0.1 to 1  $\mu\text{M}$ ), suggesting that S1P is produced and/or released by hematopoietic cells upon blood clotting. In contrast, tissue S1P levels are extremely low (nM concentrations). Thus, a large vascular gradient of S1P exists in mammals. The mechanisms involved in the establishment and/or maintenance of the S1P gradient are not known. Whether this occurs also in other vertebrates, chordates, and invertebrates is not known. S1P-like lipids are produced by all eukaryotes. The receptors for S1P appear to be restricted to vertebrates, although close homologues have been shown to exist in the chordate genome (15). The evolutionary significance of the vascular S1P gradient must be further explored.

Because platelets appear to express high levels of Sphk, lack the S1P lyase, and platelet activation leads to the appearance of S1P in the serum, it is generally assumed that platelets are a major cellular source of S1P (14). However, other hematopoietic cells (e.g., monocytes, macrophages, mast cells, neutrophils) also secrete S1P (16). Thus, release of S1P from activated and aggregated hematopoietic cells is likely to be a major source of S1P in serum. This mechanism may come into play during thrombosis and inflammation. However, under physiological conditions, the cellular source of S1P in the vascular system is not known. Although many cells are capable of secreting S1P from intracellular sources, S1P also may be formed in the extracellular environment. For example, vascular ECs secrete Sphk-1, which uses extracellular sphingosine and ATP to produce S1P (9). In addition, ceramidase and SMase enzymes also are secreted, suggesting that S1P can be formed in both intracellular and extracellular locations (7).

The S1P gradient in the closed circulatory system of mammals suggests that vascular and hematopoietic cells are constantly exposed to high concentrations of S1P. Given that the dissociation constant for S1P receptors is in the nanomolar range, cells bearing the receptors are constantly stimulated with maximal S1P concentrations. S1P<sub>1</sub> receptor is readily downregulated by ligand-induced internalization via the

endosomal pathway (17). Even though receptor recycling takes place, a very small fraction of receptors is present on the cell surface when excess ligand is present. These data suggest that S1P receptors are likely to be sequestered in the cytosol of cells in the vascular system, and this may limit receptor function for certain processes such as cell migration. Indeed, this was shown to be functionally important for lymphocyte egress from secondary lymphoid organs and the thymus. For example, interference with the S1P<sub>1</sub> receptor through the immunomodulatory compound FTY720 resulted in the inhibition of T-cell egress and immunosuppression (18). Similarly, vascular EC and vascular smooth muscle cell (VSMC) migration, which require S1P receptor on the plasma membrane, is likely to be transient in the presence of high extracellular S1P concentrations. However, the S1P gradient is likely to be reversed during thrombosis and angiogenesis, when platelet aggregation and other cell activation would release S1P in the extracellular milieu, such as the clot and the provisional fibrin matrix. The changes in S1P gradient during physiological and pathophysiological conditions may be extremely critical to the biological responses.

#### S1P FUNCTION IN VASCULAR DEVELOPMENT AND ANGIOGENESIS

The first S1P receptor to be characterized was originally isolated from vascular ECs as an immediate-early gene induced during *in vitro* angiogenesis (19). Cell culture studies show that S1P is a potent inducer of EC migration, survival, proliferation, cell–cell adhesion, and cell–matrix adhesion. It potently induces morphogenesis and tube formation in *in vitro* assays of angiogenesis (4). Vascular ECs express multiple S1P receptors. Most cell lines and strains express S1P<sub>1</sub> and S1P<sub>3</sub>, whereas some also express S1P<sub>2</sub>. For example, human umbilical vein ECs express S1P<sub>1</sub> and S1P<sub>3</sub>, whereas bovine lung microvascular ECs express S1P<sub>1</sub> and S1P<sub>2</sub>. Collaboration between the two receptors is necessary for EC morphogenesis (20). The S1P<sub>2</sub> receptor, however, may inhibit cell migration and other angiogenic phenomena, suggesting a complex regulatory mechanism in this system of angiogenesis (21). Indeed, in models of *in vivo* angiogenesis, either by itself or in concert with polypeptide angiogenic factors, S1P potently influences angiogenesis (20).

S1P also has potent effects on VSMCs. Normal rat adult VSMCs express S1P<sub>2</sub> and S1P<sub>3</sub> receptors, which are presumed to regulate G<sub>q</sub>- and G<sub>12/13</sub>-dependent vascular contraction (22). In these cells, activation of Rho GTPase by S1P<sub>2</sub> receptor results in the profound inhibition of cell migration. In the fetal or intimal phenotype of VSMCs, S1P<sub>1</sub> receptor is induced, which activates the Rac and p70<sup>S6K</sup> kinase pathways (22). These events are important for cell migration and proliferation. S1P<sub>1</sub> receptor is overexpressed in atheromatous plaques in humans, suggesting that the balanced function of different S1P receptors is important for vascular physiology and disease (22).

Knockout studies in mice have indicated the essential role of S1P<sub>1</sub> receptor in the embryonic vascular maturation. *S1p*<sup>-/-</sup> mice die *in utero* between embryonic days 12.5 to 14.5 (E12.5–14.5) of development due to hemorrhage and vascular permeability. Incomplete coverage of various blood vessels with mural cells, particularly in the arterial system was observed. This study provided evidence for a critical role of S1P<sub>1</sub> during the later phases of vascular system development (23). This process can be recapitulated *in vitro*; ECs derived from *S1p1*<sup>-/-</sup> mice show defective interaction with mural cells (24). It appears that activation of S1P<sub>1</sub> in vascular ECs triggers G<sub>i</sub>/Rac-dependent activation of microtubule assembly, which is essential for the proper trafficking of the cell–cell adhesion molecule N-cadherin to heterotypic cell–cell junctions. N-cadherin itself is activated by complex formation with catenins, lateral clustering, and phosphorylation. This mechanism of the N-cadherin-dependent activation of vascular maturation also may be important in the adult. Indeed, siRNA-mediated knockdown of the *S1P1* mRNA, which is induced in tumor microvessels, resulted in diminished vascular maturation, reduced tumor microvessel density, and attenuated tumor growth rate, suggesting the importance of the S1P/S1P<sub>1</sub> signaling system in tumor angiogenesis (25).

In addition to S1P<sub>1</sub>, other S1P receptors may also play a role in vascular development. Although single knockouts of S1P<sub>2</sub> and S1P<sub>3</sub> are viable, double knockout or triple knockouts of the three receptors led to earlier lethality with defects in the vascular system (26). This suggests that some vascular functions are regulated in a redundant manner by these S1P receptors.

#### S1P AND VASCULAR PERMEABILITY

The potent ability of S1P to induce homotypic cell–cell junction assembly (VE-cadherin-based) and heterotypic cell–cell junctions (N-cadherin-based), suggested a role for this mediator in regulating vascular permeability. Indeed, S1P treatment of cultured ECs results in cortical actin changes, which are necessary for the formation of cell–cell junctions (20). Moreover, S1P inhibits paracellular permeability in monolayer cultures of ECs (27). Importantly, vascular endothelial growth factor (VEGF)-induced vascular permeability *in vivo* is potently inhibited by acute treatment with FTY720, which is phosphorylated and acts on the S1P<sub>1</sub> and S1P<sub>3</sub> receptors as a potent agonist (28). In addition, in murine and canine models of lipopolysaccharide-induced pulmonary edema, S1P and FTY720 potently reduced EC injury and edema (29). The role of other S1P receptors, particularly the S1P<sub>2</sub> receptor, on vascular permeability is not understood. It is possible that high S1P levels in plasma are important for the physiological maintenance of vascular permeability. Importantly, pharmacologic modulation of this signaling system may provide novel therapeutic targets in the control of vascular permeability disorders, such as sepsis, Dengue hemorrhagic fever, and others.

## ROLE OF S1P IN VASCULAR TONE CONTROL

S1P<sub>1</sub>- and S1P<sub>3</sub>-mediated signaling in ECs has been linked to activation of the G<sub>i</sub> pathway, induction of intracellular Ca<sup>2+</sup> levels, and phosphorylation of mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K)/Akt (30), all of which are important for the activation of the endothelial NOS (eNOS) system. Indeed, S1P was shown to potently induce the phosphorylation and activation of eNOS, resulting in increased NO production, which is essential for vasorelaxation (31). In *S1p3*<sup>-/-</sup> mice, endothelium-dependent vasorelaxation responses are impaired (32).

In contrast, basal expression of S1P<sub>2</sub> and S1P<sub>3</sub> in the VSMCs of resistance arteries would be expected to counteract this system. Both receptors can couple to the G<sub>q</sub> and G<sub>12/13</sub> system, thus activating phospholipase C-β/Ca<sup>2+</sup>/protein kinase C (PKC) pathway and Rho/Rho-associated kinase (ROCK) pathway, respectively (30). Both of these pathways ultimately impact the actin/myosin-based system and result in VSMC contraction. Thus, in some vascular beds, such as in the basilar artery in the brain and in renal arteries, S1P acts as a potent vasoconstrictor (33,34).

Differential S1P receptor expression in ECs, injury of ECs, and S1P receptor expression in VSMCs may all contribute to the role of S1P in vascular tone control. As stated earlier, the ligand is abundant in the plasma; therefore, EC receptors are likely to be continuously activated. However, upon injury to the ECs, VSMC receptors are likely to be engaged. The role of receptor internalization is likely to limit the vasoactive responses, in particular those that depend on the NO pathway. S1P receptor expression is inducible. For example, S1P<sub>1</sub> is upregulated by shear stress, phorbol esters, and angiogenic growth factors, whereas S1P<sub>3</sub> is induced by tumor necrosis factor (TNF)-α in ECs (7). Therefore, under the influence of inflammation, thrombosis, and angiogenesis, the receptor expression profile is likely to be altered, and thus may change the vascular contractile response to S1P.

## ROLE OF S1P IN ENDOTHELIAL INJURY

Stimulation of ECs with S1P in vitro results in activation of cell survival pathways, such as those regulated by PI3K and extracellular signal-regulated kinase (ERK). Thus, S1P protects ECs from cell death induced by chemicals such as ceramide and 15-deoxy-Δ<sup>12,14</sup>-prostaglandin J<sub>2</sub>. The survival effects of S1P requires the S1P<sub>1</sub> receptor expression and involves the G<sub>i</sub> pathway (20). In many other cells, S1P protects against cell death – via both receptor-mediated and other pathways (16). For example, in addition to G-protein-dependent antiapoptotic pathways, metabolic conversion of S1P may be important for antiapoptosis. Therefore, plasma S1P may be involved in normal maintenance of EC function and health.

As discussed earlier, S1P is a potent inducer of endothelial cell–cell junctions. The proper maintenance of cell–cell

junctions is critical for proper barrier formation and thus prevents excessive vascular permeability in continuous endothelia. Thus, S1P receptor function may be critical for physiologic maintenance of EC transport and barrier properties. Because abnormal vascular permeability is a precursor to chronic tissue changes, such as abnormal fibrin deposition, inflammation, angiogenesis, and fibrosis, alterations in the S1P signaling system may contribute to a variety of chronic pathological changes. The interaction of S1P with other noxious stimuli, such as oxidant stress has not been described. However, given that S1P is a pro-survival factor in nonvascular cells treated with radiation and cytotoxic agents, it likely protects vascular cells against various injurious insults.

## S1P AND VASCULAR PATHOLOGY

In addition to the role of S1P in tumor angiogenesis, S1P signaling pathway may contribute to a number of vascular diseases, for example, restenosis after vascular injury, transplant-associated vasculopathy, angiogenesis post myocardial infarction, wound healing, and atherosclerosis.

VSMC migration into the neointima of injured vessels, followed by proliferation of VSMCs and matrix deposition, are important characteristics of restenosis after vascular injury, which is a chronic health problem in patients who receive revascularization therapy. S1P<sub>1</sub> receptor induces VSMC migration and proliferation and is expressed in pathologic lesions in atheromatous plaques (22). It also activates the critical signaling pathway regulated by ribosomal protein S6kinase (p70<sup>S6K</sup>), which is a target of the drug rapamycin. Thus, S1P<sub>1</sub> function may be important in this disease condition, and drugs that target this receptor may be useful in controlling restenosis.

Similarly, VSMC proliferation and restenosis are important complications that limit organ function in transplants. In this scenario, immune pathways are predominant and contribute to VSMC expansion and stenosis of the vessel. Importantly, many transplant therapies, such as rapamycin and FTY720, also target the effect of S1P receptors or the receptors themselves, respectively. Thus, consideration of this issue may lead to better therapeutic approaches in the control of transplant-associated vasculopathy (35).

Atherosclerosis is a complex disease that affects the majority of the population in the modern society. Although the role of S1P and sphingolipids in the pathogenesis of atherosclerosis is poorly understood, available data suggest their significant involvement. Sphingomyelin, ceramide, sphingosine, and S1P are constituents of lipoproteins. The inhibition of de novo sphingomyelin synthesis with myriocin, a potent inhibitor of the rate-limiting enzyme serine palmitoyl transferase, inhibited atherosclerosis in mouse models without affecting lipoprotein levels (36–38). This suggests that sphingolipid metabolites may play critical roles in atherosclerosis. High-density lipoprotein (HDL) fraction contains significant levels

of S1P, and this may confer the vasculoprotective and NO-releasing functions of HDL (39). In addition, S1P may regulate monocyte/macrophage functions, such as survival and inflammatory gene expression (40,41). The ability to regulate EC functions also may be important for initial phases, as well as for the progression of atherosclerosis. Further studies are needed to fully define the role and impact of sphingolipids in atherosclerosis.

### PHARMACOLOGIC APPROACHES IN THE CONTROL OF SPHINGOLIPID MEDIATORS

Given the ubiquity and potency of sphingolipid mediators in various organ systems, novel pharmacologic opportunities exist to control various disease processes in which these lipids are implicated. This is particularly true for extracellular receptors for S1P, which are G-protein-coupled and therefore are commonly referred to in the pharmaceutical industry as “druggable.” Although the current state of the pharmacologic tools for S1P receptors can be classified as primordial, a number of initiatives suggest that more refined tools will be forthcoming. S1P<sub>1</sub>- and S1P<sub>2</sub>-specific tools have been described that have immunologic effects (42,43). The vascular effects of such reagents remain to be investigated.

The developing FTY720 story suggests that S1P receptor modulation may have a potentially significant impact on human health in the future. It is a derivative of myriocin, and was developed due to its potent property to induce reversible lymphopenia without causing the myeloid-suppressive side effects of classical immunosuppressants (35). Interestingly, FTY720 is phosphorylated by sphingosine kinase-2 and the resultant FTY720-P acts as an agonist in S1P receptors (all except S1P<sub>2</sub>). FTY720-P binding does not result in receptor recycling; therefore, this compound causes the sustained internalization of S1P<sub>1</sub> receptors. This presumably interferes with the chemotaxis-sensing property of T-cell receptors, which is important for cellular egress from the lymph nodes and other peripheral lymphoid tissues (18). Currently, FTY720 is being tested for its immunomodulatory actions in transplant rejection and in multiple sclerosis. Some side effects, such as bradycardia, were noted – which is perhaps to be expected, because S1P receptor systems are involved in many organ systems. The utility of FTY720 or S1P receptor-modulatory drugs in vascular and angiogenic indications should be of interest.

### CONCLUSION

Sphingolipid biology is anticipated to yield important novel insights into the workings of the endothelium. Recent work has illustrated the important role played by sphingolipid mediators in the structure and function of the ECs. The powerful and broad-spectrum nature of the S1P signaling system in the vascular ECs is illustrative of this concept. That structurally critical lipids are mobilized in processes of signal transduc-

tion points to the economy by which evolutionary mechanisms have selected the players. The insights from the study of these simple lipids will not only lead to better understanding of physiology and pathology in the vasculature, but also will likely bring forth novel opportunities for therapeutic intervention, which will add to our armamentarium in vascular medicine.

### KEY POINTS

- Sphingolipids are important constituents of ECs.
- S1P is a major signaling lipid in ECs.
- ECs secrete S1P.
- ECs respond to S1P via its G-protein-coupled receptors.
- S1P regulates EC migration, survival, proliferation, adherens junction assembly, and NO synthesis in vitro.
- S1P regulates angiogenesis, vascular maturation, and vascular permeability in vivo.
- S1P receptors in ECs provide a novel therapeutic opportunities.

# Endothelium

## A Critical Detector of Lipopolysaccharide

---

Jaswinder Kaur and Paul Kubes

*University of Calgary, Alberta, Canada*

Endotoxin is part of the outer membrane of the cell wall of gram-negative bacteria. It also is referred to as lipopolysaccharide (LPS), owing to its historical discovery. During the 1800s, it was understood that bacteria could secrete toxins into their environment, which were broadly known as “exotoxins.” The term *endotoxin* came about following the discovery that portions of the gram-negative bacteria itself can cause toxicity. Over the next 50 years, studies focused on endotoxin revealed that the actual molecule responsible for the effects of endotoxin was in fact LPS. Endotoxins largely are responsible for clinical manifestations of the infections induced by pathogenic gram-negative bacteria such as *E. coli*, *Salmonella*, *Shigella*, *Pseudomonas*, *Neisseria*, *Haemophilus*, and others. The goal of this chapter is to discuss the receptor, signaling pathway, and effect of LPS on endothelium.

### LIPOPOLYSACCHARIDE STRUCTURE

LPS is comprised of a polysaccharide (“sugar”) chain and a lipid moiety, known as lipid A, the portion responsible for toxic effects (Figure 46.1). Lipid A is found in the exterior leaflet of the outer membrane. Lipid A is the most conserved portion of the molecule; however, it can vary according to the nature of fatty acid chains and its degree of phosphorylation. This portion is the biologically active component of LPS, because isolated lipid A or synthetic lipid A (free of contaminants) displays the same bioactivity as intact LPS in vitro and in vivo (1). Indeed, in bovine pulmonary artery endothelial cell (BPAEC) monolayers, lipid A has been shown to be the bioactive portion of LPS responsible for inducing changes in endothelial barrier function, with a dose-dependent increase in EC monolayer permeability comparable to that of native LPS (2). Incubation of BPAECs with LPS in the presence of polymyxin B, a derivative of the bacteria *Bacillus polymyxa*, which binds to the lipid A portion of LPS (3), blocked LPS-induced endothelial cell (EC) barrier dysfunction (2).

### TOLL-LIKE RECEPTORS

For a long time, the mechanism by which endotoxin initiated a signal remained elusive. Then, in 1998, positional cloning revealed Toll-like receptor 4 (TLR4) as the central component of the LPS receptor (4). TLR4 is expressed predominantly by the myeloid lineages (monocytes, macrophages, microglia, myeloid dendritic cells, and granulocytes) (5–7) in mice and humans. In human tissues, the strongest expression of TLR4 is observed in the spleen and on peripheral blood leukocytes, with weak expression apparent in other tissues (8,9). On the other hand, murine *TLR4* mRNA is expressed most strongly in the lung, heart, and spleen, but is also present in the muscle, liver, and kidney (10).

The term *Toll-like receptor* was adopted following the observed similarity between the *Drosophila* Toll receptor and mammalian TLRs. The *Drosophila* Toll receptor is a regulator of dorso-ventral polarity in fly embryos. The homology between the intracellular domains of *Drosophila* Toll and the interleukin (IL)-1 receptor was recognized by Gay and Keith in 1991 (11). The similarities of these type-I transmembrane proteins extends to both the signaling domains, which contain the Toll/IL-1 Receptor (TIR) motifs, and the ectodomains, which have multiple leucine-rich repeats. The first sequence of the mammalian TLR homolog of *Drosophila* was obtained in 1994 (12). Lemaitre and colleagues, in 1996 (13), demonstrated its importance in regulating antifungal immunity in adult flies. The first functional role for a mammalian TLR was established by Medzhitov and colleagues (14), who demonstrated that coupling intracellular domains of a TLR with the extracellular domain of CD4 resulted in the activation of the transcription factor, nuclear factor (NF)- $\kappa$ B. This induced the expression of NF- $\kappa$ B-regulated inflammatory genes, including IL-1, IL-6, and IL-8, and the costimulatory molecule B7.1, which is required for the activation of naïve T cells. Although no ligand for a TLR(s) was known, these novel observations were suggestive of a role for TLR in innate as well as

Figure 46.1. General structure of LPS. The biological activity of endotoxin generally is associated with the LPS. In particular, toxicity is a result of lipid component (lipid A) and immunogenicity with the polysaccharide components.

adaptive immunity. In 1998, it was revealed that a whole family of mammalian TLRs exist that bind to a number of different microbial ligands – and that the long-sought bacterial receptor for LPS was indeed TLR4 (4,9,15).

Mammalian TLRs have evolved in a process that began prior to the divergence of plants and animals. The TLR multi-gene family encodes conserved pattern recognition receptors (PRRs) that sense a variety of conserved pathogen-associated molecular patterns (PAMPs) that are unique to pathogens and are absent from the host cells in both the invertebrate and vertebrate lineages (16). TLRs are type-I transmembrane proteins with ectodomains consisting of leucine-rich repeat motifs that recognize the various microbial ligands. The cytoplasmic domain contains TIR motifs, which are highly conserved across the TLR families as well as through evolution, because they are present not only in animals but plants as well. TIR motifs mediate the bimolecular interactions necessary for downstream signal transduction from the TLR receptors. These germline-encoded receptors initiate signaling cascades to transcribe a diverse repertoire of genes, including antimicrobial peptides, cytokines, inflammatory mediators, and regulators of phagocytosis (17–19).

As noted earlier, the Toll signaling pathway was initially identified in *Drosophila* (13,20) and characterized for its role in initiating the innate immune response against fungal and gram-positive bacterial infections (13,21). TLR family members recognize several classes of pathogens and initiate appropriate innate and adaptive immune responses. TLR2 in combination with TLR1 recognizes lipoproteins with triacylated N-terminal cysteines, while in combination with TLR6, it recognizes diacylated lipoproteins (22,23). TLR3 recognizes double-stranded RNA, whereas LPS is recognized by TLR4 and flagellin by TLR5. Compounds such as nucleic acids and heme are recognized by the TLR7–9 family (24–26). Although the specific ligand for TLR10 remains to be identified, it has been demonstrated that TLR10 directly associates with MyD88 (myeloid differentiation primary response gene 88), the common Toll IL-1 receptor domain adapter (27). TLR11 receptor is present in mice, but only represented as a pseudogene in humans; it is known to recognize uropathogenic *Escherichia coli* (28). The ligand for TLR11 has been described as a profilin-like protein from *Toxoplasma gondii* (29). Not only are the coding sequences and function of the vertebrate TLRs highly conserved, but so too are the signaling pathways initiated by the TLRs.

## TOLL-LIKE RECEPTOR SIGNALING PATHWAYS

As discussed earlier, Toll receptors are class I transmembrane proteins that have a leucine-rich extracellular domain, a short transmembrane domain, and an intracellular signaling domain known as the TIR domain (26). TLRs have TIR motifs in their cytoplasmic tails, and signal through cytoplasmic adapter proteins that also contain TIR motifs. To date, three TIR motif-containing proteins, MyD88, Tirap (Toll-IL-1 receptor [TIR] domain-containing adapter protein), and TIR domain containing adaptor inducing interferon (IFN)- $\beta$  (Trif) have been identified. These are involved in mediating LPS signaling. Genetic evidence does suggest the existence of another adapter protein, “X,” that perhaps partially substitutes for Trif (30). More recently, an essential accessory protein for signaling, MD2, a 20- to 30-kDa glycoprotein, which is secreted and binds to an extracellular domain of TLRs, has been described (31).

TLR signaling is initiated from the cytoplasmic TIR domains. The crucial role of these domains was first demonstrated in the C3H/HeJ mice, which have a point mutation of a proline residue in the TIR domain of TLR4 (4,32). The next signaling molecule characterized downstream from the TIR domains was the TIR domain-containing adaptor protein, MyD88. MyD88 contains a TIR domain in its C-terminal portion and a death domain in its N-terminal portion. Following stimulation, MyD88 recruits a serine/threonine kinase, IL-1 receptor-associated kinase (IRAK) to TLRs via the death domains of both molecules. *MyD88*<sup>-/-</sup> mice are unable to produce inflammatory cytokines, such as tumor necrosis factor (TNF)- $\alpha$ , IL-6, and IL-12, in response to any of the TLR ligands (33).

The recruitment and activation of IRAK subsequently leads to the recruitment and activation of TNF receptor-associated factor 6 (TRAF6), which in turn activates NF- $\kappa$ B either through the I $\kappa$ B kinase complex and the kinases TAB-1 and TAK-1 (34), or through evolutionarily conserved signaling intermediates in Toll pathways (ECSIT) and mitogen-activated protein kinase (MAPK) (35). These pathways converge on NF- $\kappa$ B, which can now disassociate from its inhibitory proteins that retain NF- $\kappa$ B in the cytoplasm in a quiescent state. The liberated NF- $\kappa$ B then freely moves into the nucleus to induce the transcription of NF- $\kappa$ B-responsive genes (Figure 46.2).

To date, eleven TLR subtypes have been identified, but TLR4 is the only TLR that mediates responses to LPS (36). Interestingly, one study had suggested an additional LPS-induced response via TLR2 (37). However, these data have been discounted, because repurification of commercially available LPS resulted in abrogation of TLR2 responsiveness (indicating previous LPS samples were contaminated) (38). Furthermore, Weis and colleagues clearly demonstrated that non-LPS ligands (e.g., peptidoglycan [PGN], zymosan and lipoteichoic acid [LTA]) mediate TLR2 signaling (38). This controversy was further resolved by studies of TLR2-deficient

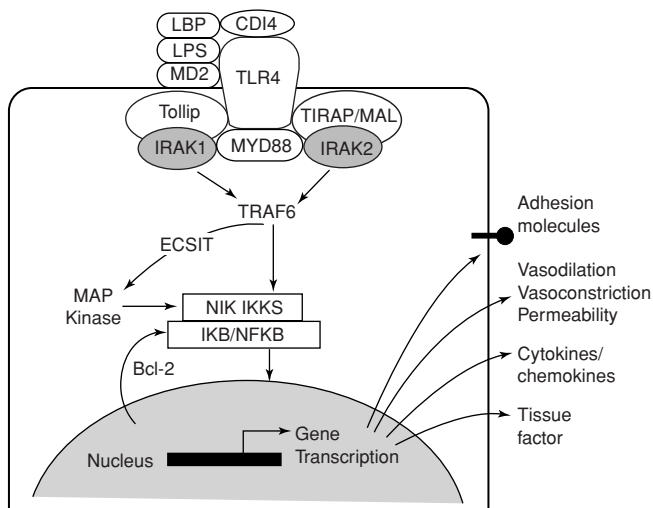

Figure 46.2. TLR4 signaling-mediated effects on ECs. LPS in the bloodstream, released by infectious gram-negative bacteria, overactivates ECs to release a number of cytokines, chemokines, and vasoregulatory mediators and to express adhesion molecules and procoagulant factors. Increased permeability also results from activation. LPS binds endothelial-expressed TLR4 in the presence of CD14 and MD2. Activation of this receptor complex mediates the recruitment of the cytoplasmic proteins MyD88, TIRAP, Tollip, IRAK 1 and 2, and TRAF6. TRAF6 ultimately activates the MAPK pathway and NF- $\kappa$ B. In quiescent cells, NF- $\kappa$ B is retained in the cytoplasm by I $\kappa$ B. Incubation of ECs with LPS leads to degradation of I $\kappa$ B and thus translocation of NF- $\kappa$ B into the nucleus. Translocated NF- $\kappa$ B binds to DNA sequences of NF- $\kappa$ B regulated target genes, such as IL-1, IL-6, and IL-8, tissue factor, and adhesion molecules.

mice, which showed robust responses to LPS administration. Although alternative signaling pathways have been suggested (39,40), most LPS preparations are principally recognized by TLR4. Possible exceptions are LPS from *Porphyromonas gingivalis* and *Leptospira interrogans*, which appear to be recognized by TLR2 (41,42).

Further evidence in support of LPS-TLR-mediated effects comes from the recent identification of spontaneous mutations in the murine *Tlr4* gene, which for many years were called “LPS-resistant mice.” These mutations render two distinct strains of mice, C3H/HeJ and C57BL/10ScCr, resistant to LPS (4). In the C3H/HeJ mouse, a missense mutation was identified in the third exon of *Tlr4*, whereas C57BL/10ScCr mice were identified as homozygous for a null mutation of *Tlr4*. A genetically engineered strain has been described that has the *Tlr4* gene deleted by homologous recombination and is also unresponsive to LPS challenges (32).

## ENDOTOXIN, TLR4, AND ENDOTHELIUM

The expression of TLR receptors on endothelium is regulated by inflammatory mediators, such as LPS, TNF- $\alpha$ , and IFN- $\gamma$  (43). LPS-stimulated ECs also release high levels of MD2 in vitro (44). Interestingly, MD2 may aid the direct binding

of LPS to TLR4 (45). Using an LPS inhibitor, E5531, it was demonstrated that TLR4 and MD2 were critical for signaling in human umbilical ECs (HUVECs), similar to observations in phagocytic cells (5). Immortalized human dermal microvessel ECs also express MD2 and respond to LPS (44). However, it has not been determined if primary ECs express MD2, use soluble MD2, or are activated independently of MD2. MD2 recently was reported to also colocalize with TLR2 and to amplify the response to TLR2 ligands (46).

Although the majority of reports suggest TLR4 is expressed by cultured ECs, one report suggests otherwise. Foxwell and colleagues (47) were unsuccessful in detecting surface TLR4 expression on HUVECs. In contrast, others reported the presence of TLR4 in HUVECs using reverse transcription polymerase chain reaction (RT-PCR) and Northern blot analysis (48). More recently, TLR4 expression on endothelium also has been shown at the protein level (49). LPS-induced NF- $\kappa$ B activation in ECs can be blocked using dominant negative mutant proteins involved in downstream Toll signaling (50). It was subsequently shown that the LPS-resistant mutant mice cannot transmit signals across the EC membrane in response to LPS (4,10,32,48). In addition, it also has been demonstrated that LPS induces the mRNA expression of TNF- $\alpha$  and IL-1 $\beta$ , and the release of IL-6, IL-8, and monocyte chemoattractant protein (MCP)-1 from human coronary artery ECs via TLR4. In the same study, LPS-induced and TLR4-mediated expression of endothelial adhesion molecules was also observed (51). However, it is unclear whether LPS directly binds to TLR4, or whether LPS induces an unidentified ligand of TLR4 that transmits the signals. Much less is known about the other TLRs in the endothelium. TLR2 is thought to be expressed in very low levels in ECs or not at all (47). However, it is upregulated by various stimuli in ECs (52).

## ROLE OF ENDOTHELIUM IN INFECTION

The strategic positioning of ECs at the interface between circulating blood and tissue allows these cells to engage in diverse physiological functions essential for organ homeostasis. ECs have been shown to regulate a number of physiological events, such as organ perfusion, permeability, adhesion of blood cells, pro-coagulation, and anticoagulation (53). Because of their prime location, ECs can encounter bacterial toxins both in the circulation and the extravascular space. However, it remains unknown whether LPS can be detected abuminally by endothelium or whether sentinel cells (macrophage, mast cells, and the like) detect the LPS in tissue and activate the endothelium. Upon their activation, ECs release vasoactive molecules to affect blood flow, and they recruit effector cells of the immune system to the site of infection. The expression of adhesion molecules allows leukocytes to transmigrate into the infected tissue. Furthermore, the activated endothelium presents a procoagulant surface and promotes the formation of clots to enclose the infected site. Therefore, these endothelial

events are absolutely essential for an efficient inflammatory response that eliminates the infectious agent. However, if the endothelium is overactivated systemically, as in sepsis and septic shock, the result may be devastating (see Chapter 141).

Sepsis and severe sepsis are caused by inappropriate inflammatory and immunological host responses to infections. Gram-negative bacterial sepsis, a common life-threatening event, often is complicated by systemic vascular collapse, disseminated intravascular coagulation, and vascular leak syndromes. One component common to all these complications is EC injury and dysfunction. It is widely believed that the dysregulation of the endothelium plays a significant role in mediating the sepsis phenotype. Aside from direct activation of the endothelium by LPS, myriad cytokines, chemokines, and other mediators also affect the endothelium and lead to vascular dysfunction.

### LIPOPOLYSACCHARIDE, CD14, AND LPS-BINDING PROTEIN

To respond to LPS directly, ECs must express CD14. Indeed, it has been shown that activation of ECs and other immune cells occurs by LPS binding to CD14, with subsequent interaction with TLR4 (54). CD14 is a glycosylphosphatidylinositol (GPI)-linked protein that is constitutively expressed on monocytes and macrophages and, to a lesser extent, on neutrophils. In addition to the membrane-bound isoform of sCD14, an alternatively spliced soluble form of CD14 (sCD14) is released from various cells and is found in normal serum or plasma (55,56). Interestingly, early studies suggested that ECs do not express CD14 (56,57) but require the soluble form to respond to LPS. However, Jersmann and colleagues (58) have demonstrated constitutive expression of membrane CD14 (mCD14) on HUVECs, where its expression was further enhanced by LPS activation. These *in vitro* studies revealed that passaging of ECs led to a loss of endothelial CD14 (58). Membrane CD14 has a short transmembrane portion consisting of 21 amino acids. Both sCD14 and mCD14 lack an intracytoplasmic region and signaling domain, suggesting that these molecules must interact with a receptor (e.g., TLR4, which is capable of transducing the LPS signal). Indeed, the primary function (59) of these proteins is to bind LPS and to facilitate the interaction of endotoxins with TLRs.

The ability of endothelium to interact with LPS via sCD14 is well established. *In vitro* studies show that ECs respond to very low levels of LPS only in the presence of serum containing sCD14. The addition of sCD14 to serum-free cultures sensitizes ECs to LPS up to 100-fold. For example, LPS-mediated inflammatory EC responses such as the release of cytokines (55) and vasoactive molecules (60), the expression of adhesion molecules, and disruption of endothelial barrier function occurs at picogram quantities of sCD14 in the presence of plasma and in nanogram quantities in the absence of plasma (61). Interestingly, it has been shown that CD14-deficient cells do not respond to low levels of LPS even in the presence of

sCD14, suggesting an essential role for mCD14 for sCD14 function. ECs, smooth muscle cells, or phagocytes from CD14-deficient mice can respond to LPS if the concentration of LPS is high enough. Recently, using *CD14*<sup>-/-</sup> mice, we observed that some vascular beds were completely resistant to LPS, whereas endothelium from other vascular beds still reacted with adhesion molecule expression. Clearly this reflected the heterogeneity of different ECs rather than simply a concentration effect, and it raises the possibility that other molecules can replace CD14. Further evidence that other LPS-recognizing molecules may exist is that anti-CD14 antibodies are incapable of completely inhibiting cell activation in response to high levels of LPS (62,63). Alternatively, high doses of LPS could bypass CD14 and directly activate downstream receptors (e.g., TLR4).

Other candidates that could potentially recognize LPS include the integrin family of adhesion molecules, CD11/CD18, and LPS-binding protein (LBP), which also bind LPS (59). Binding of LPS to CD14 is facilitated by LBP, a 60-kDa acute-phase serum protein primarily synthesized by hepatocytes (64–66). LBP transfers LPS to mCD14 as well as to sCD14. The importance of LBP in LPS-induced effects has been demonstrated in mice lacking the LBP gene; these mice are partially resistant to LPS (67). Also, administering anti-LBP in tandem with LPS protected mice from LPS-induced shock (68). The role that LBP plays in the transfer of LPS to sCD14 is unclear. However, addition of recombinant sCD14 to serum-free media restores LPS-related cytotoxicity, whereas addition of recombinant LBP has no effect, suggesting that sCD14 is the prerequisite molecule for LPS-induced endothelial activation independent of LBP.

### LIPOPOLYSACCHARIDES AND ENDOTHELIAL PERMEABILITY

A breakdown of vascular barrier function, also referred to as plasma leakage, is a classic feature of severe sepsis and septic shock. The endothelial barrier regulates the transport of cellular components, macromolecules, and fluid from the bloodstream into the surrounding tissue. Cytoskeletal proteins located along the EC borders maintain intercellular tightness in association with adherence and tight junctions (69). In response to mediators that increase permeability, ECs contract, driven by reorganization of the cytoskeleton. This contraction results in endothelial intercellular contacts opening and contributing to increases in paracellular permeability of the endothelium. The increase in endothelial permeability can be caused by direct effects of LPS on the endothelium or by a variety of inflammatory mediators, including cytokines, platelet-activating factor (PAF), and leukotrienes (LTs). These latter mediators are released from surrounding resident macrophages and mast cells or by adhering and emigrating neutrophils.

LPS has been shown to directly enhance endothelial permeability. LPS-mediated disruption of endothelial barrier function depends on CD14 and LBP (70). LPS augments

Figure 46.3. Studies have shown that the stimulation of TLR4 on the endothelium leads to the rapid surface expression of adhesion molecules. As a consequence, increased leukocyte rolling, adhesion, and transmigration occurs. Additionally, TLR4-expressing cells, such as tissue-resident macrophages, also release a number of inflammatory factors, such as cytokines and chemokines, which also act on the endothelium.

the movement of radiolabeled tracer molecules across EC monolayers in the absence of hydrostatic or osmotic pressure gradients, granulocyte effector cells, or a number of other host-derived nonendothelial mediators (2). Studies *in vitro* have demonstrated that LPS induces F-actin depolymerization and intercellular gap formation, processes that coincide with endothelial barrier dysfunction (2). This sequence of events can be inhibited by using an endotoxin-neutralizing protein to prevent the rapid LPS-induced protein tyrosine phosphorylation events. LPS-induced changes in endothelial barrier function are not dependent on new protein synthesis, because the endothelial responses occur very quickly and protein synthesis inhibitors do not decrease LPS-induced transendothelial flux (61). LPS-induced endothelial permeability is augmented by the cleavage or disengagement of the adherens junction proteins  $\beta$ - and  $\gamma$ -catenin, which are involved in maintaining cell-cell contacts. Studies strongly suggest that LPS-induced endothelial permeability is associated with enzymatic cleavage of adherens junction proteins (71).

#### LIPOPOLYSACCHARIDES AND ENDOTHELIAL-LEUKOCYTE INTERACTIONS

The recruitment of leukocytes from the circulation to the interstitium is central to the inflammatory process. Leukocyte recruitment involves a sequence of events constituting rolling, adhesion, and transmigration. These processes utilize a number of inflammatory mediators and adhesion

molecules expressed on ECs and leukocytes. Figure 46.3 illustrates the cascade of LPS-induced leukocyte recruitment on activated ECs. TLR4 activation induces not only the expression of adhesion molecules, but also the production of chemotactic agents, including chemokines and other inflammatory molecules such as PAF and LTB<sub>4</sub>. The local production of these molecules leads to the accumulation of inflammatory cells within a tissue following LPS administration (72,73). This entire cascade of leukocyte recruitment can be recapitulated on endothelial monolayers, suggesting direct effects of LPS on endothelium.

It has been demonstrated that TLR4 activation through administration of LPS to a local site induces a localized inflammation within that tissue (72,74). Using intravital microscopy to observe leukocyte recruitment, it was shown that, under baseline conditions, very few leukocytes rolled and no adhesion or emigration into the tissue occurred. However, upon local administration of LPS, significant rolling, adhesion, and subsequent leukocyte transmigration into the tissue was observed. Notably, these events were not observed in *Tlr4*<sup>-/-</sup> mice, thus confirming the involvement of the LPS-TLR4 complex in inducing inflammation in this model (74). Chimeric mice lacking TLR4 on endothelium but having normal TLR4 on circulating leukocytes had impaired leukocyte recruitment. This rapid leukocyte recruitment in response to local administration of LPS involved P-selectin, which is prestored in the Weibel-Palade bodies of ECs and is upregulated immediately by agonists such as LPS, thrombin, and oxidants. P-selectin-blocking antibodies completely inhibited the

LPS-induced leukocyte–endothelial interactions observed within the first 90 minutes (73). The LPS response was further bolstered by a second wave of recruitment after 90 minutes that was not blocked with anti-P-selectin antibodies. These delayed interactions were, however, completely blocked using E-selectin antibodies in combination with P-selectin, as well as in mice deficient in both selectins (72).

### ENDOTOXEMIA AND LEUKOCYTE RECRUITMENT

The systemic administration of LPS mechanistically is very different from a local tissue exposure to LPS. Systemic LPS administered intraperitoneally or intravenously results in widespread activation of TLR4 (75). This leads to a profound expression of adhesion molecules including E- and P-selectin, intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 on endothelium in every organ. However, this does not lead to leukocyte recruitment into all tissues. In fact, a disproportionately large number of leukocytes enter into the lungs. We do know that neither selectins nor integrins support the recruitment of leukocytes into lungs (76–79). Although the underlying mechanism for the preferred recruitment of leukocytes into lungs is unknown, chimeric mice having TLR4 on leukocytes but lacking TLR4 on endothelium did not express adhesion molecules on endothelium and did not recruit leukocytes into lungs. This suggests that the endothelial adhesive profile in lungs stimulated by TLR4 is different and dominant for subsequent leukocyte recruitment.

The liver also recruits some leukocytes during endotoxemia. Endothelial heterogeneity becomes very evident when the liver microcirculation is visualized in response to LPS using intravital microscopy. This organ constitutes a unique vascular architecture. Systemic administration of LPS has been shown to induce a significant amount of leukocyte adhesion in the collecting or central venules of the liver (80), and this adhesion was prevented in mice deficient in both E- and P-selectin. A large amount of leukocyte adhesion also was observed within the sinusoids; however, this was not inhibited by blocking selectins (80). Although we have proposed that leukocyte recruitment into the liver is a trapping phenomenon, this is a default position, because no adhesion molecule to date has been identified to be important in this recruitment process. These trapping phenomena are observed following the administration of LPS or bacteria to mice, but do not seem to be prominent in mice treated with TNF- $\alpha$  or IL-1.

As a whole, these data suggest that the mechanisms encompassing leukocyte recruitment in response to LPS can be quite different depending on the specific tissue and its vascular architecture. Several questions remain: a) is TLR4 temporally regulated by vascular bed-specific mechanisms, b) is the spatial expression (basal vs. apical) of TLR4 variable among tissues, and c) if so, does this also contribute to local versus systemic LPS responses and the adhesion molecules involved? Finally,

there clearly exist some unidentified adhesion mechanisms independent of selectins and integrins evoked by LPS; therefore, standard antiadhesion therapy may not successfully limit leukocyte sequestration in endotoxemia.

### LIPOPOLYSACCHARIDE-INDUCED PROCOAGULANT ACTIVITY

One important function of ECs is the maintenance of an antithrombotic surface. However, a consistent observation is that LPS induces tissue factor expression in cultured ECs, altering the endothelial surface from an anti- to a procoagulant state. This occurs via activation of NF- $\kappa$ B and the suppression of anticoagulant thrombomodulin (81,82). The release of tissue plasminogen activator and the expression of plasminogen activator inhibitor 1 also is increased by LPS (83). Platelet recruitment to the endothelium can cause vascular dysfunction by releasing various inflammatory molecules (84). In addition, the platelets could express adhesion molecules such as P-selectin, thus allowing neutrophil binding and activation and leading to further uncontrolled inflammation. This latter event is further underscored by the recent discovery that platelets also express TLR4 (85).

### LIPOPOLYSACCHARIDE PRIMING PHENOMENON

Much like in preconditioning in ischemia–reperfusion, studies have demonstrated that repeated LPS exposure causes a diminished inflammatory response to LPS *in vitro*, including reduced TNF- $\alpha$  expression by monocytes, macrophages, and ECs (76,77,86). In addition, it has been documented that preconditioning with LPS leads to a reduction of tissue factor, ICAM-1, urokinase-type plasminogen activator (u-PA), E-selectin, and VCAM-1 expression in response to thrombin stimulation (87). Using DNA microarray analyses it was observed that pretreatment with LPS alone resulted in induction and suppression of many other genes (5). This pretreatment with LPS consequently inhibited thrombin-induced activation of NF- $\kappa$ B as well (5).

### LIPOPOLYSACCHARIDE-INDUCED ENDOTHELIAL CELL INJURY AND APOPTOSIS

Apoptosis is another event that may be involved in the pathogenesis of severe sepsis and septic shock. A number of *in vitro* studies show apoptotic cell death of ECs in response to LPS (88), although convincing *in vivo* data is lacking. Research suggests that endothelium derived from different sites displays varying degrees of resistance to apoptosis in response to LPS. Moreover, species differences may exist. Bovine ECs derived from distinct anatomical origins are highly sensitive

to LPS-induced apoptosis, whereas human ECs are resistant (89).

It is well established that the activation of NF- $\kappa$ B is important for EC survival, and that disruption of this pathway enhances the cytotoxic effects of apoptotic proteins. Hull and colleagues (90) have shown that the C-terminal portion of TRAF6 (TRAF6-C) inhibits LPS-induced NF- $\kappa$ B nuclear translocation and c-jun N-terminal kinase (JNK) activation in ECs and hence inhibits LPS-initiated endothelial apoptosis. TRAF6-C also was shown to block LPS-altered mitochondrial transmembrane potential, cytochrome C release, and caspase activation.

### OTHER EFFECTS OF LIPOPOLYSACCHARIDES ON ENDOTHELIUM

Endothelium exposed to LPS transcriptionally upregulates nitric oxide synthase (NOS)-2 (also known as inducible NOS). In addition, experimental evidence suggests that LPS downregulates constitutive NOS-3 (also known as endothelial NOS) in endothelium (91). The intracellular signaling events involved in endothelial NOS-2 and cyclooxygenase (COX)-2 expression in response to LPS are yet undetermined. It is known that induction of NOS-2 in mononuclear cells requires binding of the LPS/CD14 complex to TLR4, with subsequent activation of NF- $\kappa$ B (1). Likely similar mechanisms are active in the endothelium as well. LPS also may contribute to endothelial dysfunction by increasing the vasoconstrictor tone of vascular smooth muscle cells, because ECs can release endothelin in response to LPS (1). A connection between endothelin and iNOS has been suggested. Hence, ECs respond to microbial toxins by hypersecreting vasoactive mediators, including vasoconstrictors as well as vasodilators. Additionally, endothelium expresses the inducible COX-2 protein (1). Similar to the isoform shift of NOS, experimental evidence suggests that a switch from COX-1 to COX-2 also may occur in ECs in response to LPS (1).

#### KEY POINTS

- The endothelium requires CD14 for activation; however, it remains unclear whether the membrane or soluble isoform is essential.
- TLR4 is the critical endothelial LPS detector.
- Endothelial TLR4 may be a critical molecule that mediates the sepsis phenotype.

#### Future Goals

- To identify additional LPS signaling pathways (independent of CD14)
- To identify the adhesion molecules involved in leukocyte recruitment into lungs and liver

# Receptor for Advanced Glycation End-Products and the Endothelium

## A Path to the Complications of Diabetes and Inflammation

Jean-Luc Wautier\* and Ann Marie Schmidt†

\**University Lariboisiere-Saint Louis and Institut National de la Transfusion Sanguine, Paris, France;* †*College of Physicians and Surgeons, Columbia University, New York, New York*

Nonenzymatically modified adducts of proteins or lipids engage the vascular endothelium by mechanisms distinct from those of the native, unmodified species. These modified adducts, termed *advanced glycation end-products* (AGEs), are particularly prevalent in diabetes, but accumulate as well in diseases such as renal failure, in states of intense inflammation, and in aging. Extracellular AGEs mediate their cellular activity by binding to the receptor for age (RAGE). Increasing evidence suggests that disease-associated ligands other than AGE may bind and activate RAGE and thus contribute to diverse tissue-damaging complications. Studies in this area have provided a framework for targeting the ligand–RAGE axis as a novel therapeutic opportunity in diabetes.

### THE PROBLEM OF GLYCATION

A range of physiological and pathophysiological states provides a ripe environment for the post-translational modification of proteins and lipids that eventuate in the formation of AGEs. Such modified species bind to and activate specialized receptors (RAGE) present on the surface of multiple cell types, including endothelial cells (ECs). AGE–RAGE interactions result in EC dysfunction, and appear to play an important pathophysiological role in several diseases, including type 1 and type 2 diabetes.

### Maillard Reaction and the Formation of Advanced Glycation Endproducts

The nonenzymatic glycation of proteins was first described in 1912, by Louis-Camille Maillard (1). This reaction begins when the carbonyl group (either aldehyde or ketone) of the reducing sugar forms a reversible Schiff base with the amino group of the molecule. Schiff bases may undergo subsequent

intramolecular rearrangements to form Amadori products (2). A series of further rearrangements may occur, including dehydration and condensation reactions to form irreversible endproducts, or the AGEs (Figure 47.1). For example, the initial Schiff base adducts formed from glucose, lysine, and N-terminal amino acid residues may rearrange to form the key intermediate, fructosamine. Fructosamine degradation and the direct reaction of  $\alpha$ -oxoaldehydes with proteins may form many types of AGEs in vivo, including bis(lysyl)imidazolium cross-links, hydroimidazolones, and monolysyl adducts (2,3).

AGEs may form in both the intracellular and extracellular environment, and are a heterogeneous class of compounds. Some may be fluorescent and of yellow-brown color; others may form stable intermolecular and intramolecular cross-links (2,4). Furthermore, the degree of AGE formation on any given species will vary depending on a range of other factors. For example, in the case of proteins, AGE depends on the endogenous reactivity of specific amino groups, and it is directly influenced by distinct factors within the environment, such as increased oxidative stress, the surrounding glucose concentration (both in the circulation and in the microenvironment), and the half-life of the protein (4,5).

It was the latter property that led to the identification in vivo of the importance of glycation in human subjects with diabetes. Specifically, Rahbar and colleagues first reported a distinct form of hemoglobin in subjects with diabetes. This species came to be known as glycosylated hemoglobin, or hemoglobin A1c, a naturally occurring minor human hemoglobin that is elevated in human diabetic subjects (6). Because of the relatively long half-life of red blood cells, the degree of modification of this hemoglobin species in diabetes is a barometer of the effectiveness of long-term glycemic control. At present, glycosylated hemoglobin is a critical tool in the armamentarium of diabetes control in the clinic and in

## Advanced glycation endproducts

Figure 47.1. Generation of AGEs. Pathways by which glucose may yield generation of Schiff bases and Amadori products and, after further molecular rearrangements, AGEs.

long-term epidemiological studies, such as the Diabetes Control and Complications Trial Research Group (DCCT) (7).

Importantly, beyond the impact of hyperglycemia, AGEs may form via other mechanisms as well. For example, it has been shown that myeloperoxidase pathways may lead to the direct generation of carboxymethyl lysine (CML)-AGEs (8). In addition, it is established that enhanced oxidative stress, either by activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and/or mitochondrial dysfunction, which typifies the diabetic milieu (9–11), may favor further AGE generation (12). Based on the existence of hyperglycemia-independent mechanisms of AGE production, it is not surprising that enhanced AGE accumulation occurs in settings beyond diabetes. For example, AGEs may form in renal failure, chronic neurodegenerative disorders, and with natural aging (13–18).

### In Vivo Modifiers of Advanced Glycation Endproducts Formation and Detoxification

In addition to direct forces that stimulate and favor AGE generation in the intracellular and extracellular compartments, a number of enzymatic reactions may further propel AGE formation or, indeed, modulate AGE removal. In the former case, the aldose reductase (AR) or polyol pathway may generate species that “feed forward” into AGE formation. In this pathway, glucose is reduced to sorbitol by AR; fructose gener-

ated by this pathway is converted into fructose-3-phosphate by the action of 3-phosphokinase (3-PK). This leads to the generation of 3-deoxyglucosone (3-DG), a central precursor in the generation of an array of AGEs, in particular, CML adducts and others (19–20).

In other settings, the glyoxalase pathway, particularly glyoxalase I, mediates AGE detoxification and removal. In ECs stably transfected to express human glyoxalase I, incubation in high-glucose conditions failed to increase AGE formation compared with nontransfected control cells (21). In natural aging, it has been found that glyoxalase activity is reduced, thereby providing a mechanism by which AGE accumulation may be even further enhanced (22). Thus, in addition to gradually enhanced generation of these species in euglycemic aging, the impaired removal or detoxification of these adducts may further exacerbate their accumulation.

### CONSEQUENCES OF ADVANCED GLYCATION ENDPRODUCTS

#### Advanced Glycation Endproducts and Effects on Structural Integrity of the Vessel Wall

AGEs may directly affect the structural integrity of the vessel wall and underlying basement membrane. For example, extensive cross-linking of AGE modifications within matrix molecules such as collagen may disrupt matrix–matrix and

matrix–cell interactions (23,24). In the intracellular milieu, nonenzymatic glycation of basic fibroblast growth factor (bFGF) may impair its function (25). Other studies indicate that AGEs quench nitric oxide (NO), thereby potentially altering vascular relaxation and function (26). When AGEs are formed directly on enzymes, such modification may modulate their function (27).

### Advanced Glycation Endproducts and Receptors

In addition to the effects of AGEs on the integrity of the vessel wall and basement membrane, AGEs have been shown to interact with specific cellular receptors. A number of cell surface interaction sites for AGEs have been identified, including macrophage scavenger receptor (MSR) type II, OST-48, 80K-H, galectin-3, CD36, and RAGE (28–32). Most of these receptors appear to remove and detoxify AGEs. One exception is RAGE, which, when bound to ligand, triggers intracellular signaling (32,33). RAGE is a member of the immunoglobulin superfamily of cell surface molecules (33). The extracellular domain of RAGE is composed of one V-type immunoglobulin domain, followed by two C-type immunoglobulin domains (33). A single hydrophobic transmembrane domain is followed by a short, but highly charged cytosolic domain that is essential for RAGE-mediated signal transduction (33). Although RAGE has subsequently been shown to be present on a variety of cell types, the very first studies identified this receptor on ECs. A plethora of evidence suggests that AGE–RAGE interactions critically modulate the clinical phenotype of diseases associated with increased ligand, particularly diabetes.

### ADVANCED GLYCATION ENDPRODUCTS, RECEPTOR FOR AGE, AND ENDOTHELIUM: BINDING AND OUTCOMES

#### In Vitro–Prepared and in Vivo–Derived Advanced Glycation Endproducts Bind Receptor for AGE

RAGE was first identified in ECs (32). In those experiments, bovine serum albumin (BSA) was incubated with reducing sugars such as D-glucose or D-ribose and, after incubation, was dialyzed free of remaining sugars. The resulting product, AGE-BSA, or its unmodified counterpart was then radiolabeled with  $I^{125}$ . When immobilized lung extract or bovine aortic ECs were incubated with  $I^{125}$ -AGE-BSA at 4°C, dose-dependent and saturable binding was noted, with a  $K_d$  of approximately 70 nM (32). Pretreatment of the monolayers with trypsin or detergent effectively eliminated AGE binding, strongly suggesting that the interaction site was, at least in part, composed of protein. Definitive evidence that RAGE was a receptor for AGE was noted by pretreatment of the monolayers with blocking antibodies to RAGE, but not nonimmune IgG. Further, transient transfection of cells largely devoid of RAGE with constructs expressing full-length functional RAGE resulted in AGE binding, compared with the absence of AGE binding in the mock vector-transfected cells (33). Finally, immunohistochemistry

performed with antibodies raised to RAGE demonstrated that the receptor indeed was present on the surface of immobilized, nonpermeabilized cultured ECs (32).

A chief concern in these first experiments was that the AGEs prepared and tested *in vitro* were artificially modified and, thus, not likely to reflect AGE species present in human fluids or tissues in diabetes. To address this issue, cultured ECs were incubated with an *in vivo* source of AGE, namely diabetic erythrocytes. In these studies, binding of diabetic erythrocytes was reduced by incubation with excess AGE-BSA, anti-AGE IgG, or in the presence of anti-RAGE IgG, but not nonimmune IgG (34,35).

Efforts to elucidate specific AGEs that might interact with RAGE led to the identification of CML-AGE products as signal transduction ligands of RAGE (36). CML-AGEs, nonfluorescent and non-cross-linked adducts, are prevalent *in vivo* and have been suggested to be the most common class of AGEs found in human diabetic tissues (37,38). CML-AGEs were radiolabeled with  $I^{125}$  and binding studies performed both on plastic tubes and in cultured cells. When CML-ovalbumin was incubated with cultured human umbilical vein ECs (HUVECs), dose-dependent and saturable binding occurred. In addition, incubation of ECs with CML-AGE resulted in increased expression of adhesion molecules, such as vascular cell adhesion molecule (VCAM)-1, and activation of nuclear factor (NF)- $\kappa$ B (36). These effects were blocked by the addition of neutralizing anti-RAGE antibodies or the overexpression of dominant negative RAGE (36).

Thus, support for the role of AGE-EC RAGE stimulation was procured by using a variety of *in vitro*– and *in vivo*–derived AGEs, as well as specific AGE structures, such as CML adducts. It is important to note that these findings do not exclude that distinct AGEs beyond CML adducts may bind to RAGE.

#### AGE–RAGE Interactions Result in Endothelial Cell Perturbation

The diabetic erythrocyte AGE–RAGE interactions discussed earlier were shown to have functional consequences. Under *in vitro* conditions, these included increased oxidant stress, as assessed by the generation of thiobarbituric acid reactive substances (TBARS) and activation of NF- $\kappa$ B (35). To assay for effects *in vivo*, erythrocytes from diabetic or control rats were infused into syngeneic nondiabetic rats. Consistent with the premise that diabetic erythrocytes bound cell surface RAGE,  $^{51}Cr$ -labeled diabetic erythrocytes displayed shorter survival compared with nondiabetic erythrocytes, an effect that was blocked by infusion of anti-RAGE IgG (35). *In vivo*, liver tissue of rats infused with diabetic erythrocytes displayed increased oxidant stress, a process blocked by anti-RAGE IgG (35). Thus, these studies demonstrated for the first time that *in vivo*–derived AGEs bound RAGE and brought about specific consequences in the cells, such as enhanced oxidant stress.

In addition to enhancing oxidant stress in ECs, AGE–RAGE signaling has been shown to alter the transcription and translation of key molecules involved in the recruitment and

activation of inflammatory cells. As indicated above, both in vitro- and in vivo-derived AGEs were reported to upregulate VCAM-1 on the surface of ECs in a RAGE-dependent manner (36,39). In other studies, infusion of AGEs into rabbits resulted in upregulation of both VCAM-1 and intercellular adhesion molecule (ICAM)-1 (40). Such findings implicate key roles for RAGE in the earliest steps initiating acceleration of vascular disease, particularly those in AGE-enriched environments as occur in diabetes and renal failure.

Ongoing studies suggested that RAGE was not solely a receptor for AGEs. As new ligands of the receptor were identified, efforts were expanded to test the premise that these molecules bound RAGE on ECs and modulated their properties.

### RECEPTOR FOR AGE IS A MULTILIGAND RECEPTOR: IMPLICATIONS FOR THE INFLAMMATORY RESPONSE

#### Proinflammatory Ligands of Receptor for AGE

##### *S100/Calgranulins*

In addition to AGEs, recent studies have shown that S100/calgranulin molecules are RAGE ligands (41). The S100/calgranulins are a family of at least 20 distinct polypeptide members, characterized by their ability to bind calcium. S100/calgranulins are expressed by a wide array of cell types, including polymorphonuclear leukocytes, dendritic cells, mononuclear phagocytes (MPs), and lymphocytes (42–44), and at one time they were believed to function exclusively within the intracellular compartment. However, S100A12 (calgranulin C or extracellular newly identified RAGE binding protein, EN-RAGE) was shown to bind RAGE in a saturable and dose-dependent manner on cultured ECs, as well as on other cells, such as vascular smooth muscle cells (VSMCs), MPs, and lymphocytes (44). Initially, it was difficult to reconcile a role for these species in receptor-mediated signaling with their established intracellular location and function. However, it has been shown clearly that discrete mechanisms exist by which these molecules may be released by activated cells (45,46), thereby allowing them to engage the cell surface receptor RAGE in an autocrine and paracrine manner.

Similar to the effects of AGEs, incubation of a prototypic S100/calgranulin, S100A12, with cultured HUVECs resulted in RAGE-dependent activation of NF- $\kappa$ B, upregulation of VCAM-1 antigen and activity, and induction of ICAM-1 protein (41). In addition to S100A12, further studies indicated that another member of the S100 family, S100b, also bound and activated RAGE in ECs. Thus, it is plausible that multiple members of the S100/calgranulin family may interact with RAGE.

##### *Amphoterin or High-Mobility Group Box-1*

Amphoterin (also known as high-mobility group box 1 (HMGB1)) was originally described and characterized as a DNA-binding protein (47). In addition to its role in transcriptional regulation, HMGB1 recently was shown to func-

tion as a soluble inflammatory mediator. Wang and colleagues demonstrated that HMGB1 is released from activated monocytes and macrophages, and contributes to the propagation of inflammation (48,49). Compared with other inflammatory mediators such as interleukin (IL)-6 and tumor necrosis factor (TNF)- $\alpha$ , HMGB1 is a relatively late marker of endotoxemia. Such findings suggest that lipopolysaccharides (LPS) may exert its often devastating effects due to multiple waves of cellular perturbation, with HMGB1 initiating a key later wave. Additional studies showed that HMGB1 release from monocytes is triggered by a vesicle-mediated pathway (50). Moreover, release of HMGB1 from necrotic, but not apoptotic cells, stimulated inflammatory mechanisms in affected tissues (51).

In subsequent studies, HMGB1 was shown to directly activate HUVECs, as evidenced by upregulation of VCAM-1, ICAM-1, and E-selectin, in parallel with the release of IL-8 and granulocyte colony stimulating factor (G-CSF) (52). Key roles for Elk and NF- $\kappa$ B pathways, at least in part via RAGE, were shown to underlie these effects of amphoterin on the modulation of EC gene expression (52). Together, these data suggest that even in the absence of diabetes and hyperglycemia, RAGE ligands may stimulate ECs to trigger vascular and inflammatory dysfunction.

##### *Mac-1*

In addition to proinflammatory S100/calgranulins and amphoterin, recent studies have indicated that RAGE is a counter-receptor for leukocyte integrin Mac-1 (also known as CD11b/CD18) (53). Further, these studies indicated that, in the presence of S100b, the RAGE-mac-1 interaction is augmented (53). Such findings suggest that a scaffold of RAGE ligands amplifies inflammatory mechanisms in the tissues. If left unchecked, RAGE-mediated ongoing and sustained inflammation, coupled with failure of regeneration mechanisms, may lead to irreversible tissue injury.

#### Receptor for AGE and Euglycemic Inflammatory Responses: In Vivo Studies

Two key observations, discussed earlier, raised the possibility that RAGE plays a pathophysiological role in *euglycemic* inflammatory conditions: (a) factors other than high glucose are able to promote AGE formation, and (b) non-AGE ligands associated with inflammation may bind to and activate RAGE. Consistent with this notion, studies in nondiabetic mice demonstrated that blockade of RAGE suppressed delayed type hypersensitivity, decreased colonic inflammation in *IL-10*<sup>-/-</sup> mice (41), suppressed experimental autoimmune encephalomyelitis, suppressed joint inflammation and destruction in a model of type II collagen sensitization, and enhanced survival and decreased inflammation in a murine model of sepsis induced by cecal ligation and puncture (54–57).

Based on the above findings, we hypothesized that RAGE might be linked to autoimmunity and inflammation in pancreatic islets. To test this hypothesis, we employed a model of adoptive transfer of diabetogenic spleen cells into NOD/scid

mice (56). Both RAGE and S100 were expressed on islet cells with an inflammatory infiltrate in sections of pancreata from NOD/scid mice that had received a transfer of diabetogenic splenocytes, but not from control NOD/scid mice that were not subjected to transfer of these splenocytes. RAGE was expressed in key populations of T cells (CD4<sup>+</sup> and CD8<sup>+</sup>) and B cells within the islet, as well as monocytes. Blockade of ligand–RAGE interactions, using soluble RAGE (sRAGE; comprising the extracellular V-C-C' Ig-like domains), significantly prolonged the time to development of hyperglycemia in NOD/scid mice compared with vehicle-treated mice subjected to adoptive transfer of diabetogenic splenocytes (56). Taken together, these findings highlight key roles for RAGE in the inflammatory response and suggest that release of these proinflammatory ligands from activated monocytes and lymphocytes may play a key role in amplification of inflammation.

### THE ROLE OF RECEPTOR FOR AGE IN MODULATING DIABETES-ASSOCIATED COMPLICATIONS

#### Hyperpermeability

Endothelial dysfunction accompanies diabetes and has been linked to the incidence and severity of cardio- and cerebrovascular complications in this disorder (58–64). Diabetes-associated EC dysfunction is manifested, at least in part, by abnormal response to acetylcholine and impaired flow-induced vasodilation. In addition, diabetes is associated with increased vascular leakage in both animal models of disease and in human subjects (65–69). To determine the role of RAGE in mediating endothelial barrier dysfunction, we employed a model of streptozotocin-induced, insulin-deficient diabetes in rats. Compared with control animals, diabetic rats demonstrated increased vascular permeability (particularly in the intestine, skin, and kidney). Importantly, this effect was inhibited in a dose-dependent manner by a single intravenous injection of sRAGE (70). Soluble RAGE was administered in a single dose after 9 to 11 weeks of established hyperglycemia in these animals. These experiments were the first to demonstrate that *in vivo* blockade of RAGE modulates an established vascular complication of diabetes (70). In the same study, the infusion of diabetic (compared with nondiabetic) red blood cells into syngeneic nondiabetic rats resulted in increased permeability in the intestine, skin, kidney, vena cava, and heart (70). The latter effect was attenuated by pretreatment with the antioxidant, probucol. These data support a key role for RAGE and oxidative stress as essential factors mediating vascular dysfunction *in vivo*.

#### Atherosclerosis

##### *Receptor for AGE and Human Diabetic Atherosclerosis*

Cipollone and colleagues examined endarterectomy specimens from diabetic and nondiabetic patients. They demon-

strated that: (a) RAGE expression was increased in diabetic atherosclerosis compared with nondiabetic controls; (b) RAGE expression colocalized with cyclooxygenase (COX)-2, type 1/type 2 microsomal prostaglandin E<sub>2</sub>, and matrix metalloproteinases (MMPs), particularly in macrophages at the vulnerable regions of the atherosclerotic plaques; and (c) increased expression of RAGE in the atherosclerotic plaques linearly correlated with the level of glycosylated hemoglobin (71). Others have reported increased expression of RAGE, in parallel with enhanced tissue factor antigen/activity, in peripheral blood mononuclear cells from type 2 diabetic patients with vascular complications compared with those without complications (72). Taken together, these data raise the possibility that the ligand–RAGE axis plays a pathophysiological role in diabetic atherosclerosis.

##### *Receptor for AGE Blockade and Atherosclerosis in Apolipoprotein E-Null Mice*

To address the question of pathophysiology, an animal model of diabetic atherosclerosis was developed, in which 6-week-old male apolipoprotein E (*ApoE*)-null mice (73,74) were injected with streptozotocin. After approximately 6 weeks of established diabetes, aortas displayed increased lesions at aortic branch points and the lesser curvature compared with nondiabetic controls (75). Quantitative analysis of multiple sections demonstrated significantly increased area and number of lesions in diabetic versus euglycemic *ApoE*-null controls (75). Histological analysis of oil red O-stained sections revealed more complex lesions (fibrous caps, calcification, necrosis, cholesterol clefts) in the diabetic specimens. Importantly, diabetic lesions displayed increased expression of RAGE protein and enhanced accumulation of AGEs, the latter as measured by enzyme-linked immunosorbent assay (ELISA) and immunohistochemistry (75).

Next, diabetic mice were treated with once-daily intraperitoneal administration of sRAGE beginning immediately at the time of documentation of diabetes and continued for an additional 6 weeks. Analysis of aortas revealed a marked dose-dependent suppression of atherosclerotic lesion area, number, and complexity in samples from diabetic *ApoE*-null mice treated with sRAGE compared with controls (75). Taken together, these findings provide evidence for a pathogenic role of RAGE in accelerated diabetic atherosclerosis.

RAGE blockade did not alter the glucose or lipid profiles, nor did it affect levels of glycosylated hemoglobin (75). Unexpectedly, however, sRAGE resulted in reduced levels of AGEs in the diabetic animals (75,76). One explanation for these observations is that suppression of RAGE-mediated oxidant stress in the vessel wall reduces subsequent formation and accumulation of AGEs. Consistent with this concept, we observed diminished susceptibility to copper-induced oxidation of low-density lipoprotein (LDL) retrieved from sRAGE-treated diabetic *ApoE*-null mice compared with LDL obtained from vehicle-treated diabetic *ApoE*-null mice (75).

To promote an increased disease burden, and thus more accurately mimic the clinical setting, diabetic *ApoE*-null mice

were left untreated for approximately 6 weeks. Mice then received daily sRAGE or vehicle for an additional 6 weeks. sRAGE administration blocked interval progression of lesion area and complexity compared with control animals (77). Treatment also resulted in decreased infiltration of MPs and VSMCs into atherosclerotic plaques. Most sRAGE-treated mice demonstrated decreased oxidant stress, as evidenced by decreased COX-2 and nitrotyrosine epitopes, and decreased inflammation, as evidenced by JE/monocyte chemoattractant protein (MCP)-1 and tissue factor antigens, MMP9 antigen/activity, and phosphorylated p38 mitogen-activated protein kinase (MAPK) (77). Again, RAGE blockade did not affect glucose or lipid profiles (77).

Recent studies have extended these findings to a murine model of type 2 diabetes. *ApoE*-null mice were bred into the *db/db* background, thereby generating hypercholesterolemic mice with leptin receptor deficient signaling. Compared with *ApoE*-null mice without diabetes, the *ApoE*-null *db/db* mice displayed significantly increased atherosclerosis. When sRAGE was administered to these diabetic mice once daily from age 9 to 11 weeks, a significant decrease in atherosclerosis at the aortic root was noted (78). In parallel, decreased vascular inflammation was observed in the animals treated with sRAGE versus vehicle (78). These findings expanded the impact of RAGE in diabetic atherosclerosis to include both models of insulin-deficient and insulin-resistant diabetes.

### Restenosis

In addition to its key role in modulating atherosclerosis, RAGE also has been implicated in exaggerated neointimal expansion after acute vascular injury. In a previous study, carotid balloon injury resulted in accelerated neointimal expansion in diabetic, insulin-resistant fatty Zucker rats compared with age-matched euglycemic controls (79). The administration of sRAGE beginning just prior to arterial injury and continuing for 1 week postoperatively resulted in a significant decrease in the intima:media ratio (I:M ratio) compared with vehicle-treated rats (serum albumin) (79). In parallel, the incorporation of bromodeoxyuridine (BrdU) was significantly decreased in VSMCs in the presence of sRAGE, thereby strongly suggesting key roles for RAGE in the response of VSMCs to arterial injury.

To further explore the pathogenic role of RAGE in arterial remodeling, we employed a well-described model of acute femoral artery endothelial denudation in euglycemic C57BL/6 mice (80). RAGE and its ligands, CML-AGEs and S100/calgranulins, were upregulated in the vessel wall consequent to injury, particularly in VSMCs (80). These studies highlight the fact that, even in the absence of hyperglycemia, AGE generation may be triggered by intense inflammatory stimulation. In this model, consequent to endothelial denudation, rapid recruitment of polymorphonuclear leukocytes to the injured vessel wall likely triggers the generation of CML, and perhaps other AGEs, by inflammatory pathways such as myeloperoxidase (8,81). In this model, RAGE block-

ade yielded significantly reduced I:M ratios (80). In other experiments, homozygous *RAGE*-null mice or transgenic mice expressing dominant negative (DN) RAGE selectively in VSMCs (driven by the *SM22 $\alpha$*  promoter) were employed. Compared to their respective littermates, homozygous *RAGE*-null mice or transgenic mice expressing DN RAGE in VSMCs displayed decreased I:M ratio on day 28 (80). Together, these data suggest that acute endothelial injury triggers the generation of RAGE ligands, which in turn are linked to RAGE-dependent VSMC proliferation, migration, and restenosis.

### Nephropathy

Yamamoto and colleagues generated transgenic mice overexpressing RAGE in EC using the *Flk-1* promoter. In that report, the authors indicated that some transgenic expression of RAGE occurred in macrophages as well. These mice were crossed with mice that develop insulin-dependent diabetes shortly after birth. Compared to single transgenic diabetic mice lacking the RAGE transgene, double transgenic mice displayed enlargement of the kidney, glomerular hypertrophy, increased albuminuria, mesangial expansion and glomerulosclerosis, and increased serum creatinine (82). Moreover, serum AGE levels were increased in the double transgenic mice. Treatment with an AGE inhibitor, (+/-)-2-isopropylidenehydrazono-4-oxo-thiazolidine-5-ylacetanilide (OPB-195), inhibited advanced nephropathy in the double transgenic mice, strongly supporting a role for the ligand-RAGE signaling axis in the pathogenesis of experimental diabetic nephropathy.

We have carried out studies in the *db/db* mouse. In the long term, these animals develop renal changes that parallel, at least in part, those evident in human diabetic kidney (83). Consistent with observations in the human kidney, we showed that the podocyte is the principal site of RAGE expression in the glomerulus of *db/db* mice. Podocyte RAGE expression was higher in diabetic compared with nondiabetic controls. Moreover, RAGE also was detected in glomerular ECs (83). Also, CML-AGE adducts and S100/calgranulins were upregulated in *db/db* kidneys (83). Compared with nondiabetic controls, administration of sRAGE to *db/db* mice resulted in reduced expression of vascular endothelial growth factor (VEGF) antigen and transforming growth factor (TGF)- $\beta$  mRNA, decreased glomerular and mesangial area, reduced thickness of the GBM, and lower urinary albumin excretion (83). Importantly, the protection against renal cortical VEGF and TGF- $\beta$  induction was confirmed in *RAGE*-null mice rendered diabetic with streptozotocin (83).

### RECEPTOR FOR AGE AND SIGNAL TRANSDUCTION

The signal transduction pathways downstream of RAGE activation in ECs and other cell types are diverse. Depending on the acuteness or chronicity of ligand stimulation, a range of signaling pathways may be activated. In the context of EC dysfunction in diabetes or other inflammatory states,

AGEs, S100/calgranulins, and amphoterin may activate ECs, as well as other cell types intimately involved in vascular disease initiation and progression, such as MPs and VSMCs. Signaling cascades activated upon ligand–RAGE interaction include pathways such as p21ras, extracellular signal-regulated kinase (ERK)-1/2 (p44/p42) MAPKs, p38 and SAPK/C-jun N-terminal kinase (JNK) MAPKs, Rho GTPases, phosphoinositide-3 kinase (PI3K), JNK/STAT pathway, and p21<sup>waf</sup>; downstream consequences such as activation of the key transcription factors NF- $\kappa$ B and cAMP-response element-binding protein (CREB) also have been reported (36,90,84–94).

Importantly, ligand-stimulated RAGE activation results in the generation of reactive oxygen species (ROS), at least in part

Figure 47.2. Endothelial RAGE: sparking a cascade of events linked to cellular perturbation and tissue injury. It is our hypothesis that endothelial RAGE is a key priming step for the activation of multiple proinflammatory mechanisms that amplify cellular perturbation in a range of disorders. We propose that in hyperglycemia, inflammation, or settings characterized by oxidative stress, acute, rapid, or sustained and chronic generation and accumulation of AGEs occurs. The interaction of AGEs with EC RAGE stimulates the generation of ROS and upregulation of proinflammatory mechanisms, such as the expression of adhesion molecules and chemokines, thereby leading to the recruitment and activation of inflammatory cells such as MP and lymphocytes. These processes may be further amplified by Mac-1–RAGE-dependent interactions. RAGE-dependent hyperpermeability enhances inflammatory cell entry into the injured vessel. Once such inflammatory cells are recruited to perturbed ECs, we posit that the generation or release of S100/calgranulins and amphoterin by these activated cells augment and sustain RAGE-activation. Then, by both autocrine and paracrine interactions, S100/calgranulins, amphoterin, and AGEs may amplify inflammation in the vessel wall and surrounding milieu, and multiple other cell types within the tissue. We suggest that initial injury triggered by EC RAGE may set the stage for the development of the diverse complications of diabetes in the macrovessels, retina, glomerulus, and central and peripheral nerves. Indeed, even in euglycemic inflammation, such as that triggered by acute EC injury or autoimmunity, we posit that EC RAGE plays a critical role in augmenting and amplifying cellular distress.

via activation of NADPH oxidase (88). Definitive roles for RAGE-mediated activation of NADPH oxidase were demonstrated in studies in *gp91<sup>phox</sup>*-null mice. Specifically, monocytes from wild-type, but not NADPH oxidase-deficient animals, displayed increased generation of tissue factor upon incubation with AGEs (95). Studies are underway to delineate if additional mechanisms, distinct from NADPH oxidase, underlie the potent ability of RAGE to generate ROS.

The cytosolic domain of RAGE appears to be critical for RAGE-dependent signal transduction and modulation of gene expression and cellular phenotype. The deletion of the cytosolic domain of RAGE (DN RAGE) abrogates ligand-mediated RAGE signaling and function both in vitro and in vivo. For example, when DN RAGE is expressed in vivo in VSMCs, cells of MP lineage, neurons of the central or peripheral nervous system, or CD4 lymphocytes, RAGE-mediated signaling is effectively suppressed, thereby strikingly modulating injury-triggered outcomes in diverse settings (36,41,55,80,91, 96–98).

#### ENDOTHELIAL CELL RAGE: IGNITING A CASCADE OF INFLAMMATORY AND TISSUE DESTRUCTIVE PATHWAYS

The last decade has witnessed many advances in our understanding of AGEs and RAGE. However, several key questions remain unanswered. How do RAGE-dependent mechanisms contribute to diverse complications in diabetes and inflammation? What is the role of EC RAGE in these processes? As illustrated in Figure 47.2, we hypothesize that, in settings of hyperglycemia, inflammation, or oxidative stress, a transient and in some cases sustained accumulation of AGEs occurs. In the vessel wall, circulating AGEs bind and activate EC RAGE, which in turn stimulates generation of ROS, increased permeability, leukocyte adhesion, and transendothelial migration. These proinflammatory reactions may lead to the local release of S100/calgranulins and amphoterin/HMGB1, which serve to perpetuate RAGE-mediated signaling and vessel injury. In the final analysis, the elucidation of the role for endothelial-derived RAGE in pathophysiology will depend on the generation and analysis of mice in which RAGE has been conditionally deleted in the endothelium.

#### KEY POINTS

- The activation of endothelial RAGE by ligands such as AGEs, S100/calgranulins, and/or amphoterin/HMGB1 is a key priming step for the activation of multiple proinflammatory mechanisms that amplify cellular perturbation in a range of disorders, such as diabetes and inflammation.

- RAGE is a multiligand receptor of the immunoglobulin superfamily expressed by ECs, other vascular cells, inflammatory cells, and target cells. Examples of target cells include ECs and vascular cells themselves, podocytes, central and peripheral neurons, and islet cells.
- RAGE-dependent signal transduction, triggered by ligands, is a key first step in activating ECs and other cells, thereby stimulating the transcription and translation of a host of genes linked to perturbation and inflammatory mechanisms.

#### Future Goals

- To dissect the precise proximal signaling mechanisms initiated in ECs and other RAGE-bearing cells by which ligand–RAGE interaction modulates a host of genes that regulate inflammatory and other critical stress responses in cells
- To test the impact of blocking RAGE in clinical settings; specifically, antagonists of the receptor. Such studies are the only means by which to definitively address the role of RAGE in the pathogenesis of inflammation and diabetes and its complications.

### COMPLEMENT FUNCTIONS IN INNATE AND ADAPTIVE IMMUNITY

The complement system evolved as part of innate immunity and as such it has an important role in host defense. Complement exhibits the four fundamental properties of innate immunity: (a) its components are encoded by the germ line, (b) its genes are invariant within a species, (c) it is constitutively poised for activation, and (d) it recognizes and is activated by large molecular motifs associated with viral, bacterial, and fungal pathogens – the so-called pathogen-associated molecular patterns, or PAMPs (1). Pathogens do not express PAMPs by choice. PAMPs are associated with critical prokaryote function, such as the barrier functions of the outer membrane lipopolysaccharide (LPS) of gram-negative bacteria and the cell wall lipoproteins of gram-positive bacteria. Many of the most virulent bacterial pathogens have evolved polysaccharide capsules as a counterdefense mechanism to cover and hide their PAMPs and thereby evade recognition by complement.

Adaptive immunity, of a type similar to that of modern mammals, evolved in the ancestors of present day jawed fish. In contrast to innate immunity, adaptive immunity (a) encodes its genes in peripheral cells (lymphocytes); (b) allows mutation and selection of genes to adapt to the antigenic experience of the individual, as opposed to the species; (c) takes 1 to 3 weeks to generate a new response; and (d) recognizes molecular details of antigens. Animals with adaptive immunity retain innate immunity, including complement, to provide a first line of defense during the interval (1–3 wks) necessary to mount a new specific adaptive immune response. In addition, when innate immunity recognizes what is dangerous, it activates antigen-presenting cells and thereby provides critical priming for an adaptive immune response (2). For example, an antigen is potentiated 1,000- to 10,000-fold for a B-cell response when it is tagged with a C3 fragment (3). Much of the data for the participation of innate immunity in adaptive immunity were derived from studies of knockout mice, and will be discussed later. Many of the components of innate immunity also are involved in responses to tissue damage, and complement is no

exception. Thus, altered host proteins that are recognized by innate immunity can become antigens for an inappropriate adaptive immune response and result in autoimmunity.

### Ancient Origins of C3 and Its Pivotal Role in Modern Complement Systems

From homology studies, it is proposed that C3 arose some 700 million years ago from gene duplication of  $\alpha_2$ -macroglobulin ( $\alpha_2$ -M), which is widely distributed in metazoans (4).  $\alpha_2$ -M has an internal thioester bond. When  $\alpha_2$ -M is cleaved by proteases, its thioester bond transacylates to the protease and thereby entraps the protease. Because pathogens routinely use proteases as virulence factors,  $\alpha_2$ -M is considered an ancient host defense molecule of innate immunity. After entrapping a protease, the complex of activated  $\alpha_2$ -M–entrapped-protease is cleared by receptors that recognize activated  $\alpha_2$ -M. In humans, the  $\alpha_2$ -M receptor is CD91/low-density-lipoprotein-receptor-related protein (5,6).

A C3-like molecule has been identified in coral, which diverged from the main trunk of evolution during the Precambrian period (7). Thus, the  $\alpha_2$ -M gene duplication must have occurred even earlier than the divergence of coral. Consistent with the coral data, homologs of C3 and C3-activating proteases are found in the ancient protostome *Carcinoscorpius rotundicauda* (horseshoe crab) (8), as well as in some deuterostomes, including Echinodermata (sea urchins) and early Chordata (sea squirts, lancelets) (9).

C3 is a 180-kDa heterodimer molecule with its internal thioester bond within the  $\alpha$ -chain. Normally, the thioester bond is protected within a hydrophobic pocket (10). When C3 is activated by specific cleavage, releasing a N-terminal fragment (C3a) from the  $\alpha$ -chain. The residual C3b molecule undergoes a conformational change that exposes the labile thioester bond, allowing C3b to dock on adjacent OH-groups by ester linkage or, less commonly, on NH groups by amide linkage (11). The acceptor molecules are not random – for example, glycophorin A is a preferred target on red blood cells (RBCs) (12), whereas thr<sup>144</sup> on human IgG1 is a specific target (13). As the universal tag of innate immunity, C3b

marks harmful molecules associated with PAMPs. Specific internalization (phagocytic or endocytic) receptors exist for C3b and each of C3b's sequentially proteolyzed membrane-bound derivatives (Table 48-1). Specificity for tagging PAMPs, as opposed to host cells, is governed by multiple attributes of the complement system, including substrate specificity for each of the complement enzymes, need for sequential activation of components, lability of active fragments, preferred acceptors of C3b, and by the presence of inhibitors of C3 activation and C5b-9 insertion at the membrane of host cells (Table 48-2).

## COMPLEMENT PATHWAYS

### C3 Activation

Three pathways evolved for efficient activation of C3: the lectin, classical, and alternative pathways (Figure 48.1). Each pathway is specialized to recognize different types of PAMPs. The lectin pathway, which is evolutionarily the oldest of the three pathways, uses mannan binding lectin (MBL) or ficolins to directly recognize PAMP sugars, such as D-mannose and N-acetyl-D-glucosamine. After binding, these lectins activate MBL-associated serine protease (MASP)-2, which in turn, sequentially activates C4 and C2. C4 was derived from C3 by gene duplication during evolution. Cleavage-activation of C4 exposes its internal thioester bond, which is within the major

cleavage fragment (C4b), and thereby allows C4b to dock on adjacent <sup>-</sup>OH or <sup>-</sup>NH groups. The activation and docking of C4b is completely analogous to the cleavage-activation of C3 and docking of C3b (see Figure 48.1). C2 is only efficiently activated if it is bound to C4b, and the resulting C4b2a enzyme cleaves C3 and C3bC4b2a cleaves C5.

The classical pathway for C3 activation evolved in the ancestors of jawed fish coincident with the origins of modern mammalian adaptive immunity. This pathway is activated when IgM and IgG bind their specific antigens and become conformationally modified. C1q recognizes the bound immunoglobulin and initiates the sequential activation of C1r and C1s, serine proteases homologous to MASP-2 of the lectin pathway. C1s, in turn, activates C4 and C2, as described for the lectin pathway (see Figure 48.1). Both MBL and C1q, once they shed their associated proteases, act as opsonins (14,15). This suggests that these recognition molecules functioned independently of their proteases and the rest of complement early in evolution and then later became incorporated into pathways to activate C3. Consistent with this hypothesis, C1q recognizes some PAMPs, such as the membranes of retroviruses and lipid A of endotoxin (16,17).

The alternative pathway is comprised of three activation proteins: C3b, factor D, and factor B; and three regulator proteins: properdin, factor I, and factor H. This pathway also recognizes PAMP carbohydrates, but by a type of "negative selection." Without any specific stimulus for activation, C3 is

<sup>‡</sup>Receptor contains SCR domains.

cleaved by the slow turnover of both the classical and lectin pathways (18). In addition, the thioester bond in C3 can be attacked by water, converting C3 into C3b-like C3. Both C3b and C3b-like C3 can bind factor B, a zymogen (19). Factor D, which is a constitutively active circulating serine protease with unique specificity for factor B in the C3bB complex, generates the C3-cleaving C3bBb convertase and C5-cleaving convertase (C3b)<sub>2</sub>Bb.

Properdin, a positive regulator, binds the alternative pathway C3- and C5-cleaving multimeric enzymes and enhances their activity by stabilizing them. In contrast, factors H and I act as negative regulators: factor H binds to the C3b and dislodges the enzymatic Bb subunit; and then factor I, using H as a cofactor, cleaves the C3b to iC3b, which is unable to participate in further complement activation because it cannot bind factor B. In addition to its C3b binding site, factor H contains sites that directly bind the polyanions and sialic acids of host cells, or to small integrin-binding ligand, N-linked glycoproteins (SIBLINGs), which in turn bind to CD44 or RGD-binding integrins on the cell surface (20,21). These binding properties allow factor H to concentrate as a peripheral membrane protein on the surface of host cells, and thereby protect the cells from autologous complement damage. Microbes lack heparin-like molecules (polyanions) and SIBLING receptors and therefore cannot concentrate factor H at their surface. As a consequence, these microbes are vulnerable to unregulated C3 and C5 activation at their surface. A few pathogens, such as

Group B Streptococci and type B *Neisseria meningitidis*, have sialic acid–containing capsules and therefore can bind factor H and circumvent factor H control.

The importance of factor H for protection of endothelial cells (ECs) is underscored by two pathologic conditions resulting from factor H mutations, namely atypical hemolytic uremic syndrome (aHUS) and age-related macular degeneration (AMD). These conditions are discussed later. Genetic deficiency of factor I leads to complete consumption of C3 due to unregulated alternative pathway activity. Factor I–deficient patients present with pyogenic infections in infancy, in a syndrome identical to that of patients with genetically determined C3 deficiency (Table 48-3).

### Activation of the Terminal Complement Sequence

C5 also was derived from C3 by gene duplication but, in contrast to C3 and C4, it lacks an internal thioester bond. C6, C7, C8, and C9 share domains distinct from those of C3 and C5, and appear to have evolved separately, but in parallel with perforin, the nongated pore-forming protein of cytotoxic lymphocytes and natural killer cells (44).

C5 is the last component to be activated by proteolytic cleavage. C5 binds to C3b adjacent to C4b2a of the lectin and classical pathway or the C3bBb enzyme of the alternative pathway, and it is cleaved to generate C5a (10 kDa), an anaphylactic fragment, and C5b (167 kDa), which initiates the terminal complement pathway that is shared by the lectin, classical, and alternative pathways. C5b sequentially condenses with C6 and then C7. C5b7 formation exposes a nascent lipid binding site and, if a membrane is adjacent, C5b7 will insert itself (45). No specific receptors exist for C5b7 binding. In the absence of an adjacent membrane, C5b7 may bind hydrophobic sites in clusterin or vitronectin and thereby become inactivated. The addition of C8 to membrane-inserted C5b7 allows a floppy transmembrane pore to form, whereas the subsequent addition of C9 forms a rigid C5b-9 pore (46). Adding more C9 to the pore widens its diameter.

### REGULATORS OF COMPLEMENT ACTIVATION

Despite the presence of numerous complement serine proteases, C1r, C1s, factor D, factor Bb, C2a, and the inhibitor factor I, only one serine protease inhibitor functions in the complement system, namely C1 inhibitor (C1 INH). Within the complement system, C1 INH is specific for C1r and C1s, although it also inhibits clotting factors XIIa, Xia, and kallikrein. Deficiency of C1 INH leads to hereditary angioedema; the local, but sometimes fatal edema that occurs with this syndrome is now known to result from kallikrein cleavage of high-molecular kininogen to produce the mediator bradykinin (47) (see Table 48-3).

Except for CD59, which inhibits complement channel formation (discussed later), the rest of the complement inhibitors are focused on limiting C3 and C5 activation. Of the C3 and C5

### Recognition Pathways

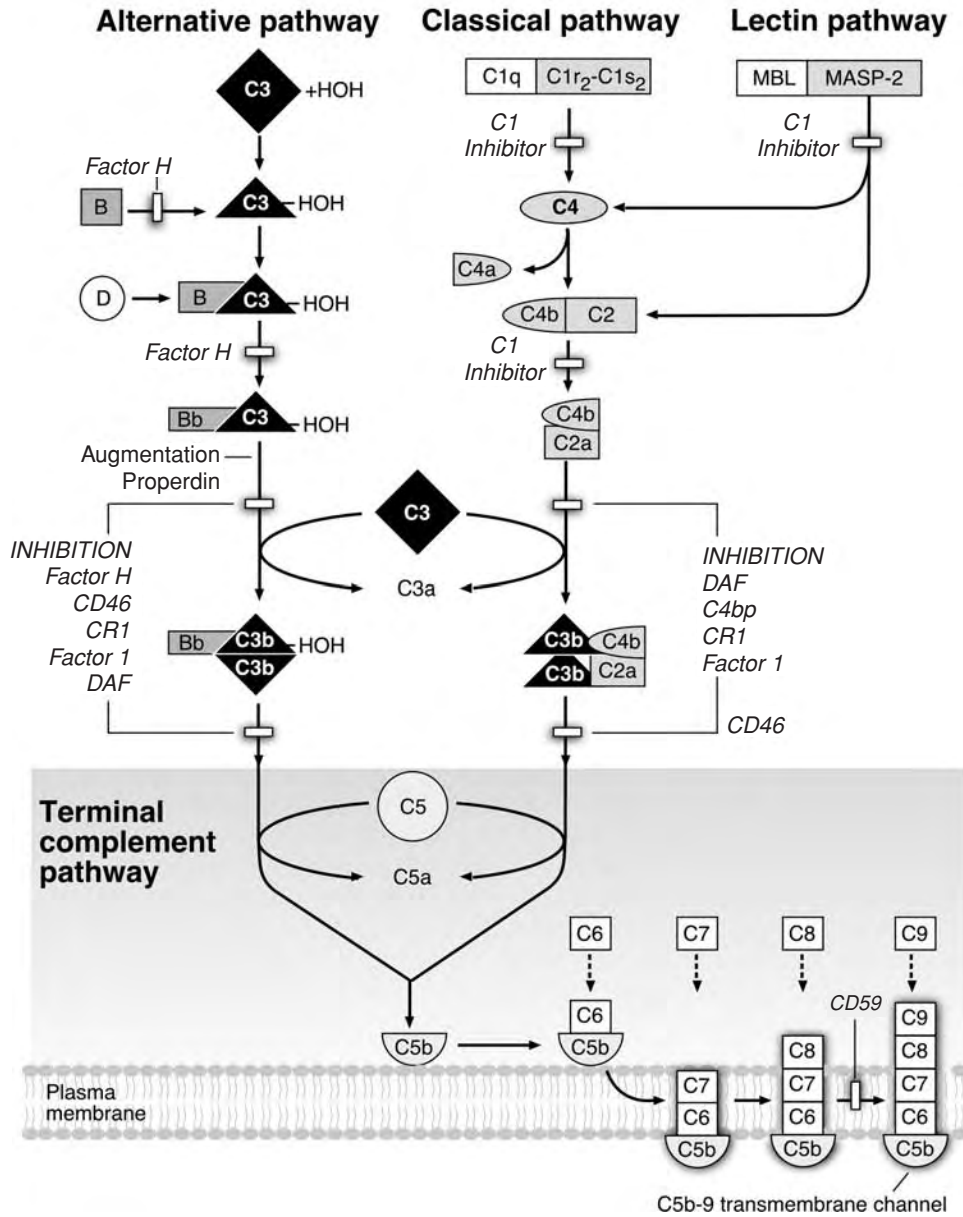

Figure 48.1. The three pathways of complement activation and common final pathway to generate the complement pore. Proteins sharing structural homology are shown in the same shade; enzymes are denoted by triangles; and major inhibitors are shown in boxes that interrupt the activation pathways. The lectin pathway is activated when MBL binds sugars associated with pathogen-associated molecular patterns (PAMPs), especially N-acetylglucosamine, mannose, and N-acetylmannosamine. The classical pathway is most commonly activated when the C1q subcomponent of macromolecular C1 binds the heavy chains of IgG and IgM after these immunoglobulins have bound their specific antigens. The alternative pathway slowly ticks over in the fluid phase as C3 reacts with water {C3b(HOH)} and becomes “C3b-like.” However, this pathway is only efficiently activated when C3b is deposited on a surface that fails to bind factor H, thereby allowing the affinity of factor B to exceed that factor H. C3 (HOH) or “C3b-like C3” is uncleased C3 in which the internal thioester bond has reacted with water, and the molecule assumes the conformation of C3b in terms of allowing factor B to bind and initiate further complement activation; C4bp, C4 binding protein; CR1, complement receptor 1 or CD35; DAF, decay-accelerating factor or CD55; MBL, mannan-binding lectin; MASP-2, MBL-associated serine protease-2.

**Table 48-3: Phenotypes of Complement-Deficient Humans and Knockout Mice**

<i>Affected Protein</i>	<i>Humans (Refs.)</i>	<i>Mice (Refs.)</i>
Mannan binding lectin-1 (MBL1)	Normally not expressed (22)	MBL1 is at least partially redundant with MBL2, see below.
MBL2	Deficiency is common, up to 10% in some populations. Associated with predisposition to infection, especially in altered host (23)	<i>MBL1<sup>-/-</sup>/MBL2<sup>-/-</sup></i> protects mice from ischemia reperfusion injury (24).
MBL-associated serine protease-2 (Masp-2)	One case report: autoimmune phenomena (25); may also have mild phenotype*	ND <sup>†</sup>
Properdin	Meningococcal infection (26)	ND
Factor B	No phenotype (27)	Normal; if backcrossed with MRL/lpr lupus-prone mice, ameliorates autoimmune disease (28)
Factor D	Meningococcal infection (29,30)	Normal; if backcrossed with MRL/lpr lupus-prone mice, ameliorates autoimmune disease (31)
C1q	93% prevalence of severe lupus-like illness (32)	Renal disease, strain-dependent (33)
C1r and/or C1s	<i>C1r</i> and <i>C1s</i> are linked genes and usually subjects are deficient in both. Deficiency is rare, and about 57% of subjects have severe autoimmune disease (32)	ND
C4	75% prevalence of SLE (32)	Decreased clearance of apoptotic cells in vitro (34)
C2	10% prevalence of SLE (32)	ND; knockout resulted in loss of adjacent genes including factor B (35)
C3	Pyogenic infections in infancy and childhood ± glomerulonephritis (26)	Decreased opsonic clearance, abnormal adaptive response, decreased inflammation; see Mouse Genome Informatics (MGI) of Jackson Labs <sup>‡</sup>
C5, C6, C7, or C8	Increased prevalence of <i>Neisseria</i> infections (26)	Very common, found in several inbred strains of mice, including AKR, DBA, NOD, NZB, and SWR; phenotypes are summarized in MGI
C9	Mild increase in prevalence of <i>Neisseria</i> infections (26)	ND
C3aR	ND	Decreased Th2-mediated inflammation, see MGI
C5aR	ND	Increased susceptibility to <i>Pseudomonas aeruginosa</i> pneumonia (36); modulates inflammation, see MGI
C1 INH	Hereditary angioedema, see OMIM**	Increased vascular permeability, see MGI
C4bp	In one family: two asymptomatic, and one with aggressive autoimmune syndrome (37)	ND
Factor H	Hemolytic uremic syndrome (HUS), see OMIM	C3 deficiency, spontaneous glomerulonephritis, increased mortality; see MGI
Factor I	Factor B and C3 catabolism, pyogenic infections in infancy and childhood, see OMIM	ND
DAF (CD55) (GPI anchored)	Genetic deficiency on RBCs has no phenotype, see OMIM; acquired deficiency associated with GPI-anchor deficiency contributes to paroxysmal hemoglobinuria (60,61).	No phenotype for knockout (38); widely expressed in wt including RBCs (39)
TM-DAF	Not expressed	ND; expression limited to mature sperm in wt (39)
Crry	Not expressed	Lethal during embryogenesis due to unrestricted complement activation in the placenta (40)
CD46	HUS and age-related macular degeneration, see OMIM	Increased fertility due to more efficient sperm; expression limited to sperm; see MGI
CR1 (CD35)	No known genetic deficiencies; acquired deficiencies occur in immune complex disease	See below
CR2 (CD21)	ND	In mice, CR1 and CR2 are alternatively spliced from the same gene; knockouts to date have resulted in deficiency of both proteins; see OMIM
CR3 (Mac-1 or CD11b/CD18)	Usually results from CD18 mutation and therefore affects all $\beta_2$ integrins and causes leukocyte adhesion deficiency. See OMIM.	Abnormal leukocyte trafficking, see MGI.
CD59a	Episodic hemolysis, stroke. See OMIM; acquired deficiency with GPI-anchor deficiency contributes to paroxysmal hemoglobinuria. See OMIM	Widely expressed, including RBCs; knockout results in mild hemolytic anemia (41)
CD59b	Not expressed	Expression predominately on testes, with low levels on RBCs; effects of knockout are controversial with respect to hemolysis (42,43)

<sup>†</sup>No data<sup>‡</sup>Mouse Genome Informatics (MGI) of Jackson Labs: <<http://www.informatics.jax.org>>\*\*Online Mendelian Inheritance in Man (OMIM): <<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM>>

inhibitors, only factor I has enzymatic activity, which cleaves C4b and C3b so that they cannot function for the further complement activation. The remaining C3 and C5 regulators are fluid-phase or membrane molecules that bind C4b or C3b and dissociate the catalytic subunit C2a or Bb of the classical pathway or alternative-pathway C3- and C5-activating enzymes, respectively. They also may act as cofactors for factor I cleavage (see Figure 48.1). Genes for the complement inhibitors are clustered in a region known as the regulators of complement activation (RCA) at 1q32. These regulators include C4 binding protein (C4bp) and factor H in the fluid phase, and complement receptor 1 (CR1 or CD35), decay-accelerating factor (DAF) (CD55), and CD46 in the membrane. Complement receptor 2 (CR2 or CD21) is in the same gene cluster and, although it does not inhibit complement, it binds the C3dg fragment of C3 and positively potentiates signaling of the B cell's antigen receptor (3). The common structural motif of the RCA proteins and their functions are discussed later and summarized in Tables 48-1 and 48-2.

The extracellular domains of the RCA C4b/C3b binding molecules are comprised of short consensus repeats (SCRs, also known as complement control protein [CCP] repeats or Sushi domains). SCRs are about 60 AA, with commonly four cysteines forming disulfide bonds between the first and third Cys residues and second and fourth Cys residues. SCRs, which are ancient scaffolding modules found in sponges (48), have varying flexibility depending on the amino acid sequences between the disulfide-bonded loops. Although the extracellular domains of RCA proteins are comprised almost exclusively of SCRs, only a few of the SCRs are involved with binding C4b or C3b (49). For example, the common allotype of CR1 (CD35) has an extracellular domain comprised of 30 SCRs. The NH-terminal 28 SCRs are organized as four long, homologous repeats (LHRs) – A, B, C, and D – of seven SCRs each (50). Mapping by substitution mutagenesis has shown that it is primarily the first three SCRs of LHR-A, -B, and -C that are responsible for binding. These are C4b in LHR-A, C4b or C3b in LHR-B, and C3b in LHR-C (51,52). The residues in LHR-D responsible for binding C1q and MBL have not been mapped (14,15). Amino acid analysis of SCRs from complement regulators have identified 11 SCR types and found that identical sequences of SCR types are repeated in proteins, providing further evidence that complement regulators and inhibitors comprised of SCRs arose from a process of gene duplication (53). SCR also are found in some noncomplement proteins, such as factor XIII,  $\beta$ -2 glycoprotein 1, and the interleukin (IL)-2 receptor, in which the SCRs function as scaffolding modules (54).

The SCR-containing membrane regulators DAF (CD55) and CD46 inhibit C3 and C5 activation: DAF causes the dissociation and decay of the C4b2a and C3bBb C3/C5 cleaving enzymes (55); whereas CD46 acts as a cofactor for factor I cleavage of C4b and C3b to iC4b and iC3b (56), respectively. Factor H, acting both as a fluid-phase inhibitor and a peripheral membrane protein inhibitor, dissociates and decays the

C3bBb enzyme and acts a cofactor for the factor I-mediated proteolysis of C3b. The extracellular domain of factor H is comprised of 20 SCRs and includes distinct binding sites for the following ligands: three for C3b, two for heparin, and one for C-reactive protein (57–59).

The non-SCR-containing membrane protein CD59 inhibits the assembly of the terminal C5b-9 complex in autologous cells. CD59 binds to C8 and C9 as the terminal complex is forming in the plasma membrane and thereby prevents the addition of the first C9 and additional C9s that widen the transmembrane channel. Both DAF and CD59 are linked to the plasma membrane by glycan phosphatidylinositol (GPI) anchors. Deficiency of GPI-anchored proteins, specifically the lack of DAF and CD59 in the affected erythrocytes of patients with paroxysmal nocturnal hemoglobinuria, leads to the abnormal deposition of C3b (60,61) and unregulated membrane insertion of C5b-9 that results in intravascular hemolysis (62).

Although the complement components of mammals are largely interchangeable, the receptors (Table 48-1), as well as regulators (Table 48-2), have species specificity. This is illustrated by the fact that human complement does not normally lyse human RBCs, but it readily lyses sheep and rabbit RBCs, which are used to assay human classical and alternative pathways, respectively. Finally, although most of the human inhibitors and receptors are homologous to mouse proteins, in the case of CR1 and DAF their functions have diverged (Table 48-3).

#### COMPLEMENT EFFECTORS: C1q EFFECTS, OPSONINS, B-CELL SIGNALING, ANAPHYLOTOXINS, AND C5b-9

Two intracellular proteins find their way to the external face of the plasma membrane and are able to bind C1q. They are calreticulin (CRT), a chaperone of the endoplasmic reticulum, and p33, a mitochondrial protein. CRT binds a collagen domain of C1q, whereas p33 binds the globular domain. Because CRT and p33 lack a membrane domain, it is assumed that they are tethered to the plasma membrane by associating with another membrane protein and that any cell signaling occurring with C1q binding is due to the associated membrane protein (63). CRT is associated with CD59 on the surface of human neutrophils (64), whereas the pattern of signaling in ECs (to be discussed later) suggests that CRT and some of p33 may be associated with  $\beta$ 1 integrin (65). Evidence also suggests that p33 is associated with the receptor for urokinase-type plasminogen activator (uPAR) on ECs (63) (Figure 48.2). Platelets, which express both CRT and p33, are activated by binding C1q (66).

Complement is the major source of opsonins for innate immunity. In adaptive immunity, complement opsonins function synergistically with specific immunoglobulin to trigger uptake by phagocytic cells. Although C1q, MBL, and C4b are all opsonins, the most effective ligands are cleavage fragments

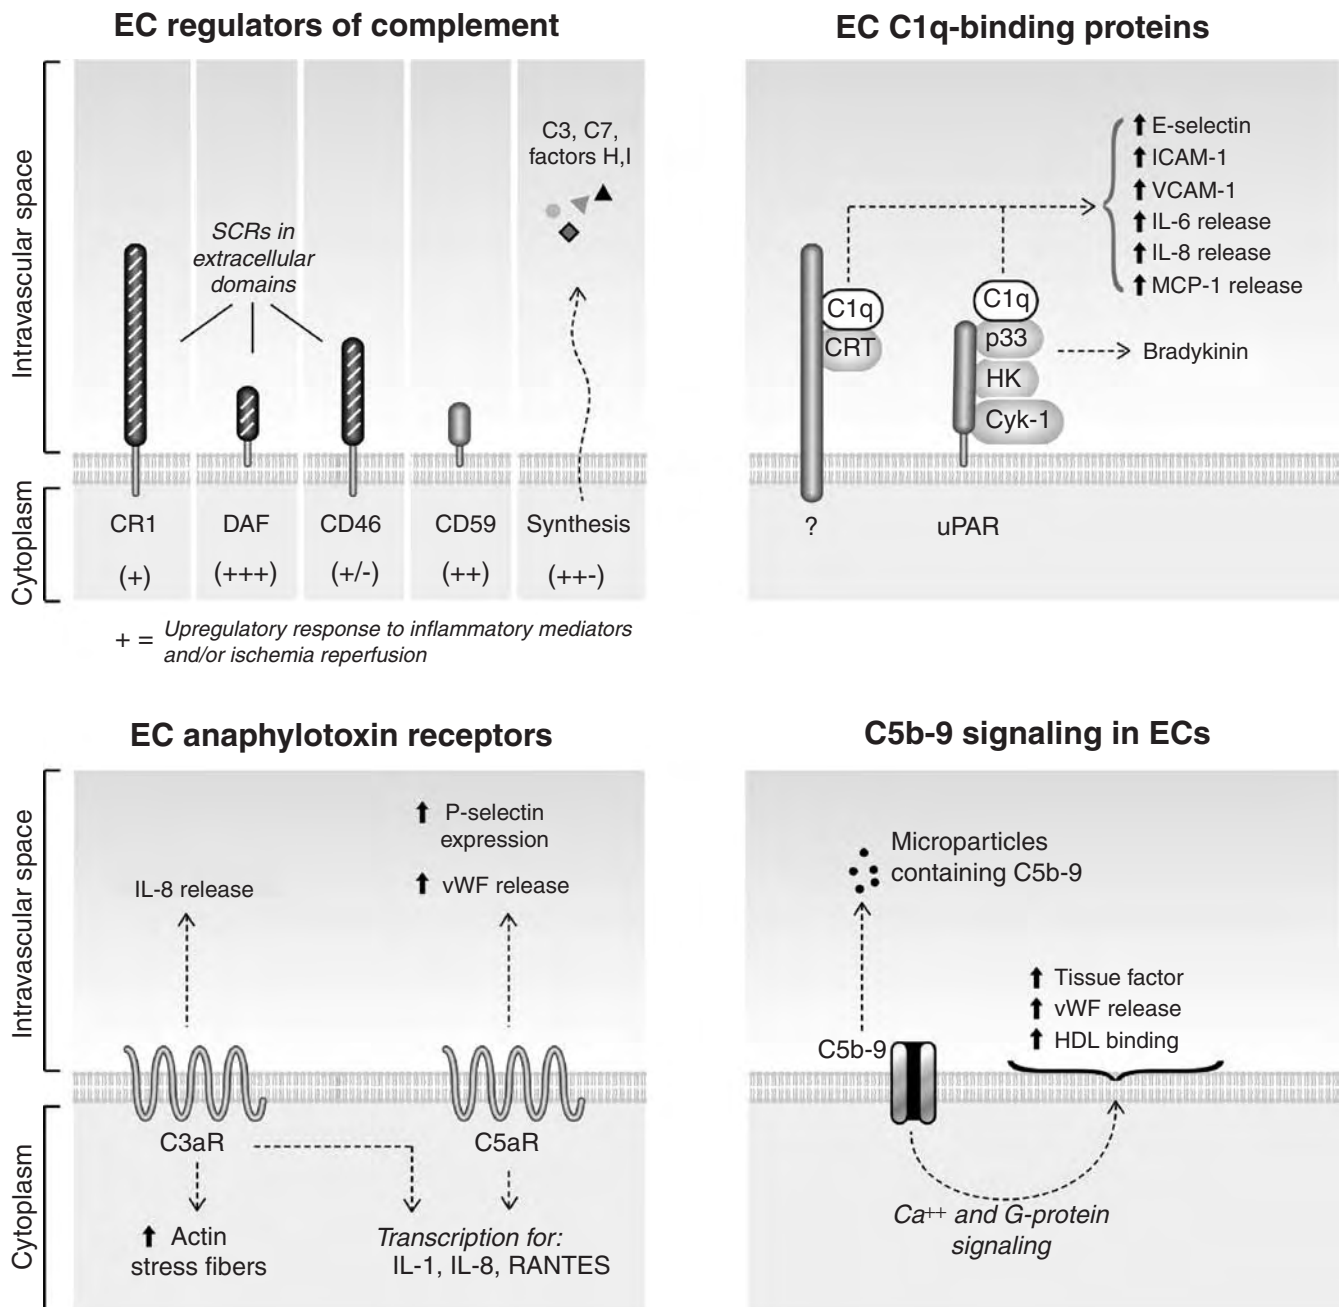

Figure 48.2. EC responses to complement agonists and noncomplement inflammatory mediators. The C1q binding proteins calreticulin (CRT) and p33 are anchored to EC plasma membrane by membrane protein thought to be a  $\beta 1$  integrin. p33 also is found in association with cytokeratin (Cyk)-1 and urinary plasminogen-activator receptor (uPAR). C3a and C5a react with their respective receptors and stimulate the immediate release of some mediators and the transcription of inflammatory cytokines. C5b-9 activates G-proteins and allows a calcium flux that results in some immediate phenotypic changes and vesiculation to remove the C5b-9 complexes (microparticles). Ischemia-reperfusion injury in vitro leads to the expression of complement receptor 1 (CR1 or CD35). Inflammatory mediators can upregulate the expression of complement regulatory molecules and lead to the synthesis of C3, C7, factor H, and factor I.

of C3. The importance of C3 results from its relatively high serum concentration (1.5 mg/mL) and the amplification of its activation by the C3-cleaving enzymes, C4b2a, and especially C3bBb, which participates in a positive feedback loop for more C3 activation (see Figure 48.1). CR1 is the receptor for C1q, MBL, C4b, and C3b of neutrophils, monocytes, and dendritic

cells, where it has an important role in phagocytosis. It also is the receptor for C1q on glomerular podocytes, where it may be involved in endocytosis. RBC CR1 has an important role in clearing complement-opsonized particles from the intravascular space (discussed later). Finally, CR1 functions as a cofactor for factor I cleavage of C3b and iC3b. When C3b is cleaved

to iC3b, it no longer can participate in complement activation but it becomes an opsonin for the integrins  $\alpha_2\beta_2$  and  $\alpha_3\beta_2$  (complement receptors 3 and 4, respectively), which are also phagocytic receptors expressed on neutrophils, macrophages, and dendritic cells.

Using CR1 as a cofactor, iC3b is cleaved to C3dg, the ligand for CR2 (complement receptor 2 or CD21), which is primarily expressed on B cells. When antigen bearing C3dg binds to the B-cell antigen receptor, the attached C3dg ligates CR2, which then signals through associated CD19 to amplify B-cell antigen receptor signaling (3). Thus, particles recognized as “foreign” by the complement system may have their C3b processed to C3dg, which has been shown in one case to potentiate 10,000-fold the threshold for B-cell activation (3). This experiment provides an explanation as to why adjuvants enhance the immunogenicity of purified antigens: Adjuvants activate innate immunity and thereby prime the adaptive immune response. Extrapolating from in vitro studies done with the Raji B-cell line, B cells without a committed antigen receptor can use CR2 to endocytose C3dg-antigen for antigen presentation (67). Studies in mice have corroborated other roles for C4 and C3, as well as their receptors, in enhancing adaptive immunity (2). Of note, although human CR1 and CR2 are encoded by distinct genes, mouse CR2 and CR1 are alternatively spliced gene products. Mouse CR2 is 67% homologous to human CR2, whereas mouse CR1 consists of the entire mouse CR2 molecule plus six additional NH-terminal SCRs that contain a C3b binding site and factor I cofactor site (68). To date, all murine knockouts target both molecules, which together are referred to as CR2/CR1.

The NH-terminal cleavage-activation of the  $\alpha$ -chains of C4, C3, and C5 generate the anaphylotoxins, C4a, C3a, and C5a, respectively. Knockouts of C4, C3, and C5 are confounded because, not only do they inhibit complement activation, they also eliminate the role of these anaphylotoxins. A specific receptor for C4a has not been identified, but receptors for C3a and C5a are well characterized: They are G-coupled and are widely and differentially distributed on leukocytes and other tissues, including endothelium. Specific knockouts of the C3aR and the C5aR have underscored complex roles for these receptors in modulating inflammation (Table 48-3). C4a and C3a, which are strongly positively charged, also can act in a receptor-independent manner to potentiate the chemokine CXCL12 (or SDF-1) (69).

Although C5b-9 often is referred to as the membrane attack complex (MAC), except in pathologic conditions, this is a misnomer. In vivo only *Neisseria* species are killed by C5b-9 (26). C5b-9, which lacks a specific receptor on autologous cells, acts like a cytokine for host cells because it permits a flux of calcium, and it stimulates heterotrimeric G-proteins of the  $G_i/G_o$  family (70). Signaling by C5b-9 must be redundant, however, because deficiency in a terminal complement component in normal humans and mice, which prevents the formation of C5b-9, has no phenotype. C5b-9 does participate in human and experimental inflammation (discussed later). Because C5b-9 is an un gated channel, it is necessary for the cell

to eliminate the channel or the cell will lyse. Both vesiculation and endocytosis have been described. When ECs are subjected to C5b-9, the cells vesiculate to eliminate the C5b-9 pore from their plasma membrane (71).

### Role of Complement in Immune Adherence-Mediated Clearance

All animals with a closed circulation face the problem of clearing their vascular space of noxious particles, such as microbes, apoptotic debris, and immune complexes. The mechanism, known as immune adherence-mediated clearance, has been conserved during evolution and involves three steps. First, particles are recognized by the complement system and tagged with opsonins. Second, using complement receptors, opsonized particles are ligated to the surface of cells. In the case of primates, erythrocytes are the cell and the receptor is CR1 (72). Finally, the particles are removed from the surface of the RBCs by phagocytic cells in the liver and spleen, and the RBCs return to the circulation (73). Nonhuman primates have a GPI-anchored CR1-like molecule on RBCs (74), whereas in humans, CR1 is a transmembrane molecule (72). Other vertebrate animals ligate complement-opsonized particles to platelets, and in mice the complement receptor is platelet-associated factor H (75).

Normal functioning of immune adherence clearance prevents inflammation by both avoiding leukocyte activation in the intravascular space and preventing blood-borne noxious particles (microbes or immune complexes) from lodging in vulnerable organs, such as the brain and kidney, and becoming a nidus of intravascular inflammation. In the absence of immune adherence, immune complexes are cleared more rapidly in vivo (76,77), but the EC becomes the target. In vitro modeling has shown that the presence of immune complexes leads to activation of neutrophils and increased permeability of an endothelial monolayer. When human RBCs are added to this mixture the inflammatory stimulus of the immune complexes is abrogated because they bind RBCs in preference to neutrophils (78).

## THE ENDOTHELIUM AND COMPLEMENT

### Effect of Inflammatory Mediators on Complement Proteins

Of the three membrane complement regulatory proteins, DAF expression is most responsive to upregulation by transcription or translation in response to inflammatory cytokines, whereas CD59 is minimally affected, and CD46 is not affected (Table 48-4) (79,80).

In contrast, incubation of coronary artery endothelial or saphenous vein ECs with C-reactive protein leads to the upregulation of DAF, CD59, and CD46 (84). Ischemia–reperfusion injury of cultured human umbilical vein ECs (HUVECs) leads to the upregulation of CR1 (86). LPS, tumor necrosis factor (TNF)- $\alpha$ , and interferon (IFN)- $\gamma$  all cause the upregulation of

**Table 48-4: Effect of Cytokines/Drugs on Complement Regulatory Molecules Expressed on Endothelial Cells**

Stimulus	DAF	CD46	CD59	References
IL-1 $\beta$	No $\Delta$	No $\Delta$	No $\Delta$	79
TNF- $\alpha$	$\uparrow$	No $\Delta$	No $\Delta$	80
Thrombin	$\uparrow$	—	—	81
IFN- $\gamma$	$\uparrow$	No $\Delta$	No $\Delta$	80
bFGF	$\uparrow\uparrow$	No $\Delta$	No $\Delta$	82
VEGF	$\uparrow\uparrow$	—	—	83
CRP*	$\uparrow$	$\uparrow\uparrow$	$\uparrow$	84
Statins	$\uparrow\uparrow$	No $\Delta$	$\uparrow$	85

$\uparrow$  – significant increase

$\uparrow\uparrow$  –  $\geq 100\%$  increase

\*C-reactive protein

the C1q binding protein, p33 (87). Inflammatory agonists also can induce ECs to synthesize complement proteins including C3 and alternative pathway components (88,89), C7 (90), and the fluid phase regulators, factors H and I (91,92).

### Complement Signaling to Endothelial Cells

#### Signaling Through C1q Binding Proteins

C1q immobilized in plastic wells causes seeded human dermal microvascular ECs to spread. The spreading can be partially inhibited by pretreating the cells with either antibody against CRT or p33, and can be completely inhibited by an RGD-containing peptide. The ability of an RGD-containing peptide to completely inhibit spreading has led to the hypothesis that  $\beta 1$  integrins are associated with one or both of the C1q binding proteins and may be mediating the signaling in ECs (65).

#### C3a and C5a Signaling in Endothelial Cells

Receptors for C3a and C5a are constitutively expressed on HUVECs and ECs in vivo. Although C3 and C5 are homologous proteins, their N-terminal fragments, liberated after the cleavage-activation of the parent molecules, show complete specificity for their respective receptors. They are both known as anaphylotoxins because of their ability to induce smooth muscle contraction. Because C3 is cleaved more readily than is C5, the molar ratio of C3a will exceed that of C5a in vivo. Their receptors are G-protein-coupled and, in the case of leukocytes, both are pertussis toxin inhibitable, whereas the C3aR of ECs is not inhibited by pertussis toxin (93). In cultured ECs, both C3a and C5a induce the transcription of mRNA for *IL-1 $\beta$* , *IL-8*, and regulated on activation normal T-cell expressed and secreted (RANTES), and the rapid release of IL-8 (94). C3a induces actin stress fibers in HUVECs, whereas C5a causes cell retraction over days, with resultant increased paracellular permeability (93). C5a also induces the rapid

release of von Willebrand factor (vWF) and upregulation of P-selectin, which results in increased endothelial adhesiveness for neutrophils (95). Thus, both C3a and C5a stimulate ECs to modulate cytokine production and affect leukocyte trafficking.

#### C5b-9 Signaling to Endothelial Cells

Signaling pathways downstream of C5b-9 have been reviewed (96). C5b-9 stimulates HUVEC degranulation, secretion of multimers of vWF, vesiculation, and binding of high-density lipoprotein (HDL) particles and their protein adaptors apolipoproteins A-I and A-II (apo A-I and A-II). C5b-9-induced degranulation is mimicked by other agonists that induce an increase in intracellular calcium, such as ionophore (97,98), but vesiculation is a specific response to C5b-9. Vesicles, which contain the C5b-9, are avid docking sites for clotting factor Va. Subsequently, Va binds factor Xa to assemble the Va,Xa prothombinase complex at the vesicle surface (71). C5b-9 also induces tissue factor expression on ECs, an effect that occurs over days and depends on secreted IL-1 as an intermediary stimulus. Thus, at least three mechanisms are in place whereby sublytic complement stimulation can lead to procoagulant signals. It is likely that C5b-9-stimulated procoagulant activity participates in syndromes involving complement fixing antiendothelial antibodies. Such syndromes include thrombotic thrombocytopenia purpura, Kawasaki disease, systemic vasculitis, and acute graft rejection (99–101).

C5b-9-induced binding of HDL and apo A-I and A-II to HUVECs depends on a cytosolic calcium flux, but cannot be reproduced by calcium ionophore (102). The receptor for HDL and apoA-I and A-II on endothelium has been identified as scavenger receptor B type I (103). One explanation for increased ligand binding is that the scavenger receptor is upregulated by C5b-9, as is DAF (80).

#### Complement-Induced Endothelial-Cell Pathology

Dysregulation of complement and damage to ECs may be due to either potent stimuli for activation and/or mutations in the complement regulatory proteins. Examples of potent complement-activating stimuli are reperfusion injury, allotransplantation, and to a greater degree, xenotransplantation. Transplant surgeons have demonstrated that long-term organ survival is adversely affected by reperfusion injury (104), illustrating that transplants are not only targets of the host adaptive immune response, but also of innate immunity's response to ischemia, which is particularly severe in organs retrieved from cadavers. Rodent models of reperfusion injury also demonstrate a central role for complement, although the mechanism of complement activation is controversial. It is likely that the target organ and the degree of ischemia affects how complement is activated because different models activate either the lectin pathway through mannan-binding lectin, or the classical pathway with the participation of natural IgM (105,106).

Biopsies of transplanted ischemically damaged human kidneys show mannan-binding lectin deposition (107).

AMD is an inflammatory condition that is characterized by focal extracellular debris, known as *drusen* (German for stones), that develop between the retinal pigment epithelial layer and its specialized basement membrane known as the Bruch membrane. Drusen contain multiple elements including vitronectin, C3 cleavage products, and C5b-9 complexes (108,109). Familial forms of AMD had been genetically linked to a region near the factor H gene, and recent data implicates a single nucleotide polymorphism (SNP) (Y404H) as highly associated with the familial form of AMD in five different patient groups (110–113). Although drusen are above the Bruch membrane, and the choroid layer containing the vasculature lies just beneath the Bruch membrane, this particular SNP is most closely associated with the variant of AMD that features neovascularization of the macula. The SNP is in the factor H domain involved in binding to host cells and C-reactive protein. It is not clear whether AMD is initiated by complement activation, or associated with complement activation. In either case, the SNP potentially compromises the ability of factor H to bind to host cells, including ECs, and protect them from errant C3 and C5 activation. Retinal pigmented epithelial cells are sources of both proangiogenic vascular endothelial growth factor (VEGF) and antiangiogenic pigmented epithelium derived factor (PEDF). In vitro, disruption of cell–cell contact, which might result from drusen formation in vivo, induces *VEGF* mRNA and inhibits *PEDF* mRNA transcription by pigmented epithelial cells (114).

In diabetic retinal microangiopathy, which is characterized by microinfarcts and neovascularization, C5b-9 is deposited in the capillaries just beneath the Bruch membrane. The absence of C4 antigen in the vessels is consistent with activation of complement by the alternative pathway (115). GPI-anchored complement regulators DAF and CD59 are relatively deficient in the lysates of retinas from diabetic subjects as compared with those from normal subjects (116). DAF and CD59 deficiency would allow unregulated C3 activation at the cell membrane and unregulated insertion of C5b-9. Further compromise of CD59 function may occur from glycation secondary to hyperglycemia (117). The membrane complement regulator CD46, which is transmembrane, is not decreased in diabetic retinas (116).

aHUS, which accounts for about 10% of all HUS cases, is not associated with infections due to Shiga toxin-producing bacteria. The microangiopathic hemolytic anemia, thrombocytopenia, and renal failure of aHUS is pathologically similar to that of HUS, but aHUS is often more severe and may be recurrent and familial. About one third of aHUS patients have functional mutations in either factor H, factor I, or CD46, which are all regulators of C3 activation (118). aHUS due to factor H mutations has been associated with recurrence after renal transplantation (119). Variable penetrance of the aHUS susceptibility has led to searches for gene modifiers, and aHUS patients are more likely to share SNPs in other complement

regulator genes when compared with a control population (120).

Atheromata are associated with complement deposition (121). Whether complement has a role in initiating the lesion is debatable, but it almost certainly has a role in sustaining the inflammation. Complement is activated, both in vitro and in vivo, when exposed to the modified lipid deposits characteristic of the atheromatous lesion (122). C-reactive protein can bind to the lipids and further activate C1. Several complement-deficient animal models have been used to investigate the roles of complement in the pathogenesis of atherosclerosis. If C3 is knocked out in atherosclerosis prone *Apoe*<sup>-/-</sup> mice, the serum lipids do not change, but two changes occur in the aortic lesions, compared with the wt *Apoe*<sup>-/-</sup> animals. First, the lesion size is increased in *Apoe*<sup>-/-</sup>/C3-deficient mice as compared with the *Apoe*<sup>-/-</sup>/C3-normal mice. Second, in the absence of C3, the aortic lesion does not mature beyond the foamy macrophage stage (123). Specifically, no smooth muscle cell proliferation occurs. C5b-9 is thought to have a role in smooth muscle proliferation (121), and C5b-9 cannot form in the absence of C3 activation. In another animal model, C6 deficiency in rabbits protects them from diet-induced aortic atherosclerosis (124). However, not all the animal data are consistent: C5 deficiency does not protect the *Apoe*<sup>-/-</sup> mouse from aortic atherosclerotic lesions (125). Only additional studies will clarify the role of C5b-9 in atherosclerosis.

Compromise in immune adherence clearance can result from the inability to opsonize particles adequately. This is one explanation for the association of a deficiency of an early classical pathway component and the risk of developing lupus erythematosus. Interestingly, the risk is greatest for developing lupus the earlier the deficient component is in the activation sequence, with a >90% risk associated with C1q deficiency (126) and only a 10% risk associated with C2 deficiency (32). It is not known whether the noxious particle that is not cleared adequately in lupus is apoptotic debris or immune complexes. Immune adherence clearance can be overwhelmed when a large burden of antigen results in the continued production of immune complexes that cannot be appropriately cleared. This occurs in subacute bacterial endocarditis and serum sickness, and the uncleared immune complexes injure the endothelium and cause clinical vasculitis.

#### KEY POINTS

- ECs are bathed in complement. High levels of membrane regulators of complement activation normally protect ECs from direct complement damage. The effective immobilization of complement opsonized noxious particles and clearance by immune adherence further protect ECs from bystander complement damage.

- Acquired and genetic deficiencies of complement regulators are linked to diabetic retinopathy, aHUS, and age-related macular degeneration.
- Compromise of complement-dependent immune adherence clearance predisposes to vasculitis.

#### Future Goals

- To gain acute control over complement activation at the time of organ transplant to dampen acute and chronic rejection
- To undertake additional studies of complement component deficiencies in atherosclerotic prone mice to delineate if complement has a role in the initiation of atheromata, or just in their progression

## Kallikrein-Kinin System

Robert Colman

*Sol Sherry Thrombosis Research Center, Temple University School of Medicine,  
Philadelphia, Pennsylvania*

Three proteins – factor XII, prekallikrein (PK), and high-molecular-weight kininogen (HK) – comprise the contact system, currently referred to as the plasma kallikrein-kinin system (KKS) (Table 49-1). HK was originally identified as a substrate (1) that yields a bioactive peptide, bradykinin (BK), when cleaved. BK in vivo stimulates microvascular permeability and arteriolar vasodilation, resulting in hypotension. Two enzymes are required for the hydrolysis of HK. In 1955, factor XII was discovered by Oscar Ratnoff in a study of a patient, John Hageman, who lacked the protein and had a very prolonged coagulation time (2). Prekallikrein (PK) was first purified from human plasma as the activated enzyme, kallikrein, after being identified by Hathaway in 1965, in a subject with modestly prolonged activated partial thromboplastin time (aPTT) (3). Factor XII autoactivates to factor XIIa, which cleaves plasma PK to kallikrein. Kallikrein then feeds back to cleave factor XII to factor XIIa. Plasma kallikrein and factor XIIa (to a lesser extent) both hydrolyze HK to form cleaved HK (HKa) and BK. The importance of HK was first apparent when three different research groups described patients deficient in HK with prolonged aPTT. One such patient, Williams (4), was identified by our laboratory to have absent BK, even in the urine. All three proteins – factor XII, PK, and HK – were cloned in the mid-1980s.

### FACTOR XII

Factor XII is encoded by a single gene of 12 kb that maps to chromosome 5, comprising 13 introns and 14 exons (5). A putative signal peptide sequence on the NH<sub>2</sub> terminus of the zymogen is located on the first exon, followed by a region of unknown homology encoded by the second exon. A type II region homologous with collagen-binding properties in fibronectin is represented by exons II and IV. Exon V codes for the epidermal growth factor (EGF)-like domain, followed by the type I homology or the fibrin finger in fibronectin, coded by exon XI. Exon VII encodes the second EGF-like domain, preceding a kringle structure and a proline-rich region on exons

VIII through IX. The light chain of factor XIIa is encoded by five exons (X–XIV). Exon XIV is the largest, consisting of 165 nucleotides encoding 55 amino acid residues of the serine protease region and 150 base pairs (bp) of the 3′ untranslated end of the mRNA (6).

The *factor XII* gene is similar in structure to the serine protease family of *tissue-type plasminogen activator (t-PA)* and *urokinase-type plasminogen activator (u-PA)* genes. The mRNA codes for a 596-amino acid, single polypeptide chain with a molecular mass of 80 kDa and an isoelectric point of  $6.3 \pm 0.1$ . Factor XII concentration in plasma is  $31 \pm 8 \mu\text{g}/\text{mL}$  ( $0.375 \mu\text{M}$ ). Human liver has been shown to express *factor XII* mRNA, and rat hepatocytes in culture synthesize factor XII. In isolated livers of estrogen- and prolactin-treated rats, factor XII is elevated. Rat *factor XII* DNA has been shown to have a functional estrogen promoter element that binds  $17\beta$ -estradiol (7). Estrogens in premenopausal women in the context of oral contraception, replacement therapy in postmenopausal women, or pregnancy all elevate factor XII (8).

Factor XII is cleaved to the two-chain factor XIIa at R353-V354, remaining connected by a disulfide bond. Further cleavage at three peptide bonds in the catalytic light chain yields the 28-kDa factor XII<sub>F</sub>, which lacks the heavy chain. Because all the cell binding sites are in the heavy chain, factor XIIa binds to platelets, neutrophils, and endothelial cells (ECs), but factor XII<sub>F</sub> does not. Targeted deletion of murine *factor XII* gene results in complete plasma factor XII deficiency. The mice do not have spontaneous or excessive injury related bleeding but they are protected against collagen- and epinephrine-induced thromboembolism (9).

### PREKALLIKREIN

The gene structure for human *PK* has only recently been determined (10); it is composed of 15 exons and 14 introns. The results of chromosomal localization for human *factor XI* and *PK* (both chromosome 4) genes strongly corroborate a gene duplication event from a common ancestor for both *PK* and

**Table 49-1: Biologic Functions of Contact Proteins**

	Receptors	Function	Human Deficiency	Mouse <sup>-/-</sup>	References
Prekallikrein	Binds to cells only in presence of HK	Cleaves pro-urokinase to u-PA (increased plasmin formation); kallikrein activates XII and hydrolyzes HK to HKa and BK	High aPTT; no excessive bleeding; not protected from thrombosis	Not yet generated	10,14
XII	gC1qR GP1b	Auto-activates to XIIa; XIIa cleaves prekallikrein to kallikrein; kallikrein hydrolyzes HK to HKa and BK	High aPTT; no excessive bleeding; not protected from thrombosis	Protected from platelet-related thrombosis but does not cause excessive hemorrhage	6,9
HK	GP1b, Mac-1, uPAR, gC1qR, CK-1	Antiadhesive displaces fibrinogen from platelets and leukocytes; VN blocks HKa binding to uPAR by forming complex with VN, thus blocking VN binding to $\alpha_v\beta_3$ on ECs. HK is proangiogenic (via BK); HKa inhibits FGF2-mediated EC proliferation (via induction of apoptosis) and VN-mediated EC migration	High aPTT; reduced/absent BK in plasma and urine; no excessive bleeding; not protected from thrombosis	Not yet generated, probably because two functional genes exist in mouse; rat deficiency results in decreased angiogenesis and increased thrombosis	21,24, 27–31, 33–35, 46,47

*factor XI* (11), about 270 million years ago. *PK* mRNA codes for a mature human protein of 609 amino acids with 58% identity to human factor XI. Plasma PK has an isoelectric point of 8.7 and an estimated plasma concentration of  $42 \pm 3 \mu\text{g/mL}$  ( $0.49 \mu\text{M}$ ). Approximately 75% circulates bound to HK (12,13), and only 25% circulates as free PK. When analyzed on a nonreduced polyacrylamide gel electrophoresis in SDS, plasma PK is shown to consist of two components of Mr 85 and 88 kDa, which differ in the degree of glycosylation. During the conversion of PK to kallikrein, its active form, a single bond (Arg371–Ile372) is split, generating a heavy chain of 371 amino acids (53 kDa) and a light chain of 248 amino acids (36 and 33 kDa), held together by a single disulfide bond (14). PK has four tandem repeats in the amino-terminal portion of the molecule due to the linking of the first and sixth, second and fifth, and third and fourth half-cysteine residues present in each repeat. This arrangement results in four groups of 90 or 91 amino acids that are arranged in “apple” domains (15) which, in addition to PK, are only seen in factor XI. The fourth repeat contains two additional 1/2-Cys residues, forming an additional disulfide bridge. A short connecting region of nine amino acids follows repeat 4, culminating at the cleavage site between the light and heavy chains. The light chain contains the catalytic triad His415, Asp464, and Ser559.

## KININOGENS

The two plasma kininogens, HK and low-molecular-weight kininogen (LK), are the products of a single-copy gene (16) in humans that maps to 3q26-qter. The human *kininogen* gene (27 kb) consists of 11 exons and produces unique mRNA, respectively, for HK and LK by alternative splicing. *HK* and *LK* both contain the coding region for exons 1 to 9, a part of exon 10 containing the *BK* sequence, and the first 12 amino acids after the carboxy-terminal amino acid of BK. Exon 11 codes for the 4-kDa light chain of LK, D5. Exon 10 contains the coding sequence for the 56-kDa light chain of HK, including domain 5<sub>H</sub> and domain 6. The mRNA for human *HK* and *LK* are 3.5 and 1.7 kb, respectively. In mice, two functional genes exist (17). This situation explains why a knockout has yet to be reported. Recent studies of expression of the human *kininogen* gene have shown that it is strongly upregulated by agonists of the farnesoid X receptor (18).

The heavy chain of HK and LK consists of three tandem repeat units related to cystatin-designated domains 1, 2, and 3 (19,20), which are coded for by exons 1 to 3, 4 to 6, and 7 to 9, respectively. Domain 1 contains a low-affinity calcium-binding site, and domain 2 inhibits calpain and cathepsin L. Domain 3 can inhibit cathepsin L, B, and H but not calpain. More importantly, domain 3, which has been expressed in

Figure 49.1. Domain organization of HK and HKa. HK is divided into six domains, D1 through D6. Plasma kallikrein cleaves HK, releasing the nonapeptide BK. The resulting protein (HKa) is a two-chain molecule held together by a single disulfide bond between D1 and D6.

*Escherichia coli*, binds to neutrophils, monocytes, platelets, and ECs with high (nM) affinity. Domain 4 contains BK, and its first five amino acids comprise a low-affinity binding site to platelets. Domain 5<sub>H</sub> (unique to HK) also has been expressed in bacteria, and is a major cell binding structure that interacts with the same cells as domain 3 but with different receptors or at different sites in the same receptor. Domain 6 has a high-affinity site for binding PK, which mediates the formation of the binary complex of HK and PK. The latter complex circulates in plasma. When HK is cleaved by kallikrein, BK is released from D4, resulting in a heavy chain (D1–D3) and light chain (D5–D6) that remain covalently linked by a single disulfide bond (Figure 49.1).

## KININOGEN RECEPTORS

HK interacts with platelets, ECs, monocytes, and neutrophils to exert discrete physiological effects. No other cells have yet been shown to bind kininogen. On platelets, two receptors have been identified. HK binding to the GPIb/IX/V complex (21) is primarily due to D3 and prevents high-affinity thrombin binding (22), thus exerting an antithrombotic effect both in vitro in human platelets and in vivo in rats deficient in HK (23). HK also binds to globular C<sub>1</sub>q receptor (gC<sub>1</sub>qR) on platelets. On neutrophils and monocytes, a major receptor is Mac-1 ( $\alpha_m\beta_2$ ) (24) to which both D3 and D5 bind (25). HK can effectively inhibit fibrinogen binding, because the  $K_D$  is 5 to 15 nM, compared to that of fibrinogen, at 600 nM (26). The reactions of the contact system and fibrinolytic proteins on the endothelial surface are summarized in Figure 49.2.

HK and/or HKa binds to three major receptors on ECs: urokinase plasminogen activator receptor (uPAR) (27), gC<sub>1</sub>qR (28,29), and cytokeratin-1 (CK-1) (30), which colocalize on the EC surface. CK-1 interacts with either uPAR or gC<sub>1</sub>qR, but uPAR and gC<sub>1</sub>qR do not directly bind to each other. This pairing is consistent with the observation that CK-1 interacts with HK through D3 and D5, whereas uPAR (31) and gC<sub>1</sub>qR bind primarily HKa through D5. The binding to ECs is tight ( $K_d = 7$  nM), requires  $Zn^{2+}$ , and results in two important reactions. The first is the cleavage of HK to HKa and BK by plasma kallikrein. Although the cleavage can occur in the fluid phase, it is limited by the presence of the protease inhibitors C1-inhibitor and  $\alpha_2$ -macroglobulin. When kallikrein is bound to HK

Figure 49.2. Interactions of contact system proteins on ECs – role in angiogenesis. Factor XII (FXII) binds to globular C<sub>1</sub>q receptor (gC<sub>1</sub>qR), which allows its autoactivation to FXIIa. FXIIa activates prekallikrein (PK) to kallikrein (Kal). Kal feeds back to cleave FXII to FXIIa. HK binds to cytokeratin (CK)-1. Kal cleaves HK to release bradykinin (BK), a stimulator of angiogenesis; HKa, an angiogenic inhibitor, remains. HKa binds to gC<sub>1</sub>qR and uPAR but not to CK-1. HK binds only to CK-1. Prolylcarboxypeptidase (PCP) activates PK to Kal. Kal cleave prourokinase (pUK) to urokinase (UK). pUK and UK bind to domain 1 of uPAR.

or receptors on ECs or leukocytes, the protease inhibitors are much less potent. Therefore HK is less susceptible to cleavage.

### ROLE OF CONTACT SYSTEM IN FIBRINOLYSIS

Plasma kallikrein is brought to the endothelial surface by HK or HKa, because it binds to D6. Two enzymes can activate the zymogen, PK, to the active enzyme, plasma kallikrein. The first already discussed is factor XIIa, which binds separately to gC1qR on the endothelial surface (32). PK also is cleaved by a membrane-associated serine protease, prolylcarboxypeptidase (33), to the active enzyme. Plasma PK cleaves prourokinase into the two-chain activated form, a reaction independent of factor XIIa. Prourokinase then hydrolyzes plasminogen to form plasmin on the endothelial surface. Because HK binds to uPAR, as does prourokinase, this is an extremely efficient kinetic process; the cell binding also protects the enzyme against plasminogen activator inhibitor (PAI)-1. This cell surface plasmin formation also is enhanced by BK, which is a potent agonist for t-PA release. Plasmin can directly hydrolyze basement membrane proteins, such as laminin and fibronectin, and cleaves collagen indirectly by activating matrix metalloproteases.

### HKa: INHIBITOR OF ANGIOGENESIS

HKa is a potent antiadhesive protein. In addition to displacing fibrinogen from neutrophils and platelets (24), HKa inhibits the binding of vitronectin (VN) to uPAR (27) and thus cell adhesion. In addition, HKa forms a complex with VN that inhibits VN binding to the integrin  $\alpha_v\beta_3$  on ECs (34). Because detachment of ECs and penetration of the basement membrane are two of the early steps of angiogenesis, the role of HK and HKa in angiogenesis has been further investigated. We observed that HK-D5 inhibited the EC proliferation stimulated by fibroblast growth factor 2 (FGF2) as well as EC migration toward VN (35). These effects are separable, because two different peptides derived from HK-D5 have separate actions—HK440 to 455 inhibits proliferation, whereas HK486 to 502 inhibits migration. Kawasaki and colleagues (36) compared these results in vitro and demonstrated that peptides that contain the sequence HGK were active in inhibiting EC migration. The synergism of these two peptides predicted that both D5 and HKa would exhibit potent inhibition of angiogenesis. This prediction was confirmed in ovo in the chick chorioallantoic membrane (CAM), where D5 had an  $IC_{50} = 100$  nM and HKa an  $IC_{50} = 30$  nM. The mechanism by which proliferation was inhibited proved to be the induction of apoptosis (37). D5 decreased cyclin D1, a critical protein in the cell cycle required for the G1–S transition. HKa, which also led to apoptosis, produced upregulation of Cdc2 and cyclin A (38). Furthermore, the induction of apoptosis was regulated by extracellular matrix proteins. HKa-induced apoptosis occurs when cells are grown on VN but not on fibronectin (39). These inhibitory

effects are mediated by HKa binding to uPAR and dissociation of the integrins  $\alpha_v\beta_3$  or  $\alpha_5\beta_1$ . This reaction then disrupts the downstream intracellular signaling, including phosphorylation of focal adhesion kinase by the Syk kinase, Yes, and the subsequent phosphorylation of paxillin (Figure 49.3). Both ECs and cancer cells must invade tissues to form vessels and to metastasize, respectively. Recently, we showed that GST-D5 can inhibit the growth of human colon cancer in vitro by preventing the G1–S transition in the cell cycle (40). Browder and colleagues (41) have shown that proteins such as collagen and plasminogen, when proteolytically cleaved, give rise to the angiogenic inhibitors endostatin and angiostatin, respectively.

### BRADYKININ: A STIMULATOR OF ANGIOGENESIS

Collagen is needed structurally for new vessel formation. Plasminogen, when activated, gives rise to plasmin, which enhances migration and angiogenesis. Because HKa and D5 were both antiangiogenic, we postulated and subsequently demonstrated that HK would be required for angiogenesis itself (42). BK was shown to stimulate neovascularization directly, consistent with our finding that inhibiting plasma kallikrein prevented the formation of BK and thus inhibits angiogenesis. Several other investigators, including Parenti and colleagues (43), also implicated BK as an angiogenic agonist which, by stimulating the B1 receptor, upregulated endogenous endothelial FGF2 by stimulating nitric oxide synthase (NOS). BK, through the B1 receptor, also stimulated human vascular smooth muscle cells (VSMCs) to secrete vascular endothelial growth factor (VEGF) (44). In contrast, Seegers and colleagues (45) indicated that the B2 receptor was involved in EC proliferation during acute synovitis. One mechanism for this effect could be the transactivation of the VEGF receptor, KDR/FLK-1 (46).

### USE OF MONOCLONAL ANTIBODY TO KININOGEN TO INHIBIT ANGIOGENESIS

HK binding to ECs is required for cleavage, which produces the angiogenic stimulator, BK. Although HK could be cleaved on the surface of leukocytes, the rapid destruction of BK by kininases ensure that it acts as a local mediator. The finding has been exploited to “treat” experimental angiogenesis using a monoclonal antibody to human HK (C11C1). C11C1 recognizes orthokinogen in chicken plasma and thus in the CAM model (42). C11C1 can inhibit FGF2 or VEGF-induced neovascularization or even BK stimulation of angiogenesis in the CAM. Mab C11C1 inhibits the growth of human fibrosarcoma on the CAM (42). These results suggested the possibility that mAb C11C1 could be used in the treatment of human tumors by targeting angiogenesis. We have recently shown that this monoclonal antibody blocks the binding to human

Figure 49.3. Action model illustrates interference with endothelial extracellular interactions by HKa and intracellular signaling required for angiogenesis. *Left:* Vitronectin (Vn) binds to both the integrin  $\alpha_v\beta_3$  and uPAR, which also bind to each other. uPAR recruits caveolin, which in turn provides an environment for activation of Yes, which phosphorylates focal adhesion kinase (FAK), which further phosphorylates paxillin. These signals lead to EC adhesion, migration, and proliferation. *Right:* HKa competes with Vn for a binding site on uPAR (domain 2/3). HKa also forms a stoichiometric complex with Vn to prevent its binding to  $\alpha_v\beta_3$ . Both these steps disrupt the downstream signaling complex seen in the left panel.

and murine ECs and inhibits the growth of human colon carcinoma as a xenograft in an immunoincompetent (nude) mouse (47). Angiogenesis is not confined to supporting cancer cell growth. Chronic reactive arthritis in rats injected intraperitoneally with proteoglycan-polysaccharide for group A streptococcus is associated with angiogenesis as well, similar to that of human inflammatory arthritis. MAb C11C1 inhibited this reactive arthritis in Lewis rats by blocking the binding of HK and the subsequent proteolytic release of BK (48).

#### BRADYKININ AND HKa: PATHOPHYSIOLOGICAL ANTAGONISTS

Because the cleavage of HK on the surface of ECs gives rise to BK, an angiogenic stimulator, and HKa, a potent angiogenic inhibitor, it was important to determine which one predominates. Hayashi and colleagues (49) solved this conundrum by testing angiogenesis *ex vivo* and *in vivo* in Brown Norway Katholique rats, which are deficient in both HK and LK. They found that angiogenesis was suppressed in the kininogen-deficient rats compared with Brown Norway Kitasato rats, which have normal plasma kininogen concentrations. Because BK has a short (30 sec) half-life but is very potent, whereas HKa has a long (9 hrs) half-life but requires higher molar concentrations, it is likely that BK turns on angiogenesis while HKa turns it off (50).

#### KEY POINTS

- The interactions of the contact system with ECs can best be illustrated by their effect on angiogenesis.
- Cleavage of HK by plasma kallikrein on the EC surface gives rise to two mediators, BK, which turns on angiogenesis, and HKa, which turns it off.
- BK, by binding to B2 receptors, initiates proliferation by intracellular signaling pathways that stimulate VEGF secretion and bind to B1 receptors, which upregulate FGF2.
- HKa binds to uPAR and ligands of selected interacting integrins. HKa physically displaces these proteins, thereby disrupting phosphorylation of Syk kinases such as Yes and focal adhesion kinase and its substrate, paxillin, thereby inhibiting migration.

#### Future Goals

- To map downstream signaling pathways that would reveal nuclear effects
- To delineate further pathways involving extracellular matrix proteins

## Opioid Receptors in Endothelium

Kalpna Gupta and Elliot J. Stephenson

*Vascular Biology Center, University of Minnesota Medical School, Minneapolis*

Opioids are well known for their highly effective analgesic properties and for their addiction-causing tendencies. The term *opioid* is derived from the Greek word *opion*, meaning “poppy juice.” Opium is obtained from the green pods of the opium poppy plant. The alkaloids morphine, codeine, and thebaine are derived from opium. Animals ranging from worms to humans produce endogenous opioid peptides. The term *opioid* encompasses both the naturally occurring (endogenous) opioids from opium poppy and animals and semisynthetic and synthetic alkaloid drugs that interact with opioid receptors. To date, four different opioid receptors (ORs) have been cloned:  $\mu$ ,  $\delta$ , and  $\kappa$  (also known as MOR, DOR, and KOR, respectively), and nociceptin/orphanin FQ (ORL1) (1). All four receptors are expressed in the vascular endothelium, where they are uniquely positioned to transduce signals from circulating opioids (synthesized centrally or by peripheral non-neuronal cells) before they reach their target tissue, the brain. Compared to our advanced understanding of the opioid–neural axis, remarkably little is known about opioid signaling in the endothelium. Recent studies indicate that opioid–opioid receptor interactions in endothelial cells (ECs) result in increased production of nitric oxide (NO), pointing to a potential role for opioid signaling in mediating vasodilation, cell adhesion, cell survival, and angiogenesis (Figure 50.1). In this chapter, we discuss the nature and mechanisms of these interactions and explore the utility of this signaling axis as a therapeutic target in vascular diseases.

### HISTORY: FROM MESOPOTAMIA TO MODERN MEDICINE

Opioids are inextricably linked to the history of mankind. In 3400 BC, the Sumerians of Mesopotamia called the opium poppy *Hul Gil*, the “joy plant” for its euphoric effect. In 460 BC, Hippocrates dismissed the magical attributes of opium but acknowledged its usefulness in treating internal and gynecological diseases as well as epidemics. Opium first began to traverse the globe when Alexander the Great conquered India

and introduced opium there in 330 BC. The first description of opium’s properties and medical use for treating diarrhea and sexual debility appeared in the ancient East Indian medical treatises *The Shodal Gadanigrah*, *Sharangdhar Samahita*, and *The Dhanvantri Nighantu* in 1200 AD. Starting in 1750, the British East India Company dominated the lucrative export of opium from India to China and, in 1800, the British Levant Company purchased nearly half of Turkey’s opium harvest strictly for importation to Europe and the United States. According to the United Nations, Afghanistan currently supplies 87% of the world’s opium.

In 1803, Friedrich Sertürner of Paderborn, Germany discovered the active ingredient in opium by dissolving it in acid, then neutralizing it with ammonia. The result: the alkaloid morphine. Morphine was lauded as “God’s own medicine” for its reliability, long-lasting effects, and safety; physicians believed that opium had finally been perfected and tamed. Ironically, this global drug that ancient and medieval humans used wisely is now abused recklessly. Modern research has resurrected the ancient status of these drugs to only a small extent because of the predominantly narrow focus on analgesia, addiction, and tolerance. In contrast, in blood vessels where opioids have a close encounter with the endothelium, they remain inadequately studied.

### OPIOID RECEPTORS

#### Overview

Although opioid binding sites were first proposed in the early 1950s and identified in mammalian brain in 1973, the first opioid receptor DOR was cloned in 1992, followed by the cloning of the other three receptors (1). All four opioid receptors are present on the endothelium (2,3). Each opioid receptor can be activated by several endogenous or exogenous opioids, although a degree of selectivity exists, as summarized in Table 50-1. Although the activity of all four receptors can be antagonized by naloxone, specific antagonists exist for each individual opioid receptor.

Figure 50.1. Schematic representation of opioid signaling in endothelium. Opioids interact with 7-transmembrane domain receptors coupled to G-proteins and stimulate the MAPK/ERK pathway via a NO-dependent mechanism. On the other hand, opioid receptors activate Akt phosphorylation and promote cell cycling. Opioid receptor signaling resembles FLK-1 signaling, which is in part caused by their transactivation of FLK-1. Activation of these intracellular signaling events leads to endothelial proliferation, survival, angiogenesis, and other vascular effects that can have opposite effects on vascular pathobiology.

Opioid receptors are seven transmembrane domain G-protein-coupled receptors (GPCRs) which are coupled to the pertussis toxin-dependent  $G_i/G_o$  type of G-proteins. Upon receptor activation, G-proteins interact with multiple effector systems, leading to the inhibition of adenylyl cyclase and voltage-gated calcium ( $Ca^{2+}$ ) channels and stimulation of G-protein-activated inwardly rectifying potassium ( $K^+$ ) channels. However, chronic activation of opioid receptors leads to adenylyl cyclase superactivation and increased levels of cyclic adenosine monophosphate (cAMP). Because cAMP is a survival factor for ECs, acute and chronic activation of opioid receptors can be a matter of cell death and survival, respectively (4,5). Thus, it is important to consider the duration of exposure when studying the role of opioids in endothelial biomedicine.

### Regulation of Opioid Receptor Expression

Receptor densities and activity are critical determinants of opioid effects. Opioid receptor expression is regulated by agonist exposure and growth factors in a heterogeneous manner (6,7). Nerve growth factor (NGF) stimulates DOR expression in PC12 pheochromocytoma cells (8); basic fibroblast growth factor (bFGF) (also known as FGF2) and platelet-derived growth factor (PDGF)-BB induce KOR in oligodendrocytes (9). Emerging data on ECs show that interleukin (IL)- $1\beta$  and vascular endothelial growth factor (VEGF) upregulate

*MOR* mRNA in human umbilical vein ECs (HUVECs) and mouse retinal ECs (mRECs) (10–12). Cocaine, ethanol, and naloxone alter opioid receptor gene expression in NG108–15 neuroblastoma hybrid cells (11). *MOR* mRNA and protein are barely detectable in normal rodent skin, but are highly upregulated in wounds (Gupta, unpublished observations). In these wounds, MOR is localized in epidermal keratinocytes and in vascular and lymphatic ECs. Because keratinocytes produce high levels of VEGF in newly formed wound epidermis (13), these data suggest that injury-mediated secretion of VEGF results in autocrine and paracrine induction of opioid receptors in keratinocytes and ECs, respectively. In pathophysiological conditions, a vascular microenvironment replete with proinflammatory cytokines and growth factors may similarly modulate opioid receptors on endothelium (Figure 50.2).

### Regulation of Opioid Receptor Activity

Like classical GPCRs, opioid receptors are regulated by a cascade of events involving receptor phosphorylation by GPCR kinases (GRKs) and subsequent  $\beta$ -arrestin recruitment, thus uncoupling the receptor from its G protein, followed by receptor endocytosis. Endocytosis may lead to degradation and secondary downregulation of the receptor. However, not all endocytosed opioid receptors are degraded; some are recycled

**Table 50-1: Opioid Receptors and Their Functions**

Opioid Receptor	Endogenous Opioids		Inducers	Signaling Pathways and Phenotype	Cellular Expression	Putative Functions
	Exogenous Agonists					
$\mu$ (MOR)	Morphine	Endomorphins	IL-1 (ECs)	PI3K/AKT, NF- $\kappa$ B (neurons)	ECs	Wound healing
	Hydromorphone	Endorphins	VEGF (ECs)	Ras/Rac	Cardiac myocytes	Heart: cardioprotective
	Fentanyl	Demorphin	IL-6 (neuroblastoma cells SH SY5Y)	PI3K/AKT, MAPK, NO in endothelial cells (assuming this is the receptor morphine was working through)	Keratinocytes	Kidney: ?
	Meperidine			Transactivation of FLK-1, PDGF- $\beta$ and EGFR receptors	Neuronal cells	Lung: respiratory depression
	Methadone			Vasodilatation	Mesangial cells	Brain
	Oxycodone			STAT3	MCF7 tumor cells	Tumors
	Sufentanil			GATA4	Monocytes	Skin
	DAMGO					Blood vessels: angiogenesis
	Etorphine					Lymphatic: lymphatic vessels
						Peripheral nerves: pain
					Retina/CNS: neovascularization/analgesia	
$\delta$ (DOR)	DADLE	Enkephalins	NGF (PC12)	STAT3, Akt	ECs	Cardioprotection
	DPDPE	Deltorphins	IL-4 (immune neuronal cells)	K <sup>+</sup> ATP channels	Adult rat ventricular myocardium	Cardiogenesis
	BW373U86			Ras/Rac/MAPK survival	Mesangial cells	IPC induced antiarrhythmic
	SNC 80			PKC, CaMKII		Ischemia-reperfusion
				Heterodimerization with $\beta$ -adrenergic receptor		
$\kappa$ (KOR)	Dynorphin 1	Dynorphin	PDGF, bFGF (oligodendrocytes)	PI3K	ECs	Cardioprotection
	U-50,488			K <sup>+</sup> ATP channels	Adult rat ventricular myocardium	Kidney
	U-69,593			PKC		
	ICI 199,441			Survival (cardioprotective)	Embryonal pluripotent stem cells	
	ICI 197,067			MAPK; GATA4	Neonatal hearts	
6'-GNTI			Heterodimerization with $\beta$ -adrenergic receptor			
Noiceptin/orphanin FQ (ORL1)	[Arg <sup>14</sup> , Lys <sup>15</sup> ] noiceptin	Noiceptin/orphanin FQ	Ciliary neurotrophic factor (CNTF)	Akt		
	ZP 120			Ras/Rac/MAPK survival		
	Ro 64-6198			PKC, CaMKII		

Figure 50.2. Opioid receptors on different cells in the neighborhood of endothelium, as well as distant cells in the pituitary-hypothalamus, modulate the endothelial microenvironment by secreting cytokines, hormones, NO, and other substances in response to external stimuli or exogenously administered or endogenously produced opioids. ACTH, adrenocorticotropic hormone.

in a cell-, agonist-, and receptor-specific manner. For example, whereas DOR is transported deeper into the endocytotic pathway and rapidly degraded by lysosomes, MOR is recycled following endocytosis (14,15). The “net signal” for relative activity of the receptor versus endocytosis is termed *relative activity versus endocytosis* (RAVE) (16). RAVE defines the relative ability of an opioid agonist to induce cell signaling. In the case of morphine, high RAVE values seem to reflect the relative inability of this agent to induce receptor endocytosis.

### Endothelial–Opioid Interactions

MOR was cloned in 1993; its presence on the endothelium was shown by binding studies in 1995 (17), and its expression in ECs was recently confirmed by sequencing (18). The presence of DOR on ECs has been inferred from studies examining the binding of OR agonists to human aortic and saphenous vein ECs (19). In contrast, other studies found that the activity of DOR agonist peptides on porcine aortic ECs was naloxone-insensitive (20), that specific opioid receptor binding of <sup>3</sup>H-morphine on bovine aortic ECs was not detectable, and that morphine was located almost exclusively within the nucleus (21). We demonstrated that MOR, DOR, and KOR are expressed on HUVECs, human dermal microvascular ECs (HDMECs), and mRECs using reverse transcription polymerase chain reaction (RT-PCR) with MOR-, DOR-, and KOR-specific primers (2,12). Importantly, we and others have shown that activation of MOR on ECs stimulates NO-mediated signaling, vasodilatation, and angiogenesis (2,17).

Pasi and colleagues (22) demonstrated that both  $\beta$ -endorphin (BEP) and morphine inhibit angiogenesis in a chorioallantoic membrane (CAM) assay. However, the concentrations of morphine tested (5–50  $\mu$ g/4  $\mu$ L; equivalent to

1.65–16.5 mM) were several log-fold higher than those found in the serum/plasma of patients being treated for pain (2 nM–3.5  $\mu$ M). We observed that morphine at concentrations up to 100  $\mu$ M stimulates EC proliferation, but is cytotoxic at concentrations  $\geq$  1 mM (2). The biological effects of opioids on the endothelium may therefore be highly dose-dependent. In any case, it has become imperative to gain a better understanding of endothelial–opioid interactions because opioids are clinically used in many diseases in which endothelial activity, angiogenesis, and blood vessel wall pathophysiology play a central role.

### OPIOID SIGNALING

#### Opioids and Opioid Receptors Promote Growth and Survival

Opioids directly induce cell proliferation, as shown in CHO, COS, and C6 glioma cells transfected with MOR, DOR, or KOR, as well as in primary adult hippocampal progenitors (1,2,23). In lymphocytes, morphine suppresses apoptosis by blocking p53-mediated death signaling via MOR Bcl-2/Bax signaling (24). In general, ORs stimulate phosphoinositide-3-kinase (PI3K)-dependent signaling, leading to proliferation and survival. For example, in CHO cells, MOR agonists stimulate a PI3K-dependent signaling cascade in a manner similar to VEGF signaling in ECs (25). DAMGO, a MOR agonist, stimulates Akt via PI3K, which inhibits apoptosis in neurons (23). Long-term treatment with DAMGO increases nuclear factor (NF)- $\kappa$ B activity in cortical neurons (26). NF- $\kappa$ B is known to be activated by G-protein heterodimers (G $\beta\gamma$ ) through the PI3-Kinase/Akt pathway (27). Opioid receptors also can modulate signals generated by classical growth factors. DOR activation potentiates the proliferation of

serum-induced neuroblastoma cells (28) and serum- and growth factor-induced proliferation in CHO cells stably transfected with the receptor (29).

Our laboratory was the first to identify an opioid-induced intracellular signaling pathway in ECs (Figure 50.1) (2). Morphine and other agonists of MOR, DOR, and KOR, which are pertussis toxin-dependent GPCRs, stimulate mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK) phosphorylation and proliferation of HDMECs. The MOR agonist DAMGO also potentiates serum-induced proliferation of HDMECs. Morphine stimulates MAPK/ERK phosphorylation and HDMEC proliferation via PI3K and NO-dependent mechanisms. Furthermore, morphine also stimulates Akt and promotes EC survival and cell cycling by upregulating cyclin D1. Among the growth factors, VEGF alone has been shown to stimulate angiogenesis via NO-dependent MAPK phosphorylation (30). Thus, opioids act like growth factors in promoting proliferation, migration, and survival via the same signaling pathway utilized by VEGF in endothelium (see Figure 50.1). These in vitro proangiogenic observations are further strengthened by the in vivo promotion of angiogenesis by morphine in tumors and wounds, described in the next section. More recently, we confirmed that morphine signaling is similar to that of VEGF in mRECs (12). In these cells, morphine also stimulates signal transducer and activator of transcription (STAT)3 directly as well as via transactivation of VEGF receptor 2 (VEGFR2)/FLK-1.

### Transactivation

Although opioids act via typical GPCRs, growth factors act via phosphorylation of their receptor protein tyrosine kinases (PTKs). GPCRs transactivate PTK receptors through multi-level crosstalk between intermediate signaling pathways (31). Therefore, it is likely that our observation of opioid-induced proangiogenic, growth- and survival-promoting signaling is in part caused by the transactivation of growth factor receptors (see Figure 50.1). Indeed, our recent studies show that VEGFR2/FLK-1 and PDGF- $\beta$  receptors are transactivated by MOR in mRECs (12). These observations are consistent with the finding that MOR transactivates the epidermal growth factor receptor (EGFR) in astrocytes (32,33). This also raises the possibility of constitutive activation of PTKs by opioid receptors in the regulation of the normal endothelial phenotype. Opioid receptors may therefore represent therapeutic targets for indirectly modulating the effect of PTK receptors such as VEGF receptors in angiogenesis.

### Adhesion and Immunomodulation

In response to stress, leukocytes express opioids (predominantly BEP) that bind to peripheral opioid receptors, leading to local pain relief in animals and humans (34). This study showed that in complete Freund's adjuvant-induced inflammation in hind paws, 43% to 58% of CD45<sup>+</sup> hematopoi-

etic cells express opioid peptides. At the inflammatory site, activated ECs expressing P-selectin, E-selectin, and platelet-endothelial cell adhesion molecule (PECAM)/CD31 are juxtaposed with BEP-expressing leukocytes. This model suggests that endothelial selectins and integrins mediate the recruitment of opioid-expressing inflammatory cells.

Experiments from our laboratory show that morphine by itself does not stimulate significant adhesion molecule expression by HDMECs in vitro, but modulates tumor necrosis factor (TNF)- $\alpha$ -induced vascular cell adhesion molecule (VCAM)-1 and E-selectin expression (Figure 50.3). TNF- $\alpha$  promotes leukocyte rolling, firm adhesion and transmigration, in part via the increased expression and/or function of endothelial P-selectin, E-selectin, and VCAM-1. Incubation of HDMECs with TNF- $\alpha$  for 4 hours resulted in 15- and 10-fold increases in E-selectin and VCAM-1 expression, respectively, as compared to unstimulated cells ( $p < 0.0001$ , Tukey-Kramer method; unstimulated (US) vs. TNF- $\alpha$  or VCAM-1, at 4 hours). After 18 hours of incubation, VCAM-1 expression had returned to baseline (US) levels, whereas E-selectin had decreased by 50% compared with 4 hours. This time-dependent reduction in VCAM-1 and E-selectin expression was blocked by coincubation with morphine ( $p < 0.0001$ ). These findings suggest that chronic exposure of ECs to morphine results in sustained TNF- $\alpha$ -induced expression of adhesion molecules.

Long-term exposure to morphine alone increases the adhesion of monocytes to saphenous vein and internal thoracic artery endothelium by 30%, the same extent as that induced by human immunodeficiency virus (HIV) gp120 (35). Prolonged exposure to both morphine and gp120 resulted in a 100% increase in adhesion, indicating that morphine acts synergistically with gp120. Thus, the effects of morphine on the endothelium depend on duration of exposure and microenvironmental conditions. Chronic exposure to morphine also potentiates the leukocyte-endothelial adhesion response to IL-1 $\beta$  in rat mesentery (36). In contrast, short-term exposure to morphine induces an NO-dependent conformational change (rounding of cells) in spontaneously activated human monocytes, granulocytes, and arterial ECs, rendering them less adhesive (37).

Adhesion molecule expression is regulated by NF- $\kappa$ B. Opioids modulate NF- $\kappa$ B expression in several cell types. Morphine stimulates NF- $\kappa$ B activation in rat heart and human NT2-N neurons (38,39). The long-term treatment of cortical neurons with the MOR agonist DAMGO increases NF- $\kappa$ B activity (26). However, Roy and colleagues found that at  $\mu$ M-concentrations, morphine inhibited NF- $\kappa$ B activation in macrophages (40).

Opioids also are believed to have immunomodulatory effects (41). Morphine induces apoptosis in macrophages by activating transforming growth factor (TGF)- $\beta$ . Data cited above and our own observations on the direct upregulation of VCAM-1 and E-selectin by morphine favor the thesis that chronic morphine treatment stimulates EC adhesion in a proinflammatory microenvironment.

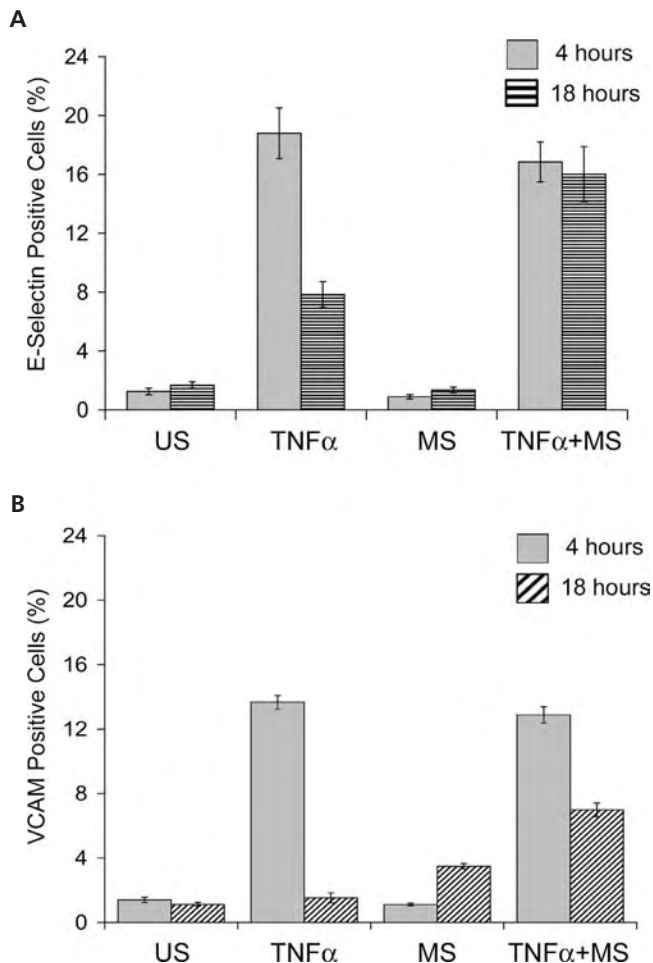

Figure 50.3. Morphine upregulates TNF- $\alpha$ -induced E-selectin and VCAM-1 expression on human dermal microvascular ECs (HDMECs) in a proinflammatory microenvironment. HDMECs were incubated with 1  $\mu$ M morphine sulfate (MS) in the presence or absence of 100 ng/mL TNF- $\alpha$  for 4 or 18 hours in serum-deplete conditions, then FACS analyzed for E-selectin and VCAM-1 expression. TNF- $\alpha$  stimulated a significant increase in both E-selectin and VCAM-1 expression after 4 hours of incubation versus unstimulated (US) cells ( $p < 0.0001$ ). After 18 hours of incubation, TNF- $\alpha$ -induced stimulation of E-selectin was inhibited by about 60% and VCAM-1 by 100%. MS did not have any effect on E-selectin or VCAM-1 except for a modest increase in VCAM-1 expression after 18 hours versus US ( $p < 0.0001$ ). However, in the presence of MS, TNF- $\alpha$ -induced downregulation of both adhesion molecules at 18 hours was significantly inhibited (TNF vs. TNF + MS at 18 hours for E-selectin or VCAM-1).  $n = 6$ ; Mean  $\pm$  SEM; Statistical analysis: Multiple comparisons by Tukey-Kramer method.

## MEDICAL IMPLICATIONS

### Ischemia–Reperfusion Injury and Cardiovascular Disease

In cardiovascular disease, ischemia and reperfusion injury are directly associated with inflammatory changes, vasoregulation, and vessel wall physiology. We found that 3 weeks of morphine treatment in clinically relevant doses upregulates endothelial NO synthase (eNOS), inducible NOS (iNOS),

cyclooxygenase (COX)-2, and heme oxygenase (HO)-1, and increases perfusion and vasodilatation in the mouse kidney (42). These opioid-induced mechanisms also mediate cardioprotection in animal models (43,44). Opioids and opioid receptors have been shown to provide cytoprotection following ischemia reperfusion injury and hypoxic insult in models ranging from murine cardiac ischemia to hibernating polar bears (45). A dramatic increase in the circulating levels of opioid peptides in hibernating mammals, and a reversal of hibernation by opioid receptor antagonists, provides an exciting example of the protective role of opioids in a hypoxia-tolerant state (45).

The induction of vasodilatation via vascular smooth muscle cell (VSMC) relaxation is one of the principal roles of endothelial NO. Opioids can directly stimulate eNOS as well as iNOS (17,46). Although eNOS-derived NO stimulates the relaxation of VSMCs, iNOS-derived NO from immune cells can cause desensitization of VSMCs to NO. Interferon (IFN)- $\gamma$  has been proposed to stimulate iNOS in T cells and to inhibit eNOS (47). Morphine negatively regulates IFN- $\gamma$  promoter activity and inhibits IFN- $\gamma$  secretion by the activated T cells via MOR (48). Therefore, opioids can stimulate endothelial NO production on one hand and impede iNOS-derived IFN- $\gamma$ -dependent NO production on the other. Thus, opioids and opioid receptors may be important in preventing endothelial dysfunction and even arteriosclerosis.

Opioids, through their different receptors, provide preconditioning and cytoprotection against ischemia in the heart (49). Opioids activate DOR and KOR, which leads to protein kinase C (PKC) activation. Activated PKC acts as an amplifier of the preconditioning stimulus and stabilizes, through phosphorylation, the open state of the mitochondrial  $K_{ATP}$  channel and sarcolemmal  $K_{ATP}$  channel. The opening of  $K_{ATP}$  channels ultimately elicits cytoprotection by decreasing cytosolic and mitochondrial  $Ca^{2+}$  overload. Chronic opioid stimulation opens  $K_{ATP}$  channels and also prevents apoptosis by activating the survival signal Akt. Studies also demonstrate that KOR stimulates cardioprotective signaling by activating mitochondrial- $K_{ATP}$  and PKC (50). In vivo, morphine reduces ischemia–reperfusion injury in isolated rat heart. The cardioprotective effects of morphine are mediated by a local opioid receptor- $K_{ATP}$  channel-linked mechanism in rat hearts. After ischemia and reperfusion, coronary flow (CF), heart rate (HR), left ventricular pressure (LVP), and the first derivative left ventricular pressure ( $LVP/dt_{max}$ ) of isolated hearts decreased significantly in this study (51). After morphine preconditioning, CF, HR, LVP, and  $LVP/dt_{max}$  increase and infarct size decreases significantly ( $p < 0.01$ ). These studies suggest that opioids, via their different receptors, provide protection against ischemic tissue injury.

All three opioid receptors appear to be involved in cardioprotection, based on the effect of specific agonist-induced activity in the heart. Stimulation of DOR after hemorrhage, during the recomensatory period, leads to improved mean arterial pressure (MAP) (52). In freely moving hemorrhaged rats, the average HR gain (bpm/mm Hg) after 2 mg/kg

Delt-Dvar (Deltorphin-Dvariant, a selective DOR agonist) treatment was greater and the  $BP_{50}$  (BP at one-half the HR range) was significantly lower than after saline treatment. The KOR agonist U50,488, along with other KOR agonists, shows antiarrhythmic actions in rat hearts, which appears to be mediated by the blockade of  $Na^+$ ,  $K^+$ , or  $Ca^{2+}$  channels, independent of KOR (53). Endomorphin-2, a MOR agonist, elicits depressor and bradycardic responses and inhibits baroreflex function when injected into the rostral ventrolateral medullary pressor area (RVLM) (54). The presence of MOR and endomorphins has been demonstrated in the general area encompassing the RVLM. Unilateral microinjections of endomorphin-2 (0.0125–0.5 mmol/L) into the RVLM elicited decreases in MAP (16–30 mm Hg) and HR (12–36 bpm) that lasted for 2 to 4 minutes. The effects of endomorphin-2 were mediated via MOR because preadministration of naloxonazine (1 mmol/L), an antagonist of MOR, abolished these responses. These effects are consistent with a known hyperpolarizing effect of opioid peptides on RVLM neurons. Furthermore, two chimeric peptides YGGFMKKKFMRamide (YFa) and [D-Ala2] YAGFMKKKFMRamide ([D-Ala2] YFa), consisting of a sequence of met-enkephalin (55), showed a dose-dependent fall in MAP in the dose-range of 13 to 78  $\mu$ mol/kg in rats. After naloxone treatment (5 mg/kg), the vasodepressor effect of [D-Ala2] YFa and YFa was only partially blocked, when compared to met-enkephalin. Partial blockade of the vasodepressive effect of YFa and [D-Ala2] YFa by naloxone may be attributed to interaction of these chimeric peptides with opioid receptors and others, such as adrenergic receptors and D-analogue receptors. A short-term, high-dose infusion of BEP improved left ventricular ejection fraction (LVEF), reduced systemic vascular resistance, blunted neurohormonal activation, and stimulated the growth hormone (GH)/insulin-like growth factor (IGF)-1 axis in patients with mild to moderate congestive heart failure (56). These changes were paralleled by a significant increase in plasma levels of glucagons, GH, and IGF-1, and a significant decrease in plasma levels of endothelin and catecholamines. In another human trial, long-term opiate exposure was suggested to mitigate coronary artery disease severity and its fatal consequences (57). These data indicate that opioid receptors provide cardioprotection directly as well as indirectly by modulating the balance between vasodilators and vasoconstrictors. Moreover, their short-term versus long-term effects are different, which warrants a systematic examination of their activity in pathological states to exploit their potential for therapy in cardiovascular disease.

### In the Brain

Hypoxia releases NO/cGMP from glial cells, which in turn increases opioid release. Thus, activation of neuronal NOS (nNOS) contributes to increased cerebrospinal fluid concentration of the endogenous opioids met-enkephalin and leu-enkephalin during hypoxia in the newborn pig. Together NO, opioids, and ATP-sensitive  $K^+$  channels contribute to hypoxia-induced pial artery dilation (58). In vitro, morphine precondi-

tions Purkinje cells against cell death under in vitro simulated ischemia–reperfusion conditions (59). Therefore, endogenous opioids and opioid receptors may be critical in vasoregulation and ischemia–reperfusion in the brain, an area that has not been explored yet for its therapeutic potential.

### In Sexual Debility

Our current understanding of opioid-induced NO and vasodilatation may be the basis for the use of opium for sexual debility as far back as 1200, described in an ancient East Indian medical treatise. (Coincidentally, the drug name Viagra is derived from the East Indian Sanskrit word *viaghra*, meaning tiger.) Penile erection results from an arousal-induced synthesis of NO in nonadrenergic-noncholinergic nerves (NANC), ECs, and cavernosal VSMCs. We speculate that opioids may stimulate nNOS and eNOS, leading to vasodilation and relaxation of cavernosal VSMCs, which in turn engorge the corpora cavernosa with blood. The subcellular mechanism by which tumescence occurs also involves NO-induced activation of soluble guanylate cyclase, increased cyclic guanosine monophosphate (cGMP) levels, and activation of cGMP-dependent protein kinase (PKG). PKG phosphorylates numerous ion channels and pumps, each promoting a reduction in cytosolic calcium. In particular, PKG activates high-conductance calcium-sensitive  $K^+$  channels, which hyperpolarize the arterial and cavernosal VSMC membranes, causing relaxation. Morphine directly stimulates the arginine/NO/cGMP/ $K^+$ <sub>ATP</sub>/PKG pathway (60). These potential effects of opioids on the genitourinary system provide the rationale for investigation of their possible therapeutic role in sexual debility.

### From Bench to Bedside – Wound Healing

It appears that injury turns on a natural switch to provide pain relief and healing by secreting BEP and upregulating MOR. The MOR agonist BEP is upregulated at the wound site in the epidermal keratinocytes and the proinflammatory cells (61). We found that MOR is upregulated several-fold in the wound margins and endothelium, as compared with undamaged skin in mice and rats (unpublished observations). Furthermore, we showed that topical application of the MOR agonist drugs morphine, hydromorphone, and fentanyl promotes healing of ischemic wounds in rats (46). These effects were not seen on systemic administration of the same drugs. Although opioids promote wound healing, the opioid receptor antagonist naloxone inhibits it and also antagonizes the healing effect of fentanyl, lending credence to the argument that MOR mediates the healing process. Opioid-induced wound healing was associated with increased cellular proliferation of both ECs and non-ECs, angiogenesis, and increased collagen formation in opioid-treated as compared with vehicle-treated wounds. These cellular changes are accompanied by upregulation of iNOS, eNOS, and VEGFR2/FLK-1 in opioid-treated wounds.

We hypothesize that topical opioids can be safely used to treat wounds and nonhealing ulcers, such as those observed in

diabetes and sickle cell disease. The small amounts of opioids applied peripherally on ischemic wounds remain undetectable in the circulation and are therefore unlikely to cause dependence or addiction. We have initiated a Phase 1 clinical trial at the University of Minnesota to evaluate the capability of topical opioids to heal wounds (62).

### From Bedside to Bench – Tumor Progression

Tumor progression and metastasis are angiogenesis-dependent. Our observations that the chronic administration of clinically relevant doses of morphine stimulate tumor angiogenesis and MCF7 breast tumor growth in mice (2) suggest that opioid receptor activity is critical in cancer progression. We observed that naloxone impedes tumor growth in this model by antagonizing estrogen receptor (ER) activity directly and also via crosstalk between ER and MOR in MCF7 cells (63). ER also is expressed on ECs, and its activation stimulates angiogenesis. Thus, naloxone-like compounds may inhibit tumor growth by targeting both endothelial and tumor cells. Opioids are currently the drugs of choice for the treatment of severe pain in cancer. Therefore, it is imperative to determine the clinical effect of opioids on tumor progression and metastasis. If confirmed in human studies, strategies to antagonizing the inadvertent promotion of tumor growth by opioids will need to be explored.

### Lacunae

Opioid pharmacology and biochemistry in the endothelium, including tolerance, internalization, and receptor dimerization and recycling, remain underexplored. Activation of MOR may be critical in vascular function in both normal physiology and pathophysiological conditions. Understanding these mechanisms will help create a safe vascular environment for use of exogenous opioids.

Our observations that opioid-induced activation of opioid receptors can transactivate various other receptors, including those for hormones such as estrogen and cytokines such as PDGF and VEGF, may provide an explanation for the limited success of many antiangiogenic therapies that target growth factors, their receptors, and PTKs. More effective blockage of endothelial proliferation and angiogenesis may require concurrent inhibition of both growth factor receptors and opioid receptors.

### CONCLUSION

This century is the beginning of a new era for appreciating the endothelial effects of opioids and their receptors, until recently believed to be confined to the behavioral and neuronal world. The existence of all four defined opioid receptors on endothelium is well documented. Of these, MOR appears to play a more critical role in vascular biology for two reasons: (a) MOR stimulates NO, which plays a key role in vascular function and

(b) opioid analgesics are MOR agonists, and are used in diseases where vascular pathophysiology and angiogenesis are critical in disease prevention or progression. The proangiogenic, survival-promoting, and NO-mediated signaling and modulation of adhesion molecule expression by opioids in the endothelium suggest that opioid receptors provide novel therapeutic targets for endothelial dysfunction and angiogenesis-dependent diseases. Results from our laboratory and others are beginning to show the therapeutic use of opioids in wound healing and cardiovascular disease, which provide a driving force to unravel the mysteries of opioid receptor activity in the endothelium.

### KEY POINTS

- Opioids may influence diverse angiogenesis-dependent diseases by activating opioid receptors on endothelium.
- Opioid receptors stimulate MAPK/ERK and PKB/Akt signaling and promote endothelial proliferation and survival.
- MOR stimulates vasoregulatory and cytoprotective signaling and mitigates ischemia–reperfusion injury.

### Future Goals

- To elucidate the role of each individual opioid receptor in the endothelium
- To develop opioid receptor antagonists to inhibit angiogenesis in cancer and proliferative retinopathy. Stimulate angiogenesis using opioid receptor agonists to promote healing of chronic ischemic ulcers
- To mitigate the consequences of tissue ischemia by opioid receptor mediated vasoregulation

### ACKNOWLEDGMENTS

The authors thank Philip M. Portoghese, Ph.D. and Robert P. Hebbel, MD for their helpful discussions from time to time, and Pankaj Gupta, MD for critical review of the manuscript. I remain indebted to Tasneem Poonawala, Chunsheng Chen, Marc L. Weber, Mariya Farooqui, and others in my lab for their dedication to opioid-endothelial research. We thank Carol Taubert for preparing the illustrations and word processing the manuscript, and Tyson Rogers for the statistical analysis. This work is supported by National Institutes of Health grants HL68802 and CA109582, the Susan G. Komen Breast Cancer Foundation, and funding from the Division of Hematology, Oncology and Transplantation, University of Minnesota Medical School.

## Snake Toxins and Endothelium

Jay W. Fox\* and Solange M.T. Serrano†

### HISTORY OF SNAKE TOXINS AND THEIR EFFECTS ON ENDOTHELIUM

Venomous snakes are by far the most feared of venomous animals. Four families of venomous snakes exist: the Viperidae (which includes vipers, adders, and pit vipers), the Elapidae (which includes the cobras, mambas, kraits, coral snakes, and sea snakes), the Colubridae (which includes the venomous rear-fanged snakes such as the boomslang and the twig snake), and the Atractaspididae – the family termed the *burrowing snakes*. In most developed countries, fatalities associated with snake envenoming are rare; however, in many tropical regions in places such as Africa, South America, and Southeast Asia, snake envenomation often is associated with a relatively high mortality rate. By definition, venomous snakes are snakes that produce venom. Approximately 2,700 different snake species exist, of which nearly one-fifth are venomous (1). Interestingly, many of the venomous snakes rarely, if ever, envenomate humans and hence are falsely considered nonvenomous. From the earliest observations of viperid snake envenomations, it was obvious that severe coagulopathic consequences occurred at both the local and systemic level. These coagulopathies, although not necessarily absent in envenomations by other snakes from other venomous families, were certainly more pronounced with snakes from Viperidae. In 1664, Francisco Redi (1626–1697) discovered that it was the venom from the snake that caused the “direful effects” associated with the bite of a snake (2). The Italian scientist Felice Fontana (1720–1805) was the first to study the effect of snake venom on blood and recognized that the effect of venom on blood coagulation properties was directly related to the toxicity of the venom (3). More recently, S. Weir Mitchell (1829–1914) focused his attention on the viperid group of rattlesnake venoms. Mitchell and colleagues demonstrated that venoms are complex mixtures of proteins whose various compositions in different snakes give rise to the different potencies observed (4). Further Mitchell and Reichert were the first to show that viperid venoms were capable of causing local and in severe cases systemic ecchymosis, necrosis, edema, and hemorrhage owing to

alterations in the capillary wall with subsequent loss of blood and hypotension (5). Thus, beginning with the first correlation of snakebite-associated, venom-induced pathologies to the association of complex venom proteins being responsible for the dramatic symptoms associated with viperid envenoming, it has been clear that viperid venoms are potent factors for the perturbation of the prey’s circulatory system with the endothelium being one of many tissues affected by the venom.

### VIPERID VENOMS, TOXINS, AND ENVENOMATION

Snake venoms represent a complex mixture of proteins, peptides, nucleic acids, and salts that vary based on snake species, populations of the same species, environment, and even sex. The toxins that are contained in the venom function for prey acquisition, digestion, and defense. With regard to prey acquisition, clearly, the ability of the venom to rapidly immobilize the prey by paralysis or circulatory system collapse is highly advantageous. Recent proteomic analyses of several individual viperid venoms indicate the presence of more than 1,000 proteins (6,7).

Most toxins in venoms can be categorized as belonging to the following groups: (a) peptides that function as neurotoxins, membrane destabilizers, or proteinase inhibitors; and (b) hydrolases and amino acid oxidases including phospholipases, hyaluronidases, acetylcholinesterases, and proteinases. This last subgroup, proteinases, likely plays the greatest role in the disruption of hemostasis. Both serine and metalloproteinases are abundant in viperid venoms (8,9), and function to degrade vessel walls and affect coagulation, respectively. The serine proteinases that function as kininogenases also may be important in this process in light of their hypotensive properties.

The pathological consequences of viperid snakebite are varied and reflect the complexity of the venom. Historically, the study of venom has been approached by using isolated toxins from the venom to characterize their biochemical and

biological properties. Although this strategy has proven helpful in delineating specific properties of many toxins, it falls short in revealing the role of a specific toxin in the context of the whole venom. The pathological effects observed with whole venom are attributable to both additive and synergistic functions of individual toxins, and hence it is experimentally difficult to know how an individual toxin functions in the context of the hundreds of other biologically active proteins and peptides in the venom. Furthermore, using that approach one only understands what one is assaying for; in other words, you will only find what you look for. Thus, when discussing individual toxins in this chapter, the reader must keep in mind two important caveats: (a) most of the studies described are with isolated toxins, and hence the biological activities ascribed to the isolated toxin may have different outcomes in the presence of the whole venom; and (b) unless specifically noted, the lack of mention of a particular activity for a protein does not imply that it has been tested for and deemed absent.

Often, snakebites, including those of the viperid snake, are “dry” bites, meaning no venom is injected. However, in productive bites by viperid snakes large quantities of venom can be injected with severe consequences, including death. Although not as predominant in viperid venoms as in elapid venoms, nevertheless neurotoxic symptoms can occur. Generally, damage of skeletal muscle occurs, including muscle pain and myoglobinuria, which in severe cases can lead to renal failure. Hemostatic alterations are most common with viperid envenoming, which often leads to hypocoagulable blood owing to direct hydrolysis of fibrinogen and/or the activation of the endogenous fibrinolytic system by venom proteinases, which may lead to systemic bleeding. Other hallmarks of viperid envenomation are local swelling, hemorrhage, edema, and necrosis. Generally, these features are caused by venom metalloproteinases, which act on vessel walls and the basement membranes and stromal extracellular matrix that surround them, to give rise to blood extravasation into the tissues. Large blisters can occur along with the subcutaneous bleeding, together contributing to local tissue necrosis. Hypotensive shock is a usual consequence of viperid envenoming because of the loss of fluids from edema and hemorrhage and hypotensive/vasodilatory peptide production. As one can imagine, many of these symptoms are interrelated and thus underscore the complex interplay of venom toxins as they give rise to the pathologies associated with viperid envenoming.

### SNAKE TOXINS THAT DIRECTLY AFFECT THE ENDOTHELIUM<sup>1</sup>

Toxins found in viperid venom that have been shown to directly affect the endothelium include (a) snake venom met-

alloproteinases (SVMPs), (b) snake venom serine proteinases (SVSPs), (c) natriuretic peptides, (d) sarafotoxins (SRTXs), and (e) vascular endothelial growth factor (VEGF)-like proteins (Table 51-1). Toxins that play an indirect role in affecting the endothelium include (a) SVMPs, (b) disintegrins, (c) SVSPs, (d) C-type lectins, and (e) bradykinin potentiating peptides.

#### Snake Venom Metalloproteinases

One of the major groups of toxins present in viperid venoms is the SVMPs, which have been rather thoroughly characterized as to their structure and function (8). The SVMPs are classified into four subgroups (PI–PIV) that vary from one another based on the presence of additional nonmetalloproteinase domains on the C-terminal side of the metalloproteinase domain (Figure 51.1; for color reproduction, see Color Plate 51.1). The nonmetalloproteinase domains (disintegrin, disintegrin-like, cysteine-rich, and C-type lectin) likely play roles in targeting the SVMPs to specific substrates. For example, the disintegrin and disintegrin-like domains may target the PII and PIII SVMPs to integrins (10), and the cysteine-rich domain may target the PIII and PIV SVMPs to von Willebrand factor (vWF) A domains (9). In the case of the PI, PII, and PIII subgroups, some members of each have been demonstrated to cause hemorrhage (11). A variety of both in vivo and in vitro studies have indicated that the primary cause of hemorrhage is the degradation or disruption of basement membrane structure around capillaries (12). Microscopically, there appears to be a clearing of regions of capillary basement membrane with a subsequent dissolution of the endothelial lining, ultimately allowing escape of capillary contents into the stroma (Figure 51.2). In vitro studies with the hemorrhagic SVMPs using basement membranes, isolated basement membrane proteins, and extracellular matrix proteins demonstrated that these metalloproteinases are effective agents for matrix degradation (13–15). The question as to why some SVMPs are hemorrhagic and others are not is still open; however, it is generally thought that the nonproteinase domains in the PIII hemorrhagic toxins subgroup are important for selectively targeting these toxins to key substrates, which, when hydrolyzed, allow for the escape of capillary contents into the stroma. Recently, the cysteine-rich domain of atrolysin A, a PIII hemorrhagic SVMP from *Crotalus atrox* venom, was shown to support binding of the toxin to a vWF A domain found in integrins (16) as well as vWF itself (9).

In addition to causing gaps in the integrity of the endothelium, SVMP-mediated disruption/degradation of adjacent basement membranes and stromal extracellular matrix may have additional effects on endothelial cells (ECs). For example, in a recent study, two structurally similar PIII SVMPs, jararhagin (from *Bothrops jararaca* venom) and berythtractivase (from *Bothrops erythromelas* venom), with differing hemostatic properties were shown to exert different effects on ECs. Both toxins caused the release of nitric oxide, prostacyclin, and interleukin (IL)-8 from human umbilical vein ECs

1 For purposes of discussion, we have divided the effects of various snake venom toxins on the endothelium into “direct” and “indirect.” However, separating direct from indirect effects is not always straightforward. Moreover, many of these toxins have both direct and indirect effects on the endothelium.

**Table 51-1: Snake Venom Toxin Activities on Endothelium and Vasculature**

<i>Toxin</i>	<i>Activity</i>	<i>References</i>
<b>Direct Effects</b>		
Metalloproteinases	Hemorrhagic	8, 10, 41, 42
Serine proteinases	Increase of capillary permeability	19, 43–45
Natriuretic peptides	Relaxation of coronary arteries	20, 21, 46–48
Sarafotoxins	Vasoconstriction; cardiotoxic	49–53
VEGF-like proteins	Increase of capillary permeability	23, 54–56
<b>Indirect Effects</b>		
Metalloproteinases	Fibrin(ogen)olytic; inhibition of platelet-aggregation; apoptosis of ECs; cleavage of vWF; binding to cell surfaces and subendothelium	25, 34, 57–62
Disintegrins	Inhibition of platelet aggregation; inhibition of angiogenesis; blocking of function of EC integrin receptors; antiangiogenic	61, 63–66
Serine proteinases	Kinin release; plasma coagulant; platelet activation; plasminogen activation; protein C activation; factor V activation	35, 67–72
C-type lectin-like proteins	Inhibition or activation of platelet functions; anticoagulant, procoagulant	73–76
Bradykinin potentiating peptides	Inhibition of ACE; potentiation of bradykinin	20, 77, 78

Figure 51.2. Ultrastructural changes. (A) Electron micrograph of a capillary in mouse gastrocnemius muscle 5 min following injection with 50  $\mu\text{g}$  of BaP1, a PI SVMP isolated from *Bothrops asper* venom. The EC (E) shows a significant reduction in its thickness and in the number of pinocytotic vesicles. The continuity of the EC also is interrupted (arrow). The integrity of the capillary basement membrane is also affected (B). Contiguous skeletal muscle cell is also seen (M). (Image was generously provided by Dr. José Gutiérrez, University of Costa Rica). (B) Electron micrograph of a normal capillary from skeletal muscle tissue of a mouse that was injected intramuscularly with saline solution. The capillary lumen (L) is surrounded by an EC that has a prominent nucleus (NU). The basement membrane (arrow) surrounds the EC. Portions of two muscle cells (M) are located in the vicinity of the capillary vessel. Magnification:  $\times 17,000$ . (Image provided by J. Gutierrez.)

(HUVECs), but in the case of jararhagin increased EC apoptosis also occurred (17). The mechanism by which these effects occurred is not clear; one could speculate that they could be the result of disrupted matrix–cell signaling, shedding of cell surface proteins, or both. Using DNA microarray studies, we demonstrated that treatment of HUVECs with snake venoms resulted in significant changes in gene expression (18). The pattern of response was consistent with a proapoptotic phenotype. In recent GeneChip studies, we showed that, in primary human fibroblasts, the PIII SVMP jararhagin activated p38 mitogen-activated protein kinase (MAPK) and triggered signaling pathways involved in integrin signaling and cellular metabolism. Similarly, two functional classes of upregulated proteins, namely those related to cell death and inflammation, were observed as being significantly populated (18). Interestingly, toxin-mediated changes in gene expression were dependent on the toxin's proteolytic activity and not on its engagement of cell surface receptors. Thus, it seems that the SVMPs can function to perturb endothelium by proteolytically targeting basement membrane and stromal extracellular matrix as well as directly functioning as a “shedase” of EC surfaces to disrupt matrix–cell signaling and lead to altered EC function and, in some cases, death.

### Snake Venom Serine Proteinases

The SVSPs are structurally homologous with serine proteinases of the chymotrypsin family, with molecular weights ranging from approximately 26 kDa to 67 kDa. Like other chymo-

trypsin family members, SVSPs are inhibited by typical active-site serine alkylation agents. They have been shown to increase capillary permeability, an effect that is generally attributable to their kallikrein-like enzymatic activity (see references listed in Table 51-1).<sup>2</sup> Interestingly, one serine proteinase, so-called capillary permeability-increasing enzyme-2, from *Agkistrodon caliginosus*, did not appear to have bradykinin-releasing activity, and its capillary permeability-inducing ability was thought to be the result of proteolytic release of peptides from fibrinogen (19).

### Natriuretic Peptides

Natriuretic peptides are a group of naturally occurring substances that counter the activity of the renin-angiotensin system. In humans three classes of natriuretic peptides exist: (a) atrial natriuretic peptide (ANP), (b) B-type natriuretic peptide (BNP), and (c) C-type natriuretic peptide (CNP). All these peptides have vasodilator and hypotensive effects and generally function via stimulation of the membrane-bound guanylyl cyclases on endothelium. ANP and BNP cause natriuresis and a reduction in intravascular volume; CNP, although also hypotensive, does not demonstrate significant diuretic or natriuretic effects. Natriuretic peptides have been isolated

2 Kallikrein digests high-molecular-weight kininogen (HK) to release bradykinin. Bradykinin binds to receptors on nearby ECs, which liberates vasoactive prostaglandins or nitric oxide, resulting in, for example, vasodilatation and increased capillary permeability (see Chapter 49).

from a variety of snake venoms, with C-type natriuretic peptides being the most common. Typically, venom CNPs have a 17-amino acid ring structure connected by disulfide bonds with various numbers of amino acids extending from the N- and C-termini. Analysis of a cDNA clone from the *Bothrops jararaca* venom gland showed that a CNP was present in a transcript containing seven tandem repeats for bradykinin-potentiating peptides followed by the sequence of the CNP (20). Venom from *Dendroaspis angusticeps*, the green mamba, contains unusual natriuretic peptides that recognize ANP-A receptors but not ANP-B receptors, for which venom CNPs are usually specific (21).

### Sarafotoxins

SRTXs are vasoconstrictive peptides isolated from the venoms of the Atractaspididae family of elapid snakes. These peptide toxins are homologous to the endothelins and affect the vasoconstriction of cardiac and smooth muscle. STRXs have 21 amino acids and two disulfide bonds. A wide variety of isotoxins have been isolated from this family of snakes, which reflect the subtle bioactivity requirements for various snakes with regard to typical prey species. The observation that these "toxins" are orthologs to the vertebrate endothelins underscores one evolutionary process by which poisonous snakes develop toxins. In this case, the protein scaffolds of normally occurring biologically active proteins and peptides are utilized and modified such that, when presented at relevant locations in appropriate concentrations, they produce the toxic effect required for the snake's survival.

### Vascular Endothelial Growth Factor-Like Proteins

VEGF-like proteins have been isolated from a variety of snake venoms and appear to function by increasing capillary permeability and/or EC proliferation. Some snake venom VEGF-like proteins (svVEGF) appear to be specific for the kinase insert domain-containing VEGF receptor (KDR/VEGFR2). Two VEGF-like proteins, Vamin and VR-1 isolated from *Viper ammodytes ammodytes* venom, show preferential binding to VEGFR2 (22). The VEGF-like protein Tfsv-VEGF from *Trimeresurus flavoviridis* venom shows preferential binding to VEGFR1 and therefore elicits potent capillary permeability-inducing activity rather than EC mitogenesis (23). Structural studies of the various svVEGF-like proteins have yielded insights into the requirements for binding interactions with the different VEGF receptors and the subsequent biological effects of such interactions (22). Regardless of the individual specificity of the various svVEGF-like proteins, their capillary permeability-inducing activity has a profound effect on the vascular endothelium and likely contributes in a synergistic manner to the production of hemorrhage, edema, and necrosis observed following envenoming. Whether the mitogenic properties of certain of the svVEGF-like proteins actually play a role in venom toxicity or pathogenesis is unclear.

### TOXINS THAT INDIRECTLY AFFECT THE ENDOTHELIUM

Five classes of toxins exist that can indirectly affect the endothelium in a manner that contributes to the overall pathological effects of the venom. These include (a) SVMPs, (b) disintegrin and disintegrin-like peptides and proteins, (c) SVSPs, (d) C-type lectin-like proteins, and (e) bradykinin-potentiating peptides. It is interesting to note that the SVMPs and the SVSPs are capable of both directly and indirectly affecting endothelium and thus have a very significant combined effect on that tissue.

### Snake Venom Metalloproteinases

The indirect effect of the SVMPs stems primarily from their capacity to induce fibrin(ogen)olysis, inhibit platelet aggregation, cause apoptosis of ECs, and/or cleave vWF. Those toxins that promote fibrin(ogen)olysis do so by cleaving the  $\alpha$ -chain of fibrinogen, giving rise to non- or poorly clottable blood (24). Many of the SVMPs also can cleave fibrin clots, thus attenuating any resolution of venom-induced hemorrhage by fibrin clots. Most PIII-type SVMPs have been demonstrated to inhibit platelet aggregation (8,16, and Figure 51.1) by virtue of the ability of their disintegrin-like/cysteine-rich domain to bind the platelet  $\alpha_2\beta_1$  integrin (25). Similarly, these domains in the PIII toxins can target the SVMP to subendothelial collagen, where they can cause further proteolytic damage to tissue structure (9).

Several SVMPs have been demonstrated to cause EC apoptosis with the mechanism associated with the proteolytic activity of proteinase. Hypothetically, one can envision endothelial apoptosis to occur because of (a) proteolysis of extracellular matrix/basement membrane adjacent to adherent endothelium; (b) proteolysis of EC surface proteins required for maintenance of cellular viability, such as receptors for extracellular matrix proteins; (c) or proteolysis of cell surface proteins involved in cell-cell interaction. SVMPs have been demonstrated to be capable of cleaving all such proteins. You and colleagues (26) isolated a PIII SVMP from the venom of *Gloydius halys* and demonstrated that its ability to cause EC apoptosis in vitro was caused by both the protein's metalloproteinase activity as well activities associated with the nonproteinase disintegrin-like/cysteine-rich domains. It is likely that these results represent a general functional feature of the PII, PIII, and PIV SVMPs in that the nonproteinase domain(s) serve as exosites to target these classes of SVMPs to specific substrates, which are then degraded by the metalloproteinase domain (7). Wu and Peng (27) demonstrated that the PIII SVMP graminelysin isolated from *Trimeresurus gramineus* venom caused EC apoptosis in vitro by a combination of proteolysis of extracellular matrix and adherens junctions comprising vascular endothelial (VE)-cadherin and  $\beta$ -,  $\gamma$ - and  $\alpha$ -catenin, resulting in cell detachment followed by activation of caspase-3 and a decrease of the bcl-2/Bax ratio.

Clearly most of the PIII SVMPs, under appropriate conditions, can cause EC apoptosis via variable sequences of proteolytic events in vitro. In vivo experiments examining EC apoptosis by SVMPs are limited. However, as mentioned previously, Gallagher and colleagues (28) have recently shown, using laser-capture microscopy of mouse muscle tissue treated in vivo with the PIII jararhagin from *Bothrops jararaca* venom, that the gene expression profiles of the affected myocytes, ECs, and fibroblasts indicate alterations of integrin-signaling pathways and upregulation of cell-death pathways reflecting disruption of cell adhesion signal transduction and the entrance of the cells into apoptosis. Under the experimental conditions used, apo-jararhagin, lacking metalloproteinase activity, did not show these properties, underscoring the role of proteolysis in affecting cellular homeostasis.

### Disintegrins and Disintegrin-Like Proteins

Disintegrins are polypeptides found in viperid venoms that bind selectively to integrin receptors to functionally block the receptor. The disintegrin polypeptides range from approximately 40 to 100 amino acid residues in length with numerous disulfide bonds. The original report of a disintegrin from snake venom showed that the peptide containing the RGD motif was capable of blocking the platelet fibrinogen receptor,  $\alpha$ IIb $\beta$ 3 to prevent platelet aggregation (29). Since then, numerous disintegrins and dimeric disintegrins, both with and without RGD motifs, have been isolated and their integrin specificities explored (30). The disintegrin peptides from snake venoms are primarily derived by proteolytic processing from precursor PII SVMPs (8,31). Evidence exists that disintegrins also can be produced from specific gene products in addition to proteolytic processing from PII SVMPs.

In addition to and/or in lieu of platelet aggregation inhibitory activity, some disintegrins have been shown to inhibit cell migration, cell adhesion, and angiogenesis, depending on the specific integrins to which the disintegrins bind (30). With particular relevance to this chapter, the ability to inhibit angiogenesis was demonstrated for the disintegrin obtustatin isolated from the venom of *Vipera lebetina obtusa* (32). Obtustatin is the shortest disintegrin discovered to date; it is a somewhat unusual disintegrin in that its inhibitory loop is two residues shorter than that of other disintegrins. The Lys-Thr-Ser sequence in the loop is critical for binding to the  $\alpha$ 1 $\beta$ 1 integrin, which is important in angiogenesis (33).

PIII SVMPs contain disintegrin-like sequences, which differ from the disintegrin domain proper in that the RGD motif is substituted with other sequences. Moreover, the disulfide bond organization differs between disintegrin-like and disintegrin proteins. Although it is generally thought that the disintegrin-like domain also can support integrin binding, direct evidence for this is lacking.

Some venom contains disintegrin-like/cysteine-rich domains proteolytically processed from PIII SVMP structures. These domains have been demonstrated to inhibit collagen-induced platelet aggregation via inhibition of platelet  $\alpha$ IIb $\beta$ 3

integrin (34). Interestingly, recombinant cysteine-rich domain from atrolysin A, a PIII SVMP from *Crotalus atrox* venom, has also been shown to inhibit collagen-stimulated platelet aggregation (16).

Thus, potential exists for many disintegrins and disintegrin-like proteins in venom to interact with EC surfaces, giving rise to a variety of biological outcomes depending on the receptor repertoire on the ECs.

### Snake Venom Serine Proteinases

Proteomic studies on viperid venoms show that these venoms are a rich source of serine proteinases (7). Many of the SVSPs in venoms have been demonstrated to affect coagulation (35). Virtually all SVSPs isolated to date are single-chain glycoproteinases with molecular masses between 26 kDa and 67 kDa – the single exception being brevinase, a heterodimeric proteinase with fibrinolytic activity isolated from the venom of *Agkistrodon blomhoffi brevicaudus*. In general, the indirect effects of SVSPs on the endothelium are owing to their abilities to act on blood components in the coagulation cascade, fibrinolysis, and/or platelet aggregation. Many SVSPs also can defibrinogenate blood but, unlike the SVMPs, these proteinases generally are specific for the  $\beta$ -chain of fibrinogen (24). Like the SVMPs, many of the SVSPs also can cleave fibrin clots. An example of venom fibrin(ogen)olytic snake venom proteinases currently in use in the clinic includes applications for fibrin clot dissolution, attesting to their potency and specificity (36).

More specifically, SVSPs have been shown to activate protein C, cleave fibrinogen A $\alpha$  and B $\beta$  chains, release fibrinogen peptides A and/or B, release kinin, activate receptors protease-activated receptor (PAR)-1 and PAR-4, cleave the  $\alpha$  chain of complement C3, activate Factor V and Factor XIII, and activate plasminogen. These effects can produce mass disseminated intravascular coagulation to incapacitate the prey. The so-called kallikrein-like SVSPs act by releasing hypotensive lysbradykinin or bradykinin from kininogen and thereby indirectly affect the endothelium. Given the numerous serine proteinases in venoms and the wide variety of proteolytic specificities, and hence biological activities that they display, it is clear that, upon envenomation, the SVSPs have a profound effect on hemostasis. This is supported by the observed coagulopathies in animal models of envenomation and many snake envenomation cases (37). Such disturbances no doubt impinge upon endothelium and endothelial function, which then further contributes to the overall pathogenesis of the venom.

### Snake Venom C-Type Lectin-Like Proteins

This family of venom proteins is distinguished by structures that have a C-type lectin fold, characteristic of the selectins and mannose-binding proteins (38). The snake venom C-type lectin-like proteins are heterodimeric proteins comprising an  $\alpha$  and  $\beta$  chain that can oligomerize to form larger structures. All the venom C-type lectin-like proteins indirectly affect the endothelium by altering platelet aggregation. The largest

class of venom C-type lectins is the platelet GPIb receptor-binding proteins. Within this class, most of the venom C-type lectins bind to GPIb and inhibit vWF binding to the receptor, whereas others bind at a different site on GPIb and inhibit thrombin-mediated activation of platelets. Another class of C-type lectins, represented by the proteins botrocetin and bitiscetin, binds to vWF and causes induction of binding of vWF to platelet GPIb to promote platelet aggregation. A third class of snake venom C-type lectins binds to platelet collagen receptor GPVI to activate the receptor and give rise to hyperaggregation. Finally, a fourth class of venom C-type lectins has been demonstrated to bind not only to GPIb but also to the integrin  $\alpha 2\beta 1$ . Because  $\alpha 2\beta 1$  integrin is expressed by ECs, venom C-type lectins of this class, as represented by rhodocetin and aggrexin, may directly influence EC phenotype (e.g., by inhibiting integrin interaction with collagen).

In summary, the snake venom C-type lectin-like proteins is a complex class of venom toxins with both pro- and anticoagulation properties, all of which indirectly and in some instances directly affect the endothelium.

### Bradykinin-Potentiating Peptides

One of the most therapeutically significant discoveries stemming from the study of snake venoms was of the bradykinin potentiating peptides found in viperid venoms. The bradykinin potentiating peptides (BPPs) are short (5–14 residues) proline-rich oligopeptides beginning with an amino terminal pyroglutamyl residue (39). These peptides are inhibitors of angiotensin converting enzyme (ACE) and thus potentiate the activity of bradykinin to give rise to an antihypertensive effect. Elucidation of BPP structures and activities played a critical role in the development of the antihypertensive drug captopril, an active site ACE inhibitor used to treat patients with hypertension. During viperid envenomation, the BPPs function in a synergistic manner with the bradykinin-producing SVSPs in the venom to give rise to vascular shock in the prey. Also, the presence of the BPPs in the venom when in the venom gland are at sufficient concentration to function as reversible inhibitors of the SVMPs and thereby minimize toxin proteolysis/degradation in the venom prior to envenomation (40). The BPPs are synthesized as a precursor protein containing tandem repeats of the BPPs in conjunction with a C-type natriuretic peptide (20).

Thus, the BPPs play an indirect role in affecting endothelium by virtue of their antihypertensive activities; they thus function in the overall coagulopathies associated with viper envenomation.

### IN VITRO VERSUS IN VIVO CONSIDERATIONS ON THE FUNCTIONS OF SNAKE TOXINS AND THE ENDOTHELIUM

The issue of in vitro versus in vivo effects of toxins in biological systems is a longstanding issue. Traditionally, snake

venom toxins have been isolated based on a particular activity they display in vitro or in vivo. Studies are then performed in an attempt to correlate and understand the in vitro activities compared to the in vivo activities. However, this is not always successful. As an example, in the early days of SVMP isolation and investigation it was shown that these protein toxins were very effective in producing hemorrhage in animal models. However, owing to limitations in substrates and assays used for proteolysis, the proteolytic activity of many of these venoms was overlooked. Later, using different substrates and assay methods, it became clear that these toxins were proteolytic and, in fact, their hemorrhagic activities were dependent on metalloproteinase activity. A second issue in the studies of venoms, whether in vivo or in vitro, is that venoms are complex, with many different biologically active proteins present that undoubtedly act in coordinated and synergistic manners to produce the symptomatic pathologies associated with envenomation by a particular snake species. Given the complexity of venom, it is almost impossible to completely understand the role of an individual toxin in the context of the whole venom, although this is clearly a goal for investigators in the field.

### KEY POINTS

- Snake venoms are complex, with many protein toxins present in the venom that can directly and/or indirectly affect endothelium function.
- Many of the toxins that affect endothelium function do so in a coordinated or synergistic manner with other toxins present in the venom to give rise to the overall effect on the endothelium and subsequently the pathologies associated with snake envenoming.
- Due to the issues noted in the previous bullets, the in vitro activities/outcomes of noted toxins on ECs may be quite different in the in vivo context of whole venom in the prey.
- Snake toxins, owing to their abilities to both indirectly and directly affect ECs and endothelium, are fascinating, useful tools for the investigation of endothelium function.

# Inflammatory Cues Controlling Lymphocyte–Endothelial Interactions in Fever-Range Thermal Stress

Qing Chen, Kristen Clancy, Wan-Chao Wang, and Sharon S. Evans

*Roswell Park Cancer Institute, Buffalo, New York*

A longstanding question in immunology revolves around the physiological benefit of the ancient fever response. Despite the fact that fever occurs at great metabolic cost, it is associated with improved survival during infection in endothermic and ectothermic vertebrate species (1). The prevailing paradigm with regard to leukocyte trafficking has been that febrile temperatures influence leukocyte delivery to tissues principally through bystander effects on hemodynamic parameters (i.e., vasodilation and increased blood flow). This chapter focuses on emerging evidence for a proactive role of temperatures in the range of natural fever (i.e., 38–40°C) in regulating the molecular events that support lymphocyte adhesion in high-endothelial venules (HEVs). HEVs are major sites of lymphocyte extravasation, serving as a locus for recirculation of blood-borne lymphocytes through peripheral lymphoid organs. Continuous entry of naïve and central memory lymphocytes across HEVs is crucial for immune homeostasis and immune surveillance. Notably, the mechanisms by which fever-range thermal stress promote lymphocyte–endothelial interactions are tightly regulated with respect to the type of vessels involved. Sustained exposure to fever-range thermal stress selectively targets adhesion in HEVs, whereas squamous endothelial cells (ECs) of non-inflamed extralymphoid organs are not responsive. The physiological fever-range thermal stimulus described here is distinct from heat shock conditions (e.g.,  $\geq 43^\circ\text{C}$ ) that globally promote adhesion in nonactivated EC. These observations support the concept that HEVs act as sentinels during febrile inflammatory responses by heightening the delivery of naïve and central memory lymphocytes to secondary lymphoid organs.

## OVERVIEW OF THE MOLECULAR MECHANISMS ORCHESTRATING LYMPHOCYTE TRAFFICKING ACROSS HIGH-ENDOTHELIAL VENULES

HEVs function as gatekeepers controlling the egress of lymphocytes out of the peripheral blood compartment and into

secondary lymphoid organs where pathogens and cognate antigens are encountered (2–4). These specialized postcapillary venules are localized in T cell–enriched zones of all secondary lymphoid organs except the spleen. The ECs lining HEVs are morphologically and biochemically distinct from the flat, squamous ECs of the majority of the vessels throughout the body. These so-called high ECs (HECs) exhibit a cuboidal morphology, allowing them to extrude into the lumen of vessels and provide an irregular surface topography. These biophysical parameters theoretically contribute to turbulent blood flow, facilitating margination of leukocytes along the vessel wall. The vasculature in vertebrate species provides an extensive surface area for potential sites of extravasation. However, under noninflammatory steady-state conditions, the majority of constitutive lymphocyte extravasation occurs preferentially across HEVs that compose a relatively small percentage of the total vasculature. The mechanisms controlling lymphocyte extravasation in HEVs of lymphoid organs is briefly discussed in the next section. Additional details regarding the molecular basis of trafficking across lymphoid organ HEVs or HEV-like vessels of inflamed tissues are described in Chapters 155 and 170.

Lymphocyte migration across HEVs is coordinated by adhesion molecules and chemokine/chemokine receptor partners. These molecules participate in a stepwise sequence of reversible adhesion events that include (a) initial tethering and rolling, (b) chemokine-mediated activation and firm adhesion, and (c) transendothelial migration (2,5,6). Extravasation of naïve and central memory lymphocytes in peripheral lymph nodes (PLN) is initiated by the L-selectin leukocyte homing receptor. Positioning of L-selectin on microvillous projections enables this molecule to initiate contact between free-flowing lymphocytes and the walls of HEVs. L-selectin binds transiently to counter-receptors on HEVs collectively termed PLN addressins (PNAd) that include CD34, glycosylation-dependent cell adhesion molecule (GlyCAM)-1,

podocalyxin, endomucin, and sgp200 (3). The N-terminal calcium-binding lectin domain of L-selectin interacts directly with negatively charged mucin domains of PNAd molecules generated by post-translational enzymatic modifications (i.e., glycosylation, fucosylation, sulfation, sialylation) (3). The sulfation determinant on PNAd recognized by MECA-79 monoclonal antibody (mAb) is absolutely required to support lymphocyte-HEV interactions in PLN (2,3,5). MECA-79-reactive PNAd molecules are not expressed on the luminal surface of Peyer patches (PP) HEVs. Instead, L-selectin binds to the mucin stalk of mucosal addressin cell adhesion molecule (MAdCAM)-1 in PP HEVs (5). The efficiency of lymphocyte tethering and rolling in PP HEVs is enhanced by binding of a second leukocyte homing receptor,  $\alpha 4\beta 7$  integrin, to a negatively charged aspartic acid residue in the N-terminal immunoglobulin domain of MAdCAM-1 (5). Lymphocyte homing in mesenteric lymph nodes (MLN) is mediated by combined interactions of L-selectin with PNAd and MAdCAM-1 as well as  $\alpha 4\beta 7$  integrin binding to MAdCAM-1 (5).

Intravital microscopy studies have elegantly demonstrated that the process of tethering and rolling dramatically reduces the velocity of lymphocytes in HEVs (5,6) (see also Chapter 170). This is most evident in higher-order venules that are located downstream from the capillary bed. Here, free-flowing lymphocytes, moving at a rate of  $>400$  to  $500 \mu\text{m}/\text{sec}$ , transition to slow rolling cells with a speed of  $\leq 50 \mu\text{m}/\text{sec}$  (7,8). The increased transit time allows lymphocytes to sample the chemokine microenvironment on the surface of HEVs. A single chemokine synthesized by HECs and stromal cells, the CC chemokine ligand (CCL)21 (TCA-4/SLC/6C-kine/exodus 2) plays a predominant role in supporting the progression from slow-rolling to firm-sticking cells in LN and PP HEVs (4,6).

Engagement of CCL21 by CCR7, a 7-transmembrane-spanning chemokine receptor on naïve and central memory lymphocytes, triggers G-protein-dependent conformational changes in the  $\beta 2$  integrin, leukocyte function adhesion molecule-1 (LFA)-1. This enables LFA-1 to bind with high affinity to its constitutively expressed counter-receptors, intercellular adhesion molecule (ICAM)-1 and ICAM-2, on the walls of HEVs (2,4,6). ICAM-1 and ICAM-2 appear to have redundant functions in HEVs based on evidence that either molecule can substitute during homeostatic trafficking under conditions in which the other molecule is not operative (i.e., during mAb blockade or in genetically deficient mice) (9). In PLN HEVs, firm adhesion of lymphocytes is primarily mediated by LFA-1/ICAM-1–2 interactions, whereas in MLN and PP, both LFA-1/ICAM-1–2 and  $\alpha 4\beta 7$  integrin/MAdCAM-1 contribute to firm adherence (5). LFA-1/ICAM-1–2 interactions have also been implicated in supporting transendothelial migration although the molecular mechanisms controlling this process in HEVs are not well understood (4–6). At extralymphoid sites of injury or inflammation, ICAM-1 is highly induced by inflammatory cytokines on cuboidal, HEVs-like vessels, where it predominates over ICAM-2 in recruitment of neutrophils, macrophages, and lymphocyte subsets (9).

## FEVER-RANGE THERMAL STRESS AMPLIFIES LYMPHOCYTE-HEV ADHESION AND LYMPHOCYTE HOMING

Local increases in temperature at sites of inflammation and, in some cases, systemic fever are cardinal features of a host response to infection or inflammation. A recent series of studies has shown that fever-range temperatures alter the tissue distribution of lymphocytes *in vivo*. In this regard, significant decreases in the number of lymphocytes are observed in the circulating pool following elevation of the core temperature of mice (10–12). This was accomplished experimentally using whole body hyperthermia (WBH) protocols developed by Repasky and colleagues to simulate the temperature and duration of physiologic fever (13). Transient decreases in the number of peripheral blood lymphocytes have also been reported in patients with advanced cancer undergoing clinical fever-range WBH therapy (12,13). In mice, it was shown that these cells redistribute to HEV-bearing organs (LN and PP) but not to organs that lack HEVs, such as spleen, liver, or pancreas (8,10,14). Investigation of the underlying mechanisms has revealed that fever-range thermal stress influences trafficking by independently stimulating adhesion in two distinct cellular targets – lymphocytes (i.e., B and T cells) and HEC (Figure 52.1). Collectively, these findings support the notion that fever-range thermal stress provides a danger signal during inflammation to proactively regulate lymphocyte egress across HEVs in secondary lymphoid organs (1,8).

### Thermal Stress Stimulates Lymphocyte Homing Receptor Function

To investigate the effect of fever-range thermal stress on lymphocyte adhesion, primary lymphocyte populations or lymphocyte cell lines expressing a defined profile of adhesion molecules (Table 52-1) were cultured *in vitro* under fever-like temperature conditions (i.e.,  $40^\circ\text{C}$ ) for 6 hours (1,8,10,15–19). This reductionist approach of solely modifying temperature conditions allowed for the identification of a role for the *thermal component* of the febrile inflammatory response in regulating lymphocyte trafficking. Changes in adhesion were evaluated under shear in frozen-section *in vitro* adherence assays where lymphoid tissue HEVs serve as substrates. Alternatively, lymphocytes treated *in vitro* with heat were evaluated for their ability to traffic to various tissues in short-term (1 hour) *in vivo* homing assays. These studies established that marked increases in lymphocyte adhesion to HEVs and homing to HEV-bearing organs (e.g., PLN, MLN, and PP) are observed following lymphocyte culture at physiologic fever-range temperatures (i.e.,  $2\text{--}4^\circ\text{C}$  above normal temperature for 6 hours) (Table 52-1) (1,8,10,15–19). Notably, fever-range thermal stress does not improve short-term homing of lymphocytes to organs that do not express HEVs such as the spleen (Table 52-1) (1,8,10,15).

Evidence for organ-specific trafficking of heat-treated lymphocytes raised the possibility that thermal stress targets

**Table 52-1: Fever-Range Thermal Stress Improves Lymphocyte–HEV Adhesion and Lymphocyte Trafficking to LN and PP Organs**

the function of known lymphocyte homing receptors. This hypothesis was confirmed using L-selectin and  $\alpha 4\beta 7$  integrin-specific function-blocking mAb or cell lines expressing a nonfunctional form of L-selectin (i.e., murine B lymphoma 300.19/ $\Delta$ cyto transfectants that lack the C-terminal 11 amino acid cytoplasmic tail) (Table 52-1) (20). Fever-range thermal stress increases L-selectin–mediated adhesion and homing of lymphocytes via engagement of PNAd on PLN and MLN HEVs as well as MAdCAM-1 on PP HEVs (Table 52-1, Figure 52.1)

(15–19). Parallel increases in  $\alpha 4\beta 7$  integrin-mediated adhesion to MAdCAM-1 on PP and MLN HEVs were demonstrated (Table 52-1, Figure 52.1) (10,21). Exquisite selectivity in thermal regulation of integrin-binding activity is suggested by results that heat treatment of lymphocytes fails to increase  $\alpha 4\beta 7$  integrin-mediated adhesion to the extracellular matrix protein, fibronectin, or LFA-1–dependent binding to ICAM-1 (15,19). An important finding is that equivalent increases in L-selectin–dependent adhesion are observed in

**Figure 52.1.** Fever-range thermal stress proactively stimulates lymphocyte–HEV adhesion. Fever-range temperatures enhance lymphocyte trafficking to lymphoid organs by exerting independent effects on the molecular events culminating in enhanced adhesion in lymphocytes and ECs of HEVs.

lymphocytes whether they are exposed to fever-range thermal stress *in vitro* or *in vivo* (i.e., during heat treatment of cultured cells or WBH treatment, respectively) (10,13,18). Multiple lymphocyte subsets were found to increase L-selectin-based adhesion to HEVs in response to thermal stress (i.e., CD4<sup>+</sup> and CD8<sup>+</sup> T cells, CD19<sup>+</sup> B cells, CD56<sup>+</sup> NK cells, CD45RA<sup>+</sup> naïve lymphocytes, and CD45RO<sup>+</sup> memory cells) (17–19). Moreover, thermal stress improves adhesion to PNA<sup>d</sup> or MAdCAM-1 substrates in lymphocyte populations of endothermic species that diverged during evolution 300 million years ago (e.g., mouse, human, chicken) (1). Collectively, these findings support the notion that thermal regulation of lymphocyte homing receptor activity confers a survival benefit that was maintained during the diversification of vertebrate species.

A growing body of evidence indicates that conventional mechanisms are not responsible for thermal control of L-selectin and  $\alpha 4\beta 7$  integrin adhesion. Thermal stress does not alter the cell surface density of these homing receptors on lymphocyte subsets (15,17–19). Moreover, fever-range temperatures do not affect the lectin-binding activity of the N-terminal domain of L-selectin (15). Electron microscopy revealed that heat also does not influence the overall distribution of L-selectin on microvillous projections (15). However, these latter results do not exclude the possibility that heat enhances L-selectin clustering in membrane microdomains that cannot be resolved by immunogold-labeled antibody reagents.

Studies were undertaken to determine if thermal stress affects the association of L-selectin with the detergent-insoluble cytoskeletal matrix as a possible mechanism for regulating the binding activity of this homing receptor. In lymphocytes maintained at normothermal temperature (37°C), L-selectin is fully extracted from the detergent-insoluble subcellular fraction (16–18,22). However, upon L-selectin cross-linking by antibodies or L-selectin ligands (GlyCAM-1), this homing receptor rapidly ( $\leq 5$  seconds) becomes associated with the detergent-insoluble cytoskeletal matrix (17,22). L-selectin interactions with cytoskeletal elements require the 11-amino acid region within the cytoplasmic tail that contains a binding site for the cytoskeletal linker protein,  $\alpha$ -actinin (17,23). These results are consistent with the notion that L-selectin becomes stably associated with the actin-based cytoskeleton during transient tethering and rolling along the luminal surface of HEVs. Remarkably, treatment of lymphocytes with fever-range thermal stress causes L-selectin to preassociate with the detergent-insoluble matrix without the requirement for L-selectin cross-linking (1,8,16–18). Thus, heat-induced association of L-selectin with the cytoskeletal scaffolding underlying the lymphocyte plasma membrane is speculated to increase L-selectin tensile strength and thereby its ability to withstand shear within postcapillary HEVs (17,18).

One of the most intriguing findings is that thermal regulation of lymphocyte adhesion can be segregated into a two-step process, thereby excluding a role of heat *per se* in directly altering the organization or conformation of adhesion molecules

in the lipid bilayer of the plasma membrane. In this regard, conditioned medium from cells treated *in vitro* with fever-range thermal stress (i.e., the “initiation phase”) can be used in the “effector phase” to stimulate L-selectin/cytoskeletal interactions as well as the binding activity of L-selectin or  $\alpha 4\beta 7$  integrin in lymphocytes maintained at normothermal temperatures (1,8,15,16,18,21). These experiments provide unequivocal evidence that soluble factors are responsible for mediating the pro-adhesive effects of thermal stress. Moreover, the source of the soluble factor appears to be remarkably cell-type specific. Hematopoietic cells (T cells, B cells, monocytes) and stromal cells (ECs, fibroblasts) are all sources of heat-induced transactivating pro-adhesive factors, whereas no activity is detected in culture supernatants of cell lines representing parenchymal cells of various organs (lung, liver, breast, brain, skin) (18,21).

These observations led to the discovery of a novel role for a well-known immunomodulatory cytokine, interleukin (IL)-6, in regulating lymphocyte homing (Figure 52.1) (1,8,18). Functional blockade of IL-6 and its receptor components – IL-6 receptor  $\alpha$  (IL-6R $\alpha$ ) and the gp130 signal transducing subunit – prevent fever-range thermal stimulation of L-selectin adhesion *in vitro* and *in vivo*. In contrast, other cytokines – including tumor necrosis factor (TNF)- $\alpha$ , IL-1 $\beta$ , interferon (IFN)- $\alpha$ , IFN- $\gamma$ , IL-8, IL-11, leukemia inhibitory factor, or oncostatin M – do not contribute to the pro-adhesive activity of thermal stress in lymphocytes under normal conditions. Thermal stimulation of lymphocyte adhesion was further found to depend on a trans-signaling mechanism that involves not only IL-6 but also a soluble form of the IL-6R $\alpha$  (1,8,18). The requirement for these two components to function together as a heterodimeric cytokine provides a sophisticated level of control in this system. Combined biochemical and pharmacological inhibitor approaches positioned extracellular-signal-regulated kinase (ERK)1/2, but not p38 mitogen-activated protein kinase (MAPK) or c-jun N-terminal kinase (JNK), in the IL-6/sIL-6R $\alpha$  signaling pathway upstream of activation of L-selectin–cytoskeletal interactions and L-selectin avidity/affinity (Figure 52.1) (18). Taken together, these data enlarge on the concept that IL-6/sIL-6R $\alpha$  trans-signaling actively contributes to immune responses by regulating leukocyte trafficking during both acute and chronic inflammation (24).

### **Fever-Range Thermal Stress Amplifies High-Endothelial Venule Adhesion**

An independent line of investigation revealed that fever-range thermal stress enhances adhesion in HEVs that are the major portals governing lymphocyte extravasation (Figure 52.1). These studies employed frozen-section *in vitro* adherence assays to compare the binding activity of HEVs in lymphoid organs of normothermal (NT) controls or mice treated 6 hours with fever-range WBH (core temperature of 39.5°  $\pm$  0.5°C). Fever-range thermal stress markedly increases the ability of PLN HEVs to support lymphocyte adhesion under shear in

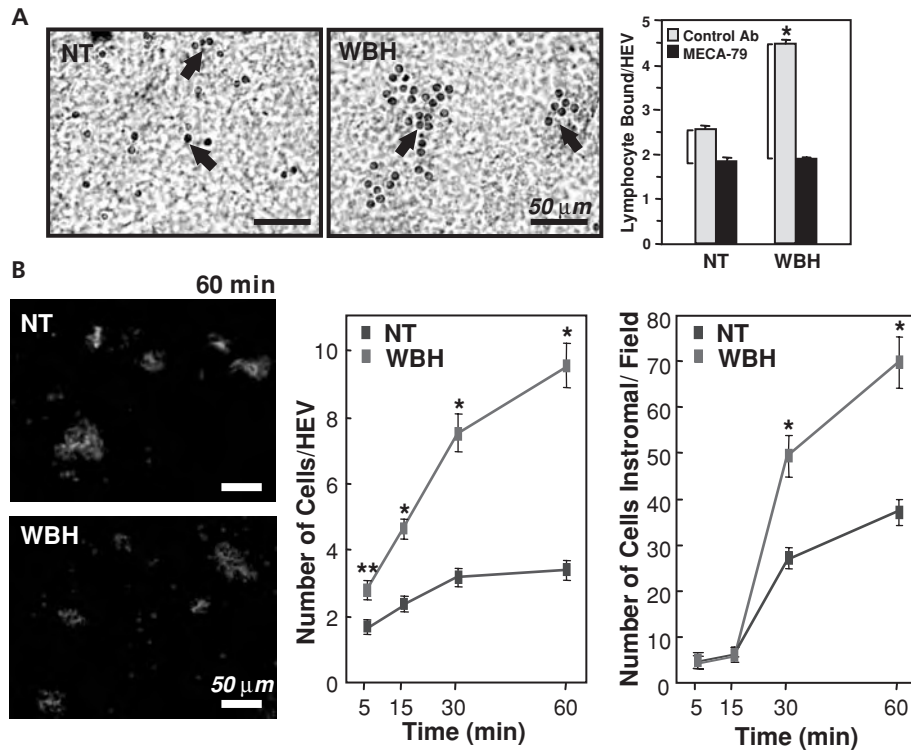

Figure 52.2. Fever-range thermal stress enhances lymphocyte adhesion to PLN HEVs (A) and homing to PLN organs (B). BALB/c mice were treated with fever-range whole body hyperthermia (WBH) for 6 hours (core temperature,  $39.5 \pm 0.5^\circ\text{C}$ ). The core temperature of normothermal control mice (NT) was  $36.8 \pm 0.2^\circ\text{C}$ . (A) Adherence of mouse splenocytes to HEVs in PLN cryosections was evaluated *in vitro* under shear. The level of L-selectin/PNAd-specific adhesion (brackets) was determined by treating PLN cryosections with MECA-79 mAb. Photomicrographs show typical images of lymphocytes (black arrows) bound to HEVs in toluidine-stained PLN tissues. The number of adherent lymphocytes was quantified by light microscopy in a total of 300–500 HEVs. For consistency in double-blind evaluation, HEVs were quantified only if they contained  $\geq 1$  adherent cell. (B) Short-term homing studies were performed essentially as described. Mouse splenocytes labeled with TRITC were injected intravenously ( $3 \times 10^7$  cells/mouse) into NT control or WBH-treated mice and PLN were isolated at the indicated time points. Cryosections of PLN were stained with PNAd-specific MECA-79 mAb and FITC-labeled goat anti-rat IgM $\mu$ . Photomicrographs show typical images of TRITC-labeled cells associated with PNAd-positive HEVs or infiltrated into the stroma of PLN tissue at 60 minutes. The number of TRITC-labeled cells associated with HEVs ( $>40$  HEVs) or stroma ( $>10$  fields;  $0.35 \text{ mm}^2/\text{field}$ ) in each sample was quantified (double-blind) by fluorescence microscopy. Data are the mean  $\pm$  SE and are representative of  $\geq 3$  independent experiments. The differences between NT and WBH-treated mice were significant by unpaired two-tailed Student *t*-test ( $*p < 0.0001$ ,  $**p < 0.001$ ). Fever-range WBH did not increase the localization of fluorescent-labeled cells in splenic tissues at 60 minutes (not shown). (Further experimental details are provided in Refs. 10 and 14.).

this *in vitro* assay (Figure 52.2A) (1,8,14). The molecular events regulated by thermal stress appear to be remarkably stable when considering that enhanced adhesion is detected in frozen tissues stored at  $-20^\circ\text{C}$ . Lymphocyte adhesion to HEVs in PLN cryosections is inhibited by the MECA-79 mAb, which recognizes a sulfation determinant on PNAd (see Figure 52.2A), as well as by mAb that bind to the N-terminal lectin domain of the L-selectin homing receptor (DREG-56, MEL-14) (1,8,10). These results confirm the requirement for L-selectin/PNAd adhesive partners in supporting lymphocyte adhesion to HEVs of heat-treated animals. Parallel increases in  $\alpha 4\beta 7$  integrin/MAdCAM-1-dependent adhesion were iden-

tified following heat treatment in PP HEVs using  $\alpha 4\beta 7^{\text{hi}}$  L-selectin $^{\text{lo}}$  TK1 cells and neutralizing mAb specific for  $\alpha 4\beta 7$  integrin and MAdCAM-1 (i.e., DATK32 and MECA-367, respectively) (1,8,10). Thermal stimulation of HEV adhesion is also observed in LN and PP organ cultures following incubation at fever-range temperatures *in vitro* (10). These data suggest that regulation of HEV adhesion occurs under local microenvironmental control and is not dependent on feedback mechanisms provided by neuronal or lymphatic systems or by the hypothalamus/pituitary/adrenal axis that orchestrates physiological responses during febrile episodes.

Thermal stimulation of adhesion at the level of the HEV correlates with improved trafficking of lymphocytes to LN and PP in short-term homing studies (1,8,14). In this series of studies, the core temperature of mice is initially raised to the range of natural fever ( $39.5^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$ ) by WBH treatment for 6 hours. Mice are then allowed to revert to their normal basal temperature ( $36.8^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$ ) prior to intravenous injection of fluorescent-labeled splenocytes and enumeration of labeled cells in various organs. Because fluorescent-tagged splenocytes are not subjected directly to thermal stress, this experimental design allows for the analysis of vascular responses to elevated temperatures. Flow cytometric analysis has shown that T and B lymphocytes constitute the major population of tetramethylrhodamine B isothiocyanate (TRITC)-labeled cells that traffic across HEVs in normothermic mice or in mice pretreated with WBH, whereas entry of monocytes or neutrophils is limited under either temperature condition (14). An example of this type of homing study is shown in Figure 52.2B. Enhanced interactions of TRITC-labeled lymphocytes with HEVs (stained with PNA-d-specific MECA-79 mAb and FITC-labeled secondary Ab) are detected in the PLN of WBH-treated mice as early as 5 minutes after lymphocyte injection. Increased lymphocyte-HEV interactions are observed in response to heat treatment at subsequent time points of 15, 30, and 60 minutes (Figure 52.2B) (8,14). Notably, lymphocyte interactions with HEVs temporally precede infiltration of fluorescent-labeled lymphocytes into the stroma of PLN organs of heat-treated animals (Figure 52.2B). These observations are consistent with the notion that HEVs are the major focal point directing lymphocyte trafficking into lymphoid organs in response to thermal stress.

The kinetics for optimal stimulation of HEV adhesion is tightly regulated. Moderate increases in HEV function are detected by *in vitro* adherence assays or *in vivo* homing studies following WBH treatment for 2 hours, whereas markedly elevated responses are observed following sustained exposure to thermal stress for 6 to 8 hours (8,14). The approximately twofold increase in lymphocyte-HEV adhesion and trafficking documented in response to fever-range thermal stress appears to represent a biologically significant amplification of lymphocyte access to lymphoid organs. Stimulation of the frequency of lymphocyte extravasation across HEVs, which is estimated to occur at a rate of  $5 \times 10^6$  cells per second in humans under normothermic temperatures (2), would be expected to profoundly enhance the potential for immune surveillance. HEV adhesion returns to normal basal levels within 12 hours of cessation of thermal stress (10). Transient regulation of vascular adhesion is in line with the sequence of events in natural fever where physiological feedback loops are designed to restore biological systems to steady-state equilibrium after resolution of an infection.

A notable finding relates to the selectivity of thermal regulation of endothelial adhesion (1,8,10). Fever-range WBH preferentially amplifies adhesion in HEVs of LN and PP, whereas no increase in adhesion is detected by *in vitro* adherence assays in squamous ECs of noninflamed extralymphoid

organs (e.g., pancreas). Moreover, WBH does not increase the localization of fluorescent-labeled lymphocytes in non-HEV-bearing organs (e.g., spleen, pancreas) in short-term homing studies (1,8,10). These findings suggest that febrile temperatures associated with infection or inflammation proactively focus the delivery of lymphocytes across HEVs in lymphoid organs, while sparing noninflamed extralymphoid sites.

The specific adhesion events targeted by thermal stress in HEVs have recently been characterized. Enhanced HEV adhesion is not accompanied by detectable increases in expression of the molecules that support primary tethering and rolling, that is, PNA-d (Figure 52.2B) or MAdCAM-1 (1,10,14). Fever-range thermal stress was instead found to regulate molecular events that control secondary firm arrest of lymphocytes in HEVs. Thus, fever-range WBH treatment of mice markedly upregulates the luminal expression of ICAM-1 on HEVs of LN and PP, leading to enhanced lymphocyte trafficking at these sites, whereas no induction of ICAM-1 is observed in noninflamed vessels of extralymphoid organs (14). Direct visualization of lymphocyte-HEV interactions by intravital microscopy further revealed that WBH treatment increases firm adhesion without influencing primary tethering/rolling interactions (14). Based on these findings, it is proposed that high-density ICAM-1 on HEVs during febrile episodes increases the avidity and/or affinity of the molecular interactions with LFA-1 on apposing lymphocyte surface membranes. It remains to be determined whether heat induction of ICAM-1, in the context of infection or inflammation, might enable this trafficking molecule to cooperate with PNA-d or MAdCAM-1 to stabilize primary adhesion events in HEVs, as reported for non-HEV systems in which overlapping roles have been defined for selectins and ICAM-1 (24).

Temperatures that exceed the range of natural fever appear to override the selectivity of vascular targeting. Heat shock ( $43^{\circ}\text{C}$ ) upregulates ICAM-1 expression as well as the ability to support lymphocyte adhesion in primary human endothelial cultures that model resting macrovascular endothelium (human umbilical vein ECs [HUVECs]) and microvascular endothelium (human dermal microvascular ECs [HMVECs]) (20,25,26). Moreover, heat shock proteins (HSPs) including HSP70, HSP60, and HSP65, which are major intracellular proteins synthesized in response to high-temperature heat shock or cellular stress, have been shown to act extracellularly to induce the expression of ICAM-1 in non-activated primary ECs (HUVECs) *in vitro* (27-30). In sharp contrast, physiologic fever-range temperatures ( $39.5^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$ ) have no effect on adhesion molecule expression (ICAM-1, E-selectin, vascular cell adhesion molecule [VCAM]-1, P-selectin, platelet-endothelial cell adhesion molecule [PECAM]-1, PNA-d, MAdCAM-1), cytokine release (IL-1 $\beta$ , TNF- $\alpha$ , IFN- $\gamma$ , IL-6, IL-11, IL-12, IL-13), or chemokine secretion (IL-8, RANTES, monocyte chemoattractant protein [MCP]-1, monokine induced by IFN- $\gamma$  [MIG]) in cultured ECs (21,31). Nonactivated endothelium is not entirely refractory to fever-range thermal stress, however, because proadhesive factors can be recovered from the

Figure 52.3. Model for fever-range thermal regulation of lymphocytes trafficking across selected vascular beds. Fever-range thermal stress in the context of inflammation or clinical thermal therapy promotes lymphocyte extravasation across cuboidal HEVs in peripheral lymph nodes (PLN), mesenteric LN (MLN), and Peyer's patches (PP). In contrast, lymphocyte-endothelial adhesion and trafficking across nonactivated squamous endothelium is not enhanced in spleen or noninflamed extralymphoid tissues.

conditioned medium of HUVECs and HMVECs following culture at 40°C (1,8,18,21). These soluble factors act in trans to stimulate the binding function of L-selectin and  $\alpha 4\beta 7$  integrin on lymphocytes. Based on these findings, it is tempting to speculate that the vast majority of vascular beds indirectly contribute to lymphocyte delivery to LN and PP during febrile inflammatory responses by providing factors that stimulate lymphocyte homing receptor function.

#### KEY POINTS

- Recent studies support the concept that febrile temperatures function as a rheostat to amplify lymphocyte trafficking to secondary lymphoid organs and thereby enhance the efficacy of immune surveillance (Figure 52.3).
- Fever-range thermal stress increases L-selectin and  $\alpha 4\beta 7$  integrin-dependent adhesion in B and T lymphocytes, thereby promoting trafficking via HEVs in LN and PP. Thermal regulation of adhesion in lymphocytes involves a trans-signaling mechanism mediated by engagement of membrane-anchored gp130 signal transduction molecules by IL-6 and a soluble form of the IL-6R $\alpha$ .

- Fever-range hyperthermia transiently promotes the binding activity of gatekeeper HEVs in lymphoid organs. As a result, thermal stress induces a substantial increase in lymphocyte binding to HEVs under shear as well as transmigration across HEVs into the parenchyma of lymphoid organs. Thermal stress does not promote adhesion in squamous ECs of non-inflamed extralymphoid organs either in vitro or in vivo.
- Selective targeting of primary and secondary adhesion events in specialized HEVs focuses the delivery of immune effector cells to peripheral lymphoid organs where the opportunity exists for optimal sensitization or restimulation of naïve or central memory lymphocytes, respectively (see Figure 52.3). In the absence of such tight control of lymphocyte-endothelial adhesion, inappropriate trafficking of lymphocytes could lead to extensive damage in non-inflamed extralymphoid tissues.

#### Future Goals

- An unresolved issue relates to how site-specific vascular targeting is maintained by fever-range thermal stress. It is probable that the unique microenvironment of lymphoid organs as well as the

differentiation/ activation status of HECs contribute to the specificity of vascular responses. It will be of interest in follow-up studies to determine if adhesion of HEV-like vessels at extralymphoid sites of acute or chronic inflammation is similarly regulated by febrile temperatures.

- Future studies are required to examine whether fever-range thermal stress initiates additional signaling events in ECs of different vascular beds, such as induction endothelial nitric oxide synthase, hemostatic factors, or apoptotic cascades.
- Major questions remain regarding the molecular mechanisms underlying thermal control of adhesion in HEVs. Inflammatory cytokines such as TNF- $\alpha$ , IL-1 $\beta$ , IFN- $\gamma$ , or IL-6 are potential candidates because they are known to stimulate vascular expression of ICAM-1 in extralymphoid organs in the context of acute or chronic inflammation (2). Moreover, increased adhesion is detected in HEVs during fever responses induced by LPS or turpentine that are associated with high systemic levels of inflammatory cytokines (10). Notably, recent studies have implicated IL-6 as the central mediator of fever-range thermal stimulation of adhesion in HEVs as well as in lymphocytes (14,18). These findings support the emergence of IL-6 as a molecular switch controlling lymphocyte trafficking across vascular barriers during acute and chronic inflammation (24,32). An important issue that awaits further investigation is how pleiotropic cytokines, such as IL-6, selectively target lymphocyte-HEV adhesion while maintaining the tightly regulated balance between physiological and pathological responses during febrile inflammatory responses.

#### ACKNOWLEDGMENTS

We thank Elizabeth Repasky and Heinz Baumann for insightful discussions relating to this work and Jennifer Black and Michelle Appenheimer for the critical review of the manuscript. This work was supported by grants from the NIH, the Department of Defense, and the Roswell Park Alliance Foundation.

# Hyperbaric Oxygen and Endothelial Responses in Wound Healing and Ischemia–Reperfusion Injury

Bryan Belikoff, Wende R. Reenstra, and Jon A. Buras

*Northeastern University, Boston, Massachusetts*

Hyperbaric oxygen (HBO<sub>2</sub>) therapy is defined as breathing 100% oxygen (O<sub>2</sub>) at a pressure greater than 1.4 atmospheres absolute (ATA) (1). HBO<sub>2</sub> is currently accepted as a clinical adjunctive therapy for the following indications: wound healing, carbon monoxide (CO) poisoning, crush injury, clostridial myositis and myonecrosis, decompression sickness, osteomyelitis (refractory), skin grafts and flaps, and air or gas embolism (1–3). HBO<sub>2</sub> therapy is administered in either a monoplace hyperbaric chamber (where the chamber is compressed with 100% oxygen) or in a multiplace hyperbaric chamber (where the chamber is compressed with air and the patient breathes 100% oxygen via a tight-fitting mask or hood) (Figure 53.1). Many benefits of HBO<sub>2</sub> therapy are gained through its effects on the endothelium, including improvements in microvascular flow, induction of proangiogenic factors, inhibition of inducible intercellular adhesion molecule (ICAM)-1 expression, and regulation of endothelial derived nitric oxide (NO) production. The ubiquitous nature of the endothelium provides a gateway for many of the HBO<sub>2</sub> protective mechanisms to be effective at a number of injury sites. This chapter reviews the effects of HBO<sub>2</sub> therapy on disease states that are most dependent on endothelial responses: wound healing and ischemia–reperfusion (I/R) injury.

## HISTORY OF HYPERBARIC OXYGEN THERAPY

HBO<sub>2</sub> therapy was born from the concept that individuals exposed to increased ambient air pressure would have improvement in many different disease states (4). Although there was no scientific basis for this concept, it was put into practice as early as 1662 by a British clergyman, Henshaw (5). Compressed-air therapy enjoyed a nonscientific founded popularity during the 19th century in a manner similar to mineral water spas (6). The French surgeon Fontaine created a mobile air pressurized operating theater in 1879 (7). The use of nitrous oxide anesthesia was observed to be safer due to the approximately doubled percentage of inspired oxygen created

by compression. Under these conditions of pressure, patients did not appear as cyanotic as usual during emergence from anesthesia (7). The benefit of compressed-air therapy for tunnel workers was first recognized by Ernest W. Moir in 1889, during construction of the Hudson River tunnel (8). During this construction project, use of a recompression chamber reduced the death rate of workers from 25% to 1.66%.

The birth of HBO<sub>2</sub> therapy occurred in 1955 when oxygen, rather than air, was used as the environment for compression. This concept was credited to Churchill-Davidson in an effort to enhance radiation therapy for cancer patients (9). Also in 1956, Boerema and colleagues suggested that compression of the operating room with O<sub>2</sub> would improve tolerance to circulatory arrest during cardiac surgery (10). As a result of promising animal experiments, hyperbaric operating theaters were constructed throughout the United States to support cardiac surgery. The development of cardiopulmonary bypass technology marked the decline of HBO<sub>2</sub> therapy usage in the 1970s. Unfortunately, HBO<sub>2</sub> was used indiscriminately and without scientific evidence for multiple medical conditions, limiting the credibility of this therapy in the eyes of the medical community. Recently, more rigorous clinical studies have demonstrated a beneficial role for HBO<sub>2</sub> therapy in treating CO poisoning and diabetic foot ulcers (2,3). Also, basic science research has begun to identify the mechanisms responsible for HBO<sub>2</sub> in hopes of providing a basis for the rational application of HBO<sub>2</sub> in clinical trials.

## PRINCIPLES AND PRACTICE OF HYPERBARIC OXYGEN

In mammals, the delivery of oxygen into the bloodstream in exchange for metabolic gases occurs at the alveolar–blood barrier in pulmonary capillaries. At this interface oxygen exists in three different forms: (a) as a gas within the alveoli, (b) dissolved in plasma, and (c) bound by hemoglobin (Hb).

Figure 53.1. Multiplace hyperbaric chamber. The multiplace chamber is compressed with air and the patient breathes 100% oxygen via mask or hood inside the chamber. (Photo courtesy of Dick Clarke.)

O<sub>2</sub> and CO<sub>2</sub> travel between the blood–gas interface by simple diffusion, resulting in the transfer of gas from areas of high to low partial pressure. The partial pressure of a gas in the gas phase is dependent on its concentration in the gas mixture and is determined by multiplying its concentration by the total pressure (mmHg) of the vessel. The relationship between the partial pressure of a gas and the concentration of dissolved gas is given by Henry's law:  $P = kC$ , where  $P$  represents the pressure of the gas in the gas phase,  $C$  represents the concentration of the dissolved gas, and  $k$  is a constant characteristic of the particular liquid (solution).

The uptake of O<sub>2</sub> can be divided into two stages: (a) diffusion of O<sub>2</sub> across the alveolar–blood barrier into the interior of the red blood cell, and (b) the reversible reaction of O<sub>2</sub> binding with Hb to form oxyhemoglobin,  $O_2 + Hb \leftrightarrow HbO_2$ .

Fick's law of diffusion states that the rate of diffusion across a barrier is proportional to the area ( $A$ ) of the membrane and inversely proportional to its thickness ( $T$ ):

$$V_{\text{gas}} = (A/T) \times D \times (P_1 - P_2) \quad (\text{Equation 1})$$

where  $D$  represents gas solubility/ $\sqrt{(\text{molecular weight})}_{\text{gas}}$ ,  $V_{\text{gas}}$  represents velocity of gas, and  $P$  represents pressure.

Normal arterial blood with a P<sub>O<sub>2</sub></sub> of 100 mmHg contains only 0.3 ml O<sub>2</sub>/100 mL or 3 mL O<sub>2</sub>/liter by simple diffusion alone. The amount of O<sub>2</sub> dissolved in the blood by simple diffusion alone is not sufficient to meet the metabolic demands of the body's tissues. Nature has circumvented this problem through the production of Hb to enhance the O<sub>2</sub> carrying capacity of blood in vertebrates (one interesting exception is the Antarctic icefish, discussed in Chapter 7). Hb is an iron-porphyrin–containing globular protein that binds dissolved oxygen in blood. The maximum amount of O<sub>2</sub> that can bind with Hb is called the oxygen capacity. The %O<sub>2</sub> saturation is calculated by dividing the number of O<sub>2</sub> molecules bound to

Hb by the oxygen capacity, multiplied by 100. The following equation shows the relationship between oxyhemoglobin and dissolved oxygen in blood and is used to calculate the total O<sub>2</sub> concentration of blood (mL O<sub>2</sub>/100 mL):

$$\{1.39 \times [\text{Hb}] \times (\%O_2 \text{ saturation}/100) + 0.003 P_{O_2} \text{ mmHg}\} \quad (\text{Equation 2})$$

As Hb becomes saturated with O<sub>2</sub>, the blood nears O<sub>2</sub> capacity. Subsequently, the P<sub>O<sub>2</sub></sub> of the blood dramatically increases, and the rate of O<sub>2</sub> diffusion across the alveolar–blood barrier slows due to the P<sub>O<sub>2</sub></sub> in the blood reaching that of alveolus. This becomes apparent in a normal individual (whose blood contains 15 gmHb/100 mL) with an arterial blood P<sub>O<sub>2</sub></sub> above 50 mmHg, where the O<sub>2</sub> combined with Hb begins to near O<sub>2</sub> capacity. If the P<sub>O<sub>2</sub></sub> of the alveoli is increased, the P<sub>O<sub>2</sub></sub> dissolved in the blood will increase, and the converse also is true.

HBO<sub>2</sub> exposure at 2.5 ATA will significantly increase the O<sub>2</sub> concentration of the arterial blood, even though the amount of O<sub>2</sub> in the blood is close to O<sub>2</sub> capacity. The ability of HBO<sub>2</sub> to enhance O<sub>2</sub> concentration is mediated by the non-Hb-dependent direct dissolution of O<sub>2</sub> in blood. By increasing the atmospheric pressure to 2.5 ATA, the P<sub>O<sub>2</sub></sub> in the alveoli will be approximately three times greater than breathing 100% pure O<sub>2</sub> alone and approximately 18 times greater than inspiring normal air at 1 ATA (760 mm Hg). This situation results in more free O<sub>2</sub> (O<sub>2</sub> not bound by Hb) dissolved directly in the blood and thus increased O<sub>2</sub> delivery in the systemic circulation. Experimentally, the entire blood volume may be replaced with normal saline under HBO<sub>2</sub> conditions and the animal may function without impairment (11).

## CHRONIC WOUNDS

Aggressive elimination of infected and nonviable tissue in combination with meticulous wound care is the foundation of successful wound healing. However, some wounds do not respond to simple wound care and progress to a chronic state. By definition, chronic wounds are recalcitrant, reoccur, and/or are progressive and refractory to a wide spectrum of treatments applied. Chronic wounds arise in a variety of situations and pathologies. The most common chronic wounds in Western medical practice are a consequence of diabetes, arterial or venous disease, sustained pressure, or therapeutic irradiation for the treatment of tumors (12).

Chronic wounds are common and constitute a significant health problem. The actual incidence and impact are difficult to assess accurately because of the wide range of disease states and pathologies associated with chronic wounds. Current therapeutic interventions for chronic wounds (beyond antibiotics and supportive care) include the use of HBO<sub>2</sub> and exogenous NO donors, as well as topical growth factors such as platelet-derived growth factor (PDGF)-BB (13–15). The beneficial effects of HBO<sub>2</sub> on wound healing are well

documented clinically, but the underlying mechanisms are relatively unknown. Basic science research utilizing both *in vivo* and *in vitro* wound healing models has demonstrated that HBO<sub>2</sub> treatment accelerates wound healing through NO-dependent mechanisms (16).

### The Effect of Hyperbaric Oxygen on Wound Healing

The rationale for using HBO<sub>2</sub> in wound healing is that the common denominator in many chronic wounds is tissue hypoxia. Hypoxemia, caused initially in wounds by vascular disruption, is a key factor that eventually limits wound healing (17). A majority of wounds have been shown to be hypoxic at the center of the wound bed. This initial hypoxia is thought to be a trigger for blood vessel growth. However, although hypoxia is thought to initiate neovascularization, it cannot sustain it. Wound healing is not sustainable in the hypoxic environment as many of the processes involved in wound healing, such as collagen deposition, fibroblast migration, and growth factor production, require oxygen for metabolism. This concept is further supported by the observation that supplemental oxygen administration accelerates blood vessel growth in a rabbit ear model (18).

### Hyperbaric Oxygen and Angiogenesis

HBO<sub>2</sub> appears to exert its beneficial effects on wound healing in part by promoting the formation of new capillaries. The effect of HBO<sub>2</sub> exposure on the endothelium became apparent after its usage as an adjunctive therapy for the treatment of diabetic foot ulcers. Clinical studies demonstrated that HBO<sub>2</sub> exposure for 90 minutes at 2.5 ATA significantly increases transcutaneous pO<sub>2</sub> levels in the dorsal foot of patients with diabetic foot ulcers (2). At the conclusion of this study, the sustained increase in tissue pO<sub>2</sub> levels was attributed in part to new vessel growth.

The formation of new capillaries from preexisting vessels, such as occurs in wound healing, is termed *angiogenesis*. Clinical and experimental evidence suggests that increasing oxygen concentration in hypoxic wound beds results in increased blood vessel growth (19,20). The mechanism by which hyperoxia might induce blood vessel growth is not well understood but is thought to involve vascular endothelial growth factor (VEGF) and angiopoietin (Ang), both potent inducers of angiogenesis.

VEGF is a 21- to 49-kDa protein and is one of the most important angiogenic growth factors involved in adult wound healing. VEGF interacts with two tyrosine kinase receptors located on the endothelial cell (EC) surface, VEGFR2 and VEGFR1, and VEGFR2-VEGF binding stimulates EC proliferation. VEGFR1-VEGF binding is antagonistic to VEGFR2-VEGF-induced EC proliferation and induces tube formation and capillary development (21,22).

Ang2 is a 70- to 88-kDa protein that is selectively expressed at sites of pathological angiogenesis. Binding of the Ang2 ligand to its EC surface receptor, Tie2, loosens the endothelium

for vascular remodeling and enhances the responsiveness of ECs to VEGF stimulation (23). Initial cellular events in angiogenesis during wound healing appear to be dependent on Ang2-Tie2 binding, whereas the later events of vessel formation depend on the availability of functional VEGF (23).

VEGF became an attractive mediator to explain the beneficial effects of HBO<sub>2</sub> therapy due to its neovascuogenic properties. Initially this association appears paradoxical, as hypoxia, not hyperoxia, was thought to be the principal inducer of VEGF. However, studies by Howdieshell and colleagues, utilizing a porcine wound model, determined that VEGF expression occurred in the absence of hypoxia (24). These authors suggested the presence of another inducer of VEGF expression. Further data suggest a role for oxygen and HBO<sub>2</sub> in VEGF regulation. In a study by Sheikh and colleagues utilizing an *in vivo* wound healing model, stainless steel wire mesh cylinders were implanted beneath the dorsal skin of rats (25). HBO<sub>2</sub> therapy was administered twice daily at 2.1 ATA for 90 minutes over 7 days. Oxygen electrodes were used to measure oxygen tensions from within the site of injury before, during, and after HBO<sub>2</sub> exposure. Baseline wound oxygen tension remained hypoxic (7.4–13.7 mm Hg) throughout the control experiment and increased significantly during HBO<sub>2</sub> to 373.2 to 537.2 mm Hg. Increased wound pO<sub>2</sub> levels were sustained at 45.6 to 150.5 mm Hg for 1 hour after the end of hyperbaric treatment. Fluid samples were collected and the results demonstrated significant increases of VEGF protein in wound fluid samples as early as 2 days after initial HBO<sub>2</sub> exposure, peaking at day 5 (25).

Conversely, *in vitro* experiments by Lin and colleagues suggest that HBO<sub>2</sub> instead upregulates expression of the proangiogenic factor Ang2, an Ang1 antagonist involved in vascular remodeling and vessel sprouting (23,26). In this study, human umbilical vein ECs (HUVECs) exposed to HBO<sub>2</sub> for 90 minutes at 2.5 ATA selectively expressed Ang2, but not VEGF (26). However, in addition to the difference between model systems, HBO<sub>2</sub> therapy was administered only once as opposed to twice daily for multiple days as in the Sheikh and colleagues *in vivo* model previously described (26).

Several possible explanations exist for the absence of HBO<sub>2</sub>-induced VEGF in HUVECs. One possibility is that prolonged or repetitive HBO<sub>2</sub> exposures may be required to induce VEGF expression. A more plausible explanation is that increased levels of VEGF protein found in the wound fluid samples *in vivo* may be derived from an alternate cell type. For example, HBO<sub>2</sub> could induce VEGF production from macrophages instead of the endothelium during the inflammatory response (27). Additionally, one must consider differences in cell type and cell origin when evaluating experimental data. HUVECs, commonly used for *in vitro* studies, may respond differently to HBO<sub>2</sub> than ECs derived from cutaneous endothelium.

Despite the above discrepancies, it is possible to envision a hypothesis explaining how HBO<sub>2</sub> enhances wound healing through the induction of both Ang2 and VEGF. If early HBO<sub>2</sub> exposures are able to induce endothelial Ang2 expression,

whereas prolonged HBO<sub>2</sub> exposures induce VEGF, then in the context of poor blood perfusion observed in wound models, HBO<sub>2</sub>'s function would be to increase oxygen tension levels, reduce metabolic cellular dysfunction, and promote an environment supporting neovascularization. The formation of new blood vessels would replenish oxygen to the ischemic tissue, and the subsequent adequate supply of oxygen would enhance wound closure.

The mechanism explaining how HBO<sub>2</sub> could increase VEGF levels is currently unknown, although regulation may occur via NO- and hypoxia-inducible factor (HIF)-1-dependent mechanisms. VEGF is transcriptionally induced in hypoxia by the binding of HIF-1 to hypoxia-response elements in the 5' promoter region of the VEGF gene (28,29). Furthermore, a recent report suggests that NO is also a regulator of VEGF expression. Under normoxic conditions, NO donors induce VEGF expression by enhancing HIF-1 binding activity in human glioblastoma A-172 and hepatoma Hep3B cells (30). This may explain in part the paradox of VEGF synthesis under both hypoxic and hyperoxic conditions, as HIF-1 binding and activity is enhanced by both hypoxia and NO. Recently, it has been shown that HBO<sub>2</sub> may both induce NO production and stabilize HIF-1 protein, providing a mechanism whereby HBO<sub>2</sub> could directly influence VEGF expression (31,32).

### Hyperbaric Oxygen, Nitric Oxide, and Endothelial Nitric Oxide Synthase

NO is a free radical gas produced by a number of cellular sources, including the endothelium, and exerts multiple beneficial effects on wound healing (33). Three isoforms of NO synthase are responsible for NO production. Each isoform shares approximately 50% sequence identity with N-terminal variability. All three isoforms – endothelial NO synthase (eNOS), inducible NOS (iNOS), and neuronal NOS (nNOS) – generate NO in an oxygen-dependent manner through the conversion of L-arginine to L-citrulline.

eNOS-generated NO diffuses from the EC to vascular smooth muscle cells, where it binds to the heme group within the active site of guanyl cyclase. This binding increases cyclic guanosine-3',5'-monophosphate production, which activates an enzymatic cascade that leads to smooth muscle relaxation and vasodilation. eNOS protein is preferentially expressed in ECs. Regulation of eNOS production and activity is multifaceted. Hyperoxia, as a result of inhalation of 100% pure O<sub>2</sub>, and shear stress within the endothelial lumen upregulate eNOS mRNA and protein expression, whereas intracellular calcium influx and calcium-calmodulin binding modulates eNOS activity (34,35).

The second NOS isoform, iNOS, is expressed in many cell types, including ECs, vascular smooth muscle cells, macrophages, polymorphonuclear leukocytes (PMNLs), and fibroblasts, following exposure to lipopolysaccharide (LPS), interleukin (IL)-1 $\beta$ , or tumor necrosis factor (TNF)- $\alpha$ . Although iNOS accounts for the majority of NO production, it is not constitutively expressed in cells. The third

NOS isoform, nNOS, is expressed predominantly in the CNS.

Multiple studies support the role of NO in wound healing. Applying exogenous NO to wounds enhances wound closure in diabetic mouse models (36). Further studies by Boykin and colleagues have demonstrated a decrease in wound closure rates in diabetic patients with decreased NO production (37). In vivo studies also demonstrate that both *iNOS*- and *eNOS*-knockout mice exhibit impaired wound healing, suggesting a specific role for eNOS in wound closure (38,39). Further wound healing experiments on aortic segments harvested from eNOS-deficient mice show retarded EC migration and EC proliferation (38). Finally, recent data utilizing an in vitro HUVEC model suggest that neovascularization occurs via an *eNOS*-dependent pathway (26).

The beneficial effects of HBO<sub>2</sub> on wound healing may be mediated by eNOS production of NO. The contribution of eNOS-generated NO from HBO<sub>2</sub> exposure was assessed in an in vitro model of I/R injury. Exposure of human and bovine ECs (BAECs) to HBO<sub>2</sub> resulted in upregulation of eNOS but not iNOS protein, suggesting that the total contribution of endothelial NO is derived from eNOS (35). Studies using *iNOS*- and *eNOS*-knockout mice have demonstrated impaired wound closure rates despite HBO<sub>2</sub> treatment (40). Evaluation of wound tissue demonstrated reduced levels of PDGF receptor- $\beta$  and epidermal growth factor receptor (EGFR) expression in response to HBO<sub>2</sub> as compared to wild-type mice (40). Taken together, the data imply that the mechanism of HBO<sub>2</sub>-enhanced wound closure may be via the NOS-dependent upregulation of wound growth factors. Additionally, a recent in vitro study shows that HBO<sub>2</sub>-induced Ang2 expression appears to be mediated by eNOS production of NO (26).

### Unifying Mechanisms of Hyperbaric Oxygen in Wound Healing

Studies to date implicate eNOS generation of NO as a unifying mechanism of HBO<sub>2</sub>-induced wound healing. Initial exposure of the endothelium to HBO<sub>2</sub> upregulates eNOS expression, leading to increases in NO levels within the microvasculature. The presence of NO decreases vasomotor tone and increases blood flow to the injured tissue. Results from wound fluid samples in the in vivo rat model suggest that the incoming blood flow will have increased pO<sub>2</sub> levels, preventing further ischemia-related tissue damage and promoting angiogenesis. Simultaneously, the increase in blood flow will increase the shear stress within the lumen of the endothelium and together with hyperoxia may further increase the production of eNOS protein and NO. A second effect of HBO<sub>2</sub>-induced endothelial-derived NO may be increased production of Ang2, with subsequent sprouting of new vessels. Further investigations with Ang2 production in vivo are required to confirm the link between eNOS and NO-induced Ang2 expression. Finally, it has been demonstrated that NO may increase VEGF levels through HIF-1, leading to enhanced vessel formation.

Taken together, it appears that HBO<sub>2</sub> is influencing angiogenesis through NO-dependent mechanisms.

### **HYPERBARIC OXYGEN AND THE ENDOTHELIUM: ISCHEMIA–REPERFUSION INJURY**

I/R injury is a complex biphasic process that results in metabolically induced cellular dysfunction and cell death. The initial phase of I/R injury is an acute interruption of blood flow within the vasculature that creates ischemia – defined as a cessation of blood flow – and an acute tissue environment of hypoxic and hypoglycemic conditions. The endothelium represents the first population of cells affected by acute ischemia and initiates multiple cellular, immunological, and physiological responses in an attempt to regain metabolic homeostasis. Although the initial period of ischemia may be corrected by removal of the obstructing lesion, a secondary period of tissue damage occurs during reperfusion involving impaired microvascular flow and is referred to as the “no-reflow phenomenon” (41). The secondary phase of microvascular stasis may be attributed to alterations in vessel tone and adhesion of PMNLs to the endothelium, with ensuing cellular and humoral mediator activation.

Prior to PMNL migration into ischemic tissue, microvascular PMNL plugs may exacerbate ischemic conditions through physical obstruction, EC activation and activation of other humoral inflammatory mediators such as the coagulation and complement cascade. Further damage to injured tissue is caused by the release of free radicals and destructive enzymes by PMNLs following endothelial transmigration (42). Indeed, tissue destruction caused by PMNL invasion into ischemic tissue may be responsible for the infarct extension observed in myocardial infarction and stroke (43–45). Furthermore, PMNL/endothelial-mediated reperfusion injury following myocardial infarction may contribute to greater scar formation during ventricular remodeling, which is a predictor of a poorer clinical outcome (46). Studies demonstrate that inhibition of PMNL adherence to the endothelium or the addition of free radical scavengers improves clinical outcome (47,48). Thus, interruption of PMNL adhesion to the endothelium and prevention/limitation of free radical formation represents a central focus in I/R injury prevention research.

HBO<sub>2</sub> has been suggested as a therapeutic intervention for I/R injury and appears to exert a beneficial effect through both disruption of PMNL adhesion and inhibition of free radical generation (49). Experimental studies have been performed evaluating the mechanisms of HBO<sub>2</sub> benefit in I/R injury models of muscle and brain *in vivo* and EC-PMNL interactions *in vitro* (35,50–54). These outcomes are surprising and paradoxical, as one would normally predict that reperfusion of previously ischemic tissue with supranormal pO<sub>2</sub> concentrations would only serve to enhance the production of reactive oxygen species (ROS) and cellular damage. However, multiple studies

have shown that although HBO<sub>2</sub> may increase ROS formation, cellular damage, as assessed by lipid peroxidation, is actually reduced (49). The mechanism for this observation, referred to as the “oxygen paradox,” remains largely undefined.

Early observations demonstrating that HBO<sub>2</sub> reduces edema and necrosis in ischemic skeletal muscle stimulated subsequent investigations into the beneficial mechanisms of HBO<sub>2</sub> in I/R injury (55). The primary benefit of HBO<sub>2</sub> in I/R injury appears to be inhibition of PMNL-EC interactions (35,56). HBO<sub>2</sub> was first noted to reduce PMNL adherence to the endothelial lining as determined by intravital microscopy in rodent gracilis muscle preparations following experimental I/R injury (57). Subsequent investigations on mechanisms of HBO<sub>2</sub> in I/R injury have focused on the CD11/18-ICAM-1 adhesion molecule axis.

### **HYPERBARIC OXYGEN AND THE PMNL–ENDOTHELIAL ADHESION AXIS**

The interaction of membrane-bound PMNL CD11/18 and endothelial ICAM-1 mediates firm adhesion of PMNLs to the endothelium. Briefly, CD11/18 is a heterodimeric protein member of the integrin family of adhesion molecules that is constitutively expressed on the PMNL cell surface (48). Binding of CD11/18 to its primary ligand, ICAM-1 causes a bidirectional cellular activation and is responsible for firm adhesion of PMNLs to the endothelial surface. ICAM-1 is an inducible 90- to 114-kDa cell surface glycoprotein and a member of the immunoglobulin superfamily (48). ICAM-1 expression may be induced by a variety of proinflammatory mediators, such as cytokines and bacterial endotoxins. I/R injury is known to induce endothelial expression of ICAM-1 *in vivo* (48). However, ICAM-1 induction appears to require both hypoxic and hypoglycemic conditions, because hypoxia alone, or hypoxia with reoxygenation, does not induce ICAM-1 expression in human aortic ECs (HAECs), HUVECs, or BAECs (35,58). The combination of hypoxia and hypoglycemia followed by normoxic/normoglycemic conditions is required to induce ICAM-1 expression in HUVECs and BAECs (35).

Initial studies on HBO<sub>2</sub> interference with the CD11/18–ICAM-1 axis were performed in a model of CO poisoning. CO represents a subtype of I/R injury by creating global ischemia as opposed to the classic compartmentalized ischemic models (59). CO poisoning creates localized hypoxia through binding of CO to heme structures found in Hb and cytochromes, diminishing oxygen transfer to Hb in the capillary lung beds and preventing the dissociation of oxygen-bound Hb in the systemic capillary circulation, thus interfering with oxidative metabolism. The effects of CO poisoning after CO elimination are analogous to transient vascular interruption of cerebral blood flow and result in increased levels of lipid membrane peroxidation, leukocyte infiltration, hypotension, and cerebral hypoperfusion (59). *In vivo* studies of CO poisoning in rodent models demonstrated that the beneficial effect

of HBO<sub>2</sub> is mediated by interruption of CD11/18-mediated adhesion to the endothelium and not by suppression of PMNL activation (60). Further studies on human blood samples exposed to HBO<sub>2</sub> confirm the inhibitory effect of HBO<sub>2</sub> on PMNL adherence (60). The mechanism of inhibition appears to involve inhibition of membrane guanylate cyclase (60). The inhibitory effects of HBO<sub>2</sub> exposure at 2.8 ATA or 3.0 ATA on human PMNL adherence and respiratory burst function were reversible after 21 hours, suggesting that HBO<sub>2</sub> may be nondetrimental to innate host defense mechanisms (53).

The importance of endothelial ICAM-1 in mediating I/R injury has been described in multiple models (48). Inhibition of ICAM-1 via antibody interference inhibits PMNL EC binding in vitro and blocks PMNL binding, tissue infiltration, and tissue damage in vivo (61). Further in vivo studies using mice genetically deficient in ICAM-1 support the beneficial effects of ICAM-1 inhibition during renal I/R injury; *ICAM-1*<sup>-/-</sup> animals demonstrated decreased PMNL infiltration and were protected from ischemic injury to the kidney (62). Additionally, ICAM-1-deficient mice prove resistant to I/R injury in cerebral I/R injury models (63). Thus, both in vitro and in vivo data suggest that endothelial ICAM-1 may represent a valuable target for therapeutic intervention in I/R injury.

I/R injury models demonstrating HBO<sub>2</sub> prevention of PMNL/endothelium adhesion led to recent studies investigating the effects of HBO<sub>2</sub> exposure on ICAM-1 expression (35,36). In an in vitro I/R injury model, HUVECs and BAECs were exposed to hypoxia and hypoglycemia (mock ischemia) for 4 hours and then exposed to normoxia and normoglycemia for 20 hours (mock reperfusion) (35). ECs exposed to 2.5 ATA HBO<sub>2</sub> for 90 minutes at the initiation of mock reperfusion demonstrated a significant reduction in ICAM-1 protein expression. HBO<sub>2</sub> treatment also prevented adhesion of PMNLs to mock I/R injured ECs, suggesting that HBO<sub>2</sub> treatment may also prevent PMNL adhesion through ICAM-1 regulation (35). The ability of HBO<sub>2</sub> to reduce ICAM-1 expression following I/R injury was recently confirmed in vivo using a rodent musculocutaneous flap model (56).

HBO<sub>2</sub> is similar to any other pharmacological mediator as it exhibits a clear dose-dependent effect. For example, in contrast to HBO<sub>2</sub>'s suppressive effect on endothelial ICAM-1 expression following I/R injury, other studies have shown that isolated, prolonged HBO<sub>2</sub> exposure of healthy mice to 3.0 ATA for 3 to 6 hours or isolated ECs 100% oxygen at 1 ATA for 24 hours or more actually upregulates ICAM-1 expression and enhances PMNL adhesion (64,65). As a result, it appears that the endothelium is sensitive to the duration of HBO<sub>2</sub> exposure and that the EC metabolic state may influence the ultimate cellular response.

### Hyperbaric Oxygen, Nitric Oxide, and Ischemia-Reperfusion Injury

NO may play a central role in the mechanism of HBO<sub>2</sub> protection during I/R injury. As a result of I/R injury damage to

the endothelium, NO production by eNOS is compromised, and several studies have demonstrated that NO is protective through inhibition of PMNL infiltration and PMNL-induced tissue damage during I/R injury (41,66,67). As described earlier, HBO<sub>2</sub> selectively induces eNOS protein in cultured HUVECs and BAECs (35). Furthermore, following I/R injury, HBO<sub>2</sub>-mediated downregulation of ICAM-1 production is prevented by the presence of L-N-arginine methyl ester (L-NAME), a NOS inhibitor (35). Consequently, HBO<sub>2</sub> appears to regulate ICAM-1 production on the EC surface via NO production from eNOS. Recently, HBO<sub>2</sub> was shown to increase NO production by eNOS and also to increase *eNOS* mRNA expression in vivo following I/R injury in a rodent gracilis muscle model (31). These studies confirm the central role of the endothelium in mediating HBO<sub>2</sub> protection following I/R injury.

### Unifying Mechanisms of Hyperbaric Oxygen in Ischemia-Reperfusion Injury

The mechanism of HBO<sub>2</sub> action in preventing I/R injury appears to be associated with an increase in eNOS and NO production, a decrease in ICAM-1 production, and a concomitant reduction in PMNL-endothelial adhesion. Interestingly, the expression of other endothelial adhesion molecules, such as E-selectin, may also be suppressed by HBO<sub>2</sub> following I/R injury (68). Review of the adhesion molecule transcriptional control reveals that the heterodimeric transcription factor nuclear factor (NF)- $\kappa$ B serves a positive, central role in gene regulation (69). Furthermore, NF- $\kappa$ B activity is negatively regulated by increased NO levels in ECs, as exogenously applied NO may reduce NF- $\kappa$ B activation and adhesion molecule gene transcription (66). These data support the possibility that the mechanism of HBO<sub>2</sub> involves increased production of NO from eNOS with subsequent downregulation of NF- $\kappa$ B activity and adhesion molecule expression. Furthermore, NO may exert a suppressive effect on PMNL membrane guanylate cyclase, which could then interfere with CD18 function (70). In this regard, HBO<sub>2</sub>-induced NO could have an anti-adhesive effect on both components of the PMNL-endothelial axis during I/R injury (Figure 53.2).

Preliminary work suggests that HBO<sub>2</sub> may inhibit NF- $\kappa$ B DNA-binding activity and nuclear translocation of the p65 subunit of NF- $\kappa$ B in ECs using an in vitro I/R injury model (J. Buras, unpublished observations). Other indirect evidence supporting this hypothesis comes from in vivo studies on the HBO<sub>2</sub> regulation of Toll-like receptor 4 (TLR4) activation. LPS-challenged rats exposed to HBO<sub>2</sub> at 2.5 ATA for 60 minutes demonstrated reduced PMNL intestine mucosal infiltration and also inhibited nuclear NF- $\kappa$ B translocation to the nucleus (71). Based on these observations, it is plausible that HBO<sub>2</sub> may downregulate NF- $\kappa$ B activation and serve as an anti-inflammatory stimulus in the setting of I/R.

Figure 53.2. Unifying antiadhesive effects of HBO<sub>2</sub> on the endothelium during I/R injury. HBO<sub>2</sub> may affect multiple components of EC-inflammatory cell adhesion. Effects of HBO<sub>2</sub> may be mediated via activation of NO production from eNOS, resulting in local vessel dilation, inhibition of NF-κB activation with subsequent reduction of cell adhesion molecule expression.

## CONCLUSION

The effect of HBO<sub>2</sub> on the cellular response is clearly linked to the exact disease state of the host (e.g., during wound healing or I/R injury). Furthermore, the effect of HBO<sub>2</sub> on the endothelium is dose-dependent and suggests that further emphasis be placed on the development of oxygen as a drug.

## KEY POINTS

- HBO<sub>2</sub> therapy has a wide range of effects on the endothelium during several different disease states, including improvement of microvascular flow, induction of proangiogenic factors, augmentation of inducible cell adhesion molecule expression, and regulation of NO production.
- Exposure of the endothelium to HBO<sub>2</sub> upregulates eNOS expression, leading to increases in NO levels within the microvasculature.
- NO may increase VEGF levels through HIF-1.
- HBO<sub>2</sub>-induced endothelial-derived NO may increase production of Ang2.
- HBO<sub>2</sub> reduces PMNL-EC interaction by reducing CD11/18 function and downregulating EC ICAM-1.
- Reduction of EC ICAM-1 by HBO<sub>2</sub> is dependent on NO production.
- HBO<sub>2</sub> may inhibit adhesive EC properties by reducing NF-κB activation.

## Future Goals

- To clarify the signaling mechanisms responsible for the observed effects of HBO<sub>2</sub> and explain how the same elevation in Po<sub>2</sub> may elicit disparate cellular responses in different disease states

## Barotrauma

---

Deborah A. Quinn and Charles A. Hales

*Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts*

Clinical barotrauma to the lung induced by mechanical ventilation, including pneumothorax, has been recognized as a problem for many years, but it is only in the past 10 years that the more subtle effects of mechanical ventilation on the lung have been recognized (1). The first comprehensive study that showed mechanical ventilation with high pressures and high tidal volumes in normal lungs caused pulmonary edema was carried out by Webb and Tierney in 1974 (2). In 1988, Dreyfus and colleagues, by using thoracoabdominal strapping to limit lung stretch during mechanical ventilation with high airway pressures, showed no ensuing pulmonary edema occurred with high pressures when the lung was not allowed to stretch (3). A negative pressure extrathoracic ventilator was then used, showing that pulmonary edema occurred at large tidal volumes, even though airway pressures were low. This demonstrated that lung stretch occurring with artificial ventilation, and not airway pressure, was the mechanism causing lung injury. Positive end-expiratory pressure may modify the response to lung stretch as occurs at disproportionately high tidal volumes. Although some data in rats support this concept (1), applying positive end-expiratory pressure to humans with lung injury and lowering the tidal volume simultaneously did not protect the lung (4). Along with lung edema, mechanical ventilation with high tidal volume ventilation has been shown to cause a release of inflammatory cytokines and chemokines with a subsequent influx of neutrophils into the lung (5). This combination of pulmonary edema and lung inflammation caused by barotrauma, or, perhaps more correctly, volutrauma, secondary to mechanical ventilation, has been termed ventilator-induced lung injury (VILI).

The use of low tidal volumes to avoid VILI has been shown to decrease mortality in patients with acute lung injury (ALI) who require mechanical ventilation (6). ALI and the more severe form of ALI, the adult respiratory distress syndrome (ARDS), are associated with nonhomogeneous damage to the lung. As a result, even moderate-sized tidal volumes can cause overdistention of the less severely involved, hence more compliant, areas of the lung. These latter effects may be modeled by applying high tidal volumes to animals with normal lungs. In vitro

cell stretch models have been used to study the mechanisms of stretch-induced changes in the endothelium (1).

The aim of this chapter is to show that the endothelium plays a key role in barotrauma from VILI. We present data that support a role for the endothelium in VILI-mediated pulmonary edema (Table 54-1) and lung inflammation (Table 54-2).

### LUNG CAPILLARY LEAK AND ENDOTHELIAL INJURY WITH HIGH TIDAL VOLUME VENTILATION

The edema in VILI arises from alterations in permeability rather than changes in hydrostatic pressure. In contrast to hydrostatic pulmonary edema (as occurs with congestive heart failure), VILI-associated permeability-type edema results in increased dry lung weight, increased extravasation of <sup>125</sup>I-labeled fibrinogen and Evans blue dye bound to albumin, and increased protein in bronchoalveolar lavage (BAL) fluid (1). Furthermore, we have shown that high-volume mechanical ventilation for 2 hours in rats results in an increased wet/dry lung weight ratio, despite a minimal rise in pulmonary artery pressure and no change in the left atrial pressure (7). The mild increase in pulmonary artery (and presumably intracapillary) pressure was insufficient to induce pulmonary edema, thus confirming that the lung leak in VILI is associated with a disruption of lung microvascular barrier function. In animal models, the development of capillary leak is an early event, occurring as early as after 1 hour of mechanical ventilation (D.A. Quinn and C.A. Hales, unpublished observations) and continues to rise at 2 hours of ventilation (7,8). Edema formation precedes the production of cytokines and the influx of neutrophils, suggesting that cytokines and neutrophils are not necessary for edema formation in the early stages of VILI (8). However neutrophils may contribute to the edema formation in the later stages by preventing its resolution.

The endothelium has been shown to play a key role in mediating high tidal volume ventilation-induced capillary leak

**Table 54-1: Mechanical Stretch-Induced EC Alterations That May Contribute to Pulmonary Capillary Leak with High Tidal Volume Ventilation**

<i>Endothelial Alteration</i>	<i>Experimental Model</i>	<i>References</i>

through two mechanisms (Table 54-3): (a) direct barotrauma-induced stress failure and (b) stretch-induced changes in endothelial intracellular signaling and cell membrane leading to barrier dysfunction.

VILI is accompanied by severe morphological damage to the alveolar endothelium. Ultrastructural studies using electron microscopy have revealed detachment of endothelial cells (ECs), gaps in the endothelium and focal endothelial blebs, and accumulation of interstitial edema. The damage to the epithelium is patchy. In some areas complete destruction of Type 1 cells occurs, whereas Type II cells are preserved (1). In addition, plasma von Willebrand factor (vWF), a biochemical marker of endothelial injury, was significantly elevated in rats with acid-injured lung ventilated with 12 mL/kg as compared with rats ventilated with 6 or 3 mL/kg (9). Together these data suggest that VILI may cause direct injury to the endothelium and stress failure of the capillary membrane; inactivation of surfactant leads to increased filtration (1). The combination of increased capillary leak and increased filtration leads to flooding of the alveoli with high-protein edema. Cyclic stretch also increases transepithelial permeability *in vitro* and may also contribute to lung stretch-induced capillary leak (10). However, the contributions of epithelial cell permeability are less well studied. Stretch-induced transepithelial permeability was not altered by inhibition of protein kinase C (PKC) or tyrosine kinase *in vitro* (10).

In addition to causing mechanical stress failure, high tidal volume ventilation may promote changes in EC signaling,

which in turn contribute to capillary leak in VILI, including influx of intracellular calcium and alterations of myosin light chain (MLC) kinase, phosphotyrosine phosphatase, tyrosine kinase, 5-lipoxygenase (5-LO), inducible nitric oxide synthase (iNOS), and phospholipase A2 activity. Mechanical stretch has been shown to initiate calcium entry through nonspecific cation channels of endothelial monolayers and lung epithelial cells (11–13). In isolated perfused rat lungs, Parker and colleagues found that gadolinium, a nonspecific blocker of stretch-activated cation channels, attenuated the increase in capillary filtration caused by ventilation with high pressures (14). Under *in vitro* conditions, stretch-induced calcium entry has been associated with activation of MLC phosphorylation and increased permeability of pulmonary artery EC monolayers (15). Inhibition of MLC phosphorylation or inhibition of calcium entry through calcium channels blocked high tidal volume ventilation-induced capillary filtration in isolated perfused rat lungs (16). Pulmonary artery ECs exposed to cyclic mechanical strain of 18% but not 5% caused an increase in MLC, p38 mitogen-activated protein kinase (MAPK), and extracellular signal-regulated kinase (ERK)1/2 phosphorylation and actomyosin remodeling (17). Cyclic mechanical strain (18%) also significantly enhanced thrombin-stimulated MLC phosphorylation and thrombin-induced pulmonary artery endothelial monolayer permeability, as measured by transendothelial electrical resistance. Mice deficient in MLC kinase had increased length of survival with lipopolysaccharide (LPS) plus VILI as compared to wild-type mice. The amount of lung edema and inflammation was not compared between knockout mice and wild-type mice in this study (18).

Lung stretch-induced capillary permeability has been reported to be dependent on activation of tyrosine kinases. Bhattacharya and colleagues found that lung expansion activated rat pulmonary endothelial tyrosine kinases in isolated blood-perfused rat lungs (19). Parker and colleagues used a phosphotyrosine phosphatase inhibitor (phenylarsine) and a tyrosine kinase inhibitor (genistein) to assess the role of these enzymes in lung stretch-induced capillary permeability in isolated perfused rat lungs (20). Inhibition of phosphotyrosine phosphatase was shown to lead to an increase in susceptibility of rat lungs to high tidal volume ventilation, whereas inhibition of tyrosine kinase attenuated capillary permeability.

The use of knockout mice has contributed to the investigation of role 5-lipoxygenase, iNOS, and phospholipase A2 activity in lung stretch-induced capillary leak. (See Table 54-4 for a summary of knockout mice used in the study of VILI.) Both mice deficient in 5-lipoxygenase and iNOS had decreased capillary leak and lung inflammation when exposed to high tidal volume ventilation as compared to wild-type litter mates (21,22). To explore the role of phospholipase A2 activity in VILI, both mice deficient in Clara cell secretory protein (CCSP), which have decreased phospholipase A2 activity, and inhibitors of phospholipase A2 activity were used (23). Increased phospholipase A2 activity had been found in bovine aortic ECs exposed to cyclic mechanical strain, and it was

**Table 54-2: Mechanical Stretch-Induced EC Alterations That May Contribute to Cytokine Production and Lung Neutrophil Influx with High Tidal Volume Ventilation**

Activation of iNOS	Intact mouse model	22

hypothesized that lung stretch would also increase phospholipase A2 activity (24). In mice exposed to large tidal volume mechanical ventilation, phospholipase A2 activity was increased in wild-type mice as compared to nonventilated controls and even higher levels in *CCSP*<sup>-/-</sup> mice exposed to large tidal volume mechanical ventilation. The use of a phospholipase A2 inhibitor decreased phospholipase A2 activity in both wild-type and *CCSP*<sup>-/-</sup> mice exposed to large tidal volume mechanical ventilation. Increased levels of phospholipase A2 activity was correlated with increased pulmonary capillary leak and lung inflammation. Inhibition of phospholipase A2 activity decreased both lung inflammation and lung capillary leak. TNF (tumor necrosis factor)- $\alpha$  was found to be not critical for lung stretch-induced capillary leak in knockout mice (25).

In addition to expressing barrier properties, the normal lung microvascular endothelium regulates lung fluid osmotic water permeability through water channels. Ten types of aquaporin channels that regulate water movement exist. Aquaporin 1 channels are strongly expressed throughout the microvascular endothelial beds outside the brain (26). In the lung endothelium, they are preferentially localized in the caveolae (7). Aquaporin 5 is also found in the lung on the apical membrane epithelial cells (26). We found that HgCl<sub>2</sub>, which inhibits aquaporin channels by binding to cysteine on the channel, worsened high-tidal volume-induced pulmonary edema (Figure 54.1) (7). Infusion of cysteine, by providing alternative binding sites for HgCl<sub>2</sub>, blocked this effect. There was no effect of HgCl<sub>2</sub> on lung edema with low tidal volumes. Though aquaporin 1 and aquaporin 5 have been shown to regulate lung fluid osmotic water permeability, neither *aquaporin 1-*

nor *aquaporin 5*-knockout mice showed evidence of impaired alveolar clearance (26). The effects of high tidal volume ventilation have not been studied in *aquaporin 1-* or *aquaporin 5*-knockout mice. *Aquaporin 1*-knockout mice have not shown alterations in lung edema in other models of ALI, including sepsis and acid aspiration (27,28). Other factors may account for the role for aquaporins in lung edema formation in VILI. It is possible that stretch may have increased aquaporin channel expression or activity, but this has not been studied. Alternatively, the stress failure of the endothelium as seen on electron microscopy may also lead to loss of aquaporin channels and decreased ability to regulate fluid osmotic permeability secondary to the high levels of protein leak found in VILI.

In summary, the endothelium plays an important role in the lung stretch-induced pulmonary capillary leak both through the direct effects of barotrauma leading to stress failure and by stretch-induced intracellular and membrane changes that cause increased endothelial layer permeability.

#### THE ROLE OF THE ENDOTHELIUM IN HIGH TIDAL VOLUME VENTILATION-INDUCED INFLAMMATION

In contrast to its early effects on endothelial permeability, large tidal volume ventilation results in a delayed induction of cytokine production and neutrophil influx. Studies of high tidal volume ventilation in animal models (including mice, rats, sheep, and rabbits) have demonstrated increased levels of macrophage inflammatory protein (MIP)-2 (which is analogous to interleukin [IL]-8 in humans), IL-1 $\beta$ , IL-6,

VILI refers to in vivo studies of ventilator-induced lung injury; CS refers to in vitro studies of cells under cyclical strain; perfusion refers to ex vivo studies using perfused isolated lung. Pi, phosphorylation.

and TNF- $\alpha$  in the BAL fluid. These changes correlated with increased expression of the corresponding mRNA in the lung parenchyma (29). The source of these cytokines has not been identified in vivo, but in vitro cyclic stretch induces production of IL-8, IL-6, and IL-1 $\beta$  in alveolar epithelial cells; IL-8 and IL-6 in pulmonary artery ECs; and IL-8 in macrophages (30–34). Production of chemotactic cytokines is temporally related to an influx of neutrophils into the alveolar space, as evidenced by myeloperoxidase assay (which measures influx of neutrophils in the interstitium, vessels, and airways) and by BAL (which measures movement of the neutrophils into the airways).

The mechanism of stretch-induced cytokine production has been found to involve activation of the c-jun N-terminal kinase (JNK) and nuclear factor (NF)- $\kappa$ B pathways. In the intact mouse treated with subcutaneous injection of

SP600125, a specific inhibitor of JNK, and in mice deficient in either JNK1 or JNK2, there was an attenuation of MIP-2 production and neutrophil influx (35). Studies of in vitro cyclic mechanical stretch showed that cyclic stretch-induced IL-8 production was dependent on both activation of JNK and NF- $\kappa$ B in alveolar epithelial cells and JNK in pulmonary artery ECs (32,33). Similar studies examining a role for NF- $\kappa$ B have yet to be performed in pulmonary artery ECs exposed to cyclic stretch. However, in human umbilical vein ECs (HUVECs), laminar shear stress resulted in a dose- and time-dependent increase in NF- $\kappa$ B nuclear translocation and induction of IL-8 mRNA expression (31).

Another possible mechanism of stretch-induced IL-8 expression is the production of reactive oxygen species (ROS). In aortic ECs, cyclic stretch has been shown to induce ROS levels through an nicotinamide adenine dinucleotide (NADH)/

nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-dependent pathway (36). We have shown that the antioxidant N-acetylcysteine blocks stretch-induced production of IL-8 in alveolar epithelial cells in vitro (37) and attenuates high tidal volume ventilation-induced lung neutrophil influx in vivo (38). Whether a similar mechanism holds true for pulmonary artery ECs remains to be seen.

In addition to IL-8, IL-6 (another inflammatory cytokine) has been found to be increased in the serum of ARDS patients ventilated with large tidal volumes (39). In HUVECs, constant uni-axial strain<sup>1</sup> resulted in rapid (15 minutes) phosphorylation and degradation of I $\kappa$ B and translocation of NF- $\kappa$ B to the nucleus and subsequent induction of *IL-6* mRNA expression (2 hours). This effect was blocked by NF- $\kappa$ B inhibitors pyrrolidine dithiocarbamate (PDTC) and SN50, or antisense oligodeoxynucleotides for NF- $\kappa$ B subunits p65 and p50 (30). The stretch-induced activation of NF- $\kappa$ B in HUVECs was found to be transduced by cell membrane integrins. Continuous uni-axial strain of HUVECs caused phosphorylation of FAK and paxillin, markers of integrin activation. GRGDNP, a blocker of integrin activation, abolished stretch-induced IL-6 production. Inhibitors of PKC and phospholipase C also blocked IL-6 production and NF- $\kappa$ B activation, suggesting that mechanical stretch results in integrin activation, causing downstream activation of PKC and phospholipase C with subsequent translocation of NF- $\kappa$ B to the nucleus and transcription of *IL-6* mRNA (40). We have also found in airway epithelial cells that cyclic stretch-induced IL-6 production was blocked by the inhibition of NF- $\kappa$ B and JNK activity with antioxidants (37).

Cyclic stretch has been shown to induce intercellular adhesion molecule (ICAM)-1 and P-selectin expression in HUVECs and kidney mesangial cells (41,42). ICAM-1 was found to be necessary for cyclic stretch-induced adhesion of monocytes to HUVECs and neutrophils to mesangial cells (41,42). In the lung, adhesion molecules are not always necessary for migration of leukocytes, especially in the capillary bed, although they may be important in the postcapillary venules (43). In mice, however, infusion of a neutralizing anti-L-selectin antibody prevented high tidal volume-induced

1 In vitro cell stretch can be performed with bi-axial strain (i.e., strain applied in two dimensions) or uni-axial strain (i.e., strain applied in one dimension).

Figure 54.1. Effect of tidal volume on lung water content. Lung water content in rats as assessed by wet/dry weight ratio was not affected by volume ventilation at 85 breaths per minute for 2 hours with tidal volume (TV) of 7 mL/kg (Group II) compared to nonintubated control rats (Group I) but was increased by TV of 20 mL/kg (Group III). HgCl<sub>2</sub>, a competitive inhibitor of aquaporins 1 and 5, significantly ( $p < 0.05$ ) worsened the wet/dry weight ratio in rats ventilated at a TV of 20 mL/kg (Group VI) but not at 7 mL/kg (Group V). Equimolar infusions of cysteine 5 minutes after the HgCl<sub>2</sub> prevented the excess increase in lung wet/dry weight ratio caused by the HgCl<sub>2</sub> in the rats ventilated at TV 20 mL/kg (Group VIII). \* $p < 0.05$  from TV 7 mL/kg (Group II) or normals (Group I); # $p < 0.05$  from TV 20 mL/kg. sequestration of neutrophils (44). In another study, administration of a new anti-inflammatory agent that blocks CD11b/CD18 (the leukocyte  $\beta$  integrin that binds ICAM-1) inhibited neutrophil infiltration in surfactant-depleted rabbits on mechanical ventilation (45). Taken together, these data implicate an important role for the endothelium in mediating lung neutrophil influx with high tidal volume ventilation.

Changes in the extracellular matrix (ECM) may also affect EC function during mechanical ventilation. The ECM of the lung is made up of many different components, including collagens, elastin, proteoglycans (PGs), and stromal cells. PGs are a heterogeneous group of molecules that make up the ground substance of the ECM. PGs consist of a core protein to which one or more glycosaminoglycans (GAGs) are covalently attached. The GAGs in the lung include chondroitin sulfate, dermatan sulfate, heparan sulfate, and hyaluronan (HA). HA is a negatively charged, linear GAG composed of alternating N-acetyl glucosamine and glucuronic acid in repeating disaccharide units, with no covalently linked protein core. High-molecular-weight HA (>500 kDa; HMW HA) is an important component of the lung interstitium and functions to maintain the structural integrity and compliance of the normal

lung. Low-molecular-weight HA (<500 kDa; LMW HA) can function as an intracellular signaling molecule in inflammation. We have found increased production of LMW HA in lung parenchyma of rats exposed to high tidal volume ventilation (46). LMW HA can be produced by de novo synthesis by HA synthase 3 (HAS3). We have found that mice lacking HAS3 do not produce LMW HA in response to high tidal volume ventilation and were resistant to high tidal volume ventilation-induced cytokine production and neutrophil influx (47). LMW HA (200–300) induced IL-8 in human pulmonary artery ECs by binding to CD44, Toll-like receptor (TLR)2, TLR4, and RHAMM (48). Low-molecular-weight HA fragments have also been found to induce IL-8 expression by human microvascular ECs isolated from neonatal dermis (49) and TLR4-blocking antibody inhibited HA fragment-induced IL-8 production. As compared to wild-type mice, TLR4-deficient mice failed to increase serum MIP-2 production in response to infusion of HA fragments.

Circulating HA has been shown to be cleared by sinusoidal ECs in the liver. In patients with hepatotoxicity, and therefore damaged sinusoidal ECs, increased levels of both HMW and LMW HA have been found along with increased levels of serum IL-8, suggesting the increased levels of LMW HA may have led to inflammation (50). Thus, another source of IL-8 production with high tidal volume ventilation may be via the production of LMW HA, which in turn induces IL-8 production by ECs.

In addition, we have found increased levels of LMW HA in the serum of rats ventilated with high tidal volumes and in the serum of patients with ARDS (D.A. Quinn and C.A. Hales, unpublished data). We have previously shown that high tidal volume ventilation of the lung caused increased capillary leak in the kidney (51). We hypothesize that lung stretch increased expression of HAS3, leading to increased production of LMW HA. The LMW HA produced in the lung can be released into the circulation, potentially leading to activation of the systemic endothelium.

#### KEY POINTS

- The endothelium plays a key role in lung barotrauma caused by VILI.
- The endothelium modulates lung stretch-induced pulmonary capillary leak both through the direct effects of barotrauma, leading to stress failure, and by stretch-induced intracellular and membrane changes that cause increased endothelial layer permeability.
- The endothelium modulates lung stretch-induced inflammation through upregulation of neutrophil binding sites, the production of cytokines through

stretch-induced oxidant production with JNK and NF- $\kappa$ B activation, and through stimulation by inflammatory mediators, such as LMW HA produced during lung stretch.

#### Future Goals

- Many of the data here have been produced in ECs from a variety of sources and not only pulmonary artery ECs. It has been shown that ECs from different vascular beds behave differently. These data need to be confirmed in pulmonary artery ECs both in vitro and in vivo experiments.
- The role of nonprotein, noncytokine stimulants of endothelium, such as LMW HA, is a new and exciting field. These inflammatory mediators need further exploration and may provide a new target for therapeutic interventions.

## Endothelium and Diving

Alf O. Brubakk, Olav S. Eftedal, and Ulrik Wisløff

*Norwegian University of Science and Technology, Trondheim, Norway*

Diving, as a method for exploring and exploiting the underwater world, requires equipment and methods that have been available for only about 200 years. The first practical procedures for decompression from dives were developed by Boycott and colleagues (1) at the beginning of the 1900s. With the development of the self-contained underwater breathing apparatus (SCUBA) in the 1940s, divers were able to swim freely, and saturation diving methods<sup>1</sup> developed in the 1950s allowed divers to stay under pressure for weeks.

Divers may reach a depth of 50 m using air as their breathing gas. Beyond 50 m, it is necessary to employ helium mixtures, owing to depth-related toxic effects of nitrogen and excessive oxygen tension. For a review of the general effects of diving on the organism, the reader is referred to Bennett and Elliott (2).

The major risk of injury associated with diving relates to decompression upon return to the surface. Gas will be taken up in solution by the tissues of the body during the dive proportional to the depth, and the uptake is exponentially related to the time spent under pressure. The gas content at the bottom is given by Henry's law:

$$C = P \times L \quad (\text{Equation 1})$$

where P is partial pressure of the gas and L is the solubility coefficient.

Upon returning to the surface, this excess gas must be eliminated. Gas elimination follows an exponential curve, with time constants determined by blood flow to the different tissues. If pressure is reduced faster than gas can be eliminated, the partial pressure of gas in the tissue will be higher than the environmental pressure. This supersaturation can lead to gas coming out of solution, forming bubbles. These bubbles are considered to be the cause of clinical symptoms, so-called decompression sickness (DCS). Symptoms of DCS include pain in muscles or joints or more severe symptoms from the cardiovascular and the central nervous systems.

Vascular bubbles can be observed following nearly all decompressions (3). In the majority of dives, no acute clinical symptoms occur, and these bubbles have therefore been termed "silent bubbles" (4). Intravascular gas bubbles are more likely to form on the venous side of the circulation, both because the inert gas tensions are higher here than on the arterial side and because the blood pressure is lower (5). These bubbles may become lodged in the pulmonary vasculature and eliminated, or they may gain access to the arterial circulation via a patent foramen ovale (PFO) or vascular shunts in the lung. Such shunts seem to open even after light exercise (6). Several studies have documented that neurological DCS is related to the presence of a PFO (7,8), thus indicating that arterialization of vascular bubbles may be one important mechanism for injury. However, other mechanisms have also been proposed (9).

A working hypothesis for this chapter is that vascular bubbles play an important role in the pathophysiology of neurological DCS by altering endothelial cell (EC) phenotypes. Even if acute clinical symptoms are lacking, such alterations could form the basis for possible long-term injuries. An important goal is to identify the properties of the bubble and/or host that determine progression to DCS and to use this information to prevent injury and long-term sequelae.

A search on PubMed using the keywords *endothelium* and *diving* yielded nine hits, only one of them published after 2000. Similarly, a search for *endothelium* and *decompression* generated nine hits, including four from our own laboratory, whereas *endothelium* and *gas bubbles* gave 21 hits, only seven of these related to diving. Thus, the endothelium has not been a major focus in diving research.

### MECHANISMS OF VASCULAR BUBBLE FORMATION

De novo formation of gas bubbles requires supersaturations exceeding those found in the vascular system after a dive by a factor of 50 to 100 (10). Thus, it is widely held that bubbles

<sup>1</sup> Saturation diving is a method in which the diver stays at pressure for a period long enough for complete equilibration of gas tensions so that no further uptake of gas takes place (usually at least 24 hours). This method typically is used for deep commercial diving.

grow from preformed nuclei. These nuclei are likely gas filled and have been estimated to measure  $\approx 1 \mu\text{m}$  in diameter (11). Experimental data point to their presence in the vascular system under normal conditions, although not in free-flowing blood (12–15). Harvey points out that “if bubbles come from nuclei they must arise from gas nuclei sticking to or formed on or within the endothelial linings of the vascular system or extravascular spaces, and only when they have enlarged to the point of instability do they pass into the blood stream” (15). As bubbles do not readily form intracellularly (10), there are probably no nuclei inside the ECs.

Bubbles are extremely stable on hydrophobic surfaces (16). Thus, lipid-rich microdomains on the surface of the endothelium (e.g., caveolae) may have a particular propensity for formation of and/or stable attachment to bubble nuclei (17). These are also locations where nitric oxide (NO) is produced (18). Caveolae are invaginations in the vascular wall (17), and may represent a stabilizing mechanism for bubbles (19). This indicates that caveolae are attractive sites for the formation of bubble nuclei. A reduction in surface tension of hydrophobic membranes has been shown to increase the number of stable nuclei (20). The latter study also showed a lack of correlation between bubble formation and surface tension of the fluid above the membrane; if anything, the reverse seemed to be true.

However, as we have previously demonstrated that a small reduction in surface tension of serum will significantly increase bubble production in vivo (21), we have to assume that this reduction reflects a reduction of surface tension of the vessel wall. Thus, we can hypothesize that spatial and temporal differences in surface tension of the vessel wall contribute to the large intra- and interpersonal variation in bubble formation by variation in the number and size of bubble nuclei.

Increased body fat is associated with increased vascular bubble formation and an increased risk for DCS (22,23). A correlation exists between blood lipids and obesity (24,25), and an increase in blood lipids in individuals suffering from obesity would decrease surface tension of blood and probably also of the vessel wall. Thus, it is likely that obesity will increase both the number of nucleation sites and the size of nuclei and bubbles. Because the speed of bubble growth is significantly influenced by the size of the nuclei, these individuals may be at risk for faster bubble growth during dives, increasing their susceptibility to DCS as the risk of DCS is related to the volume of gas in bubbles (26).

The growth of bubbles is determined by the LaPlace equation:

$$P_{\text{bubble}} - p_{\text{amb}} = 2\gamma/R + \delta \quad (\text{Equation 2})$$

where  $P_{\text{bubble}}$  is the gas tension inside the bubble,  $p_{\text{amb}}$  is the gas tension in the fluid surrounding the bubble,  $\gamma$  is the surface tension of the liquid-gas interface,  $R$  is bubble radius, and  $\delta$  is additional deformation pressure opposing bubble expansion.

If the gas tensions in the fluid (e.g., blood) exceed the gas tension inside the bubble, the bubble will grow. As a reduction

in surface tension will reduce the pressure gradients required for growth, a reduction in external deformation pressure (e.g., blood pressure) will have the same effect. Note also that an increase in bubble radius will reduce pressure inside the bubble.

Even if no direct observation of this exists, bubbles are probably formed from nuclei adhering to the endothelium. Their presence in free-flowing blood must indicate that the adhering forces have been reduced or that they have grown to a size that allows them to be washed away by the bloodstream. It is well established that an increase in venous blood flow caused by muscle contraction increases the number of bubbles observed the venous outflow tract after a dive.

### FACTORS INFLUENCING BUBBLE FORMATION

In studies of rats we have shown that the number of vascular bubbles observed following a dive can be significantly reduced by performing heavy physical exercise 20 hours before the dive (Figure 55.1). This protective effect was absent when exercise was performed 48 hours before the dive, even in highly trained rats (27). Moreover, exercise sooner than 10 hours before the dive had no effect on bubble formation. Similar findings have been reported in humans. In divers performing a dive to 18 m, bubble formation was significantly reduced in those that performed heavy exercise 24 hours before the dive (28). A study by Blattau and colleagues indicated that exercise at lower intensities 2 hours before a dive might have similar effects in divers (29).

Exercise induces production of endothelial-derived NO in the vascular system through increase in blood flow and shear stress, not only in the organs directly involved in the exercise (30,31). NO is not only a potent vasodilator but also reduces the “stickiness” or adhesiveness of cellular particles to the endothelial surface (32,33). This may also reduce the number of nuclei available for bubble production. The very

Figure 55.1. Median bubble grades in sedentary and exercised rats (90-minute intervals at 90% max). The reduction in bubble grade in the animals exercised 20 hours pre-dive is significant. (Data used with permission from Wisloff U, Brubakk AO. Aerobic endurance training reduces bubble formation and increases survival in rats exposed to hyperbaric pressure. *J Physiol.* 2001;537(Pt 2):607–611.)

microdomain that is believed to promote adherence of bubble nuclei, namely the caveolus, is also a key regulator of NO production in ECs (18). We have shown that exogenous NO before a dive reduces bubble formation after the dive, a similar effect as was achieved by exercise 20 hours pre-dive. NO blockade increases bubble formation (27,34,35).

Traditionally, efforts to reduce formation of bubbles, hence incidence and/or severity of DCS, have focused mainly on reducing supersaturation by slowing the rate of ascent. Although there is no question that these protocols have reduced DCS-related morbidity, there still remains considerable room for improvement (36,37). Based on the above observations, we believe that the endothelium represents a potentially valuable target for preventing serious (e.g., neurological) DCS.

Traditionally, the correlation between weight and the propensity to form gas bubbles has been attributed to the fact that nitrogen is far more soluble in fat than it is in water (38), thus resulting in a positive correlation between body weight and supersaturation of nitrogen. However, an alternative explanation relates to differences in surface tension. Surface tension is negatively correlated with the number of bubble nuclei (20). A reduction in surface tension may be brought about by an increase in lipids in the blood. We have shown that exercise 24 hours before, or NO donors given immediately before, a dive reduces the amount of bubbles in heavy rats. Conversely NO blockade promotes bubble production in sedentary light rats (27,34,35). These observations indicate that NO is an important mechanism of bubble formation. However, exercise 24 hours before the dive prevents the bubble-inducing effect of NO blockade in light rats, thus there must also be NO-independent mechanisms involved. Interestingly, this effect is not observed in heavy rats (Alf O. Brubakk, unpublished observation). We have also seen that exercise immediately before a dive reduces the protective effect of 24 hours pre-dive exercise and NO donors in heavy, but not in light, animals (39).

It has been shown that blood lipids are increased by approximately 30% immediately after heavy exercise (37). This is followed by a decrease in total blood lipids over the next several hours (38), whereas high-density lipoprotein (HDL) is increased 24 hours after exercise (39). Elevation of blood lipids reduces surface tension, which in turn facilitates production of bubble nuclei (19). Also, low-density lipoprotein (LDL) and cholesterol have been shown to decrease NO production, whereas HDL increases NO activity (40,41). This can explain the time-dependent response of exercise on bubble formation. One might also speculate that the differences observed between light and heavy rats in effects of exercise may be caused by different levels of blood lipids, but to our knowledge this has not been studied.

The observations discussed earlier are summarized in Table 55-1. Based on these data, one might speculate that lean animals have lower basal levels of lipids and hence fewer bubble nuclei pre-dive and fewer bubbles during/post-dive. A study by Wisløff and colleagues has shown that heavy rats have

higher levels of blood lipids than leaner rats (40). This will, however, not explain why NO blockade promotes bubble formation in lean animals, an effect that is prevented if exercise is performed 24 hours before the dive. One might speculate that the protective effect of exercise observed 24 hours prior to diving may be related to a time-dependent reduction in circulating lipids. The resulting effects on surface tension will promote washing out of existing bubble nuclei and will serve to inhibit formation of new bubble nuclei. This could be a mechanism to explain why exercise 24 hours before a dive protects lean but not heavy animals that are NO blocked. In the lean animals, with possible lower lipid levels, exercise will reduce blood lipids, allowing endothelial adhesiveness to be reduced sufficiently to allow washing out of bubble nuclei, although the effect is not strong enough in the fat animals with blocked NO. This mechanism could also explain why heavy exercise shortly before decompression could affect bubble formation in heavy but not lean animals. The findings above support the hypothesis that bubble nuclei and their adherence to the endothelium are critical for bubble formation in the blood. However, once bubbles get larger, a reduction in surface tension in the blood will reduce adhesiveness to the vessel wall (41), thus allowing more bubbles to enter the bloodstream.

Other substances may also play a role in bubble formation. Bradykinin is a potent vasodilator, acting by increasing endothelial production of endothelial hyperpolarizing factor (EDHF), which acts on the smooth muscle of the vessels by an NO-independent mechanism (42). In normal endothelium, NO is apparently the main vasodilator; when the endothelium is injured, EDHF production is increased. Bradykinin is, however, also a potent proinflammatory hormone, increasing adhesiveness of cellular elements to the vessel wall (43). Some studies have shown that EDHF may have anti-inflammatory properties, reducing the adhesiveness of the endothelium, similar to the effect of NO (44), indicating that the response to endothelial injury is quite complex.

Chryssanthou and colleagues developed an experimental model in genetically obese mice and showed that the lighter

Figure 55.2. FMD in controls and after a single air dive to 280 kPa for 80 minutes. (Data used with permission from Brubakk AO, Duplancic D, Valic Z, et al. A single air dive reduces arterial endothelial function in man. *J Physiol.* 2005;566(Pt 3):901–906.)

animals did not develop lethal DCS, whereas the heavier animals died following massive bubble formation (45). However, if bradykinin was given to the animals during decompression, mortality dramatically increased. Bradykinin given prior to compression did not have this effect. His group also showed that if anti-inflammatory drugs were administered prior to decompression, mortality was dramatically reduced (46). Bubbles were not measured, but it appears that fewer bubbles seem to be formed in the control animals who did not receive bradykinin (46). This evidence indicates that properties of the endothelial surface are of considerable importance for bubble formation after diving.

### EFFECT OF BUBBLES ON THE ENDOTHELIUM

As discussed earlier, the endothelium plays an important role in the formation of decompression-induced vascular bubbles. Several studies show that once formed, bubbles will damage or reduce the function of the endothelium in a dose-dependent manner (47–49). A recent study in experienced divers showed that arterial endothelial function as evaluated by flow-mediated dilatation (FMD) was reduced after a single air dive where very few venous gas bubbles could be detected in the pulmonary artery (Figure 55.2) (50). Philp and colleagues showed in rats that circulating ECs could be detected in the blood in proportion to the severity of DCS (51).

Activation of the endothelium may lead to the formation and release of so-called endothelial microparticles (EMP) (52). These may reduce endothelial function (53), possibly by increasing expression of the endothelial adhesion molecules such as vascular cell adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1, and E-selectin and by influencing NO production. Increased EMP levels have been reported in a number of cardiovascular diseases and

after using a heart–lung machine (54). It is therefore not unlikely that gas bubbles from dives can lead to such activation. Oxygen radicals may also activate endothelium (55). This is probably also part of the dive effect observed above, as the reduction in endothelial function can be prevented by administering the antioxidants vitamins E and C before the dive.

Ward and colleagues (56) demonstrated that gas bubbles may activate complement in vitro. C5a is a potent molecule generated from complement activation through cleavage of C5 and is usually accompanied by formation of the membrane attack complex (MAC). C5a increases endothelial P-selectin expression, secretion of von Willebrand factor, and smooth muscle contraction. Complement activation will lead to activation of neutrophils and the formation of MAC that will lead to the destruction of nucleated cells (57). This process leads to adhesion of leukocytes to the endothelial layer and eventually to their transport through the endothelium. Activation of neutrophils has been demonstrated during decompression from saturation dives (58). In the skin, C5a will lead to erythema and edema and promote infiltration of inflammatory cells (59). This picture is very similar to what can be actually observed in the skin of divers following decompression. It is of interest to note that skin changes related to decompression are associated with the presence of a PFO (60).

Using monoclonal antibodies, Bergh and colleagues (61) demonstrated dose-dependent activation of C5a by gas bubbles in vitro. They also showed that the response was similar regardless of the content of the bubble, indicating that it was the surface of the bubble that was of importance for activation. The study also reported considerable variation in response over time (a period of 6 months) both in rabbits and man. This variation was not considered by Ward and colleagues, who claimed that individuals could be divided into sensitive and nonsensitive groups according to the degree of activation of complement and that clinical symptoms of decompression illness were related to the degree of activation (62).

In a subsequent study on divers, Hjelde and associates have been unable to verify Ward's finding (63). However, interestingly enough, the study showed that those individuals who had a low level of C5a before the dive produced many gas bubbles. Furthermore, a single air dive seemed to reduce the level of C5a. We have no explanation for this observation, but the reduction in C5a levels in the blood may indicate that diving and gas bubbles activate C5a receptors as well as C5a, thus leading to binding of C5a and hence removal from the blood in vivo. Shastri and colleagues also failed to observe any activation of C3a after a dive (64). However, activation of C5a has been demonstrated by Stevens and associates (65) in divers up to 14 hours after they had been treated for DCS. Anti-C5a failed to protect the rabbit endothelium against injury after exposure to gas bubbles (66).

The data previous indicate that the effect of bubbles on complement is complex in vivo. It has been shown that complement activation and increased production of C5a will lead

to increased expression of circulating endothelial adhesion molecules about 4 hours after injury (67). This is in good agreement with our finding that a reduction in endothelial function is observed between 1 and 6 hours after exposure to gas bubbles (48). If decompression with endothelial damage leads to an inflammatory response, this may reduce NO bioavailability (68). An increase in VCAM-1 and ICAM-1 was observed in the blood of divers 5 minutes after surfacing; this effect lasted 24 hours (69).

Complement activation seems to be the main mechanism for acute lung injury not caused by gas bubbles (70). Activation and damage to ECs during acute inflammation can lead to leakage of plasma proteins and microvascular hemorrhage, which appear to be major contributing factors in the development of acute lung injury. The changes in pulmonary function seen in divers, including a reduction in carbon monoxide diffusion capacity and lung compliance (71), would support the hypothesis that inflammatory processes in the lungs are a result of the decompression process. The reduction in diffusion capacity is quite rapid and follows the development of bubbles (72). Hyperoxia can lead to an increased expression of vascular adhesion molecules (73), thus it is reasonable to suggest that exposure to increased oxygen tensions during the dive and bubbles during decompression may have additive effects.

Based on the above, the endothelium in the lung vasculature must be considered a primary target organ for gas bubbles and is probably exposed to gas bubbles to a greater or lesser degree in all decompressions. Generally, in diving the main focus on the lungs has been on their role as a filter, through which the bubbles are eliminated before they can be transmitted to the arterial side, where their potential for damage is greater. However, as pointed out above, bubbles will probably also enter the arterial circulation, either as a result of high gas load on the lungs that exceeds the filtering capability (74) or through shunts or a PFO.

Most divers have repeatedly been exposed to vascular bubbles during their career. If clinical signs of serious DCS can be avoided, exposure to vascular bubbles does not seem to injure the spinal cord (75). In a group of 10 amateur and 10 professional divers who had performed extensive diving, no histological changes could be seen. Five of the divers had a history of mild musculoskeletal DCS and several had aseptic bone necrosis (likely related to recurrent decompression). In the brain, significant loss of cells in the ependymal layer of the ventricles could be detected in a group of experienced divers when compared to controls (76). This is probably caused by gas bubbles in the spinal fluid; such bubbles will probably primarily adhere to the lining of the ventricles. Gas bubbles in the vascular system in the brain can lead to breakage of the blood-brain barrier (77). Broman and colleagues have demonstrated that even very short contact between gas bubbles and endothelium (1–2 minutes) will lead to such breakage (78). Furthermore, studies in rabbits indicate that such contact leads to endothelial damage and progressive reduction of cerebral blood flow and function (79).

## PREVENTION OF ENDOTHELIAL INJURY

It has been shown that exposure to 280 kPa oxygen for 45 minutes, as in hyperbaric oxygen (HBO<sub>2</sub>) therapy, inhibits B2-integrin-dependent adherence of neutrophils to the endothelium (80,81). Pre-dive treatment with HBO<sub>2</sub> has been shown to protect against lung and CNS injury following decompression, probably through the same mechanisms (82). This anti-inflammatory effect is probably also a key factor in the response to HBO<sub>2</sub> for treatment of manifest decompression sickness. It is also worth noting that exercise prevented CNS injury in the pig model of decompression sickness used by Broome and associates (83). However, in the latter study the time between the last exercise bout and the dive was not reported. Thus, it is formally possible that the beneficial effects were related to a reduction in bubble production, as observed in rats and humans following exercise 24 hours before a dive (27,84).

Heat shock proteins (HSPs) are activated in response to a number of stressors, including hyperoxia or hypoxia, heat, cold, exercise, and some heavy metals or drugs. They have an important function in controlling the folding and structure of proteins and protect the cells from injury (85). Divers may be exposed to a number of stressors (hyperoxia, hard physical work, exposure to infections, etc.) that could possibly induce HSP formation. We have shown in rats that a short increase in body temperature to 42°C 24 hours before the dive reduced mortality by 50% and that this exposure increased HSP70 levels but not HSP90 or endothelial NO synthase (eNOS), and that bubble formation was not affected (A. O. Brubakk, unpublished observation). These findings are supported by a study showing increased HSP70 expression in animals with decompression sickness (86). Exercise also has an effect on HSP expression, and HSPs may represent a link between flow-mediated induction of shear stress and NO (87). A study by Siu and colleagues (88) showed that moderate exercise increased HSP70 48 hours after the last exercise bout. Other studies have shown that HSP70 increased immediately after exercise, with a new increase 24 and 48 hours later (89). Recently it has become clear that exercise (90), as well as hyperbaric oxygen (91,92), can act as a preconditioning regimen, protecting against injury, probably through the regulation of HSP and NO. Lochner and associates (93) showed that preconditioning in the presence of N(G)-nitro-L-arginine methylester (L-NAME) attenuated this effect, and an NO donor had the same effect as preconditioning by ischemia. Thom and colleagues showed that hyperoxia increases NO production by increasing HSP90 expression (94). HSP seems to be of crucial importance for preventing an increased production of radical oxygen species. HSP90 is an important modulator of eNOS production, determining the balance between NO and reactive oxygen species and may thus be of importance in preventing injury caused by increased oxygen tensions (95).

However, some data indicate that HSP activation can also increase damage to the endothelium. Certain bacteria produce HSPs, which are strongly antigenic and can trigger a

significant immunoresponse (96). One study demonstrated increased endothelial damage in animals with such a response (97). Infections still are a significant problem in saturation diving operations (98). Consequently, if the bacterial flora in the saturation chamber can produce such an immunological response, saturation diving may have a higher risk of endothelial damage due to bubbles than other types of diving.

Further studies are needed to elucidate the role of HSPs in the prevention of DCS and bubble injury.

## CONCLUSION

It is well documented that gas bubbles occur both in the arterial and the venous side of the circulation following decompression from a dive. Even if many questions still exist, we think it is well documented that these bubbles will reduce endothelial function. We suggest that this may be a central mechanism in the development of serious decompression injury and possibly also long-term effects of diving. Traditionally, protection against DCS and serious injury has been focused on influencing bubble formation by changing ascent procedures from a dive. The data presented in this chapter indicate that vascular bubble formation, which may be important for central nervous system injury, is significantly influenced by the properties of the endothelium. As these properties can be changed in various ways, it opens up a novel way of preventing injury from diving.

### KEY POINTS

- Vascular gas bubbles leading to endothelial dysfunction are the main cause of neurological injury following decompression.
- Vascular gas bubbles are formed from nuclei adhering to the vascular wall.
- Exercise and/or NO reduce the adherence to the vessel wall and prevent vascular bubble formation.
- An increase in vascular lipids will increase the number of nuclei and vascular bubbles.
- HSP may protect against bubble-induced injury.

### Future Goals

- A reduction in the incidence of DCS has occurred over the last 40 years. However, the relative number of incidents of DCS involving the central nervous system has increased. The data presented indicate that injury of the CNS may be related to vascular bubble formation and endothelial function. Although nearly all research in this field has focused on supersaturation and methods to prevent that, future improvements may be related to methods to

improve endothelial function and hence influence nucleation. If the relationship between bubble formation and lipids is confirmed, then increasing obesity in the diving population will pose additional challenges. One testable hypothesis can be that individuals with increased levels of cholesterol have an increased risk of DCS and increased bubble formation.

- Age, and possibly a low aerobic capacity, is considered a risk factor for DCS. Our studies have shown that exercise performed 24 hours before a dive prevents bubble formation and that this effect is related to NO production. These studies did not show any protective effect of increased aerobic capacity. However, some human data indicate that bubble formation and the risk of DCS is related to aerobic capacity (22,99). The ability of the endothelium to produce NO is reduced in subjects, though, and this is an effect that can be improved by exercise (see Chapter 56). In a group of subjects older than 60 years, Taddei and colleagues (100) found that those who performed regular exercise ( $\text{VO}_2$  max 63.7 mL/kg/min) had a significantly better endothelial function than sedentary individuals ( $\text{VO}_2$  max 38 mL/kg/min). Thus, the importance of aerobic capacity and the timing of exercise in relation to the dive should be evaluated.
- One significant problem in repeated dives that has never been satisfactorily solved is the question about the safe time between dives. Generally it is assumed that the reason a second dive is considered more risky is that there remains inert gas in the body, leading to an increased supersaturation in the second dive. However, the work described in this chapter indicates that the problem also may be related to the endothelial lining being damaged by the first dive. Thus, studies of the repair process and the factors involved may change dive procedures. This can be studied both experimentally and by determining endothelial function following dives of different severity.
- Studies by Wisløff and associates have shown that differences in endothelial function probably are genetically determined and that these differences are linked to aerobic capacity (40). This could be a key to understanding the significant interindividual differences in bubble formation observed. In studies in which two groups of divers of similar age and physical characteristics performed the same dive, bubble formation varied by a factor of 100 between the groups (50). Changes in gene expression due to environmental factors may be of importance.

- Numerous studies have shown that endothelial dysfunction is independently related to future cardiovascular events (e.g., myocardial infarction, stroke, transient ischemic attack) (101). It is thus conceivable that repeated endothelial injury caused by vascular gas bubbles may contribute to the development of atherosclerotic lesions and that this may be a basis for long-term effects of diving.
- The studies described indicate that drugs may be used to modify decompression and to reduce the risk of bubble formation and hence the risk of serious neurological injury. This is of particular importance if rapid decompressions have to be performed as in evacuation from a sunken submarine or emergency evacuation from a saturation chamber. Based on the above, possible candidates for such an approach are NO donors, statins, anti-inflammatory drugs, or HSP.

ACKNOWLEDGMENTS

The studies that form the basis for this review have been supported mainly by the Norwegian University of Science and Technology (NTNU); by Phillips Petroleum Norway through the HADES program; and by the Norwegian Petroleum Directorate, Norsk Hydro, Esso Norge, and Statoil under the “dive contingency contract” (No 4600002328) with Norwegian Underwater Intervention (NUI).

## Exercise and the Endothelium

---

Ulrik Wisløff, Per M. Haram, and Alf O. Brubakk

*Norwegian University of Science and Technology, Trondheim, Norway*

Today's human body was "designed," through natural selection, to maximize fitness in the early ancestral environment, a time in which physical activity was obligatory for survival (see Chapter 16). As an important corollary, the human body is not ideally suited for the modern Western lifestyle, where inactivity is the norm. Indeed, physical inactivity is now established as an independent risk factor for cardiovascular morbidity and mortality, an effect that is similar to that of high blood pressure, high levels of blood lipids, and smoking combined (1). An important prerequisite for reversing this trend and prolonging life is to encourage a change in societal attitude such that physical activity, and not a sedentary lifestyle, is viewed as the physiological and behavioral norm. Indeed, exercise training results in reduced primary and secondary vascular events, independent of amelioration of other cardiac risk factors. Exercise is associated with significant physiological adaptations in many systems, including skeletal, muscle, heart, metabolism, and the vasculature. Central to the protective effect of exercise on endothelium is increased bioavailability of nitric oxide (NO), achieved through increased production of NO and decreased reactive oxygen species (ROS)-mediated inhibition of NO activity. The goals of this chapter are to describe some of the long- and short-term adaptations to exercise in the blood vessel endothelium, to review potential intracellular signaling pathways and other molecular mechanisms associated with these adaptations and to relate these changes to integrated performance and health effects.

### ENDOTHELIAL FUNCTION

The endothelium was previously regarded as an inert cellular layer lining the blood vessels, but it has since been acknowledged as an important organ with autocrine and paracrine functions. The endothelial isoform of NO synthase (eNOS) produces NO, which is the most important endothelial-derived relaxing factor. In addition to relaxing vascular smooth muscle, NO counteracts the formation of

atherosclerosis through inhibition of leukocyte adhesion and invasion, smooth muscle cell proliferation, platelet aggregation, and inflammation. In short, NO is critical for endothelial function. Abnormalities in one or more pathways that ultimately regulate the availability of NO may lead to endothelial dysfunction, which is characteristic of cardiovascular disease and coronary risk factors, including hypertension, hypercholesterolemia, cigarette smoking, diabetes mellitus, and obesity. Importantly, endothelial dysfunction, as defined by impaired endothelial-dependent vasorelaxation, has been identified as an independent risk factor and a strong prognostic marker of long-term cardiovascular morbidity and mortality in latent and manifest cardiovascular disease (2). Thus, the preservation of endothelial function should be a major therapeutic goal.

### IS THERE A LINK BETWEEN AEROBIC CAPACITY AND ENDOTHELIAL FUNCTION?

It is generally accepted that there exists a close link between aerobic capacity (maximal oxygen uptake) and endothelial function in humans (3). In a recent study, we added support to these observations by demonstrating that rats with inborn low aerobic capacity had reduced endothelial function compared with high-aerobic-capacity controls, as determined by acetylcholine-mediated vascular relaxation in isolated ring segments of carotid arteries (4).

In keeping with these observations, many studies have demonstrated an ameliorating effect of exercise on endothelial function and aerobic capacity, even in rats with inborn low-aerobic capacity (Table 56-1) (5). It is widely held that these benefits are most pronounced in (and perhaps even limited to) subjects with preexisting endothelial dysfunction. For example, exercise has been shown to improve endothelial function in rats with metabolic syndrome (5) (a syndrome that includes a cluster of risk factors of cardiovascular disease such as weight gain, high blood pressure, reduced endothelial

**Table 56-1: Summary of Animal and Human Exercise Studies**

<i>Health Status (Refs.)</i>	<i>Acute Exercise</i>	<i>Chronic Exercise</i>	<i>Detraining</i>
Normal rats (23)		10 weeks of high-intensity endurance training (8-min intervals at 90% of maximal oxygen uptake for 1 h, 5 d/week) improved aerobic capacity and endothelial function.	Endothelium-dependent dilation regressed completely within 2–4 weeks after cessation of training.
Normal rats (19)	A single bout of high-intensity exercise (4 × 4 min at 90% of maximal oxygen uptake) improved endothelium-dependent dilation with peak response at 12–24 hours post-exercise.		Improvement absent 48 hours post-exercise.
Normal rats (19)		6 weeks of high-intensity exercise (4 min intervals at 90% of maximal oxygen uptake, 1 h, 5 d/week) induced larger adaptation than observed after a single bout of exercise.	Effect lasted for about 1 week.
Rats with metabolic syndrome (5)	A single bout of high-intensity exercise (4 × 4 min at 90% of maximal oxygen uptake for 1 h) improved endothelial function measured 24 hours post-exercise. No effect after a single bout of exercise at 70% of maximal oxygen uptake.		Improvement absent 48 hours post-exercise.
Rats with metabolic syndrome (5)		8 weeks of intensity-controlled endurance training improved aerobic capacity and endothelial function.	
Rats with postinfarction heart failure (6)		10 weeks of intensity-controlled endurance training improved aerobic capacity and endothelial function.	
Rats with high aerobic capacity (5)	Moderate (70% of maximal oxygen uptake) and high (90% of maximal oxygen uptake) aerobic intensity improved endothelium-dependent dilatation after a single bout.	Moderate (70% of maximal oxygen uptake) and high (90% of maximal oxygen uptake) aerobic intensity improved endothelium-dependent dilatation after 8 weeks of regular exercise.	
Pigs (18)	7 days of endurance training in pigs resulted in improved endothelium-dependent vasodilatation.		
Humans with chronic heart failure (22)		4 weeks of daily handgrip training improved flow-dependent dilatation.	Improvement absent 6 weeks after ceasing handgrip training.
Patients with stable coronary artery disease (7)		12 months of exercise training (20 min of bicycle ergometry per day at 70% of maximal heart rate) gave similar or better outcome compared to patients that underwent percutaneous coronary angioplasty.	
Patients with coronary artery disease (8)		Six times per day for 10 minutes on a bicycle ergometer at 80% of peak heart rate, 4 weeks, improved endothelial function.	

*(continued)*

Table 56-1 (continued)

<i>Health Status (Refs.)</i>	<i>Acute Exercise</i>	<i>Chronic Exercise</i>	<i>Detraining</i>
Patients with coronary artery disease (9)		Three times daily for 10 minutes on row ergometer and three times daily for 10 minutes on bicycle ergometer, 4 weeks, improved endothelial function.	
Patients with coronary artery disease (10)		Three times daily for 10 minutes on a row ergometer and three times daily for 10 minutes on a bicycle ergometer, 4 weeks, improved endothelial function.	
Patients with coronary artery disease (12)		After 4 weeks of in-hospital training (60 min of bicycle ergometry per day), all training patients were enrolled in a 5-month home-based program of 20 minutes' ergometry training per day and one group training session per week. Home-based endurance training sustained part of the effects of hospital-based endurance on endothelium-dependent vasodilation in coronary artery disease. However, acetylcholine-induced increases in CBF were lower after home-based exercise.	
Patients with coronary artery disease (25)		8 weeks of combined strength and endurance training with large muscle groups or home-based training sessions performing continuous aerobic exercise at 70%–85% HR <sub>peak</sub> for up to 45–60 minutes. Both exercise training regimens improved endothelium-dependent conduit vessel dilation in subjects with CAD.	Training-induced changes lost 8 weeks after cessation of training.
Patients with chronic heart failure (11)		4 weeks, six times daily for 10 minutes on a bicycle ergometer at 70% peak oxygen consumption gave correction of endothelial dysfunction.	
Patients with chronic heart failure (31)		12 weeks of either interval training (90% of peak heart rate) or moderate exercise (70% of peak heart rate) intensity improved flow-mediated dilatation in the brachial artery in patients with postinfarction heart failure. More robust changes after high-intensity training.	Still improved endothelial function in patients that trained interval at 1–3 years follow-up after cessation of the training project.
Patients with chronic heart failure (24)		8 weeks of three 1-hour circuit sessions of whole-body exercise (both strength and endurance) each week. Exercise training improved endothelium-dependent and -independent vascular function and peak vasodilator capacity in patients with CHF.	Training-induced changes lost 8 weeks after cessation of training.
Humans with type 2 diabetes (26)		8 weeks, three 1-hour sessions of combined strength and endurance exercise as well as cycle ergometry and treadmill walking at 70% to 85% of peak HR. Endothelium-dependent vasodilation was enhanced in both conduit and resistance vessels.	Endothelial function returned to baseline 8 weeks after cessation of training.

<i>Health Status (Refs.)</i>	<i>Acute Exercise</i>	<i>Chronic Exercise</i>	<i>Detraining</i>
Obese adolescents (27)		8 weeks, three 1-hour sessions of combined strength- and endurance exercise involving both cycle ergometer and resistance training. Cycle ergometry was maintained at 65%–85% of maximum HR and resistance training intensity at 55%–70% of pretraining maximum strength. Exercise training normalized endothelial dysfunction.	Endothelial function returned to baseline 8 weeks after cessation of training.
Humans with metabolic syndrome (30)	Flow-mediated dilatation in the brachial improved following single-bout interval training (90% of maximal heart rate), but not single-bout moderate-intensity exercise (70% of maximal heart rate).	Flow-mediated dilatation in the brachial improved following a 16-week endurance training program at both levels of exercise intensity, but more robust changes after high intensity training.	Improved endothelial function after a single bout of exercise lasts for 72 hours post-exercise.
Healthy humans (13)		10 weeks of supervised, standardized, aerobic and anaerobic training, consisting of daily 3-mile runs and upper-body strength and endurance exercises improved endothelial function.	
Healthy humans (14)		8-week training regime consisted of three 1-hour sessions of whole body exercise each week, concentrating on the large muscle groups of the lower limbs. Selected torso and upper-body exercises, which did not involve handgripping or forearm exercise, were also included. No change in endothelial function was observed.	
Healthy humans (17)		The training program consisted of four 1-hour running sessions per week. The intensity of training was adjusted to correspond to 70%–80% of each subject's VO <sub>2</sub> max. Endothelium-dependent vasodilatation in forearm vessels decreased by 32%–35%	

function, hyperinsulinemia, and increased triglyceride concentration in blood) and postinfarction heart failure (6), as well as in humans with chronic heart disease (7–12). In contrast, studies in healthy subjects reveal conflicting data with some showing improved (13), unaltered (14–16), or even depressed (17) endothelial function. Based on recent data from our laboratory in inactive healthy rats, we believe that the discrepancies in the literature regarding the effect of exercise in normal healthy subjects are explained in part by differences in the exercise protocol and timing of assays relative to the last exercise bout. On the other hand, it seems that endothelial function is well preserved in young, healthy women and men, and that a high aerobic training status due to long-term aerobic training does not improve the dilating capacity any further, but that athletes have larger diameter of their arteries compared to untrained counterparts and thus have a larger “functional capacity” (i.e., blood-transporting capacity) of their vessels (15,16).

## TIME COURSE OF ADAPTATION AND REGRESSION

Although regular exercise is known to improve endothelium-dependent arterial relaxation, less is known about how fast the salutary effects appear after initiating a training program and how long the effects last after cessation of exercise.

## ADAPTATION

The endothelium is a highly adaptable organ and only a few days of exercise training have shown beneficial effects. For example, as little as 7 days of endurance training in pigs resulted in improved endothelium-dependent arterial vasodilatation (18). Recently we carried out a detailed analysis of the effect of high-intensity endurance training and detraining upon endothelial function in rats (19). As shown in

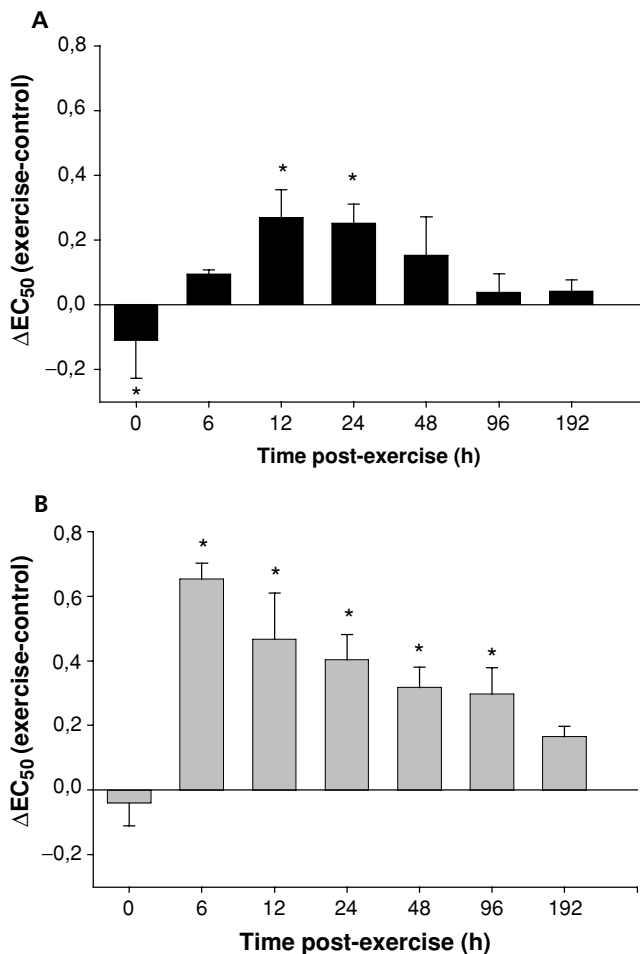

Figure 56.1. Exercise-induced endothelium-dependent vasodilatation. Endothelium-dependent vasodilatation after a single bout of exercise relative to sedentary controls (A) and 6 weeks of exercise training (B).  $EC_{50}$  values = the dose that evokes 50% of maximal dilatation. \* $p < 0.05$ . (Data used with permission from Haram PM, Adams V, Kemi OJ, et al. Endothelial adaptation following regular and acute exercise. *Eur J Cardiovasc Prev Rehabil*. 2006;13:585–591.)

Figure 56.1, endothelial function in healthy animals improved across a full spectrum of exercise duration. Most notably, we demonstrated that even a single bout of exercise yielded significant changes in endothelium-dependent dilation (Figure 56.1), in line with a study of healthy elderly humans (20). These findings were subsequently confirmed both in rats with intrinsic high- and low aerobic capacity (21).

## REGRESSION

Whereas regular exercise is known to increase endothelium-dependent arterial relaxation, little is known about the response to detraining. Current literature suggests that localized and systemic exercise-induced improvements in endothelial function are quickly lost following the cessation of training. For example, 6 weeks after ceasing 4 weeks of daily hand-grip training in patients with chronic heart failure, flow-

dependent dilatation had returned to pretraining levels (22), and endothelium-dependent vasorelaxation regressed completely within 2 to 4 weeks of detraining after finishing a 10-week endurance program (interval training at 85% of maximal oxygen uptake 5 days per week) in previously untrained rats (23). In line with these data, endothelial function returned to baseline 8 weeks after cessation of 8 weeks of endurance training in patients with congestive heart failure (24), coronary artery disease (25), and type 2 diabetes (26) and in obese adolescents (27,28). In healthy rats the beneficial effects of a 6-week endurance training program was lost after 1 week of inactivity (19). In our own detailed analyses of training and detraining, we found that increased endothelium-dependent dilation after a single bout of exercise peaked at 12 to 24 hours and was reversed after 2 days (Figure 56.1). In contrast, 6 weeks of interval training was associated with greater adaptation and a more gradual return to baseline (approximately 1 week) following cessation of activity (Figure 56.1) (19).

The above considerations regarding adaptation and regression provide important new insights into the effect of exercise training on endothelial function. First, exercise regimens of short duration (including single bout) and long duration (several days per week for more than 4 weeks in published studies) significantly influence endothelial function. The finding that a single bout of exercise is able to initiate a substantial improvement in endothelial function may change the way we look at exercise as a tool in the prevention and rehabilitation of cardiovascular disease. Knowing that the benefits of exercise begin after one bout of exercise can be very motivating for individuals starting in a rehabilitation program, and also for the physicians prescribing the program. Also, beneficial effects of exercise on endothelial function regress after cessation of training, the pattern of which depends on the nature of the initial exercise regimen. Furthermore, these data suggest that even highly trained individuals cannot “store” exercise-induced improvements in endothelial function for a long period of time and that regular exercise is necessary for long-term preservation of endothelial function.

## EFFECTS OF HEALTH STATUS AND EXERCISE INTENSITY

As mentioned earlier, the discrepancy in the literature pertaining to the effect of exercise on endothelial function is likely related to interstudy variation in training regimens and the time lag between the last exercise bout and the measurement of endothelial function. One important variable in the training regimen, which is often overlooked, is the intensity of exercise. Exercise intensity should ideally be defined as a workload corresponding to either a given percentage of maximal oxygen uptake or maximal heart rate (29). Unfortunately, many studies employ fixed-intensity (expressed in absolute terms; e.g., km/h) exercise throughout the experiment, despite the fact that the intensity of the load required to induce physical conditioning increases as the performance improves during

the course of training (29). Hambrecht and colleagues (7–12) report that moderate-to-high exercise intensity partly reverses endothelial dysfunction in patients with coronary artery disease but they do not determine the effects of different exercise intensities.

In rats with intrinsic (inborn) high aerobic capacity, both moderate (70% of maximal oxygen uptake) and high (90% of maximal oxygen uptake) aerobic intensity improve endothelium-dependent dilatation after either a single bout of exercise or 8 weeks of regular exercise (21). In contrast, in rats with metabolic syndrome, only high-intensity training improved endothelial function after a single bout of exercise, whereas both moderate exercise intensity and high-intensity interval training improved the endothelial function after 8 weeks of endurance training (21). Consistent with these findings, flow-mediated dilatation in the brachial artery in patients with metabolic syndrome was improved following a single bout of high-intensity interval training ( $4 \times 4$  minutes at 90%–95% of maximal heart rate, separated by 3-minute active pauses at 70% of maximal heart rate) but not single-bout moderate-intensity exercise, whereas the same patients benefited from a 16-week endurance training program at both levels of exercise intensity (although there was significantly larger improvement in interval-trained subjects) (30). Finally, 12 weeks of either interval training or moderate exercise intensity improved flow-mediated dilatation in the brachial artery in patients with postinfarction heart failure, but again the most robust changes were seen in interval trained subjects ( $4 \times 4$  minutes at 90% of peak heart rate, separated by 3 minutes at 60%–70% of peak heart rate) (31).

In summary, most studies suggest that patients with pre-existing endothelial dysfunction respond more favorably to high-intensity training (9,23,32). However, there exists one study that shows detrimental effect on endothelial function after 12 weeks (30 minutes for five to seven times per week) of continuous high intensity bicycling (75% of maximal oxygen uptake) (33). Recent data indicate that this may be a matter of when the measurements are being done in relation to the last exercise bout (19).

## MOLECULAR MECHANISMS OF EXERCISE-MEDIATED PROTECTION OF ENDOTHELIUM

### Nitric Oxide

General agreement exists that exercise-induced endothelium-dependent vasodilatation is due primarily to shear stress-mediated induction of endothelial-derived NO bioactivity, brought about by increased NO production and attenuation of oxidative stress. For example, short- and long-term exercise has been shown to induce NO synthesis and vasomotor responses to acetylcholine and L-arginine but not to sodium nitroprusside, pointing to the importance of the endothelium in mediating this effect. We have shown that improved endothelial response after both a single bout of exercise and

chronic exercise is inhibited by the L-arginine antagonist, N(G)-nitro-L-arginine methyl ester (L-NAME) (19).

Hambrecht and colleagues (9) showed that eNOS protein (phosphorylated and unphosphorylated) was upregulated in the mammary artery from patients subjected to exercise prior to coronary artery bypass surgery. Furthermore, compared with active controls, sedentary mice displayed reduced eNOS protein expression and endothelium-dependent vasorelaxation, effects that were reversed with subsequent exercise (34). Shear stress and/or exercise not only increases eNOS mRNA and protein but also results in increased vascular endothelial growth factors (VEGF) levels and secondary phosphorylation of Akt, which in turn phosphorylates and activates eNOS activity (Figure 56.2) (35). Importantly, the importance of eNOS in mediating adaptation to exercise was demonstrated in studies of eNOS<sup>-/-</sup> mice (36).

The bioavailability of endothelial-derived NO is dependent not only on the expression and posttranslational modification of eNOS, but also on the local redox state. Superoxide anions react with NO (37) to form the peroxynitrite anion (38), resulting in quenching and reduced bioavailability of NO. Peroxynitrite is a strong oxidant that uncouples eNOS by oxidizing the zinc-thiolate center, leading to decreased production of NO. Together, these effects promote endothelial dysfunction.

Interestingly, strenuous exercise is associated with oxidative vascular stress and impaired vascular function in ring segments of aorta from rats immediately following activity (19). These effects are reversed by L-NAME, implicating NO, hence peroxynitrite, as a central mediator of this acute response (19). Consistent with this hypothesis, decreasing the level of superoxide anions by adding superoxide dismutase (SOD) in the perfusion buffer enhanced the vasodilation, whereas disabling the extracellular superoxide dismutase by adding diethyldithiocarbamate (DETCA) further decreased vasodilation.

With chronic exercise training, the potential deleterious effect of the oxygen free radical on NO bioavailability is offset by an upregulation of antioxidant enzymes (17,37) such as cytosolic copper-and-zinc-containing superoxide dismutase (39) and the downregulation of pro-oxidative enzymes. Taken together, these changes lead to increased half-life of NO and improve eNOS function.

### Endothelium-Derived Hyperpolarizing Factor and Prostaglandins

In addition to NO, several other vasodilating agents exist, the most debated being the endothelium-derived hyperpolarizing factor (EDHF). This is an L-arginine antagonist and indomethacin-resistant factor released from the endothelium, which probably diffuses into the vascular smooth muscle and causes hyperpolarization and vasorelaxation (40). Currently it seems like EDHF has a major influence in small arteries, whereas NO is the dominant vasodilator in larger arteries such as resistance and conduit arteries (40). EDHF has yet to be identified, but several possible candidates exist, such as arachidonic acid products and potassium. Conflicting results

Figure 56.2. A simplified schema of signal transduction in ECs that contribute to regulation of endothelial function. exist to whether EDHF is reduced in disease, and even less evidence exists for an exercise-induced increase in EDHF.

Prostaglandins (PGI) can be potent vasodilators, but their relevance in exercise-induced vasodilation has been debated.

Woodman and colleagues (41) suggest that exercise reverses the endothelial dysfunction induced by a sedentary lifestyle and high-fat diet through upregulation/restoration of both NO- and PGI-mediated vasorelaxation.

### Exercise and Endothelial Caveolae

eNOS resides in 50 to 100 nm invaginations of the plasma membrane termed *caveolae*. Caveolae consist of the protein caveolin-1, phospholipids, sphingolipids, and cholesterol (42). The physiological role of caveolae is an area of intense research interest. Several functions have been proposed, including vesicular transport, cholesterol homeostasis, and, more recently, cell signaling (see Chapter 73). According to the “caveolae-signaling hypothesis” (43), caveolin-1 provides oligomeric docking sites for organizing and concentrating signaling molecules within caveolae membranes (44). In line with this hypothesis, eNOS is bound to and inhibited by caveolin-1 in caveolae (45). Studies in *caveolin-1*<sup>-/-</sup> mice (45,46) demonstrate unstable basal vessel tone and vigorous acetylcholine-mediated NO production, indicating a lack of inhibition from caveolin-1. The interbreeding of *ApoE*<sup>-/-</sup> and *caveolin-1*<sup>-/-</sup> animals resulted in a significant reduction in atherosclerotic lesion area (47), suggesting an important role for caveolae in the formation of atheroma. However, in vitro experiments in which bovine aortic endothelial cells (ECs) were exposed to shear stress led to an increase in the number of caveolae, in addition to increased phosphorylation of eNOS and subsequent production of NO (48).

As discussed earlier, we have characterized rats selected for aerobic capacity over 11 generations, yielding a strain of rats with either high or low aerobic capacity (4). Those with high aerobic capacity resembled a healthy athletic phenotype, whereas those with low aerobic capacity had metabolic syndrome, including endothelial dysfunction. We determined the relationship between endothelial function and caveolae density, both in sedentary and exercising animals of both strains. The main findings in this study were (a) a low density of luminal caveolae was associated with a classical high-risk profile for cardiovascular disease including endothelial dysfunction, low maximal oxygen uptake, high adipose mass, relative glucose intolerance, and high blood pressure; and (b) exercise upregulated luminal caveolae density and reduced the cardiovascular risk profile. To our knowledge these are the first data reporting a relationship among caveolae, exercise, and health status. The data add important information to the proposed functions of caveolae in that a low luminal endothelial caveolae density reflects a high cardiovascular risk profile, whereas a high density reflects a low cardiovascular risk profile. Intervention in the form of exercise increased the number of caveolae in addition to modifying the risk profile by reducing blood pressure, increasing endothelial function and oxygen uptake, and reducing the amount of abdominal fat.

### CONCLUSION

Substantial knowledge linking the EC function to clinical effects of exercise training has emerged over the last decade. In individuals with endothelial dysfunction, accumulating evi-

dence suggests of the beneficial effects of training on quality of life and survival. As presented in this chapter, several molecular mechanisms and signaling pathways for exercise-induced changes in ECs function are being uncovered and provide the basis for modern exercise physiology and directions of future research.

### KEY POINTS

- High-intensity endurance training is more beneficial for improving endothelial function than moderate exercise.
- A single bout of high-intensity exercise may improve endothelial function for up to 2 days.
- It is not possible to “store” exercise-induced improvements in endothelial function for a long period of time. Thus, regular exercise is necessary for long-term preservation of endothelial function.

### Future Goals

- To determine the optimal intensity and frequency necessary for improved endothelial function, both in animal models for in-depth study of the cellular and molecular mechanisms and in humans for clinical relevance
- To seek new knowledge in cellular and molecular biology in relation to exercise and pathological physiology to improve treatment of endothelial dysfunction (including the role of EDHF and caveolae)
- To implement the increasing knowledge of basal physiological mechanisms into everyday practice of sports and medicine

## The Endothelium at High Altitude

Nicholas L.M. Cruden and David J. Webb

*Centre for Cardiovascular Science, University of Edinburgh, United Kingdom*

The endothelium is a complex organ that, besides providing a selectively permeable barrier, contributes to the regulation of vascular tone and vascular remodeling, oxidative homeostasis, and the immune response. Acute exposure to hypoxia results in a decrease in the endothelial release of vasorelaxant factors such as nitric oxide (NO) and an increase in the production of vasoconstrictors such as endothelin-1. This imbalance in mediators of vascular tone, combined with alterations in endothelial cell (EC) permeability, is thought to play a key role in the pathogenesis of acute mountain sickness (AMS) (1), high-altitude cerebral edema (HACE) (1), and high-altitude pulmonary edema (HAPE) (2). Besides changes in the regulation of vascular tone, alterations in endothelial function at high altitude may be associated with increased levels of oxidative stress and inflammation. Finally, the endothelium appears to be important in mediating the changes in blood vessel structure that occur as a result of chronic exposure to high altitude.

### ACUTE RESPONSE TO HYPOXIA

The major physiological consequence of exposure to acute hypoxia and high altitude is organ-specific vasoconstriction (3). Within the pulmonary vascular bed, for example, hypoxia-induced vasoconstriction is an important mechanism for matching ventilation and perfusion. A dysfunctional endothelial response, however, may lead to exaggerated vasoconstriction, alterations in regional blood flow, and ventilation-perfusion mismatches. Moreover, an exaggerated hypoxic vasoconstrictor response may lead to capillary stress failure, alterations in EC permeability, and ultimately tissue edema. Not surprisingly, therefore, endothelial dysfunction at high altitude has been implicated in the pathogenesis of two potentially life-threatening conditions that occur in otherwise healthy subjects exposed to altitudes of greater than 3,000 m – HACE (1), intracerebral fluid accumulation characterized by ataxia and altered consciousness that may progress rapidly to coma and death, and HAPE (2), a noncardiogenic pulmonary

edema. Interestingly, hypoxic vasoconstriction alone does not appear to be sufficient for the development of altitude-related disease (4) and additional aspects of EC dysfunction, or injury, have been implicated. These are discussed below.

### ENDOTHELIUM-DEPENDENT VASOMOTOR FUNCTION

ECs respond to hypoxia by releasing a number of vasoconstrictor agents, including endothelin-1 and platelet-derived growth factor (PDGF)-B (5). Plasma concentrations of endothelin-1 are elevated in mountaineers exposed to high altitude and are higher still in mountaineers prone to HAPE (6–8), the increase in plasma endothelin-1 correlating with the rise in systolic pulmonary artery pressure and the degree of hypoxia (8).

In contrast, levels of endothelial NO synthase (eNOS) are reduced in ECs exposed to hypoxia and associated NO production is impaired (9). Consistent with this, exhaled NO concentrations are reduced in HAPE-prone individuals (10). Moreover, inhalation of NO reduces pulmonary artery systolic pressure in subjects with HAPE to levels found in subjects without HAPE (11). NO also suppresses the increase in endothelin-1 production by ECs exposed to hypoxia (5). Therefore, reduced NO concentrations associated with hypoxic exposure will result both in impaired vasodilatation and an increase in the production of the vasoconstrictor endothelin-1.

### REACTIVE OXYGEN SPECIES

Reactive oxygen species (ROS), or oxygen-free radicals, are highly toxic molecules that contain one or two unpaired electrons. Under hypoxic conditions, ROS are generated as a result of increased xanthine conversion to uric acid by xanthine oxidase, releasing the potent ROS superoxide. Additional mechanisms implicated in the production of ROS include leukocyte activation, catecholamine oxidation, and disruption of the

mitochondrial oxidative respiration (12). Increased oxidative stress impairs endothelial function (13). Evidence of increased oxidative stress has been reported in humans exposed to high altitude (14) and may result in direct damage to the EC membrane leading to increased capillary permeability, a feature of both HAPE and HACE. In addition, ROS can interact with and inactivate NO, leading to decreased NO bioavailability (13,15). Although a number of studies have reported a treatment benefit with antioxidant therapy in the prevention of AMS, a syndrome of nonspecific symptoms that is largely thought to precede the development of HACE (16–18), this has not been a universal finding (19). Further work is required to fully characterize the role of ROS and antioxidant therapy in the pathophysiology of high-altitude acclimatization and illness.

## INFLAMMATION

EC expression of interleukin (IL)-1 $\alpha$ , -6, and -8, as well as macrophage chemotactic protein, is increased under hypoxic conditions *in vitro* (20–22), and plasma concentrations of IL-6 are raised in subjects ascending rapidly to high altitude (23). Elevated plasma concentrations of soluble E-selectin at high altitude provide further evidence of altered EC function, or EC injury, under these conditions (6,24). It has been suggested that soluble E-selectin has a protective effect on the endothelium (25). Membrane-bound E-selectin is a glycoprotein produced exclusively by ECs that mediates endothelium–leukocyte interactions. Proteolytic cleavage of E-selectin from the EC surface results in the release of soluble E-selectin into the circulation, where it may impede the action of its

membrane-bound form, blocking endothelium–leukocyte adhesion, enhancing tissue perfusion, and reducing ischemia-induced damage (26).

Additional data supporting a role for inflammation in the pathogenesis of high-altitude illness include increased cytokine concentrations in bronchoalveolar lavage (BAL) fluid from subjects with established HAPE (27–29), an association between HLA genotype and HAPE (30), and the response of high-altitude headache to anti-inflammatory drugs (31,32). However, the absence of an elevated neutrophil count or cytokine concentrations in bronchoalveolar lavage fluid early in the development of HAPE would suggest that inflammation occurs as a secondary event and is not a primary pathophysiological mechanism (33).

## SIGNAL TRANSDUCTION

The  $P_{O_2}$  of arterial blood is approximately 150 mm Hg and in tissues is approximately 40 mm Hg (5). Under hypoxic conditions, tissue oxygen tension may fall as low as 15 to 30 mm Hg. ECs sense and respond to oxygen tensions below 70 mm Hg, but details of how this is achieved remain unclear (5). Proposed mechanisms include heme-containing proteins that undergo conformational change under hypoxic conditions (5), alterations in cellular concentrations of ROS (34), and shifts in the relative balance between ROS and NO production (35). Downstream signaling pathways implicated in the endothelial response to hypoxia include activation of protein kinases and transcription factors such as AP-1, hypoxia-inducible factor (HIF)-1, and nuclear factor (NF)- $\kappa$ B (5,36) (Figure 57.1).

Figure 57.1. Schematic summary of effects of exposure to high altitude on EC function.

## CHRONIC RESPONSE TO HYPOXIA

Chronic exposure to hypoxia and high altitude is associated with extensive vascular remodeling characterized predominantly by an increase in vascular smooth muscle (37). Chronic hypoxic exposure induces EC production of a number of molecules that have potent smooth muscle cell chemotaxic and mitogenic properties (5). These include endothelin-1, PDGF-B, and vascular endothelial growth factor (VEGF). In contrast, NO, levels of which are reduced under hypoxic conditions, inhibits fibroblast and smooth muscle cell mitogenesis. Thus hypoxia would appear not only to induce factors that promote vascular remodeling but also to inhibit the synthesis of mediators that normally keep this process in check. The consequences of an increase in vascular smooth muscle, particularly within the lungs, is not clear, but it may reflect a natural adaptive mechanism designed to protect individuals chronically exposed to high altitude from the capillary failure, characteristic of HACE and HAPE, that may occur on reentry to high altitude (37).

## CONFOUNDING FACTORS

In addition to hypoxia, subjects at high altitude may be exposed to extreme cold and varying degrees of physical exercise. Elevated plasma concentrations of endothelin-1 and E-selectin have been reported following extreme, but not mild, cold exposure (6,38). Moreover, evidence suggests that moderate-intensity exercise may upregulate endothelial NO bioavailability and improve endothelium-dependent vasodilatation and antioxidant function (13,39). In contrast, high-intensity exercise may increase circulating markers of oxidative stress (40). At present, however, the interplay of cold exposure and exercise with the alterations in endothelial function observed at high altitude is poorly understood.

### KEY POINTS

- Alterations in endothelial function occur on exposure to high altitude and appear to play a central role in the process of acclimatization.
- An abnormal EC response to high-altitude exposure has been implicated in the pathogenesis of altitude-related illnesses such as AMS, HACE, and HAPE.
- Some data support the use of antioxidant therapy in the treatment of AMS and even greater support for inhaled NO as a therapy for HAPE.
- Further work is required to examine the potential of the EC and its products as therapeutic targets in the treatment of high-altitude-related diseases.

## Endothelium in Space

---

Janice V. Meck\* and Ralph E. Purdy†

\* *University of Texas at Houston, NASA/Johnson Space Center;*

† *University of California, Irvine*

Of all the challenges to the endothelium discussed in the chapters within this volume, perhaps the most extreme is the challenge presented when members of a bipedal species that has evolved exquisite cardiovascular controls to support life on Earth, decides to leave its natural environment to explore a world without gravity. We speak of our pioneering astronauts. This chapter describes the cardiovascular changes that the human body undergoes when it leaves Earth to reside in a zero-gravity (actually microgravity) environment for even short periods of time and discusses how the vascular endothelium (particularly the endothelial nitric oxide synthase [eNOS] enzyme) may participate in the adaptations. We also discuss how other forms of NOS might respond to spaceflight. Results from the ground-based rodent model of microgravity, hindlimb unloading, also will be discussed as they have helped determine mechanisms of cardiovascular adaptations. Finally, we speculate about possible adaptations to spaceflight that have not yet been measured.

When exposed to microgravity, the human body undergoes changes in physiological function that appear to be normal adaptations to the new environment (Table 58-1). The cardiovascular system in particular undergoes profound changes. Unfortunately, these adaptations leave the cardiovascular system ill-equipped to handle a sudden return to the gravity of Earth. The most universal symptom after landing, experienced by virtually every astronaut, is postflight orthostatic intolerance. This manifests at a minimum as an increased heart rate response to upright posture and at a maximum as frank orthostatic hypotension and presyncope (lightheadedness, nausea) or even syncope (fainting). Another universal postflight symptom is decreased exercise capacity after landing. Both of these adverse effects present substantial risks if rapid physical activity or emergency egress is required during or immediately after landing. Given the ambitious goals for future space exploration enunciated by the National Aeronautics and Space Administration (NASA), the development of effective countermeasures to microgravity-induced cardiovascular changes is a pressing need. It is also important to note that

500,000 Americans suffer from a chronic syndrome of orthostatic intolerance, and that all long-term bed-rest patients, as well as quadriplegic patients (1), are at risk for developing orthostatic intolerance. Thus, countermeasures developed for astronauts also have the potential to be effective in the treatment of hundreds of thousands of orthostatic intolerance patients.

The present state of our knowledge of microgravity-induced cardiovascular changes is based on numerous experiments, conducted both in actual microgravity of spaceflight and in simulated microgravity on the ground, over four decades. Head-down bed rest often is used as a ground-based model of microgravity for the study of humans. The most commonly used microgravity model for rodent studies has been hindlimb unloading, during which animals are suspended by their tails at an angle that raises their hind legs so that they locomote only with their forelegs (Figure 58.1).

The hindlimb-unloading rodent model simulates in many ways the cardiovascular effects of spaceflight in humans. These effects include muscle atrophy, hypovolemia, resting tachycardia, impaired baroreflex responses, and reduced ability to vasoconstrict. Studies of astronauts before, during, and after spaceflight have identified the major hemodynamic and neurohumoral adaptations that are associated with orthostatic intolerance. In turn, the rodent hindlimb-unloading studies have provided insights into the mechanisms underlying these hemodynamic and neurohumoral changes. Important to this chapter, evidence suggests that nitric oxide (NO) mechanisms may underlie or, at least contribute to, all of the major parameter changes that characterize microgravity-induced cardiovascular adaptations.

### CARDIOVASCULAR ADAPTATIONS TO SPACEFLIGHT

During the normal daily activities of humans on Earth, the blood pressure gradient between the head and feet rapidly

**Table 58-1: Common Physiological Effects of Spaceflight**

↓	Blood volume

and repeatedly can change from no gradient in the supine position to a gradient of about 130 mm Hg in the upright position. A normal human is exquisitely adapted to accommodate these gradient changes and maintain constant, adequate blood flow to the brain. Most people can arise from a nap on the sofa, walk into the kitchen for a drink, and then sit down in a chair without fainting. They are unaware of the multifaceted, redundant system of monitors and controls, evolved over the millennia, which allow them to make these movements. Some of the tools that help maintain blood flow to the head are mechanical, such as the one-way valves within, and the large skeletal muscles that surround the deep veins

in the legs. Others involve continual adjustments by the autonomic nervous system or adjustments to maintain intravascular volume. Still other controls exist within the vasculature itself to regulate local flow and pressure. All these mechanisms evolved within the confines of Earth's gravity, but when a human enters the unique environment of space, the influences of gravity are removed, and the body must adapt to an environment it has not previously experienced. During spaceflight changes in posture become hemodynamically irrelevant; locomotion utilizes primarily the arms, rather than the legs; blood pressure becomes uniform throughout the body; the heart has less work to do; there is no up or down; and the weight-bearing bones bear no weight. The large hemodynamic changes that occur during spaceflight were anticipated and feared by early flight surgeons. There were many who feared that the first humans who were launched into space would not survive, but over the last four decades we have learned that the human body has a remarkable ability to adapt and work efficiently within the microgravity of space. However, although the adaptations to microgravity are appropriate, they leave the body ill-prepared to return to Earth. About 20% of returning astronauts are clearly hypotensive and presyncopal on landing day after spaceflights of about 2 weeks, and about 83% are hypotensive and presyncopal after 4- to 6-month flights (2). The hallmarks of postflight orthostatic hypotension are decreased plasma volume coupled with an inappropriately vascular resistance response upon standing.

**PLASMA VOLUME LOSS**

Hypovolemia in returning astronauts is a universal finding that has been well described. When a human first becomes weightless, a rapid cephalad fluid shift occurs, which is thought to trigger an early diuresis. Atrial natriuretic peptide increases dramatically early in flight and increases renal sodium excretion (3). After several days the plasma volume stabilizes at a new level that is lower than before flight and stays at that level for at least 6 months (2). From inflight photographs, which show astronauts' "chicken legs," it is evident that the main loss of volume is in the legs. Central volume, which is monitored by the cardiopulmonary baroreceptors in the chest, is maintained. There have been many efforts to restore this loss of volume. In 1985, NASA mandated that astronauts must consume salt tablets and water equivalent to a liter of isotonic saline prior to landing, but still plasma volume is decreased an average of 9% from preflight after landing (4-6). During head-down tilt, attempts to restore plasma volume with a liter of intravenous saline failed because the extra fluid was quickly eliminated (7). Thus, the body actively maintains the plasma volume at the level it perceives to be appropriate in microgravity and resists attempts at intervention intended to restore volume to levels that are appropriate in normal gravity. The resultant hypovolemia is a primary contributor to postflight cardiovascular deconditioning.

## HYPOADRENERGIC RESPONSES

Another cardiovascular adjustment to microgravity is a change in the autonomic response to baroreceptor input. During the weightlessness of space the central nervous system receives entirely different input from the arterial baroreceptors. In the absence of gravity, there is no tendency for blood to “pool” in what on Earth would be dependent limbs. Consequently, the central nervous system receives no baroreceptor input to counter upright posture. This appears to effect a central remodeling, such that the capability for proper integration and initiation of appropriate sympathetic efferent responses to hypotensive input is lost. This results in an inadequate vascular resistance increase with upright posture. Interestingly, this remodeling occurs to a greater extent in some individuals than others (4–6).

On landing day, after having spent up to 6 months in an environment where it was not necessary to respond to changes in posture, the sympathetic nervous system has approximately 1 hour from the time the engines ignite for reentry, to readapt and respond within the full force of Earth’s gravity. It must not only “remember” how to respond but also compensate for the reduced blood volume. The longer the flight, the more difficult it is to “remember” (2). During and after landing, if a hyper-sympathetic response is not initiated during upright posture, astronauts become presyncopal. Three separate studies have shown that astronauts who do become presyncopal do not release appropriate amounts of norepinephrine during post-flight upright tilt tests (4–6). The mechanism for this appears to be central. When intravenous injections of tyramine, an indirect sympathomimetic, were given before and after spaceflight, it was found that, after flight, the amount of norepinephrine released by the tyramine injections was not reduced, compared to preflight, in either presyncopal or non-presyncopal astronauts (5). This provided strong evidence that baseline norepinephrine synthesis and availability are not reduced as a result of spaceflight, but rather that spaceflight had reduced the ability of the central nervous system to organize an appropriate sympathetic response to baroreceptor input. During this time, several studies using the hindlimb unloading in rats provided important new information in support of this idea.

The possibility of changes in central integration of baroreceptor input was pursued using the hindlimb-unloading rat model mentioned above. In a landmark study, afferent aortic depressor nerve traffic versus efferent renal sympathetic nerve traffic was measured during pharmacologically induced pressure decreases. After hindlimb unloading, baroreceptor afferent traffic decreased appropriately when arterial pressure decreased, but the resultant increase in efferent sympathetic traffic was attenuated. Thus the “gain” of the baroreflex was attenuated. This indicates a dysfunction of the ability of the central nervous system to integrate hypotensive afferent input and organize an appropriate efferent response. A schematic representation of the baroreflex is presented in Figure 58.2. In a follow-up study, the same group reported enhanced GABA-

mediated inhibition of efferent sympathetic traffic in the rostral ventrolateral medulla (RVLM) after hindlimb unloading (8).

What role might NO play in hypothesized changes in central regulation of blood pressure after spaceflight? It is well known that endogenous NO plays a generalized role in autonomic regulation of blood pressure by decreasing sympathetic output (9) and also by influencing norepinephrine synthesis (10) and release (11). It can act within the paraventricular nucleus (PVN) of the hypothalamus, where parvocellular neurons project to the nucleus of the solitary tract (NTS), the caudal ventrolateral medulla (CVLM), the RVLM (12), and to sympathetic preganglionic neurons in the spinal cord (12). All these areas are important in cardiovascular control. Functional data suggest that NO inhibits these PVN neurons, as pharmacological blockade of NOS in the PVN increases efferent sympathetic traffic (13). Thus, increases in neuronal NOS (nNOS) activity in the PVN of the hypothalamus may inhibit efferent sympathetic activity in response to baroreceptor input. NO-producing neurons in many areas of the brain are activated by stress. It is reasonable to suggest that nNOS would be increased during the stress of spaceflight and landing and may inhibit sympathetic responsiveness. This line of research and reasoning provides important insight into a possible mechanism by which the central nervous system may remodel during spaceflight and lead to inadequate sympathetic responses to standing, resulting in orthostatic hypotension in astronauts after spaceflight.

## VASCULAR REMODELING

We have so far discussed changes in neural regulation of blood pressure as a mechanism for the low standing vascular resistance on landing day. Another possible mechanism is that the vasculature itself may remodel during spaceflight. Data from astronauts have not been conclusive. When pressor responses to intravenous injections of phenylephrine (an  $\alpha_1$  adrenergic agonist) were measured, there were no differences between preflight and landing day. In addition,  $\beta_2$  adrenergic receptors were not changed from preflight (5). However, before flight, pressor responses to phenylephrine were smaller in those astronauts who are destined to become presyncopal on landing day than in those who are not. These data suggest that adrenergic receptor responses are not affected by spaceflight, but that individual differences in vascular responsiveness may indicate preflight predisposition to postflight problems. Other data suggest different conclusions. Whitson and colleagues showed a marked increase in plasma norepinephrine on landing day, and a nearly fivefold increase in plasma renin activity (suggesting high levels of angiotensin, a powerful vasoconstrictor), with no parallel increase in total peripheral resistance (14). In a third study, nonpresyncopal astronauts had significantly greater norepinephrine release with standing on landing day but no increase in resistance, also suggesting impairment of vasoconstrictor responses (6).

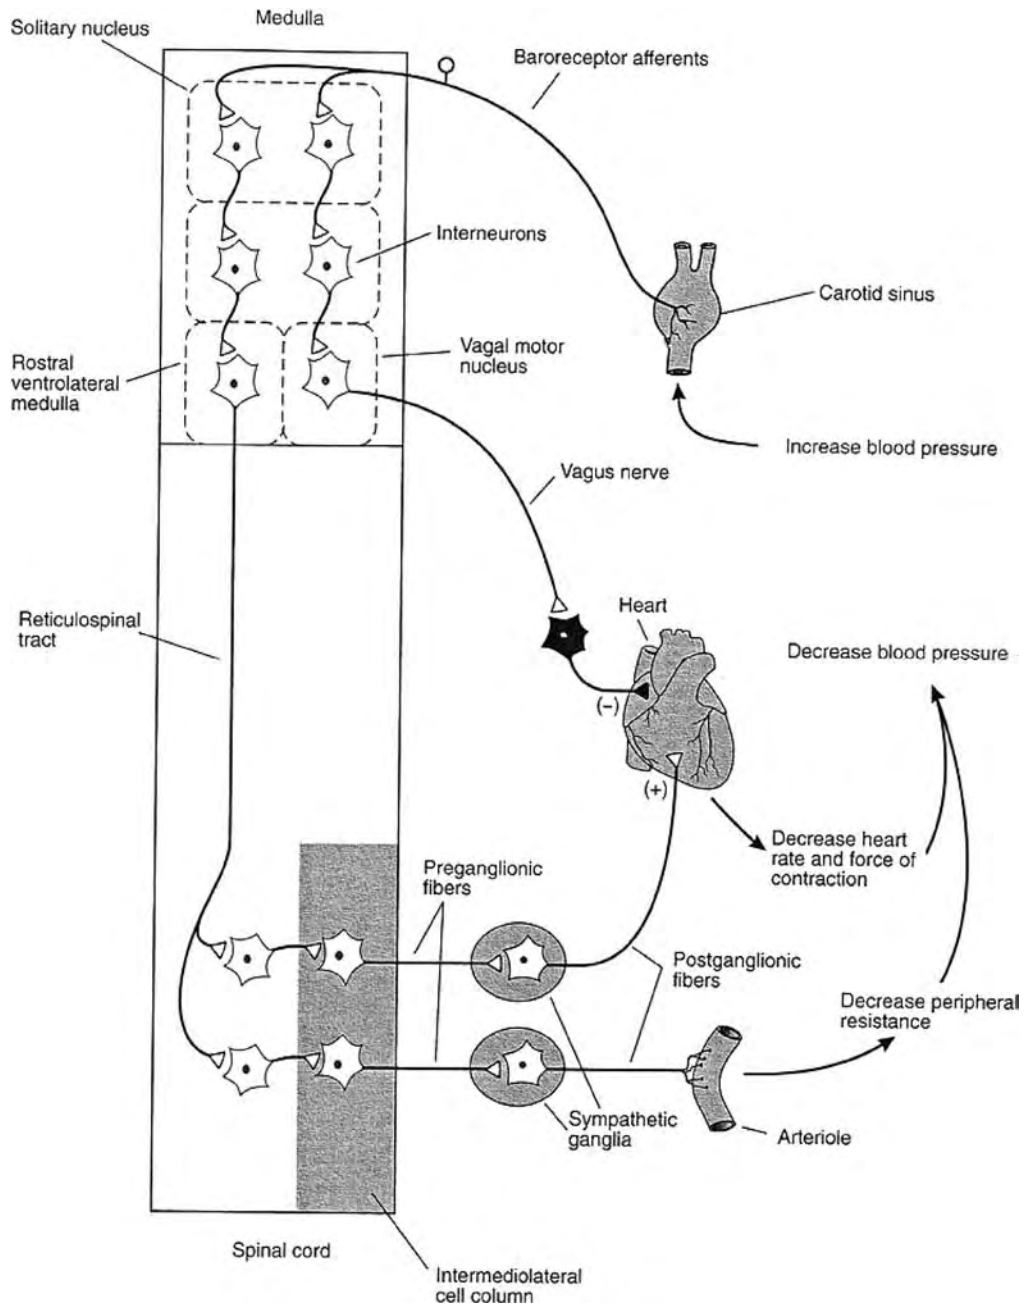

Figure 58.2. Schematic representation of the baroreflex. (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM. *Principles of Neural Science*. New York: Appleton & Lange; 1991.)

There is every reason to believe that the vasculature would remodel in response to the large changes in local hemodynamic forces experienced when the body becomes weightless. On Earth, vessels in the legs experience much higher pressures than those in the arms, as well as large changes in pressures throughout a 24-hour period. During spaceflight, those factors are missing. The legs are not used for locomotion, they do not bear weight, they become differentially dehydrated, their skeletal muscles atrophy, and interstitial pressures probably change. The arms, on the other hand, are the primary means of locomotion, particularly in crew members who per-

form extravehicular activities (EVAs) or spacewalks. It follows that the vasculature in the arms and the legs would experience opposite, although not equal, changes in flows, pressures, and shear forces when they go from Earth to space. One could therefore reasonably theorize that the vasculature in the arms might adapt differently to spaceflight than the vasculature in the legs. Virtually no studies have been performed on astronauts regarding this matter. Therefore, we must turn once again to our animal model.

During hindlimb unloading, flow is changed in many vascular beds. In particular, the cephalad fluid shift caused by

hindlimb unloading increases flow in the upper body (15) and decreases flow in the lower body (16). The changes in flow appear to correlate with parallel changes in both structure and function. Vasculature in the forelimbs shows hypertrophic remodeling, whereas that in the hindlimb shows atrophic remodeling (16). There also are decreases in the media cross-sectional area in arteries in the hindlimb but not the forelimb (16), suggesting atrophic remodeling in the hindlimb but not the forelimb.

Changes in flow as discussed earlier change shear stress, which is a powerful stimulus for the modulation of eNOS expression. It varies directly with flow and inversely with the cube of the vessel radius. Endothelial function varies with shear stress over a time course dictated by changes in both flow and vessel radius (16). Studies of endothelial responses in hindlimb-unloaded rats support the idea of differential changes in function in the forelimbs versus the hindlimbs. In *ex vivo* preparations of the carotid artery and other arteries in the upper body, hindlimb unloading causes increases in flow (17), increased responses to acetylcholine (18), upregulation of eNOS (19), and a decreased contractile response, which is restored toward control levels when the endothelium is removed (18). In the pulmonary artery, also positioned to experience increased blood flow during hindlimb unloading (20), there occur enhanced responses to acetylcholine and an increase in eNOS protein after hindlimb unloading (20). In isolated pulmonary artery rings, contractile responses are smaller in hindlimb unloaded animals than in control animals, but pharmacological blockade of eNOS abolishes the difference (20). In contrast to changes in arteries in the upper body, soleus muscle-feed arteries in the hindlimb show reduced vasodilatory responses to acetylcholine injections (21) and reduced eNOS expression (22). Additional studies of the soleus muscle-feed arteries illustrate the time-dependent nature of changes in endothelial function and flow-induced artery remodeling. At the beginning of hindlimb unloading, shear stress (calculated from measured flow and internal diameter) is reduced because of the decrease in flow (16), but it is restored to pretreatment levels after 14 days of hindlimb unloading. This is because the low blood flow stimulates arterial remodeling so that lumen diameter is decreased, thereby increasing shear (16). These changes in shear stress affect endothelial function. The initial decline in shear stress is responsible for the decrease in eNOS and in acetylcholine-induced vasodilator response observed at 14 days. On the other hand, because shear stress is restored to normal at 14 days, the acetylcholine-induced vasodilator response returns to normal at 28 days. Thus, hindlimb-unloading-induced changes in shear stress are followed, after a lag time, by changes in both eNOS expression and endothelium-mediated vasodilation (16).

It is not clear if or how microgravity-induced changes in endothelial function might affect performance on landing day. If hindlimb unloading of a quadruped can initiate such significant structural and functional changes in vascular beds in the upper and lower body, it is reasonable to expect

that when the head-to-foot pressure gradients are eliminated in humans the changes in vascular structure and function would be even greater. However, because responses are vascular bed-specific, it is difficult to predict overall hemodynamic effects. Even if the vascular beds in the upper body increase eNOS expression, enhance endothelial function, and diminish responses to vasoconstrictors during spaceflight, opposite changes in the leg vasculature might negate any overall hemodynamic effect. In addition, the time-dependent nature of microgravity-induced changes in endothelial function discussed earlier would limit the potential impact as flight duration increased. Flight-induced changes might be complete prior to landing. Although these changes may be entirely appropriate during flight, they could be one of many factors underlying postflight orthostatic intolerance.

This discussion of the possible contribution of vascular endothelium to orthostatic intolerance is important in the consideration of a therapeutic intervention. The localized and time-dependent nature of microgravity-induced changes in the endothelium argues against the utility of targeting this cell layer therapeutically. Moreover, inhibition of eNOS by such nonselective NOS inhibitors such as N(G)-nitro-L-arginine methyl ester (L-NAME) is known to elevate blood pressure into the hypertensive range (23). Thus, any therapeutic strategy aimed at eNOS inhibition would require the difficult task of achieving a stable, partial eNOS inhibition. On these grounds, it currently appears impractical to consider the endothelium and eNOS as therapeutic targets.

If the overproduction of NO is to be considered a possible cause of decreased vascular responsiveness and resistance, then by far the most likely candidate is the NO produced by inducible NOS (iNOS). Inducible NOS is known to be responsible for the severe hypotension associated with circulatory shock, and NOS inhibitors have been shown to be effective in those patients (24). Following induction, iNOS is active for up to 20 hours, and produces NO in nanomolar concentrations, one thousandfold greater than the amount produced by eNOS.

*In vivo* evidence for a role for iNOS in simulated microgravity has also been obtained. First, plasma NO is elevated after hindlimb unloading in rats (25). Second, selective inhibition of iNOS both lowers plasma NO and elevates the post-hindlimb-unloading blood pressure to normal (26). Western blot analysis has shown that, along with nNOS, iNOS is upregulated following hindlimb unloading in rats in many tissues, including the aorta, heart, and kidney (27). Blood pressure responses to injections of norepinephrine are smaller in hindlimb-unloaded rats than in control rats. In contrast, injections of the specific iNOS inhibitor aminoguanidine causes a much greater pressor response in hindlimb unloading than in control rats (27). This supports the possibility that the elevated iNOS expression is sufficiently widespread in the vasculature to exert a systemic hemodynamic effect – that is, the consequent elevated concentrations of NO would render the vasculature less responsive to endogenous vasoconstrictors. In an individual vessel, iNOS also appears to be more active after hindlimb unloading. Precontracted femoral artery

rings exposed to L-arginine undergo nearly complete relaxation. This response is abolished by aminoguanidine. The contractile response of the femoral artery to norepinephrine also has been studied (18). In the presence of L-arginine, hindlimb-unloaded femoral arteries contract less in response to norepinephrine than controls. However, similar to the systemic response, aminoguanidine abolishes the differences. A presently unresolved issue is the lack of evidence for increased iNOS expression in hindlimb-unloaded femoral arteries using Western blot analysis (19).

The evidence cited above indicates that upregulation of iNOS and the consequent production of NO is sufficiently widespread among vascular beds to have important hemodynamic effects. It is possible that the increased production of NO by iNOS may contribute to low peripheral resistance, low venous return, and greater susceptibility to orthostatic hypotension on landing day. Thus, it is reasonable to suggest that specific iNOS inhibition may represent a potential countermeasure for the prevention and/or reversal of orthostatic intolerance.

## CONCLUSION

In the entire history of human adventure and exploration, the decision to leave the planet and venture into outer space was by far the boldest. It required the development of a plethora of engineering and hardware systems. At the outset of space exploration, the human system was feared to be the most vulnerable, yet has proven to be wonderfully adaptive and plastic. It can adapt and function nominally in space and return to normal function on Earth in a short period of time. The vascular endothelium has great adaptability, and the studies reviewed in this chapter demonstrate that the endothelium plays a significant role in the physiological accommodation to spaceflight. Moreover, the endothelial, neuronal, and/or inducible NOS sources of NO are likely to participate in nearly every aspect of cardiovascular deconditioning and the consequent orthostatic intolerance. eNOS, nNOS, and iNOS are changed differentially by microgravity. The regulation of eNOS appears to be mediated, in part, by hemodynamic changes, but the causes of the changes in neuronal and inducible NOS are unknown. These are among the many unanswered questions that remain to be addressed. Perhaps NOS-knockout mice can be flown in the future.

### KEY POINTS

- Spaceflight results in orthostatic hypotension.
- The etiology is multifactorial, but NO may play an important role. All current evidence resides in hindlimb-unloaded rat data.

- Upregulation of nNOS contributes to impairment of baroreceptor-mediated increases in sympathetic flow during orthostatic (hypotensive) challenge.
- eNOS expression is regulated locally by differential hemodynamics, thus overall contribution to orthostatic hypotension is unclear.
- iNOS expression is upregulated in noncardiovascular and cardiovascular tissue, has global hemodynamic effects, and constitutes a potential site for therapeutic intervention.

### Future Goals

- To determine the therapeutic value of iNOS blockade to prevent and/or reverse the orthostatic hypotension associated with spaceflight, long-term bed rest, and spinal cord injury

## Toxicology and the Endothelium

---

Howard D. Beall and J. Douglas Coffin

*Center for Environmental Health Sciences, University of Montana, Missoula*

Toxic substances represent important inputs for endothelial cells (ECs). EC toxicity represents an emerging research area in the discipline of toxicology. Toxic agents can be classified as toxins of biological origin such as hormones, cytokines, and plant and animal toxins. Alternatively, toxicants are of anthropogenic origin – e.g. industrial chemicals, solvents, and polycyclic aromatic hydrocarbons. Toxicants also include naturally occurring substances released by human activity that are moderately toxic or nontoxic at low levels but highly toxic when released to generate high levels. Examples of these include metals (Hg, Cd, and Pb) and metalloids (As). Table 59-1 shows examples of toxins and toxicants that have been shown to affect the endothelium.

The endothelium is the first barrier to come into contact with toxic agents in the systemic circulation. Exposure of ECs to low levels of such substances is frequent and non-harmful. High-level exposure may lead to significant toxicity. Many agents – such as cytokines (tumor necrosis factor [TNF]- $\alpha$ ), drugs (antibiotics), hormones (corticosteroids, estrogens), ethanol, and trace metals – cause general damage to ECs or “endothelial dysfunction.” At that point, the endothelium loses its ability to homeostatically adapt to the toxic insult and becomes part of the resulting pathology.

Given that the structure and function of the endothelium are heterogeneous, the effects of toxins on EC phenotype may vary between different organs. Most cardiovascular pathologies can be related to endothelial toxicology, and these include coronary artery disease or atherosclerosis, arteriosclerosis, arrhythmia, hemorrhagic or thrombotic stroke, hypertension, thrombosis, infection, and peripheral vascular disease. Some of the best-known examples are snake venoms that cause edema, hemorrhage, or thrombosis; insect toxins that cause local edema; or drug overdoses that block vasoregulation. Endothelial toxicity can also contribute to diseases of the vascular system. Arsenic exposure has been shown to exacerbate atherosclerosis through oxidative stress and inflammation (1). On the other hand, toxic agents such as cadmium can produce a hypertensive response that, when prolonged,

causes secondary damage to the endothelium (Table 59-1). Toxicity-mediated thrombosis often requires activation of the endothelium as a critical step (2).

In this chapter, general responses of ECs to toxic exposures are presented along with the pathological consequences of those exposures. Selected model toxic agents are discussed that best represent the field of endothelial toxicology. Finally, this chapter includes an important discussion on how endothelial toxicity may impair vascular development.

### MECHANISMS OF TOXICITY

Toxic exposures to the endothelium generate a variety of responses that fall into homeostatic or pathological categories including cell differentiation, proliferation, adhesion, apoptosis, and metabolic changes. These manifest as changes in the vasculature such as vasodilation or vasoconstriction, inflammation, atherogenesis, angiogenesis, thrombosis, or edema. Depending on the manifestation, the outcome may be acute or chronic and either moderate or severe. The molecular mechanisms and regulatory pathways controlling these responses are often related to homeostasis or a particular disease, and they are described in detail throughout this volume. However, they have not been well characterized or defined in relation to toxicology. The molecular interactions that generate these vascular problems are better described and they include oxidative stress, lipid peroxidation, blockage of electron transport, and also many interactions in which toxic agents act as agonists or antagonists to important regulatory molecules such as cell surface (e.g., cytokine, growth factor, and hormone) receptors, ion channels, and transporters.

A common mechanism of toxicity is generation of reactive oxygen species (ROS) or reactive nitrogen species (RNS) leading to oxidative stress. Oxidative stress can directly injure the endothelium (3), which can then have an impact on other vascular cell types, such as smooth muscle cells and fibroblasts. Toxicant-induced oxidative stress may also trigger

**Table 59-1: List of Toxins and Toxicants Reported to Affect Endothelium**

<i>Toxin/Toxicant</i>	<i>Example</i>	<i>Effect</i>	<i>Pathology</i>	<i>References</i>
<b>Biotoxins</b>				
Endotoxin	LPS	Act, Dys, Apop	Sepsis, Edema	11,22,77–79
Snake venom	Fer-de-lance	Dys, Ox, Nec	Edema, Hem, Gangrene, Throm	17,33
Virus	Ebola, influenza	Dys, Ox, Nec	Edema, Hem	34,36,80,81
Homocysteine		Act, Dys	Athero, Inflam, Throm	2,28,82
Hormones	Corticosteroids, estrogens	Act, Dys	AMD, Ret, TA	83,84
Cytokines	TNF- $\alpha$ , INF	Act, Dys, Apop, Adh	Hyper, Athero, PVD	6,12,85–89
Growth factors	VEGF	Act, Prolif, Diff, Apop	Hyper, Athero, TA, Edema	14,90,91
Chemokines	IL-8	Act, Dys, Prolif, Diff, Apop	KS, Hem, TA	92,93
OxLDL		Apop	Athero	5
Cardioglycosides	Ouabain	Apop	Hyper	7
Eicosanoids		Dys	Hyper	94
<b>Metalloids</b>				
Arsenic		Act, Dys, Ox	Athero, Hyper, PVD, Inflam, Throm	1,24,38,39,44,46
<b>Metals</b>				
Iron		Ox, Apop, Nec	Vasculopathy	29
Lead		Ox, Dys	Hyper	19
Mercury		Dys, Apop	Vasculopathy	18
Cadmium		Dys	Hyper	20
Nickel		Act	Inflam	30
<b>Drugs</b>				
Catecholamines	Norepinephrine, serotonin	Act, Dys, Ox	Hyper, Throm	23,95,96
Antineoplastics	Fluorouracil, bleomycin	Dys	Hyper, Edema	97,98
Antibiotics	Rapamycin, gentamicin	Dys, Apop	Athero, Edema	15,99
Antihistamines	Tranilast	Dys	AMD, Ret	31
Anesthetics	Nitric oxide	Dys	Edema, Hyper	21
Analgesics	Coxibs	Dys	Throm	25
<b>Industrial Toxicants</b>				
Solvents, benzene, and derivatives	Ethanol, benzopyrene, benzene	Dys, Act, Ox	Inflam, Edema, Stroke	16, 32
Halogenated hydrocarbons	PCBs	Ox, Dys	Athero, Inflam	100,101
Dioxins	TCDD	Dys	Vasculopathy	102

Toxins reported to affect endothelium by causing activation (Act), dysfunction (Dys), oxidative stress (Ox), apoptosis (Apop), proliferation (Prolif), leukocyte adhesion (Adh), or necrosis (Nec). These alterations in ECs are associated with pathologies such as atherosclerosis (Athero), hypertension (Hyper), inflammation (Inflam), thrombosis (Throm), age-related macular degeneration (AMD), tumor angiogenesis (TA), peripheral vascular disease (PVD), retinopathy (Ret), Kaposi sarcoma (KS), and hemorrhage (Hem). Other abbreviations include PCB (polychlorinated biphenyls), TCDD (2,3,7,8 tetrachlorodibenzo-*p*-dioxin), Coxibs (cyclooxygenase inhibitors), INF (interferon  $\gamma$ ).

endothelial apoptosis or produce an inflammatory response in which initial damage to the endothelium leads to recruitment and adhesion of inflammatory cells and release of cytokines, chemokines, and growth factors (2–4). Lipid peroxidation, associated with ischemia/reperfusion injury, causes damage to cell membranes with subsequent alteration of transmembrane regulatory proteins and instability of organelles (mitochondria, Golgi, and endoplasmic reticulum). ECs damaged through antibiotic-mediated lipid peroxidation often undergo premature apoptosis (5,6).

Besides oxidative stress, endothelial damage leading to endothelial dysfunction can also occur by the direct cytotoxic action of drugs and chemicals (Table 59-1). For example, cardioglycoside such as ouabain or digoxin bind Na/K transporters, causing endothelial dysfunction (7). Alternatively, nontoxic chemicals may be bioactivated to toxic metabolites by enzymes in vascular cells. ECs express a range of enzymes capable of activating chemicals to toxic species, including amine oxidases, cytochrome P450 isozymes, and the prostaglandin synthetase complex of enzymes (8).

## ENDOTHELIAL ACTIVATION/DYSFUNCTION FROM TOXIC EXPOSURES

Exposure to toxic agents can cause endothelial activation that is characterized by an increase in secretion of proteins or metabolites. Factors expressed or released by activated endothelium include adhesion molecules such as intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 (9,10). Expression of cytokines such as TNF- $\alpha$  and chemokines including interleukin (IL)-8 are reported as responses to toxic insults related to sepsis or lipopolysaccharide (LPS) exposure (11,12). Growth factor response to endothelial toxicity is well documented with vascular endothelial growth factor (VEGF) family members most often reported (9,13–16). Toxicity-mediated thrombosis or hemorrhage is related to endothelial activation or dysfunction and is best exemplified by snakebites (17). Finally, altered hemostasis is a well-documented vascular response to toxic exposures based on changes in nitric oxide (NO) (9,18–20) or endothelin (ET)-1 (19,21–23). Patterns of activation depend not only on the toxic compound but also on the site within the vascular tree. Sustained endothelial activation can lead to endothelial dysfunction, defined by abnormalities in one or more functions, including changes in vasomotor control, barrier properties, leukocyte trafficking, inflammation, hemostasis, and apoptosis.

## VASOMOTOR CONTROL

ECs are normally in a vasodilatory state due to secretion of NO and vasodilatory prostaglandins such as prostacyclin (PGI<sub>2</sub>), and either of these can be altered in a toxic insult causing hypertension or hypotension (21,24,25). Toxicity may result in impaired response of the vasculature to endothelium-dependent relaxation (EDR). An important mediator of EDR is NO, synthesized from L-arginine, nicotinamide adenine dinucleotide phosphate (NADPH), and oxygen (O<sub>2</sub>) by endothelial NO synthase (eNOS). Oxidative stress from exposure to toxic agents could potentially decrease the bioavailability of NO by several mechanisms. Generation of superoxide anion (O<sub>2</sub><sup>-</sup>), an ROS that reacts rapidly with NO to form a powerful oxidant, peroxynitrite (ONOO<sup>-</sup>), may be increased in activated ECs or surrounding tissues. Excess superoxide anion could originate from NAD(P)H oxidases on the EC membrane, the mitochondrial respiratory chain, or uncoupled eNOS (26). In addition, ONOO<sup>-</sup> can oxidize and inactivate an essential eNOS cofactor, tetrahydrobiopterin (BH<sub>4</sub>), thereby uncoupling eNOS and decreasing NO production (27).

Endothelial activation/dysfunction may also be associated with the release of angiotensin-converting enzyme (ACE) (12,16,28–31) and ET-1 (4,19,21,23), which results in a further shift of the vasomotor balance toward the vasoconstrictive side. This can aggravate existing hypertension and ultimately

increase cardiovascular morbidity and mortality (4). On the other hand, hypertension itself can cause endothelial dysfunction by directly damaging ECs.

## Barrier Function

Another form of endothelial dysfunction resulting from toxic insult is loss of endothelial barrier integrity. The failure of this barrier could lead to serious pathological consequences, especially for specialized endothelium such as the blood–brain barrier (12,32). For example, certain types of venom (17,23,33) or viral proteins (34–36) may cause severe edema or hemorrhage by disrupting the integrity of, or even obliterating, the endothelial barrier. Overproduction of oxidants leading to oxidative stress can disrupt the endothelium by disorganization of critical junctional proteins, including vascular endothelial (VE)-cadherin (37).

## Leukocyte Trafficking and Inflammation

ROS and RNS generation attributed to toxic exposures may activate ECs to produce cytokines, chemokines, and adhesion molecules. Leukocytes (e.g., T cells and monocytes) are thus recruited to the EC surface, attach to the surface, and are translocated to the subendothelial space (4,9,10,30,33). This is an important mechanism underlying atherosclerosis that is, for example, associated with arsenic toxicity (1,24,38,39).

## Hemostasis

ECs are key mediators of coagulation, and they secrete a range of both procoagulant and anticoagulant factors. Chronic inflammation with release of proinflammatory cytokines creates a procoagulant state in the endothelium, and in the case of atherosclerotic disease it may cause weakening and rupture of plaques, potentially leading to myocardial infarction or stroke (40). Direct damage to the endothelium caused by mechanical means or administration of an irritating substance can cause formation of a thrombus at the site of the injury.

## PATHOLOGICAL CONSEQUENCES OF ENDOTHELIAL INJURY

The most important pathological consequence of endothelial activation/dysfunction is the development of atherosclerosis. Atherosclerosis is the single most important contributor to other cardiovascular diseases. Endothelial dysfunction has been documented both in the early stages of atherosclerosis as well as in patients at risk for development of, but with no clinical evidence of, coronary artery disease (3). An activated or damaged endothelium can also promote thrombotic or hypertensive disease (41).

Cardiovascular disease is a complex set of disorders involving multiple cell types and organ systems. Endothelial

activation/dysfunction can both contribute to and result from cardiovascular disease. The remainder of this chapter focuses on toxic agents and their specific effects on ECs.

### MODEL SYSTEMS FOR STUDYING ENDOTHELIAL TOXICOLOGY

Until recently, there were very few EC model systems available for studying toxic responses of the endothelium. Aortic ECs of bovine and porcine origin were used most often in toxicology studies along with cells from the human umbilical vein. In the last few years, human arterial ECs have become available commercially, including cells of aortic, coronary artery, and pulmonary artery origin. A lingering problem is the paucity of rodent EC models to support toxicology studies. Steady progress has been made culturing murine ECs, but it is still difficult to obtain more than three or four doublings. Many tumor angiogenesis models have been adapted for studies in endothelial toxicology, including the use of Matrigel (42,43). The obvious advantage for murine models in toxicology is access to the many excellent transgenic and knockout mouse models available for functional studies.

### SELECTED ENDOTHELIAL TOXIC AGENTS

Agents that have been identified as endothelial toxic agents include butadiene, acrolein, metals and metalloids, and various drugs including aspirin, cocaine, and the antineoplastic agent cyclophosphamide (8). Of course, many more drugs and chemicals exist that are cytotoxic to ECs (see Table 59-1). In addition, natural substances such as homocysteine, oxidized low-density lipoprotein (oxLDL), and bacterial endotoxins can elicit toxic responses by ECs. This section is devoted to several well-characterized toxic substances, some of which are single agents and others complex mixtures.

#### Arsenic

In recent years the metalloid arsenic has received considerable attention in endothelial toxicity studies. Natural arsenic levels in drinking water are very high in some locales, and it is released into the environment by human activities in other regions, increasing exposure risk in human populations (1,44). Chronic exposure to arsenic in drinking water has been identified as a risk factor for a number of cardiovascular diseases, including peripheral vascular disease (1), ischemic heart disease (1,24,38,39,45), and hypertension (46). In mouse models of atherosclerosis, significantly exacerbated lesions have been documented in mice that are chronically exposed to arsenic in their drinking water (24,38). The important pathophysiological role of the EC in atherosclerosis and other cardiovascular diseases should stimulate further research into the effects of arsenic on this cell type.

Arsenic exposure studies using a variety of cultured ECs have shown increased ROS and RNS generation, potentially leading to oxidative stress. The oxidative stress is believed to result in altered EC proliferation, adhesion, and apoptosis (47–49). Vascular NADPH oxidases have been implicated in the increased formation of superoxide anion in ECs treated with arsenic (50). Increased NO synthesis in aortic ECs in response to arsenic has also been reported (51), but this remains controversial as the response to arsenic appears to be dependent on cell type, arsenic species, and concentration (52). A plausible explanation may be that peroxynitrite is produced by the scavenging of NO by superoxide anion. Evidence for increased peroxynitrite formation in arsenic-treated aortic ECs has been reported (39). In any case, the evidence suggests that ECs exposed to arsenic produce ROS and RNS, which cause oxidative stress, activation of the endothelium, and, ultimately, endothelial dysfunction.

Direct evidence for endothelial dysfunction from arsenic exposure has recently been documented in a comprehensive study using both *in vitro* and *in vivo* assays. Treatment of rat aortic rings with arsenic inhibited relaxation induced by acetylcholine, a standard methodology for determining endothelial dysfunction (46). In the same study, live rats were administered arsenic intravenously. Arsenic pretreatment prevented blood pressure reduction from acetylcholine infusion, the first demonstration of the inhibitory effect of arsenic on vasomotor tone in an animal model (46). These findings support the epidemiological evidence showing that chronic arsenic exposure is associated with the development of hypertension (46).

Epidemiological evidence has also suggested that arsenic may increase the potential for thrombus formation (44). In response to this finding, an *in vivo* study was conducted in rats that showed enhanced platelet aggregation and arterial thrombus formation following chronic arsenic treatment (44). A possible mechanism behind this effect is increased expression of P-selectin, an important protein involved in the adhesion of platelets to ECs.

#### Metals

Mercury, lead, and cadmium are environmental contaminants that have been implicated in EC toxicity. Acute mercury (53) intoxication has been associated with hypertension in both human case reports and controlled animal studies. Inorganic mercury is known to cause injury to ECs. In a recent study using environmentally relevant exposures, mercury chloride caused structural and functional damage to rat endothelium and loss of endothelial-dependent vasoreactivity (18). Chronic low-level lead exposure has also been associated with hypertension in humans and animals through a mechanism that may include generation of ROS and RNS by ECs (2,19). Lead neurotoxicity may be due in part to alterations in the integrity of the blood–brain barrier (12,32). Cadmium also is recognized as an endothelial toxicant and may contribute to neurological diseases or stroke (54) by causing an inflammatory response

that involves activation of ECs. Like lead, cadmium exposure can cause disruption of the blood–brain barrier (54). Other metals, including chromium and nickel, may activate ECs and initiate toxic mechanisms. Iron also has been implicated in endothelial dysfunction in relation to oxidative stress leading to EC apoptosis or necrosis in vasculopathy (29).

### **Cigarette Smoke**

Cigarette smoking is a major risk factor for atherosclerosis and other cardiovascular diseases. Cigarette smoke contains thousands of chemical components, many of which are highly toxic. A major effect of inhaled cigarette smoke is induction of oxidative stress. As discussed previously, ROS (resulting from cigarette smoke) react with and inactivate NO produced by ECs. This produces other oxidants such as peroxynitrite and decreases NO availability, leading to endothelial dysfunction. Components of cigarette smoke stimulate adhesion molecule expression and leukocyte adhesion to ECs, an early step in atherogenesis (4). Cigarette smoking affects the endothelium indirectly through activation of platelets (55). Platelet activation increases their adherence to ECs. This leads to a prothrombotic state in the vasculature and increased potential for acute coronary or cerebrovascular events.

### **Particulate Matter**

The effect of air pollutants, especially particulate matter, on cardiovascular disease is an area of recent concern and increased research activity (56). Particulate matter is composed of many potentially toxic components, including polycyclic aromatic hydrocarbons, metals, and the particles themselves. Inhaled particulate matter deposits in the lungs and causes the expected respiratory effects, but epidemiological studies also show that cardiovascular morbidity and mortality increase on high air pollution days (57). The mechanisms behind the systemic cardiovascular effects of locally deposited particles are largely unknown.

Most of the evidence points to inflammation as a common mechanism in the cardiovascular toxicity of inhaled particulate matter. The EC is at the center of this inflammatory response. Rats that were exposed to residual oil fly ash (ROFA), a model of particulate matter, by intratracheal instillation exhibited diminished endothelium-dependent dilation in the systemic microvasculature (58). Furthermore, increased rolling and adhesion of leukocytes on ECs were observed in the microvasculature, suggesting that ROFA had produced a systemic inflammatory response (58). A relationship between particulate matter exposure from air pollution and carotid intima-media thickness, an indicator of early atherosclerosis, was recently demonstrated in an epidemiological study carried out in Los Angeles, California (59). Particulate matter–induced endothelial activation/dysfunction leading to atherogenesis is one plausible explanation for this reported association. Future work should focus on the specific components of particulate matter that con-

tribute to endothelial activation/dysfunction and downstream pathologies.

### **ENDOTHELIAL TOXICOLOGY IN VASCULAR DEVELOPMENT**

The best known toxic agent affecting vascular development is thalidomide. Administration of thalidomide to pregnant women from 1959 to 1961 led to severe cases of amelia and phocomelia in their children (60). The mechanisms for the limb deformations were largely unknown in that era, but recent use of thalidomide as an angiogenesis inhibitor in chemotherapy (61,62) has regenerated interest in determining the molecular basis for thalidomide's effects on angiogenesis with possible applications to development. Previously published data show that, regardless of the cause, failure to vascularize limbs during development can lead to limb defects (63) similar to amelia. Based on the effects of thalidomide on tumor angiogenesis, thalidomide could be inhibiting limb angiogenesis as a means to cause amelia or phocomelia. Recent studies have revealed that thalidomide increases endothelial oxidative stress (64), providing an example of endothelial dysfunction through increased apoptosis. Based on these results, a general model for toxicity-based oxidative stress and endothelial dysfunction can be constructed (Figure 59.1) whereby a toxic exposure inhibits angiogenesis and blocks perfusion. This leads to hypoxia or anoxia that causes extensive tissue damage in the developing limb and subsequent teratogenesis. Moreover, consideration of these results in the context of developmental field models (65,66) suggests that the limb bud vessels may be necessary to ensure proper positioning of the precursors needed for formation of other tissues, such as bone, nerves, and muscle.

Arsenic is another toxin implicated in impairment of vascular development and subsequent teratogenesis, miscarriage, low birth weight, and/or premature delivery in humans (53). As mentioned previously, arsenic exposure to the endothelium *in vitro* results in production of ROS and RNS, such as peroxynitrite, which can alter the NO balance (Figure 59.1). Either collectively or alone, any of these arsenic stress-related effects is sufficient to cause endothelial dysfunction manifest as increased apoptosis (45), decreased proliferation (67), and possibly altered cell adhesion or migration as the key components to arsenic-mediated vascular dysmorphogenesis. These results suggest that arsenic-based teratogenesis is caused by a lack of neovascularization/perfusion of developing structures in the embryo. The subsequent hypoxia causes tissue damage in the embryo, resulting in teratogenesis and possibly miscarriage should the vascular dysmorphogenesis occur in the placenta.

Preeclampsia is one of the most common problems associated with preterm delivery, low birth weight, and miscarriage. The exact cause of preeclampsia is unknown, but it is linked to defects in placental vasculogenesis similar to our observations with arsenic exposure and placental insufficiency. Current

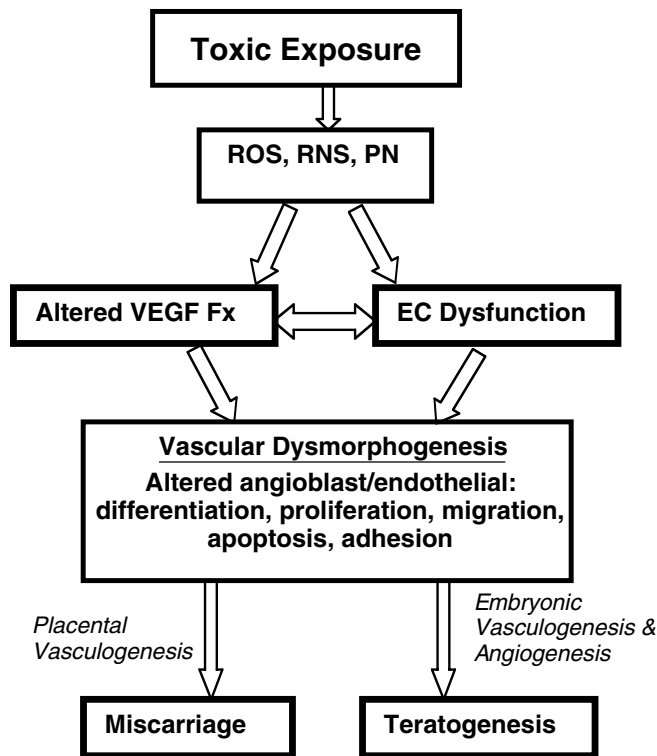

Figure 59.1. Schematic relating endothelial toxicity to oxidative stress, including production of ROS, RNS, and peroxynitrite (PN). Oxidative stress leads to alteration of the VEGF regulatory axis and EC dysfunction, affecting angioblast differentiation, proliferation, migration, apoptosis, and adhesion. These are all key processes in vascular morphogenesis, and, therefore, toxicity triggers dysmorphogenesis manifest as miscarriage if involving placental vasculogenesis, or teratogenesis if involving either vasculogenesis or angiogenesis in the embryo.

models suggest that the molecular mechanism for preeclampsia centers on the VEGF regulatory axis whereby increases in the soluble FLT-1 receptor result in an inhibitory sink for VEGF (and placental growth factor [PlGF]) (68,69). Genetic mouse models have established the importance of the VEGF signaling axis in development; deletion of a single allele of VEGF or homozygous knockout of *FLT-1* or *FLK-1* results in embryonic lethality. The results of the preeclampsia studies provide important proof of principle that abnormalities in the VEGF pathway may be linked to impaired development in humans (69,70). Hypothetically, exposure to environmental toxicants could cause or at least exacerbate vascular pathologies of unknown origin, such as preeclampsia, because hypoxia-inducible factor (HIF)-1, which regulates VEGF expression, is related to the aryl hydrocarbon receptor (71,72).

Dioxins are another candidate for triggering developmental vasculotoxicity and dysmorphogenesis. Unlike arsenic and thalidomide, no data exist associating dioxins with a human condition to show a definitive effect on the embryo or fetus – i.e., teratogenesis, miscarriage, or preterm delivery. However, TCDD exposures in zebrafish, lake trout, and chick embryos

all reveal vascular dysmorphogenesis related to metabolism by the CYP1A1 cytochrome P450 and alteration of VEGF or the VEGF receptor FLT-1 (13,73,74).

Neovascularization of developing tissues is mediated by vasculogenesis and angiogenesis (75,76). The fundamental cellular and molecular bases for the two modes of vascular development have unique distinctions but intersect with growth factor and signaling pathways that regulate EC differentiation, proliferation, migration, and adhesion during morphogenesis. Although developmental vasculotoxicity has not been specifically or definitively linked to alterations in these processes, the current data show that arsenic toxicity primarily affects placental vasculogenesis, whereas the effects of thalidomide are relatively specific to limb bud angiogenesis (Figure 59.1). Further studies are needed to clarify this distinction. Should these interpretations hold up to continued elucidation of the mechanisms and scrutiny of the models, vascular toxicology may prove an interesting means for not only characterizing the molecular and cellular mechanisms for vascular development but also for providing clues for therapeutic manipulations.

## CONCLUSION

The endothelium is a key target for toxic events that fundamentally alter cardiovascular physiology facilitating cardiovascular disease, miscarriage, and teratogenesis.

## KEY POINTS

- Toxic exposures generate stress reactions in the endothelium that alter normal physiology and developmental processes.
- Generation of ROS and RNS by toxic agents causes oxidative stress and inflammation leading to endothelial activation and dysfunction.
- Endothelial dysfunction in the adult results in exacerbation of cardiovascular diseases such as hypertension and atherosclerosis. Angioblast/endothelial dysfunction during development can result in miscarriage or teratogenesis.

## Future Goals

- Toxicology should be a major consideration in human epidemiologic models applied to diseases and fecundity for both human and agricultural populations.
- Endothelial toxicology requires further investigation, consideration, and inclusion in the etiology of cardiovascular disease.

- The relationship between developmental toxic exposures and vascular dysmorphogenesis needs elucidation for practical prevention of miscarriage and teratogenesis.

## Pericyte–Endothelial Interactions

Mark W. Majesky

*Carolina Cardiovascular Biology Center, University of North Carolina at Chapel Hill*

Blood vessels are built and maintained by two interdependent cell types, endothelial cells (ECs) and mural cells. Signals exchanged between these two cell populations control the formation, remodeling, maturation, and function of the vascular network. Pericytes are smooth muscle-like mural cells with unusual properties that play highly dynamic roles in the microvasculature. In response to signals produced by ECs, pericytes invest and partially cover the microvessel wall, where they act to stabilize nascent endothelial tubes, provide essential survival factors, inhibit EC proliferation, and guide vessel wall remodeling. Proper investment of vessel walls with pericytes is a critical and necessary step in vascular development and angiogenesis (Figure 60.1). The purpose of this chapter is to review the multiple roles that endothelial–pericyte interactions play in the development and function of microvessels.

### PERICYTE INVESTMENT OF MICROVASCULAR ENDOTHELIUM

The acquisition of a pericyte coating around microvessels (terminal arterioles, capillaries, post-capillary venules) is referred to as *investment* (1). The process of investment includes the fundamental steps of cell migration, alignment, contact, and phenotype changes associated with mural cells interacting with ECs. These individual steps overlap in time and are controlled by multiple signaling pathways. Investment of blood vessels with pericytes is a reversible process that is highly responsive to changes in rate and direction of blood flow (2,3). Pericyte investment is mediated by a variety of different factors secreted into the local environment, including platelet-derived growth factor (PDGF)-B, angiopoietin 1 (Ang1) and angiopoietin 2 (Ang2), sphingosine-1-phosphate (S1P), transforming growth factor (TGF)- $\beta$ 1, and nitric oxide (NO) (4–9). The microvascular defects in mice with mutations in these secreted pericyte investment factors are summarized later. For additional details not covered here, the reader is directed to several excellent recent reviews (1,10,11).

### Platelet-Derived Growth Factor-B

Possibly the most well-studied mediator of endothelial–pericyte communication is PDGF-B. ECs make PDGF-B (12–14), and its production is upregulated by elevated shear stress (15) and sprouting angiogenesis (4,16,17). The highest levels of PDGF-B expression are localized to the lead migratory tip-cell of the endothelial sprout (17). Once secreted by the endothelial sprout, PDGF-B interacts reversibly with constituents of the microvascular extracellular matrix (ECM), particularly heparan sulfate proteoglycans (18,19), via matrix-retention motifs in the C-terminus of the mature growth factor. Binding of PDGF-B to the ECM results in the establishment of a local concentration gradient around the newly formed capillary vessels. Pericytes express PDGF-receptor  $\beta$  (PDGF-R $\beta$ ) and respond to a local gradient of PDGF-B by proliferation to expand the pericyte pool and by directed migration toward the endothelium (4,20,21). These responses to PDGF-B also are true for smooth muscle cell (SMC) investment of developing large arteries and veins (16). Chemotaxis in response to a PDGF-B concentration gradient is normally followed by pericytes contacting ECs, extending processes around the microvessel wall, and exhibiting phenotype changes associated with enhanced vessel stability and maturation. Null mutations in PDGF-B or PDGF-R $\beta$  result in vascular malformations associated with failure to recruit or expand the pericyte component of some but not all developing vessels leading to microaneurysms and microvascular ruptures (Table 60-1) (4,20,22,23). Of particular interest is the finding that selective deletion of only the matrix retention motif in PDGF-B also produced defects in investment of pericytes around the microvessel wall (24). These defects are seen as reduced numbers of total pericytes, poor attachment of the surviving pericytes to the endothelium, and the extension of pericyte cytoplasmic processes away from, rather than around, the microvessel wall (24). The long-term consequence of deletion of the PDGF-B matrix retention motif included severe retinal degeneration, glomerulosclerosis, and chronic renal insufficiency (24). The importance of PDGF-B

Figure 60.1. A nascent endothelial plexus recruits pericytes to form a stable microvessel network. Critical endothelial-derived factors that direct pericyte recruitment include PDGF-B, Ang1 and Ang2, TGF- $\beta$  signaling via the type III TGF- $\beta$  receptor endoglin, and sphingosine 1-phosphate. Pericyte-endothelial interactions are required to produce a stable, functional microvessel wall. Pericytes provide essential survival factors, promote junction formation between ECs, and inhibit EC proliferation.

for pericyte investment is underscored by the finding that even in *PDGF-B*<sup>+/-</sup> mice, that express one-half the wild-type levels of PDGF-B, significant reductions in pericyte numbers in brain and retinal microvasculature could be found (25).

### Sphingosine-1-Phosphate

Another important pathway for mural cell recruitment is signaling via the endothelial differentiation gene 1 (*Edg1*)/S1P receptor (S1P1). *Edg1*/S1P1 is a G protein-coupled serpentine receptor that binds S1P, a secreted sphingolipid that is produced by ECs and platelets. Mice lacking *Edg1*-mediated signaling have pericyte investment defects that closely phenocopy *PDGF-R $\beta$* -deficient mice (6). Loss of *Edg1*/S1P1 signaling in ECs results in failure of microtubule polymerization and loss of proper trafficking of N-cadherin to polarized plasma membrane domains. This defect results in loss of N-cadherin-dependent cell-cell adhesion between ECs and pericytes, leading to microaneurysms, hemorrhage, and embryonic death between embryonic day (E)12.5 and E14.5 (26). A phylogenetically conserved role for S1P-signaling in the control of cell migrations important for cardiovascular

Table 60-1: Knockouts with Pericyte/Vascular Phenotypes

Gene	Survival	Phenotype	References
<i>PDGF-B</i>	Dies at birth	Mural cell recruitment defects	4,22
<i>PDGF-R<math>\beta</math></i>	Dies at birth	Mural cell recruitment defects	16,23
<i>Edg1/S1P1</i>	Embryonic lethal	Failure to recruit SMCs	6
<i>Tie2/Tek</i>	Embryonic lethal	Failure of EC remodeling	29,31
<i>Ang1</i>	Embryonic lethal	Failure of EC remodeling	5
<i>Ang2</i>	Dies after birth	Lymphatic vessel defects	32

<i>Endoglin</i>	Embryonic lethal	Failure of EC remodeling	7
<i>FoxC2</i>	Dies at birth	Multiple cardiovascular defects	67

development is illustrated by the zebrafish mutant *miles apart* (*mil*). The *mil* mutation was identified by positional cloning and shown to encode a G protein-coupled receptor of the lysosphingolipid receptor family that is activated on binding S1P (27). Zebrafish *mil* embryos exhibit cardia bifida due to failure of the bilateral cardiac primordia to migrate to the midline and form the tubular heart (27).

### Angiopoietins

Identification of a pair of orphan tyrosine kinase receptors with immunoglobulin and epidermal growth factor-like ectodomains that are specifically expressed in ECs, called Tie1 and Tek/Tie2, led to the discovery of the angiopoietins Ang1 and Ang2 (5,28-30). Ang1 is produced by mural cells, binds to and activates Tek/Tie2 receptors on ECs, and signals maturation processes involving cell-cell and cell-matrix interactions leading to stable, leak-resistant vessels. Tie2-deficient embryos die by ED10.5 with multiple foci of hemorrhage and edema (29,31). Initial formation and patterning of early blood vessels are normal in Tie2-deficient embryos, but subsequent vascular remodeling including pericyte and SMC investment is defective. Histological examination revealed that vascular defects result from a breakdown in cell-cell communication between ECs and mural cells, leading to failure of ECs to properly adhere to underlying basement membrane and to each other. The role of Ang2 seems to depend on what other factors are present in the microenvironment. In the absence of vascular endothelial growth factor (VEGF), Ang2 acts as an antagonist of Ang1, leading to vessel destabilization, regression,

endothelial apoptosis, and anti-angiogenesis (32,33). In the presence of VEGF, Ang2 is proangiogenic and facilitates vascular sprouting, branching, and elongation (33). Ang2-deficient mice have no defects in embryonic vascular development but exhibit major functional abnormalities in lymphatic vessels after birth. Unlike its previously demonstrated properties as an antagonist of Tie2 signaling, the effects of Ang2 on lymphangiogenesis are more compatible with its activity as an agonist for Tie2 in lymphatic ECs (34).

### Transforming Growth Factor- $\beta$ 1

TGF- $\beta$ 1 is a multifunctional cytokine that has diverse effects within the vascular system. Studies of vascular development in knockout mice reveal the importance of TGF- $\beta$ 1 signaling in multiple steps of vessel formation and maturation. Approximately 50% of TGF- $\beta$ 1 $^{-/-}$  embryos die by ED10.5 because of defects in yolk sac vasculogenesis and hematopoiesis (35). TGF- $\beta$  signals through a receptor complex that consists of three different subunits, type I, II, and III (36). ECs express a specialized type III TGF- $\beta$  receptor called endoglin. Endoglin-deficient mice die around E11.5 due to defects in embryonic vascular remodeling that are distinctly different from the defects seen with TGF- $\beta$ 1 $^{-/-}$  embryos. The primary deficiencies in endoglin $^{-/-}$  embryos are in pericyte and SMC recruitment, resulting in fragile vessels that fail to sustain the increases in blood flow and pressure that accompany normal growth of the embryo (7). Early stages of vasculogenesis and hematopoiesis are normal, but arterial wall remodeling fails in endoglin $^{-/-}$  mice. Interestingly, venous ECs do not express endoglin. A study of TGF- $\beta$ 1 signaling in yolk sac vessels of endoglin $^{-/-}$  mice showed reduced levels of activated, phospho-Smad2 in ECs that were correlated with defects in mesenchymal cell recruitment and SMC differentiation leading to fragile, dilated, and rupture-prone vessels (8). Because endoglin is only expressed in ECs, and defects are observed in mural cells, endoglin signaling is thought to control the production of soluble factors by ECs that mediate pericyte and SMC recruitment during angiogenesis. At present, the identity of these factors is not clear.

### Nitric Oxide

The diverse nature of factors that promote pericyte recruitment by ECs could reflect a requirement for distinct, nonredundant steps in investment. However, it is also true that many of these diverse signals, including PDGF-B and TGF- $\beta$ , activate a common response in ECs, namely production and release of NO by endothelial NO synthase (eNOS). To test the role of NO in pericyte recruitment, Kashiwagi and colleagues studied tumor angiogenesis in mice following injections of transplantable B16 murine melanoma cells. Tumor-bearing mice that were treated with the eNOS inhibitor N<sup>G</sup>-monomethyl-L-arginine (L-NMMA) exhibited reduced pericyte recruitment and decreased mural cell coverage around angiogenic vessels when compared with vehicle-

treated mice (9). In cell culture assays, inhibition of eNOS resulted in greatly reduced directional migration of mural cell progenitors toward ECs (9). These studies suggest that NOS activity in the endothelium plays an important role in the communication between ECs and mural cells required to build normal vessel walls.

### PERICYTE ALIGNMENT AND CONTACT WITH ENDOTHELIUM

Pericytes are not equally distributed over the surface of microvessels. Rather, they are most frequently found localized over endothelial cell-cell junctions and at microvascular branch points. Moreover, pericyte density varies considerably among different capillary beds (1). Pericyte coverage of the abluminal surface area ranges from 10% to 50% depending on the microvascular bed (11). The highest pericyte density is found in microvessels in the central nervous system (CNS), possibly because of their involvement in maintaining a blood-brain barrier. The morphology of pericyte-endothelial contacts reflects the function of the particular microvascular bed (11). For example, in tissues involved in gas exchange (lung, placenta), pericytes are only sparsely distributed in the microvasculature thus allowing for more or less unrestricted passage into and out of the circulation. In a study of the microvascular responses to histamine-induced inflammation, pericytes were observed to form umbrella-like covers over gaps between ECs, serving to restrain extravasated cells and large plasma proteins from escaping the vessel wall (37). Likewise, interleukin-2 produced a generalized leakage of capillary vessels that was accompanied by pericyte realignments to cluster along EC junctions (38). Unlike SMCs in larger arteries and veins that are separated from the endothelium by one or more layers of ECM, pericytes are located within the EC basement membrane, where they make direct contacts with ECs via tight and gap junctions (39,40). In addition, pericyte-derived products, such as Ang1, have been shown to induce the expression of the tight junction protein occludin in cultured brain microvascular endothelium (41). Moreover, immunoreactive N-cadherin and  $\beta$ -catenin are found in a clustered distribution in capillary ECs that matches pericyte coverage and is lost upon detachment of pericytes from microvessels (39). The importance of homotypic N-cadherin-mediated adhesion between pericytes and ECs was demonstrated by the disrupting effects of blocking antibodies to N-cadherin on brain angiogenesis in developing chick embryos (42).

### PERICYTE ORIGINS AND PHENOTYPES: INFLUENCE OF ENDOTHELIUM

The embryonic origins of pericytes are unclear. Based on their expression of some of the common marker genes for SMCs, such as smooth muscle (SM)  $\alpha$ -actin and desmin, it is often presumed that pericytes are a SMC that is localized

to the microvasculature (43). However, pericytes also express markers that are not uniformly expressed by vascular SMCs, such as high-molecular-weight melanoma antigen (called NG2 in the mouse) (44). Very few lineage mapping studies have addressed whether pericytes share the same origin in development as SMCs. The little evidence that has been reported argues that pericyte origins may be at least as diverse as that of vascular SMCs. For example, a neural crest origin has been demonstrated for pericytes in the brain (11). Moreover, several reports suggest that arteriolar SMCs can serve as a progenitor pool for pericytes. Thus, upstream SMCs have been reported to detach from the arteriolar wall and migrate downstream along capillary basement membranes to adopt a pericyte-like phenotype in skeletal muscle arterioles in newborn rats (45,46). Unlike cardiac and skeletal muscle, vascular SMCs and pericytes are capable of considerable cell migration and proliferation while maintaining expression of differentiated contractile protein marker genes (47–49). A more recent study employed chimeric mice that were made by reconstituting C57Bl/6 mice with syngeneic bone marrow. In two different models of angiogenesis (B16 melanoma tumors or VEGF-A injections), the bone marrow-derived cells found in newly formed vessel walls were not ECs but rather NG2-positive pericytes that did not detectably express the smooth muscle markers SM  $\alpha$ -actin or desmin (50). It also is possible that many pericytes are a type of multipotential mesenchymal cell that gives rise to SMCs when acted upon by endothelium but can adopt alternative cell fates when different signals are encountered. For example, pericytes have been shown to produce bone-forming cells, adipocytes, and myofibroblasts depending on environmental cues, leading to the suggestion that they are a kind of multipotential “reserve” cell that participates in wound repair, tissue remodeling, osteogenesis, and angiogenesis (51). An important question yet to be resolved is whether pericytes also can produce ECs and, if so, what roles that process may play in angiogenesis and tissue repair. Regardless of the source of pericytes, it is likely that common endothelial-derived signals are involved in their recruitment, given the phenotypes of *PDGF-B/PDGF-R $\beta$ <sup>-/-</sup>* mice (20,39).

An important but poorly understood process is how ECs and pericytes become specialized to function in tissue-specific ways in different vascular beds. One critical step in this process is the determination of arterial–venous identity. Previous models, based in part on arterialization of vein grafts, held that arterial identity was conferred on ECs by high rates of blood flow, oxygen content, or intraluminal pressures that are characteristic of the arterial circulation. However, analysis of transcription of the *ephrinB2* locus in vascular development suggested that arterial–venous identity is genetically determined and is an inherent property of ECs even before the onset of blood flow in the embryo (52). Evidence in support of a genetic pathway for specification of arterial or venous identity for ECs quickly followed, particularly from studies of vascular development in zebrafish embryos where the early steps in vasculogenesis are readily accessible and observable (53). Those studies showed that midline structures, including

the notochord, release the signaling protein sonic hedgehog, which stimulates the nearby somites to produce VEGF. Among the target cells for VEGF are ECs that are induced to express arterial-specific markers in a notch-dependent manner (54).

In addition to arterial–venous identity of the endothelium, studies of *ephrinB2-LacZ* reporter mice indicate that SMCs in arteries and arterioles also selectively express this arterial-specific marker (55). Moreover, mural cell expression of *ephrinB2-LacZ* can even be traced down to the level of pericytes that ensheath the capillary walls where it abruptly terminates about midway between terminal arterioles and postcapillary venules (55). During neovascularization in adult tissues, arterial-specific markers appear as early as new pericytes can be identified (56). These data show that arterial–venous identity is an early and intrinsic property of both ECs and mural cells not only in developing embryos but also in adult tissues as well (55,56).

Analysis of transcriptional regulation of the human von Willebrand factor (*h $\nu$ WF*) gene provided strong evidence for a molecular basis of EC diversity within the vascular system. For example, when 487 bp of 5′-flanking sequence from the *h $\nu$ WF* gene were used to drive a  $\beta$ -galactosidase reporter gene in transgenic mice, reporter gene activity was detected in adult brain vasculature, but not in heart, kidney, or aorta (57). By contrast, when 2182 bp of genomic sequence from the same *h $\nu$ WF* locus were tested, reporter gene expression was now found in the heart, skeletal muscle, and brain of adult mice (58). Transplantation of adult cardiac tissue into subcutaneous positions in the ear resulted in induction of reporter gene expression from the 2182 bp *h $\nu$ WF* transgene in auricular microvessels that were in close proximity to the cardiac graft, suggesting an important role for specific target-tissue-derived factors in directing the patterns of *h $\nu$ WF* transgene expression previously described (58). Subsequent analysis showed that cardiac myocytes stimulated microvascular ECs to produce PDGF-AB, which activated the endothelial PDGF-R $\alpha$  to trigger upregulation of *h $\nu$ WF* reporter gene expression (59). These studies suggest that endothelial phenotypic diversity has a transcriptional basis that is, at least in part, determined by the unique properties of individual target tissues.

## PERICYTE FUNCTIONS

Proper incorporation of mural cells is indispensable for blood vessel formation and function. During embryonic development, ECs form a dense network (or plexus) of vessels that is in excess of what will be needed to establish a functional circulation. Vascular pruning reduces the number of vessels to a final density required for efficient tissue perfusion. In the retina, newly formed microvessels are immature and vulnerable to regression until pericytes are recruited (60). The investment of retinal microvessels by pericytes marks the close of a “plasticity window” and the onset of vascular maturation. An important role for EC-derived PDGF-B in retinal pericyte recruitment was verified by the phenotype of mice with

endothelium-specific deletion of PDGF-B (61). These mice exhibited a range of retinal microvascular defects that resemble those seen in diabetic retinopathy (61). In fact, pericyte density throughout the CNS was greatly reduced, with a corresponding increase in capillary regression and microaneurysms (61). However, the precise role of pericyte–endothelial communication in maturation of the retinal vasculature remains unclear as estimates of the number and location of pericytes depend on the markers used, and more recent studies with newer and more selective pericyte markers suggest that pericytes are abundant in both immature and mature retinal microvessels (39).

Endothelial–pericyte communication includes growth-control signals that inhibit cell proliferation. For example, although sprouting angiogenesis proceeds normally in the absence of pericytes, the diameter of pericyte-deficient microvessels in the global *PDGF-B*-knockout mice is abnormal (20). Capillary vessel diameters are either increased or decreased in the absence of pericytes, most likely due to vascular bed-specific responses to the loss of endothelial growth control signals normally provided by pericytes. Indeed, previous studies in cell culture models provided evidence that pericyte investment inhibits EC proliferation, in part via activation of latent TGF- $\beta$ 1 (62). This conclusion is supported by subsequent findings of EC hyperplasia in *PDGF-B*-knockout mice (4,20). Loss of pericytes also leads to defects in formation of EC junctions (20). Along with dilated vessel segments, loss of mechanical support provided by pericytes and their associated ECM makes these vessels prone to dilation and rupture (4,20).

It is commonly assumed that endothelial tubes initially form without pericyte involvement, and that subsequent acquisition of pericyte coverage then leads to vessel remodeling, maturation, and stabilization. However, new evidence suggests that pericytes can invest actively sprouting endothelium and, in some cases, may actually be pioneer cells for angiogenesis that precede the movement of EC sprouts into tissue environments. Moreover, it has been reported that pericyte tubes can be found in tumor vasculature and developing retina with no evidence of ECs in these vessels. Indeed, perfusion of tumor-bearing mice with fluorescein-tagged dextran suggested that pericyte tubes can even support sustained blood flow (63). Nevertheless, given the very small distances that may exist between pericytes and the vascular lumen with even a thin profile of endothelium still intervening, the existence of pericyte-only vessels remains to be conclusively established. Regardless of this caveat, our concepts of the function of pericytes in angiogenesis will need to include the very earliest steps in vascular sprouting and tissue invasion (11).

In addition to serving as microvascular support cells, pericytes also exhibit properties of multipotential mesenchymal cells that are capable of differentiating into myofibroblasts, adipocytes, osteoblasts, and macrophage-like phagocytic cells (64). As such, the functions of pericytes *in vivo* most likely extend beyond their familiar role as endothelial support cells in angiogenesis to encompass important activities in wound

healing, bone and connective tissue remodeling, and as effector cells of inflammation. For example, pericytes in brain microvessels have been shown to respond to inflammatory cytokines, such as tumor necrosis factor (TNF)- $\alpha$  and interferon (IFN)- $\gamma$ , by upregulating the expression of the leukocyte adhesion molecule intercellular cell adhesion molecule (ICAM)-1 and acquiring the activity of an antigen-presenting cell for primed T-lymphocytes via expression of MHC class II molecules on their surface (65,66).

## PERICYTE–ENDOTHELIAL CELL INTERACTIONS IN VASCULAR DISEASE

Defects in pericyte–endothelial interactions have been implicated in the development of a variety of vascular diseases including diabetic microangiopathies, particularly of the retina, Raynaud syndrome, early stages of scleroderma, various central nervous system disorders including multiple sclerosis and Alzheimer disease, vascular calcification, and fibrotic disorders (1,11). Some of the disorders in which defects in pericyte-EC communication have been suggested to play a pathogenic role are discussed later.

### Lymphedema

Pericytes are normally absent from lymphatic vessels. But in a condition known as lymphedema distichiasis (LD), lymphatic vessel function is defective as a result of a mutation in the forkhead-containing transcription factor FoxC2. In mice made deficient in FoxC2 by gene targeting, lymphatic vessels were found to have an increased investment with pericytes and a lack of formation of lymphatic valves (67). The absence of FoxC2 appears to respecify lymphatic endothelium to express a more vascular endothelial phenotype, including increased expression of PDGF-B, reduced VEGFR3 expression, and increased levels of endoglin expression (67). A consequence of this switch in endothelial identity appears to be expression of a gene set for pericyte–mural cell investment.

### Scleroderma

Scleroderma refers to a heterogeneous group of fibrotic disorders characterized by extensive deposition of connective tissue, mostly collagen, in either a localized (usually skin) or generalized (including internal organs) distribution. It is postulated to be an autoimmune disease with a strong microvascular component (68). In progressive systemic scleroderma, capillaries are reduced in number, exhibit perivascular infiltrates of lymphocytes and macrophages, and develop extensive fibrosis (69). Microvessels at the periphery of the sclerotic zone were found to exhibit a more than twofold increase in pericyte density, whereas in the sclerotic zone itself very few blood vessels are found at all (70). Moreover, during the early stages of systemic scleroderma, increased expression of PDGF-R $\beta$  was found on pericytes, suggesting an unusually activated state of

these perivascular cells, possibly contributing to the characteristic perivascular fibrosis found in these patients (71).

### Calcification

Ectopic calcification of blood vessels is a common complication of aging and atherosclerosis. Recent studies show that angiogenesis plays an important role in atherosclerotic plaque progression (72). One of characteristic features of advanced, complicated lesions of atherosclerosis is plaque calcification. Angiogenesis is thought to promote ectopic tissue calcification via cytokines and growth factors that are released from capillary ECs and via the formation of osteoprogenitor cells from resident microvascular pericytes (51).

### Hypertension

In hypertension, the number of SM  $\alpha$ -actin-positive pericytes in brain microvessels of spontaneously hypertensive rats (SHR) was reported to be four times greater than in normotensive Wistar-Kyoto rats (73). Although this may reflect endothelial dysfunction in the SHR strain, it is possible that a systemic pattern of excess pericyte investment by hypertensive endothelium may be an important contributor to increased peripheral resistance in hypertension.

### Diabetic Retinopathy

A loss of pericytes in the retinal microvasculature is one of the earliest histological changes in diabetic retinopathy (74). Pericyte “drop out” also is reported in a number of animal models of diabetes (75). Retinal microvessels have a higher density of pericytes than most other capillary beds and are very sensitive to any change in pericyte numbers. For example, in conditional *PDGF-B*-knockouts where loss of PDGF-B was restricted to the endothelium, pericyte reductions of 50% or more were associated with the development of retinal lesions in one or both eyes (61). Pericyte loss initially triggers EC death and capillary regression, followed by exuberant vascular proliferative responses, retinal fibrosis, and contraction, resulting in retinal detachment and blindness. Therefore, disruptions in the careful balance of endothelial-pericyte interactions in the retinal vasculature can set into motion a reactive sequence of events with severe consequences. The finding of retinopathy in *PDGF-B*-knockout mice suggests that changes in pericyte number or function might actually direct the course of disease rather than serve only as a reactive marker of the condition (76).

## PERICYTE-ENDOTHELIAL INTERACTIONS AS TARGETS FOR ANTIANGIOGENIC THERAPY

Antiangiogenesis therapy is generally regarded as a promising adjunct to current treatments for cancer. The tumor microvasculature exhibits a number of important differences in organi-

zation and function when compared to normal microvascular beds (77). The vascular network of most solid tumors lacks a clear hierarchy of arterioles, capillaries, and venules. Although pericytes are present in tumor vessels, striking differences exist in their shape and organization that suggest abnormalities in endothelial-pericyte communication (78). Pericytes in pancreatic tumor vessels were irregular in shape, exhibited only loose contacts with capillary endothelium, and displayed frequent cytoplasmic extensions that projected abnormally into the tumor tissue (78). When tumor-bearing mice were injected with a small-molecule tyrosine kinase inhibitor that has target selectivity for the PDGF-R $\beta$  (SU6668), pericytes were observed to detach from capillary endothelium, and the tumor vessels in pancreatic islet neoplasms were found to regress (79). When combined with an inhibitor of VEGF receptors (SU5416), the two kinase inhibitors together were more effective at arresting tumor growth at all stages of tumor development that were studied than either inhibitor alone (79). These and related findings have led to the idea that interfering with pericyte-endothelial communication would be an effective antitumor angiogenesis strategy. On the other hand, the idea that improving tumor vasculature would be desirable for cancer chemotherapy also has been proposed. According to this strategy, careful scheduling of a sequence of agents that could improve the function of tumor vasculature would allow more effective delivery of oxygen and chemotherapeutic drugs into the tumor mass to be achieved thereby making the tumor more vulnerable to cytotoxic therapy (80). Whether inhibiting or promoting tumor angiogenesis turns out to be the most effective treatment strategy may depend on the type of tumor, the stage of tumor progression, and the extent of tumor invasion or metastasis. In any case, a detailed understanding of the mechanisms by which ECs and pericytes interact to form and maintain blood vessels will provide a rich resource for new drug targets to enhance or inhibit therapeutic angiogenesis.

## CONCLUSION

This brief review has emphasized the importance of cell-cell communication between ECs and pericytes in the formation, remodeling, and function of microvessels. Although the complexity of the signals exchanged between these two cell types is daunting, it is encouraging that genetic approaches are providing important and detailed insights into this intricate cross-talk. The analysis of microvascular defects in the *PDGF-B*-knockout mouse, for example, has revealed a remarkable specialization of the endothelial tip cell in angiogenic sprouts for migration and signaling. Further study of this specialized EC phenotype will no doubt identify additional secreted factors that control and coordinate pericyte responses during angiogenesis. An important area for further study concerns the origins of pericytes in adult tissues and whether pericyte deficiencies in vivo can be considered approachable by stem/progenitor cell therapy. Finally, further study of endothelial-mural cell interactions during vascular

development will continue to provide important clues as to how these two cell types communicate in adult tissues to build and remodel the microvasculature.

#### KEY POINTS

- Pericyte–EC communication is essential for functional microvascular network formation in development and angiogenesis.
- Pericyte investment of capillary vessels provides critical survival and maturation signals for the endothelium.
- ECs produce multiple signals to recruit pericytes and mural cells, including PDGF-B, S1P, Ang1, and TGF- $\beta$ 1.
- Pericytes can exhibit the properties of multipotential cells, capable of differentiating into chondrogenic, osteogenic, adipogenic, and neurogenic cell types.
- Pericyte–EC communication offers multiple targets for new approaches to anti-angiogenesis therapy.

#### Future Goals

- To undertake a comprehensive characterization of the endothelial tip-cell phenotype in angiogenesis; this will significantly advance our understanding of how pericytes are recruited to areas of neovessel formation
- To determine what spectrum of mesenchymal cell types can be produced by pericytes in the microvasculature and to identify the signals that control pericyte fates in normal and disease tissues

#### ACKNOWLEDGMENTS

#### HISTORICAL OVERVIEW OF PERICYTE RESEARCH

1812 William Wood identifies painful subcutaneous glomus tumors as a vascular neoplasm. Glomus tumors would be shown later to be composed of pericytes.

1873 Rouget describes highly branching connective tissue cells associated with capillary walls. These cells, sometimes called Rouget cells, will later become commonly known as pericytes.

1923 Zimmermann identifies and names "pericytes" using a modification of Golgi's silver impregnation stain for nerve cells. This stain-

ing technique allowed the long, thin, and highly branched cell processes characteristic of microvessel-associated pericytes to be seen in tissue sections.

1924 Masson describes the normal structure of the glomus body, a small neurovascular complex sensitive to variations in temperature that regulates arteriolar blood flow. The glomus body shunts blood from arterial to venous systems without an intervening capillary network. Found in fingers, toes, and nail beds, glomus bodies contain abundant sensory nerves, accounting for the painful sensations of pericyte-rich glomus tumors.

1940 The Clarks report their observations on microvessels in rabbit ear chambers. Their studies revealed the highly dynamic and reversible nature of endothelial–pericyte interactions in response to changes in blood flow in living blood vessels.

1942 Stout and Murray identify the epithelioid cells in glomus tumors as a type of pericyte. Stout went on to identify and characterize a related but more invasive pericyte-derived neoplasm, which he named hemangiopericytoma.

1961 Majno and Palade identify a role for pericytes in control of microvascular permeability in response to histamine or serotonin.

1983 Gitlin and D'Amore describe an improved method for isolation and culture of retinal pericytes that becomes widely used to study pericyte properties in vitro.

1994 Targeted gene deletion studies in mice by Betsholtz and by Soriano identify a crucial role played by PDGF-B signaling, via the PDGF- $\beta$  receptor, for pericyte recruitment in vascular development and angiogenesis.

# Vascular Smooth Muscle Cells

## The Muscle behind Vascular Biology

---

Shivalika Handa, Karolina Kolodziejska, and Mansoor Husain

*Toronto General Hospital, University of Toronto, Ontario, Canada*

Vascular smooth muscle cells (VSMCs) may be considered end-effector organs of the vasculature. They mediate the vaso-motor responses orchestrated by the endothelium and are the principal pathogenic agents in diseases such as atherosclerosis, restenosis, and hypertension. Indeed, VSMCs represent an ideal target for the therapy of these conditions.

In atherosclerosis, for example, endothelial cells (ECs) and macrophages are primarily involved in the initiation of this disease, whereas VSMCs are typically the last to manifest pathological change (Table 61-1). However, once they do, the proliferative, synthetic, and matrix-modulating capacities of VSMCs underlie obstructive lesion formation and play a critical role in determining plaque stability (1).

VSMCs are highly responsive to their environment and are able to switch their phenotype from quiescent and contractile to migratory, synthetic, and proliferative (2). Various cues from the surrounding milieu, such as hormonal signals from overlying ECs, cytokines from invading macrophages, and mechanical stresses on the vessel wall, can both initiate and sustain the modulation of VSMC form and function.

Under normal conditions, ECs lining the arterial lumen act as sentinels and gatekeepers. By virtue of their location, ECs are the first to respond to circulating factors and hemodynamic stresses, rapidly relaying these signals to VSMCs for transduction (3). ECs also prevent circulating cells and macromolecules, such as lipids or plasma proteins, from penetrating the underlying intima and media indiscriminately. This insulates the underlying VSMCs from stimuli that might otherwise activate them or initiate their phenotypic conversion. However, when ECs become diseased or damaged this barrier function may fail (4). Under these circumstances, ECs elaborate molecular “alarm bells” that initiate inflammatory cell adhesion (5), thrombosis, vasoconstriction, and eventually VSMC proliferation. As such, a symbiotic relationship exists between ECs and VSMCs: ECs need VSMCs to carry out specific tasks, and VSMCs require the protection and guidance of ECs to do so.

In this chapter we will overview the role of VSMCs in vascular function and disease, highlighting how this cell type is the “muscle” behind vascular biology, and how learning the language spoken between the endothelium and VSMCs reveals pathophysiological insights and may lead to novel therapeutic approaches.

### HISTORY

#### Early Descriptions of Vascular Smooth Muscle Cells: A Cell with Two Faces

As early as 1911, comparative-staining reactions described the vascular wall of elastic and muscular arteries as mostly “mucoïd,” showing metachromatic material that was thought to be a precursor to elastin (6). By the late 1950s, the tunica media of elastic arteries was described as containing an atypical VSMC, lacking well-defined sarcolemmal envelopes and dense masses of cytoplasm, and not as spindle shaped as the classical VSMCs described in other arteries. Rather, these cells were termed fibroblast-like but were recognized as VSMCs because of the presence of myofilaments (6). Such descriptions are some of the earliest on the presence of a synthetic phenotype of VSMCs in vivo.

Based on immunostaining and high-resolution electron microscopy, we again learned that the synthetic phenotype of VSMCs displays many characteristics similar to those of fibroblasts. Specifically, synthetic-type VSMCs harbor finger-like projections, an increased prevalence of rough endoplasmic reticulum and Golgi bodies, and underdeveloped or discontinuous basement membranes (7). However, in contrast to fibroblasts, these cells stain positively for smooth muscle (SM) myosin-1, and SM myosin heavy chain (SM-MHC) isoform B (8). Nevertheless, controversy remains as to how and whether the phenotypically modulated synthetic VSMC can be distinguished from a fibroblast or from a putative bipotential precursor known as the myofibroblast. For further details on

**Table 61-1: Comparison between Vascular Smooth Muscle Cells and Endothelial Cells**

	VSMCs	ECs
Activation	Proliferative, migratory Synthetic phenotypes Dedifferentiation, transformation	Procoagulant, proadhesive, proinflammatory phenotype
Spatial heterogeneity	Differences between VSMC and pericytes Differences between regions of large and small vessels and between intimal, medial, adventitial VSMC	Differences between large and small vessels, between same-sized vessels in different organs, and between neighboring ECs
Origins	Splanchnic and lateral plate mesoderm during early development Marrow-derived circulating and vessel resident progenitors in adults	Splanchnic and lateral plate mesoderm during early development Marrow-derived circulating progenitors in adults
Cell-cell communication	Respond to EC-derived PDGF, NO, and endothelin-1	Respond to VSMC-derived Ang1
Ca <sup>2+</sup> entry or Ca <sup>2+</sup> -release from internal stores	Contraction in contractile cells Migration and proliferation in synthetic cells	NO release and vasodilation
Hemodynamic forces	Strain	Shear stress and strain
Response to		
Serine proteases	✓	✓
Cytokines (TNF)	✓	✓
Chemokines	✓	✓
Growth factors	✓	✓
LPS	✓	✓
Cell Cycle	Vessel resident cells normally exist in G <sub>0</sub> growth arrest Recurrent reentry into cell cycle in response to injury, mitogens, and cytokines	Vessel resident cells normally in G <sub>0</sub> growth arrest Proliferation and capture of circulating progenitors participating in endothelial repair
Implicated in Disease	Hypertension Atherosclerosis Restenosis Shock	Thrombosis Inflammation Hypertension Atherosclerosis Restenosis Organ rejection

TNF, tumor necrosis factor; LPS, lipopolysaccharides.

the most current molecular methods for distinguishing these two cell types, the reader is referred to a recent review (9).

## DEVELOPMENT

The phylogeny of VSMCs and ECs remains elusive. Vertebrates, such as the well-studied zebrafish (*Danio rerio*) and African clawed frog (*Xenopus laevis*), possess highly organized vascular networks consisting of both cell types. These model organisms have proven to be powerful tools for

understanding vascular development, including patterning, vasculogenesis, and angiogenesis. Invertebrates such as the nematode (*Caenorhabditis elegans*) and fruit fly (*Drosophila melanogaster*) display visceral smooth muscle cell (SMC) and skeletal-like muscles, as well as cardiac muscles in the case of *Drosophila* (10–14), but neither possesses VSMCs or ECs.

The vascular system of the developing vertebrate embryo is assembled via two distinct mechanisms. Initially, EC precursors (i.e., angioblasts) undergo specification from the mesoderm and proliferation. Subsequently, these migrate and come together to form a primitive network of vessels. Such de

novo assembly of a vascular plexus has been termed *vasculogenesis*. In amniotes, there exist two main sites for primary vascular network formation: the yolk sac blood islands and the embryo proper (15). Successive remodeling involves sprouting and branching of new vessels from preexisting ones, transforming the primary plexus into a highly elaborate EC network now acting to recruit SMCs and pericytes. Generally, the latter step is excluded from capillaries. In the adult, well-characterized examples of angiogenesis accompany tissue growth, pregnancy, the female reproductive cycle, and wound healing. Pathologically, angiogenesis plays a critical role in diabetic retinopathy, tumor growth, and metastasis (16). The role of VSMCs or pericytes in the formation of vessels larger than capillaries – that is, where they may be required for structural integrity – is just beginning to be understood (17).

Although the source of angioblasts or hemangioblasts (bipotential precursors of endothelial and hematopoietic lineages) is the splanchnopleural and local mesoderm (15), the origins of VSMCs are more confounding. Most SMCs originate from splanchnic mesoderm and local mesoderm, however VSMCs of the coronary arteries originate from epicardium (18–21) and VSMCs of the aortic outflow tract are derived from neural crest (22,23).

At the molecular level both vasculogenesis and angiogenesis are initiated via vascular endothelial growth factor (VEGF), a powerful mitogen and chemoattractant of angioblasts. Its signaling is mediated via VEGF receptors VEGFR1 (FLT-1) and VEGFR2 (FLK-1/KDR) expressed on ECs (24–26). VEGFR2 is the earliest known marker of developing ECs and begins to be expressed at embryonic day (E)7.0 in the mouse (24). Angiogenesis, being the more complex process, requires vasodilatation and increased EC permeability, followed by destabilization of surrounding VSMCs and matrix, enabling new sprout formation (16). Remodeling depends on angiopoietin 2 (Ang2) signaling through its receptor Tie2, expressed on all ECs, as well as activation of matrix metalloproteinases (MMPs), chymases, and other proteases. Proliferating ECs migrate to assemble a new adjoining vessel and begin secreting platelet-derived growth factor (PDGF)-B, thus attracting local VSMC precursors (27). Contact between these two cell types initiates a cascade of events leading to vessel stabilization and maturation. Upon transforming growth factor (TGF)- $\beta$ 1 activation, ECs cease to proliferate and migrate and reduce their VEGFR2 expression, whereas SMCs acquire their mature phenotype. The expression of Ang1 by VSMCs signals back to ECs through the Tie2 receptor to ensure vessel stabilization (17).

In addition to participating in EC signaling, VSMC progenitors also require expression of a number of transcription factors to become differentiated to their typical contractile form. These include the serum response factor (SRF) and its cofactor myocardin, the MADS-box family members Smad5 and myocyte enhancer factor 2C (MEF2C), lung Kruppel-like factor (LKLF), and heart and neural crest derivatives expressed transcript (dHAND) (28,29). Coordinate expression of SM-specific contractile and cytoskeletal proteins has become a standard for assessing differentiation status. The ear-

liest of all such markers is SM $\alpha$ -actin, expressed at E9.0 in the mouse, followed shortly by SM22 $\alpha$ , SM $\alpha$ -actinin,  $\alpha$ - and  $\beta$ -metavinculin, then h-caldesmon, h1-calponin, and SM1 isoform of SM-MHC, with the SM2 isoform of SM-MHC being a late molecular marker of maturing VSMCs (2). Similarly, the use of temporal expression patterns of proteins associated with the EC lineage, beginning with TAL1 and VEGFR2, through platelet-endothelial cell adhesion molecule (PECAM)-1 (also known as CD31), CD34, vascular endothelial (VE)-cadherin, and Tie2, has become a standard tool for tracking endothelial development (30).

Assembly of vessels must naturally reflect their future function, be it in an aorta, capillary, or a venous or arterial vessel. EphrinB2 has been found to mark future arterial, but not venous ECs, while in a complementary manner EphB4 (a receptor for ephrinB2) marks the venous endothelium. This divergence occurs at the earliest stages of the capillary plexus formation when these cell types are intermingled and virtually indistinguishable, indicating possible cross-talk between these two populations (31). Importantly, vessel-specific signals that VSMC recruitment and differentiation must also exist. This can be inferred from studies defining arterial- (and not venous- or visceral-) specific promoter elements in the SM22 $\alpha$  gene (32,33).

It is worth noting that the exploitation of this knowledge base for the regeneration or bioengineering of large-sized vessels containing both ECs and VSMCs has yet to occur. Our ability to “grow” blood vessels large enough to restore impaired organ perfusion may depend on the application of such insights. On the other hand, the potential for targeting genetic therapies to specific vascular beds has been realized for both ECs (34,35) and VSMCs (36–39), at least in animal models.

## PHYSIOLOGY

### Cardiac, Skeletal, and Smooth Muscle: Specialized Functions More Different than Alike, with Surprising Regenerative Capacity

The adult human body contains three distinct muscle tissues: skeletal, cardiac, and smooth. Skeletal muscle cells are large, multinucleated cells that contain actin and myosin filaments arranged in parallel within functional groups or sarcomeres. This organization gives rise to striations that are a distinctive feature of these cells and visible by light microscopy (40). Skeletal muscle cells are believed to be terminally differentiated and incapable of mitosis. However, regenerative repair of this tissue is possible and appears to occur from resident satellite cells or circulating precursor cells (41,42). Skeletal muscle cells will not contract unless stimulated to do so by nearby nerve cells; therefore, this tissue also is known as striated voluntary muscle (40).

Cardiac muscle cells are comparatively smaller in size than skeletal muscle but also are striated and generally thought to contain only one centrally placed nucleus. However, these cells are capable of close alignment or fusion with each other to

form myotubes and fibers, which may then appear multinucleated. Traditionally, we have also viewed cardiac myocytes as being terminally differentiated cells incapable of cell division and have thought of cardiac muscle as a tissue that cannot regenerate after injury due to the absence of satellite cells (40). These concepts have recently been challenged, both by the recognition of cardiac-resident or circulating stem cells capable of making new cardiac myocytes (43,44) and by genetic animal models in which cardiac myocytes overexpressing cell cycle proteins have been shown to retain proliferative potential (45). In the context of endothelial biomedicine, it is particularly important to highlight here recent studies demonstrating that circulating human CD34<sup>+</sup> (i.e., endothelial) progenitor cells (EPCs) can be programmed to transdifferentiate into cardiomyogenic cells (46) and that human EPCs can form direct tubular communications with cocultured cardiomyocytes (47). Indeed, both transdifferentiation and cell fusion are believed to explain the observed regenerative potential of human EPCs in mouse models of cardiac injury (48). Cardiac muscle tissue is known as striated involuntary muscle (40), as the nervous system provides only indirect control over the heart rhythm, which can be independently sustained by specialized pacemaker cells in the sinoatrial (SA) and atrioventricular (AV) nodes.

By contrast, SMCs are small, spindle-shaped mononucleated cells that do not undergo cell fusion or myotube formation. The actin and myosin filaments in these cells are organized differently from skeletal or cardiac cells such that no striations are present. Without requiring a progenitor population (although these also exist [49–54]), SMCs can self-replicate and regenerate after injury. Visceral SM contractions can be triggered by the autonomic nervous system, such as in the enteric plexus of the gut, but these cells generally contract either spontaneously or in response to coordinated hormonal signals and are consequently termed *involuntary muscle* (40).

### The Physiology of Muscle Contraction

The main function of a muscle cell is to contract. Both striated and nonstriated muscle types share a common mechanism of contraction known as the sliding filament model. At the beginning of a cycle, myosin cross bridges are bound to actin with high affinity, creating the rigor state. Cross bridges are detached upon binding to ATP, which is hydrolyzed followed by a weakly bound reattachment of the myosin head. Release of inorganic phosphate (P<sub>i</sub>) permits transition into strongly bound force-generating states that are terminated by ADP release. This, however, is where the similarities end.

In striated muscle cells, contraction is initiated by release of acetylcholine from nerve cells, which triggers an action potential by stimulating the opening of membrane calcium (Ca<sup>2+</sup>) channels, allowing an influx of extracellular calcium. Contraction follows a rise in the intracellular calcium concentration ([Ca<sup>2+</sup>]<sub>i</sub>), and relaxation occurs when the [Ca<sup>2+</sup>]<sub>i</sub> drop. In striated muscle cells, the interaction of calcium with troponin activates contraction.

In SMCs the situation is distinctly different (55). Calcium binds to calmodulin (CaM), and this complex interacts with the catalytic subunit of myosin light chain kinase (MLCK). Ca<sup>2+</sup>/CaM-activated MLCK then phosphorylates serine 19 on the regulatory light chain of myosin, MLC-20. Phosphorylation of MLC-20 is the “on” switch for actin-activated ATPase activity, which follows the sliding filament pathway to contraction. Decreases in [Ca<sup>2+</sup>]<sub>i</sub> inactivate MLCK, which permits dephosphorylation of MLC-20 by myosin light chain phosphatase (MLCP). Dephosphorylation of MLC-20 inhibits ATPase activity and the muscle relaxes.

Most importantly, contraction-inducing increases in [Ca<sup>2+</sup>]<sub>i</sub> in VSMCs can be brought about by two very different mechanisms. The first is somewhat analogous to what occurs in striated muscle and is known as electromechanical coupling. This pathway involves changes in the resting membrane potential of smooth myocytes, leading to depolarization and influx of extracellular calcium through voltage-gated calcium channels (VDCCs). Coupled with calcium-induced calcium release (CICR) from the sarcoplasmic reticulum (SR), increases in [Ca<sup>2+</sup>]<sub>i</sub> occur and contraction ensues through Ca<sup>2+</sup>/CaM-mediated activation of MLCK. In electromechanical coupling, resting negative membrane potentials (typically –40 to –70 mV) are restored by potassium channels and sodium–potassium exchanger activity. This closes VDCC and stops further influx of extracellular calcium. The [Ca<sup>2+</sup>]<sub>i</sub> can then be returned to basal levels by the sarcoplasmic-endoplasmic reticulum Ca<sup>2+</sup>-ATPase (SERCA) pumps (56) and efflux via the plasma membrane Ca<sup>2+</sup>-ATPase (PMCA) pumps and, to a much lesser extent, the sodium calcium exchanger (NCX) (57). Even after Ca<sup>2+</sup> levels are lowered and Ca<sup>2+</sup>-CaM-dependent MLCK activity is lost, smooth muscle relaxation will not occur until MLCP does its work.

Although only employed by a few select visceral myocytes, electromechanical coupling enables autonomic nervous system control over smooth muscle contraction. Tonic or steady-state SMCs respond to excitatory stimuli by graded depolarizations only, whereas phasic smooth muscle responds with action potentials (58). The former is an important function for SMCs that need to be maintained in a contractile or rigor state for long periods of time and at very low metabolic cost. An example of this in the human body is in the smooth muscle of certain sphincters.

The second pathway through which contraction-inducing increases in the [Ca<sup>2+</sup>]<sub>i</sub> are brought about is pharmacomechanical coupling. This route is independent of any changes in resting membrane potential and does not require extracellular calcium. This pathway involves receptor–ligand interactions on the cellular membrane, which activate second messenger signaling molecules that lead to the release of sequestered compartments of intracellular calcium (55). Importantly, spatially and functionally distinct intracellular calcium stores exist in VSMCs that enable Ca<sup>2+</sup>-dependent functions other than contraction to be carried out in much the same way (59–61). Although the role of calcium regulation in the control of cell cycle will be discussed below, we will focus here on the

mechanisms through which hormonal signals from the endothelium achieve contraction in underlying VSMCs.

Principally, pharmacomechanical coupling in VSMCs is initiated by a hormone–receptor interaction between a specific ligand and its G-protein–coupled receptor (GPCR). This leads to activation of phospholipase C (PLC), which generates inositol 1,4,5-triphosphate (IP3) (62). IP3 binding to IP3 receptors (IP3R) located on the SR mediates release of this particular calcium store and an increase in  $[Ca^{2+}]_i$  (63). It is important to recognize that in addition to producing an IP3-mediated increase in  $[Ca^{2+}]_i$ , GPCR-signaling also activates other molecular participants that sensitize the VSMCs to  $Ca^{2+}$ -initiated contractions through a variety of molecular mechanisms acting either directly or indirectly on MLCK and MLCP. The Rho/RhoA/Rho-associated kinase (ROCK) pathway (64), amongst others, is a critical mediator of such added functionality, which is a dominant feature of pharmacomechanical coupling and absent from electromechanical coupling. The importance of these pathways to VSMC contractility in specific, and cardiovascular function in general (65), is highlighted by the efficacy of pharmacological agents specifically targeting this pathway (66,67). Along similar lines, specific members of the RGS family of proteins (regulators of G-protein signaling) expressed in VSMCs have been shown to dampen GPCR-dependent calcium transients, and mice deficient in RGS2 exhibit profound hypertension (68). However, much still needs to be learned about regulation of VSMC contraction. For example, in transgenic mice designed to have reduced  $[Ca^{2+}]_i$  by virtue of forced overexpression of human PMCA4b in VSMCs, the resultant phenotype was one of increased vascular reactivity and elevated blood pressure (69). Although not completely elucidated, the mechanism believed to be active in this model involves the subcellular localization of this particular PMCA, and its coassociation and inhibition of neuronal nitric oxide synthase (nNOS) (69).

Because of the time needed to produce IP3 and mediate the successive steps involved in sensitization and contraction, VSMC contractions brought about by pharmacomechanical coupling may take as long 1 to 3 seconds to take effect (55). Although such a delay would be unacceptable for striated muscle functions, this putative disadvantage is more than compensated by the intricate “remote control” of VSMC tone and function offered by this pathway. Indeed, without VSMCs having evolved pharmacomechanical coupling, every contractile VSMC would need to be electrically linked to a depolarizing EC or neuron. Having said that, experimental evidence supports a physiologically important role for gap-junction–mediated connectivity between VSMCs themselves (70).

### Maintaining the Vascular Wall: It's About More than Contractility

The human body contains blood vessels of many different shapes and sizes. The largest arterial blood vessels are elastic arteries. These contain many layers of VSMCs alternating with sheets of elastic laminae. The smallest artery that contains

VSMCs is the precapillary arteriole, which may have only a single layer. Because it is obvious that the structures of these two types of vessels are very different, one cannot assume that their physiologies will be the same. For example, although presumably exposed to similar “risk factors” in vivo, only large or conduit arteries are associated with atherosclerotic plaque formation, whereas the smaller arterioles, or resistance arteries, are not. It is tempting to speculate that this could be due more to fundamental differences in the number and nature of VSMCs residing in these locations than to differences in EC biology.

Remodeling responses also are markedly different between these two types of vessels. In conduit arteries, the outer diameter of the vessel is often enlarged, without a reduction in lumen size. This form of remodeling is referred to as *outward hypertrophic remodeling*, a state in which an increased lumen diameter and medial cross-sectional area are present (71). By contrast, resistance vessels typically undergo *inward eutrophic remodeling*, where the lumen is decreased but the cross-sectional area of the media has not changed. The precise mechanisms mediating this type of remodeling are not yet known, but one of the theories put forward is that intimal proliferation is balanced by medial apoptosis. In some cases, resistance arteries also exhibit *inward hypertrophic remodeling*, where the lumen diameter is decreased and the medial cross-sectional area has enlarged (71).

What physical forces determine vessel wall proportions, and what laws govern remodeling? In normal arteries, the product of blood pressure and lumen size determine the thickness of the vascular wall (72). Since the mean pressure in conduit arteries is relatively constant, the determining factor for wall thickness is the radius of their lumens. By Laplace's law (Equation 1), for any given pressure, the larger a vessel's radius the greater the outward stretching force known as *wall tension* will be (73):

$$T = PR/2t \quad (\text{Equation 1})$$

The only way to reduce wall tension is either to lower intraluminal pressure (not physiologically feasible) or increase wall thickness. Since the endothelial and adventitial layers of an artery are structurally “weak,” the media must meet most of the stress on the vessel wall. As vessels with larger radii will require more layers of medial VSMCs and more structural matrix elements, one would intuitively expect a higher prevalence of proliferative- and synthetic-type VSMCs in the media of larger elastic arteries. Indeed, culturing and cloning studies have shown that two distinct populations of VSMCs can be found in the medium-sized internal thoracic artery of humans (74). Studies of SMC-specific transgene expression in vivo provide further evidence for VSMC-subtype-selective gene regulation (75–77).

The radius of the lumen also is determined by the size and activity of the vascular bed it serves (72). Vessel branching increases as one moves away from the core of the body, which permits vascularization of distal tissues. Understandably, the lumen of the blood vessel progressively decreases as branching increases. Although the role of blood pressure may be limited

in determining normal vessel diameter, the role of blood flow is critically important, especially in small resistance arteries (72). ECs sense differential shear or frictional forces imposed by varying blood velocities. Increased velocity leads to increased lumen diameter mediated by EC signaling and VSMC relaxation. Likewise, reduced flow velocity decreases lumen diameter through VSMC constriction. Understanding the communications between the EC sensor and the VSMC effector is thus central to understanding both the dynamic and structural changes to vessel size and systemic hemodynamics (3).

## **PATHOLOGY**

Atherosclerotic and restenotic coronary and cerebrovascular diseases remain the leading causes of death and disability in our society, and VSMC proliferation is the histological hallmark of these lesions (1,78,79). Although intraluminal stents have reduced the negative remodeling that accompanies angioplasty (80,81), in-stent stenosis due to the migration and proliferation of VSMCs remained, until recently, a serious and not infrequent complication (82). Brachytherapy and drug-eluting stents have limited the incidence and extent of in-stent stenosis (83–85), however, efforts aimed at elucidating the fundamental mechanisms that govern VSMC proliferation remain highly relevant to our understanding of atherosclerosis and its consequences. Yet, despite enormous efforts aimed at understanding the molecular and cellular basis of proliferative vasculopathies, it is both remarkable and unfortunate that so little of this research has translated to the clinical arena. These difficulties are likely due to the inherent redundancies present in biological signaling systems and the consequent failure of therapies aimed at upstream pathways. Accordingly, many groups have focused their efforts on improving our understanding of the final common pathway of cell cycle progression in VSMCs. Indeed, the success of drug-eluting stents owes much to their targeting of the VSMC cell cycle (86).

It is noteworthy that the ability of differentiated VSMCs to repeatedly reenter the cell cycle is unique among mature myocytes. Indeed, this property underlies the phenotypic plasticity of VSMCs and forms the very basis of their pathogenic potential. Thus, it may be incumbent upon us to also address the molecular mechanisms involved in the development and differentiation of VSMCs, as they may improve our ability to identify and prevent the dedifferentiation of VSMCs in disease (2,9).

### **Phenotypic Plasticity of Vascular Smooth Muscle Cells**

A remarkable feature of VSMCs is their ability to modulate their phenotype between quiescent contractile and synthetic proliferative states. This process was initially recognized in cell culture where structural changes in VSMCs during early primary cell culture were observed (87). Cells undergo phenotypic modification such that they lose their contractile

apparatus and exhibit disorganization of myofilaments, show increased presence of endoplasmic reticulum and Golgi, increase the synthesis of DNA and RNA, and become highly proliferative (7). Morphologically, synthetic VSMCs show a rounded or polygonal shape versus the elongated spindle shape of the contractile phenotype. Subsequently, functional observations revealed that these cells also synthesize and secrete collagen and elastin (7), thereby earning the designation “synthetic” phenotype.

Following these important observations, several investigators have shown that culturing VSMCs from large elastic arteries from bovine (88) and human (74) sources results in phenotypically distinct cell types. Additionally, it has been shown that in vascular proliferative diseases such as atherosclerosis, VSMCs take cues from the surrounding environment, neighboring ECs, and modified macromolecules such as low-density lipoprotein (LDL) to switch to a synthetic phenotype, which are a dominant pathogenic force in neointima and plaque formation (2).

An important and interesting observation from these and other studies is that synthetic-type VSMCs downregulate expression of marker genes such as *SM $\alpha$ -actin*, *SM22 $\alpha$* , and *SM-MHC* (89) and concomitantly upregulate a set of genes required for synthetic, migratory, and proliferative functions (9). This process is reminiscent of the developmental or undifferentiated state of smooth muscle and is often referred to as *dedifferentiation*. Recent discovery of VSMC and EC progenitor cells circulating in the blood and capable of incorporating into damaged vasculature or contributing to neovascularization of tissues in need of repair have challenged and expanded our understanding of this complex system (54).

The mechanisms underlying these processes will need to be harnessed for effective regenerative therapies, and they highlight an important concept in pathogenesis: our body's two primary biological programs, development and defense, share common pathways. Indeed, this concept has provided strong rationale for studies in developmental biology and opens the door to new tools, such as stem cell technologies, to aid in the therapy of a large variety of human diseases.

## **Cardiovascular Disease**

Cardiovascular disease is a leading cause of death in North America (90), affecting more than 70 million Americans (91). Moreover, this burden will continue to grow as people with two or more risk factors for cardiovascular disease – smoking, obesity, hypertension, diabetes, etc. – make up 28% of all adults. Of primary relevance to this chapter on VSMCs are the vascular diseases of atherosclerosis and hypertension.

### ***The Role of Vascular Smooth Muscle Cells in Atherosclerosis***

Atherosclerosis is an inflammatory disease involving lipid accumulation within the wall of muscular and elastic arteries, causing plaque formation. These plaques consist mostly of

foam cells, which are macrophages and/or VSMCs that have taken up lipid particles, necrotic cell debris, cholesterol esters, and calcium deposits. Lesion formation in humans occurs as early as childhood, at which stage the lesion is often described as a fatty streak and consists mainly of macrophages and T lymphocytes (1).

The formative cell biology of this disease has long been a topic of much interest. The popular response-to-injury hypothesis implicates the ECs as the initiating culprit. Although early theories were based on endothelial denudation as the key first event, more recent attention has been given to dysfunction of *intact* endothelium as the starting point. ECs dysfunction can be caused by many factors, such as elevated modified LDL levels, free radicals formed from smoking, shear stresses in high blood pressure, genetic defects, and infections by viruses and/or bacteria (1).

Injury to the endothelium leading to dysfunction results in increased expression of adhesion molecules and chemokines, such as vascular cell adhesion molecule (VCAM)-1 and monocyte chemoattractant protein (MCP)-1, and subsequent recruitment and accumulation of blood leukocytes to the area (5,92). Injury to the endothelium also increases its permeability, thereby decreasing its ability to form a protective barrier to the underlying vascular cells (4). Blood platelets, monocytes, and other immune-related cells are free to enter the vascular wall, where they proliferate and, in combination with ECs, produce cytokines and growth factors such as PDGF, TGF- $\beta$ , and fibroblast growth factor 2 (FGF2) (1).

These molecules all stimulate VSMC proliferation and migration, which leads to neointima formation and thickening of the vascular wall. At this stage, the blood vessel can undergo outward hypertrophic remodeling to compensate for the increased medial cross-sectional area. Accumulation of macrophages and other blood cells within the vascular wall provides a source of hydrolytic enzymes and other immune-related responses that lead to the formation of a necrotic core. Continuous VSMC migration and proliferation combined with the inflammatory response leads to an enlarged lesion that becomes covered by a fibrous cap. Eventually, dilatatory compensation by the vessel wall reaches its outward limit and the growing plaque begins to occlude the lumen area and obstruct blood flow (1).

In the coronary arteries, this process may manifest first as angina, described as an oppressive pain or tightness in the chest, and a potential warning sign of a more dangerous cardiovascular event. Continued disease progression can lead to complete occlusion of the blood vessel at the site of plaque formation or plaque rupture, leading to occlusion and embolism by thrombus. As described, these events may occur in a coronary artery, leading to myocardial infarction; in the peripheral vasculature, resulting in critical limb ischemia; or in cerebral vessels, causing stroke. Approximately three-quarters of all deaths resulting from cardiovascular disease are a consequence of such complications of atherosclerosis (91).

Known for their migratory and proliferative capacity, VSMCs are key mediators in the progression of atherosclerosis.

In this disease, VSMCs respond to signals sent from the diseased endothelium and other inflammatory cell types, thereby playing the role of a late but critical accomplice. A focus on this pathogenic potential has resulted in a large number of studies on the mechanisms by which VSMCs migrate and proliferate, only some of which will be briefly reviewed in the following section.

### *Mitogens, Calcium, and Cell Cycle Control*

VSMCs in the vasculature are primarily quiescent and rely on specific signals to initiate migration and proliferation. Such signals arise from different sources, such as activated macrophages, platelets, ECs, or other “transformed” VSMCs. One major stimulant of VSMC migration and proliferation is PDGF, which is produced by platelets and macrophages within atherosclerotic lesions; however, ECs and VSMCs have been shown to be additional important sources of this critical chemoattractant and mitogen (2). Indeed, the unique receptor and signaling pathways through which the different PDGF isoforms stimulate both migration and proliferation of VSMCs have been the focus of several studies to which the reader is referred (93–95). A recent review further details the lessons learned from mouse models of global and tissue-specific perturbations in PDGF signaling (27).

TGF- $\beta$  also has been shown to be involved in VSMC proliferation, matrix deposition, and neointima formation in transgenic and injury models of atherosclerosis (96). However, studies involving this molecule have yielded contradictory results. Some have shown that TGF- $\beta$  promotes VSMC differentiation, whereas others have shown that neutralizing antibodies to TGF- $\beta$  promote the development of atherosclerosis (2).

The cellular transcription factors that mediate the signals of these and other mitogens have been extensively studied. For example, the proto-oncogenes *c-fos*, *c-myc*, and *c-myb* are early-response genes that follow growth factor–receptor binding in VSMCs (97). Temporally late in this sequence, the *c-myb* gene encodes the nuclear phosphoprotein c-Myb, a transcription factor that plays a key role in promoting late G<sub>1</sub>/S phase cell cycle progression in this cell type (98). First, antisense oligonucleotides to *c-myb* (99), and then unique dominant negative c-Myb (39) constructs were used to demonstrate that reductions in c-Myb activity abolish the normal rise in both resting and stored  $[Ca^{2+}]_i$  as cells move to the G<sub>1</sub>/S transition. This effect was partly due to a significant increase in the Ca<sup>2+</sup> efflux rate of dominant negative (DN)-Myb–transfected cells (98), mediated in part by increased mRNA and protein levels of plasma membrane Ca<sup>2+</sup>-ATPase 1 (PMCA1) and PMCA4 (98,100). The importance of PMCA1 as a critical regulator of Ca<sup>2+</sup> efflux and  $[Ca^{2+}]_i$  was specifically demonstrated in both growth-arrested and proliferating VSMCs, without manipulations of c-Myb (101).

Although other c-Myb–dependent targets, unrelated to calcium regulation, also may play a role in regulating VSMC proliferation (102–105), the importance of the Ca<sup>2+</sup>-mediated effects cannot be overstated. Indeed, a number of

investigators have shown that the regulation of cell cycle-associated  $[Ca^{2+}]_i$  and cell cycle progression also is dependent on SERCA-maintained  $Ca^{2+}$  stores (106–110) and the IP<sub>3</sub>-responsive  $Ca^{2+}$ -release pathway (111–115). For example, treatments with Thapsigargin, a known SERCA inhibitor, have been shown to inhibit the proliferation and migration of venous (116) and arterial VSMCs (117). Of interest, preliminary data suggest that in addition to the known cell cycle-associated decreases in PMCA, expression levels of the most abundant isoforms of SERCA (SERCA2) and the IP<sub>3</sub> receptor (IP<sub>3</sub>R1) also are regulated during G<sub>1</sub>-to-S phase cell cycle progression of VSMCs (118) and that these may also be mediated by c-Myb (119). These observations are consistent with the ability of c-Myb to act as both a *repressor* (100,120,121) and activator of transcription (102–105,119) and implicate c-Myb as a fundamentally important master switch for cell cycle  $Ca^{2+}$  homeostasis (122,123).

Taken together, the above data strongly support the existence of a  $Ca^{2+}$ -sensitive checkpoint in G<sub>1</sub>/S. Although many investigators have similarly demonstrated the importance of  $[Ca^{2+}]_i$  in cell cycle progression (124,125), remarkably little is known about the precise manner in which  $Ca^{2+}$  mediates this effect. Given the temporal association of cyclin E and the cyclin-dependent kinase-2 (cdk2) with the G<sub>1</sub>/S interface (126,127), and the fact that cdk2 expression levels are  $Ca^{2+}$ /CaM-responsive (128), it seems reasonable to hypothesize that the cdk2/cyclin E complex may mediate the  $Ca^{2+}$ -sensitivity of G<sub>1</sub>/S transitions. Indeed, preliminary data show that cdk2 and cyclin E are coexpressed at the G<sub>1</sub>/S interface of VSMCs and that their activity at this cell cycle stage is  $Ca^{2+}$ -dependent (129,130).

In addition to studies employing VSMCs *in vitro*, the issue of whether c-Myb-directed therapies would be of physiological importance *in vivo* has been addressed (97,122). In the first tissue-specific approach described, a carotid artery denudation model of restenosis in the mouse was used to show that VSMC proliferation and neointima formation were significantly inhibited by DN-Myb expression (39). However, these experiments were conducted in young animals with presumably intact endothelial function and normal carotid arteries. Given that the biology of VSMCs from atherosclerotic vessels is distinct from those of normal vessels, the question of whether c-Myb- or other cell cycle-directed therapies targeted specifically to VSMCs will be of benefit in preventing or reducing restenosis in atherosclerotic arteries or atherosclerosis itself remains unanswered.

Notwithstanding the evidence supporting a role for c-Myb in the proliferation of VSMCs, little is known of its role in the embryonic development and differentiation of VSMCs. For that matter, little is known, in general, of the mechanisms underlying the phenotypic plasticity and ability of VSMCs, but not other myocytes, to dedifferentiate. Although one study has suggested a potential role for *c-myb* in the development of neural crest-derived SMCs (131), this may have been confounded by the poor specificity of the antisense *c-myb* oligonu-

cleotides employed (132–134). Mouse embryos homozygous for the *c-myb* allele (*c-myb*<sup>-/-</sup>) appear to perish at approximately E15.5 because of failed hematopoiesis (135). Given that the discovery of *c-myb* was based on its sequence similarity to leukemia-causing oncogenes (136), and that its critical role in myeloid differentiation had already been established (136–139), attributing the phenotype of *c-myb*<sup>-/-</sup> mice to a disorder of hematopoiesis was expected (135). Whether subtle defects in cardiovascular development were present in the *c-myb*-knockout embryos was never specifically examined. However, the normal expected frequency of pups generated in crosses to enable tissue-specific expression of a DN-Myb suggested that interference with c-Myb in a spatiotemporal pattern defined by the *SM22 $\alpha$*  promoter employed in this study did not result in abnormalities of cardiovascular development (39). These data suggested that c-Myb-dependent genes either do not play a role in the development of cardiac and/or vascular structures at time points defined by *SM22 $\alpha$* -expression or that there exist redundant (or DN-Myb-insensitive) pathways active during differentiation and development but not during pathogenic proliferation of adult VSMCs. This would represent an extremely important distinction, with broad implications for VSMC-directed gene therapies. Indeed, the question of whether c-Myb plays a role in the development and differentiation of VSMCs through assays employing embryonic stem (ES) cells (140–142) harboring reporter genes activated by SMCs, and more specifically VSMCs, differentiation (32,75,143,144) are now of interest.

Further insight into the mechanisms underlying VSMC proliferation have been gained by studying the effects of inhibiting the action of a negative regulator of cell proliferation such as TGF- $\beta$  (145) or the glucocorticoid receptor (146). In an atherosclerotic mouse model, mice that were injected with antibodies against the PDGF- $\beta$  receptor exhibited decreased lesion size and reduced numbers of intimal VSMCs (147). Recently a group of investigators published findings of inhibited serum-stimulated SMC proliferation with DNazymes, moieties that target translational start sites of specific genes such as *Egr-1* (148).

### **Stents: Marrying Metals, Medicines, and Marrow**

As outlined earlier, atherosclerosis is a highly prevalent disease, and its complications affect hundreds of millions of people worldwide. This enormous market, and the need for effective solutions to restore and maintain the patency of narrowed and occluded atherosclerotic vessels, have driven biotechnology research for several decades. A particularly promising development has been the marriage between mechanical device manufacturers and basic biomedical scientists – producing the recent offspring known as the drug-eluting stent (DES).

A stent is composed of a thin and initially collapsed wire network designed to open as a cylindrical tube inside the lumen in which it is deployed. This inflation at very high pressures presses the stent circumferentially out against the occluding plaque and/or thrombus in the vessel. This restores blood flow

to the target tissue, with the stent's tensile strength preventing elastic recoil or vasospasm. Initially, the use of bare metal stents was common; however, early thrombotic closure within the stent and late in-stent restenosis were not infrequent problems. Although the development of potent antiplatelet agents such as GpIIb/IIIa antagonists (149) and ADP receptor antagonists (150) greatly reduced the former, in-stent restenosis remained the Achilles' heel of this technology. Consequently, variations on the simple wire stent were explored to prevent the malignant VSMC proliferation that characterized this particularly troublesome lesion.

Utilizing radiotherapy, stents themselves were made radioactive by direct ion implantation of  $^{32}\text{P}$ . At low doses (0.14  $\mu\text{Ci}$ ), radioactivity may prevent VSMC proliferation, as shown in a pig model of coronary disease (151). However, the beneficial effect of low-dose radiotherapy appeared to be limited to short-term studies of up to 28 days postimplantation (151). When the experimental model was followed for 6 months after stent implantation, studies showed that higher doses of radiotherapy (24–48  $\mu\text{Ci}$ ) were more effective, with the caveat that the stented area displayed delayed healing in the form of incomplete endothelialization (152). Radiotherapy also has been shown to induce medial thinning and adventitial scarring in both the human and the pig (153). Nevertheless, the subsequent use of transient intra-arterial radiation or "brachytherapy" by means of a beta emitter brought transiently to the site of a treated in-stent restenosis has shown sustained efficacy over 2 years of follow-up and remains popular in some centers (154,155). However, one study comparing radiotherapy with DES in patients with in-stent restenosis suggests the latter to be a better choice (156).

DES for the treatment of in-stent restenosis, and first-time coronary artery lesions prone to restenosis, has become the subject of several clinical studies. Commonly used drugs are paclitaxel, which prevents VSMC proliferation and migration *in vivo* (157); rapamycin, which has antiproliferative and anti-inflammatory effects in humans after angioplasty and has been shown to repress proinflammatory and proadhesion molecule expression (158); and sirolimus, which inhibits VSMC proliferation by blocking cell cycle progression (86). Clinical trials have shown beneficial effects of paclitaxel-eluting stents 9 months after implantation (159), and when multiple, overlapping stents are used to cover a large area, favorable effects have been observed up to 2 years postimplantation (160).

A new and exciting technology has emerged involving the use of stents that capture EPCs. Stents coated with antihuman CD34 antibodies trap circulating EPCs, which attach to the stent and subsequently form a functional endothelial layer over the stented area. These stents offer an advantage over the use of pharmacological agents in that by producing a new, functional EC layer, the vasculature is essentially rebuilt, whereas pharmacotherapy is limited by the bioavailability of the drug. Results of the first clinical trial using this stent have shown that this is a feasible and promising technique for stent-based treatment of coronary artery disease (161).

### *The Role of Vascular Smooth Muscle Cells in Hypertension*

Approximately one in every three Americans has high blood pressure (91), which is defined as a systolic pressure of 140 mm Hg or higher and diastolic blood pressure of 90 mm Hg or higher. Hypertension affects more men than women until the age of 55, after which there is a higher prevalence of women with hypertension (91). Of those with this condition, as many as 30% are unaware and 25% are on medication but do not have optimal blood pressure control (91).

Many of the mechanisms underlying hypertension remain unknown. However, there have been a vast number of basic and clinical studies, each focused on a particular "mediator" of the disease. The initiating factors can vary from smoking and EC dysfunction, to pregnancy, renal dysfunction, genetic diseases, and so on. One common theme in hypertension is that although the initiating mechanism may be variable, progression of the disease is dependent on VSMC function and structure. Specifically, remodeling responses, hypertrophy, and contractile responses of the vessel wall all rely on VSMC biology. Therefore, studies on the intricate regulation of contraction, relaxation, and regulated growth of VSMCs will be central to therapeutic breakthroughs in this disease.

In the vasculature, shear stress, acetylcholine, and other factors induce  $\text{Ca}^{2+}$  release in EC. This in turn activates endothelial NOS (eNOS), which then produces nitric oxide (NO), otherwise known as endothelial-derived relaxing factor (EDRF). This molecule can then diffuse to underlying VSMCs, activate soluble guanylate cyclase (sGC) to produce cyclic GMP (cGMP), and mediate VSMC and overall vessel relaxation (162). Nitroglycerin, an age-old therapy for coronary artery disease, is a NO-donor that also stimulates sGC to produce cGMP. Both endogenous and exogenous NO-stimulated cGMP relax VSMCs through two main pathways: first, by decreasing  $[\text{Ca}^{2+}]_i$ , and second, by altering the calcium sensitivity of the contractile apparatus (163). Once formed, cGMP activates cGMP-dependent protein kinase (PKG). Via phosphorylation, this enzyme inactivates membrane calcium channels, increases potassium channel activity, decreases IP<sub>3</sub>-mediated activity of IP<sub>3</sub>R, and deactivates PLC, which reduces IP<sub>3</sub> production. PKG acts to reduce the sensitivity of the cell's contractile system by increasing the activity of MLCP (163).

As intimated earlier, the Rho-GTPase system is important in regulating the contractile, migratory, and phenotypic status of SMC. The Rho family of proteins carries out its signaling mechanisms by binding and activating Rho-kinases (ROCK). These effector enzymes regulate, again by phosphorylation, many important molecules in the cell. ROCK phosphorylate MLC to induce nominal direct contractile effects, however, more significant is their inhibitory phosphorylation of MLCP, which dramatically increases contractility of the VSMC. In essence, the Rho/ROCK pathway increases the calcium sensitivity of VSMCs such that lower  $[\text{Ca}^{2+}]_i$  are required for contraction. ROCK activity also can increase actin stress fiber and focal adhesion formation and mediate cell migration by

reorganization of the actin cytoskeleton, and it also plays a role in the phenotypic modulation of VSMCs (64).

Sphingosine-1-phosphate (S1P) is released from activated platelets in the blood. This molecule acts on specialized S1P receptors (endothelial differentiation gene [Edg] receptors) located on both ECs and VSMCs. S1P has been shown to be involved in the maintenance of ECs barrier integrity, migration, and proliferation (164). Depending on which receptor subtype S1P is acting on, it can either induce or inhibit VSMC proliferation and migration (164). S1P has been shown to be an upstream mediator of Rho-GTPase pathways (165), activation of PLC/IP3-mediated calcium release from the SR, and phosphorylation of MLC by ROCK, subsequently sustaining VSMC contraction (166).

As mentioned earlier, the causes of hypertension are variable and scientists engaged in this field argue the respective importance of their particular pathways of interest. Vascular biologists believe that the root problem stems from an imbalance between contracting and relaxing forces in the ECs and VSMCs; endocrine and renal experts will implicate the renin-angiotensin system or disproportional salt and water retention in the kidneys; whereas neurophysiologists will implicate neurohormones and the sympathetic nervous system. On these specific topics, the reader is referred to recent reviews (3,167–170). Finally, there is an unequivocal genetic component to human hypertension, and animal models such as the spontaneously hypertensive rat, syngeneic rat strains, or various transgenic mouse models have implicated many individual genes or sets of genes as crucial contributors (69,171–175). Although it is clear that no single mechanism acts in isolation to perpetuate hypertension, the participation of the VSMC at either the systemic or organ-specific level is undeniable.

## THERAPY

### Common Cardiovascular Drug Treatments that Directly Target Vascular Smooth Muscle Cells

*HMG-CoA reductase inhibitors*, otherwise known as statins, are often prescribed to patients with high cholesterol or those at a significant risk for cardiovascular disease. Initially used for their lipid-lowering effects, statins are now recognized as multifunctional and of benefit in a variety of conditions. In addition to lowering plasma LDL and increasing high-density lipoprotein (HDL) concentrations, statins have been shown to inhibit VSMC proliferation, act as anti-inflammatory agents, inhibit platelet function, and improve endothelial function (176).

*Angiotensin-converting enzyme inhibitors* (ACEI) block the ability of ACE to convert angiotensin (Ang)-I to Ang-II, through its activation of the angiotensin receptors (AT1 and AT2), mediates potent vasoconstriction but also has proliferative effects on VSMCs (177). Ang-II stimulates the expression of other mitogens, adhesion molecules, chemotactic proteins, cytokines, oxidized LDL, and MMPs (178), all of which contribute to atherosclerotic plaque instability. An additional

therapeutic effect of ACEI is their ability to prevent the ACE-mediated degradation of bradykinin (BK), an endogenous activator of eNOS, thereby capturing all the salutary benefits of NO. Indeed, ACEI have been commonly prescribed to patients with cardiovascular disease now for many years. ACEI have been shown to be beneficial by increasing plaque stability and decreasing inflammation in the vascular wall (178), and these biological findings have translated into significant clinical benefits (179).

*Angiotensin-receptor blockers* (ARBs) work in a slightly different manner but have similar effects to those of ACEI. The ARB competitively inhibit AT-1 and/or AT-2 receptor activation, achieving all the benefits (and side effects) of blocking Ang-II, but not those of preserving BK (180). ARB treatment can correct small artery remodeling responses in patients with hypertension (181).

*Calcium channel blockers* (CCBs) are often prescribed for their negative inotropic and chronotropic effects on the heart. As described earlier, cardiac muscle relies on calcium entry to induce contraction, at a rate that is carefully regulated by pacemaker cells. Cardiac contractility, heart rate (and thus myocardial oxygen demand), and arrhythmias can all be treated with CCB. Although pharmacomechanical coupling appears to be the dominant contractile pathway in VSMCs, these myocytes also harbor VDCC, and CCB may achieve their vasodilatory and antihypertensive properties in part by limiting calcium entry. CCB inhibit voltage-dependent calcium entry via T-type and L-type channels, which results in vasorelaxation and are certainly effective agents for the treatment of hypertension (182).

## DIAGNOSTICS

As reviewed earlier in this chapter, the initiation of vascular disease is often due to endothelial dysfunction, disordered ECs signaling, and abnormal VSMC responses. Eventually, VSMCs receiving prolonged and specific pathological signals may transform to a migratory, synthetic, and proliferative phenotype that underlies vascular disease.

Currently, noninvasive medical diagnostic tools enabling molecular analysis of ECs or VSMCs at early or late stages of disease are few and far between. This is a fundamental limitation that requires attention, as the clinical implementation of much basic science knowledge will be difficult to achieve without such tools. Although still considered to be “in development,” physicians may soon be armed with technologies capable of detecting some characteristic molecular perturbations associated with abnormal hemodynamic forces, oxidative stress, adhesion molecule expression, and vascular cell apoptosis (see later). These developments may permit earlier and more accurate diagnoses, allowing more specific regenerative or reparative approaches. Having said that, there exists a critical need for a greater number and variation of probes designed for the molecular imaging of ECs and VSMCs. To become clinically useful, these probes will have to be nontoxic,

specific, and detectable with high-resolution imaging. Meanwhile, some of the currently available noninvasive and invasive techniques utilized for studies of VSMCs are briefly reviewed.

### *Computed Tomography*

This radiographic technique has undergone rapid redevelopment with the arrival of 64-slice cameras that can image vessel walls and provide angiographic images of remarkable clarity (183). This technique can also measure calcification in the aorta and coronary artery, a finding that correlates with obstructive coronary artery disease, and to a lesser extent with cardiac event rates (184).

### *Magnetic Resonance Imaging*

The nonradiographic imaging offered by MRI has revolutionized many areas of clinical medicine and surgery. Its potential for application as a molecular diagnostic tool for the vasculature is reviewed elsewhere in this volume (see Chapter 176). With respect to VSMC imaging, MRI can characterize a carotid atherosclerotic plaque, defining different components of the plaque, namely the fibrous cap, necrotic core, and calcium deposition (185). This imaging technique also can quantify size or volume of plaque, detect breaks in the fibrous cap, and identify thrombotic events within the plaque (185). Of particular interest is the possibility of coupling MRI with ferromagnetic tracers composed of nanoparticles linked to antibodies targeting specific cell surface markers. Such a strategy has been used, for example, to define the expression of VCAM-1 in ECs of atherosclerotic animals (186).

### *Single Photon Emission Computed Tomography and Positron Emission Tomography*

Single photon emission computed tomography (SPECT) and the much-higher-energy coincidence-imaging made possible with positron emission tomography (PET) have been mainstays for the noninvasive diagnosis of flow-limiting coronary stenosis and viable myocardium. However, their potential as platforms for molecular imaging has only just begun to be realized (187). Radionuclide tracers coupled to anti-Annexin-V antibodies have been shown to detect apoptosis in the myocardium (188), and similar “hot spots” in the vessel wall have correlated with inflammatory transformation of atherosclerotic plaque (189,190).

### *Gluteal Artery Biopsy*

This powerful technique has been successfully exploited in human subjects with hypertension to explore the vasomotor physiology and molecular biology of small arteries in this condition (71). After a 1 cm horizontal incision is made in the upper external gluteal quadrant, a 1 × 0.5 × 0.5 cm cube of superficial subcutaneous tissue and immediately underlying fat are excised. In this specimen, several small arterioles can be microdissected and employed for perfusion myography (191) or biological and biochemical analyses. No skin

is removed, facilitating repeat procedures and rendering the intervention small, minimally invasive, and well-tolerated one. Patients describe little residual discomfort, and practically no complications occur (71).

This technique is particularly useful, because larger arteries may not show changes in lumen diameter due to eutrophic remodeling. By contrast, small arteries typically exhibit signs of inward remodeling. As such, the effectiveness of antihypertensive medicines on arterial remodeling can be directly monitored (191) and correlations made between vessel structure and function.

### KEY POINTS

- VSMCs are the muscle behind the EC, the two cell types existing in a symbiotic relationship that begins in development and continues through to disease.
- VSMCs are unique muscle cells capable of migrating, contracting, proliferating, synthesizing, and destabilizing their surrounding matrix components on remote cues from circulating plasma proteins, ECs, platelets, and inflammatory cells.
- The contractile phenotype of VSMCs has elaborate spatially and functionally distinct calcium stores that are tightly regulated and used to effect a variety of calcium-dependent functions, the foremost of which is pharmacomechanical coupling.
- The proliferative phenotype of VSMCs has equally elaborate cascades of transcription factors that regulate calcium homeostatic mechanisms, which ultimately mediate calcium-sensitive cell cycle proteins and cell cycle progression.
- Both phenotypes of VSMCs participate in disease, the contractile phenotype mediating abnormal vasomotor control in hypertension, and the proliferative phenotype mediating the remodeling of hypertension, atherosclerosis, and restenosis.
- By targeting VSMC pathobiology, the marriage of implantable stent technology with radiation, anti-inflammatory and antiproliferative medicines, and EC capture has significantly altered the long-term success of angioplasty procedures for restenosis and atherosclerosis.
- Most of the most commonly prescribed drugs in cardiovascular medicine have important mechanisms of beneficial action via their effects on the VSMCs.
- Diagnostic advances including molecular imaging and small-tissue biopsies with attendant studies on vessel structure and function will be the windows through which the next generation of insights in vascular health and disease will be observed.

# Cross-Talk between the Red Blood Cell and the Endothelium

## Nitric Oxide as a Paracrine and Endocrine Regulator of Vascular Tone

Sruti Shiva and Mark T. Gladwin

*Vascular Medicine Branch, National Heart, Lung, and Blood Institute;  
National Institutes of Health; Bethesda, Maryland*

The endothelium and red blood cells, although often studied in isolation, clearly interact to modulate nitric oxide (NO)-dependent vascular homeostasis, including basal blood flow, shear- or flow-mediated vasodilation, and hypoxic vasodilation. NO, produced by endothelial NO synthase (eNOS), plays a fundamental role in regulating blood flow. Recent data implicate a critical function for hemoglobin and the erythrocyte in regulating the bioavailability of NO in the vascular compartment. In fact, a delicate balance exists between endothelial NO formation, which is produced tonically and in response to shear stress (modulated by red blood cell mass), and NO scavenging by the erythrocytic hemoglobin. The scavenging of NO by hemoglobin inside an intact red blood cell is greatly diminished by diffusional barriers to NO – intrinsic to and surrounding the red cell. Compartmentalization of hemoglobin by the red cell also limits extravasation of hemoglobin dimers into the interstitial compartment. Intravascular hemolysis disrupts this balance by the release of hemoglobin from the red blood cell into plasma. This extracellular hemoglobin is then able to scavenge endothelial-derived NO approximately 600-fold faster than erythrocytic hemoglobin, thus disrupting NO homeostasis. This may lead to vasoconstriction, decreased blood flow, platelet activation, increased endothelin (ET)-1-dependent vasoconstrictor activity (because NO modulates ET receptor expression to promote a vasodilator phenotype), adhesion molecule expression, and end-organ injury (1,2). This suggests a novel mechanism of disease for hereditary and acquired hemolytic conditions such as sickle cell disease and malaria. In addition to providing an NO scavenging role in the physiological regulation of NO-dependent vasodilation, hemoglobin and the erythrocyte may deliver NO as the hemoglobin deoxygenates. Although this process has been ascribed previously to S-nitrosated

hemoglobin (SNO-hemoglobin), recent data from our laboratories suggest that deoxygenated hemoglobin reduces the ubiquitous blood and tissue anion nitrite ( $\text{NO}_2^-$ ) to NO, leading to vasodilation along the physiological oxygen ( $\text{O}_2$ ) gradient.

In this context, the endothelium can be considered a signaling organ that generates both paracrine NO and endocrine  $\text{NO}_2^-$  (in addition to other putative endocrine NO-modified species). In the remainder of this chapter, we outline the basic principles by which NO mediates local signaling between the red cell and endothelium; describe a role for the endocrine action of nitrite, a newly uncovered storage form of NO; and describe how nitrite may potentially be used as a therapeutic agent to treat diseases characterized by endothelial dysfunction and organ ischemia.

### ENDOTHELIUM-DEPENDENT VASODILATION AND PARACRINE PROPERTIES OF NITRIC OXIDE

In 1933, the German physiologist Schretzenmayer demonstrated that increased blood flow to the canine femoral artery could result in an increased blood vessel diameter (3), thus demonstrating the physiological property of endothelium-dependent flow-mediated vasodilation. Almost 50 years later, in 1981, Furchgott and colleagues proposed that the endothelium produced a vasodilator substance called *endothelium-derived relaxing factor* in response to acetylcholine stimulation. They experimentally demonstrated that endothelium-denuded aortic rings paradoxically constricted rather than dilated on exposure to acetylcholine (4). The surprising revelation that this paracrine (endothelium-to-smooth muscle) relaxing

factor was the free radical gaseous molecule NO led to a Nobel prize for Furchgott, Ignarro, and Murad (4–9).

The endothelium expresses NO synthase enzymes that catalyze the O<sub>2</sub>-dependent conversion of the guanidino group of L-arginine to NO, producing L-citrulline as a byproduct (10, 11) (Table 62-1). To mediate vasodilation, the NO generated diffuses to underlying vascular smooth muscle cells (VSMCs), where it binds to the heme group of soluble guanylate cyclase to activate the enzyme. Activated soluble guanylate cyclase in turn produces cyclic GMP (cGMP), a second messenger that drives a kinase cascade that ultimately results in relaxation of the smooth muscle. The discovery of this pathway cemented the vital role of the endothelium as a master organ system regulating vascular homeostasis by producing paracrine vasodilator, antioxidant, antithrombotic, and antiproliferative mediators.

We now understand that vasomotor tone is determined by an exquisite balance of vasoconstrictors, vasodilators, and receptors expressed by the endothelium. Although the list of both paracrine and endocrine vasodilators produced by the endothelium is expansive (Table 62-2), NO is responsible for maintaining approximately 25% of basal blood flow (12–14), 100% of flow- or shear-mediated blood flow (15), 40% to 50% of acetylcholine-dependent blood flow (16), and 10% of exercise-dependent blood flow (17). It also contributes importantly to heat-mediated flow (18). (The emerging role of endothelium-derived NO in the regulation of hypoxic vasodilation is discussed later in this chapter). NO further regulates the levels and biochemical fate of superoxide through a direct reaction that also regulates levels of bioactive NO and forms the potent oxidant peroxynitrite (ONOO<sup>-</sup>). NO also alters

the production of other vasodilators such as prostacyclin; modulates the distribution and concentration of the potent vasoconstrictor ET-1 and its receptors; inhibits thrombosis at multiple levels; is an intermediate in the vascular endothelial growth factor (VEGF) signaling pathway; and tonically down-regulates endothelial adhesion molecules, such as intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and P- and E-selectin (2). It is increasingly apparent that this system becomes unbalanced in diseases of the cardiovascular system, such as pulmonary hypertension and coronary artery disease. Patients with systemic hypertension, pulmonary hypertension, diabetes, obesity, and atherosclerotic vascular disease all demonstrate impaired production of endothelium-derived NO (13,16). In fact, the coronary vasculature of these patients paradoxically constricts with exposure to acetylcholine, thus recapitulating Furchgott's isolated rabbit aortic ring experiments (13). The expansive role of NO in vascular health and disease supports the assertion that NO is a central regulator of homeostatic vascular function.

#### **RED BLOOD CELLS AND HEMOGLOBIN MODULATE THE BIOLOGICAL FATE OF ENDOTHELIUM-DERIVED NITRIC OXIDE**

Although the paracrine exchange of vasoactive mediators between the endothelium and smooth muscle has been studied extensively, the role of the intravascular compartment in regulating NO homeostasis only recently has been explored. Although intravascular shear stress on the endothelium from

blood flow stimulates eNOS and the production of NO, hemoglobin within the red blood cell exerts an opposing effect on NO homeostasis by scavenging NO and decreasing NO bioactivity (19,20). Because NO is highly diffusible, its inactivation and spatial localization depends on its reactivity with other molecules, including heme proteins and reactive oxygen species (ROS) on both sides of the endothelium (21). Because the small uncharged NO molecule is freely and randomly diffusible, in a given area where NO is produced, such as the endothelium, a spatial gradient of NO concentration occurs. Owing to this random diffusion, this gradient is constrained by scavenging reactions even if these reactions occur on only one side of the endothelium. Thus, even NO generated on the basolateral side of the endothelium is susceptible to scavenging by an intravascular NO sink (22).

In particular, NO reacts at nearly diffusion-limited rates ( $10^7 \text{ M}^{-1}\text{s}^{-1}$ ) with both oxy and deoxyhemoglobin within the vasculature (19,23). When hemoglobin is oxygenated, reaction with NO yields the inert molecule nitrate and methemoglobin (Equation 1), while NO binds to the iron of deoxyhemoglobin to form iron-nitrosyl hemoglobin (Equation 2) (19,23–25).

In chemical terms, these reactions approach the diffusion limit and are essentially irreversible. These chemical equilibrium kinetics create a paradox in vascular biology. From a kinetic and equilibrium standpoint, the high concentration of hemoglobin (10 mM concentration in heme) present in blood should (theoretically) rapidly consume most available NO synthesized by the endothelium before it diffuses to the smooth muscle cell layer (26). Stated differently, the proximity of an irreversible high-affinity NO sink (hemoglobin) should severely limit the diffusional radius of NO from its endothelial source. The solution to this paradox requires compartmentalization of hemoglobin within the erythrocyte, which generates diffusional barriers for NO that decrease the reaction rates between NO and hemoglobin. In addition to an intrinsic diffusional barrier created by the erythrocytic membrane and submembrane protein scaffolding (27,28), there exists an unstirred layer around the red blood cell membrane (29,30) and an erythrocyte-free zone that forms along the endothelium as red cells centrally concentrate in laminar flowing blood (31–33). The combination of these barriers decreases the reaction rate of NO with hemoglobin by over 600-fold under physiological conditions. This allows NO to escape inactivation by hemoglobin and diffuse to the smooth muscle to mediate local paracrine activity (29,30,32,33). In addition to the formation of diffusional barriers, the compartmentalization of hemoglobin in the red cell prevents extravasation of hemoglobin dimers into the interstitial compartment (19,34).

Figure 62.1. Disruption of NO-dependent vascular signaling by hemolysis. NO is produced by the enzyme NOS in the endothelium. Under physiological conditions, NO diffuses into the smooth muscle cells as well as into the lumen of the vessel to mediate vasodilation and a host of other responses important to maintaining vascular homeostasis. NO bioactivity is limited by its chemical reactivity with molecules such as intraerythrocytic hemoglobin and superoxide generated from xanthine oxidase. The reaction of NO with hemoglobin is limited by diffusional barriers around the red blood cell and along the endothelium. During intravascular hemolysis, cell free oxyhemoglobin in the plasma ( $\text{Fe}^{\text{II}}-\text{O}_2$ ) rapidly scavenges NO, converting it to nitrate ( $\text{NO}_3^-$ ). This decreases NO bioavailability to both smooth muscle cells and other vascular targets of NO, leading to a disruption of vascular homeostasis. For color reproduction, see Color Plate 62.1.

Although the NO–hemoglobin dioxygenation reaction (Equation 1) and iron-nitrosylation (Equation 2) are reduced by compartmentalization of hemoglobin in red cells, the scavenging reactions remain significant and contribute to vascular tone and the maintenance of NO as a paracrine signaling molecule. The half-life of NO in whole blood is less than 2 milliseconds, and increasing hematocrit reduces NO availability and raises blood pressure. This pressor effect is notable during polycythemia and with the clinical treatment of anemia using erythropoietin (35,36). The NO-scavenging effects of red cell hemoglobin are likely teleologically balanced by opposing effects of erythropoietin on inducing NOS expression and by shear-mediated NO synthase activation (37,38).

### Disruption of Nitric Oxide–Dependent Vascular Homeostasis in Hemolytic Disease

During intravascular hemolysis, erythrocytes lyse and release hemoglobin into the plasma, disrupting the diffusional barriers between NO and hemoglobin (Figure 62.1 for color reproduction, see Color Plate 62.1). (1,2,20,39). This compartmentalized hemoglobin rapidly oxidizes NO to nitrate, inhibiting NO-dependent responses in the vessel. This idea is supported by *in vitro*, animal, and human studies that demonstrate that cell-free hemoglobin at concentrations as low as 6  $\mu\text{M}$  completely inhibits acetylcholine-mediated vasodilation and produces vasoconstriction (40–42). A reduction in NO bioavailability is characteristic of a number of pathologies that share a component of intravascular hemolysis, such as sickle cell disease and paroxysmal nocturnal hemoglobinuria (2,39).

Our group has shown that the plasma from patients with sickle cell disease contains higher concentrations of cell-free hemoglobin ( $4.2 \pm 1.1 \mu\text{M}$ ; ranges from undetectable to 20  $\mu\text{M}$ ) than healthy controls ( $0.2 \pm 0.1 \mu\text{M}$ ), and stoichiometrically consumes NO *in vitro* and *in vivo* (39). In these patients, higher cell-free hemoglobin levels also correlated with a resistance to the vasodilatory effects of infused sodium nitroprusside, further supporting the hypothesis that NO scavenging by cell-free hemoglobin can disrupt NO-dependent vascular homeostasis (39). Vasodilation during infusions of NO donors (nitroprusside, nitroglycerin, NONOates) is blunted in patients with sickle cell disease (39,43) and in transgenic mouse models of sickle cell disease (44–46). This resistance to NO correlates with plasma hemoglobin levels (39,45). Apart from contributing to the pathogenesis of hemolytic diseases, NO scavenging by cell-free hemoglobin is thought to contribute to the toxicity of the stroma-free hemoglobin-based blood substitutes. In clinical and preclinical trials, the administration of these substitutes led to systemic hypertension (47), smooth muscle spasm (48), decreased organ perfusion (49), and risk of death, consistent with a decrease in NO bioactivity (2). In addition to adversely affecting blood flow, NO scavenging has other implications within the vasculature. Physiologically, NO tonically inhibits the transcription of soluble vascular cell adhesion molecules (VCAM-1 and ICAM-1) in endothelial cells (ECs). Thus, a decrease in NO bioactivity also leads to an increase in the expression of VCAM-1 and ICAM-1 (39,50,51). NO inhibits platelet activation, thrombogenesis, and clot stability, and it regulates ET-1 expression and the distribution of its receptors (52–55). NO also plays an

intermediary role in the VEGF signaling pathway. It is therefore likely that chronic NO inactivation in hemolytic diseases has extensive downstream consequences on vascular homeostasis, thrombosis, and angiogenesis.

Indeed, hemolytic conditions such as sickle cell disease and paroxysmal nocturnal hemoglobinuria are associated with relative hypertension (compared to the hypotension of nonhemolytic anemias) (56), pulmonary hypertension (57,58), and esophageal and smooth muscle dystonias during paroxysms of hemolysis (59). In addition to the release of hemoglobin during hemolysis, the red blood cell also contains large quantities of arginase. Increases in plasma levels of this enzyme, which metabolizes arginine to ornithine, reduce the substrate for eNOS. In patients with sickle cell disease, plasma arginase activity increases in direct proportion to intravascular hemolytic rate (60). Furthermore, increased arginase activity and an associated low arginine:ornithine ratio is associated with pulmonary hypertension and risk of death in these patients (60).

Epidemiological data increasingly suggests that chronic intravascular hemolysis produces a state of hemolysis-associated endothelial dysfunction and a progressive proliferative vasculopathy. The clinical manifestations of this vasculopathy include pulmonary hypertension, cutaneous leg ulceration, priapism, and stroke (20,61,62). Pulmonary hypertension is a recognized complication of sickle cell disease, thalassemia, paroxysmal nocturnal hemoglobinuria, spherocytosis, stomatocytosis, and microangiopathic hemolytic anemias, such as hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) (57,63,64).

Multiple systems have evolved to limit the toxicity of cell-free plasma hemoglobin, including the high-molecular-weight haptoglobin system (prevents extravasation of hemoglobin and limits NO scavenging) (40,65,66); hemopexin; CD163 hemoglobin scavenger protein (which not only mediates haptoglobin-hemoglobin clearance but also upregulates interleukin [IL]-10 and heme oxygenase 1) (67); and the heme oxygenase 1/biliverdin reductase/p21 pathways, which exert anti-inflammatory, antioxidant, and antiproliferative effects (68–72).

### NITRIC OXIDE AS AN ENDOCRINE MEDIATOR

Although the NO radical has a half-life of only 2 milliseconds in whole blood, a number of studies suggest that in addition to a local paracrine activity, NO may possess an endocrine bioactivity within the blood. These studies suggest that NO is somehow stabilized, transported, and bioactivated at remote sites within the vasculature:

- In humans, NO gas inhalation (80 ppm) has limited effects on basal blood flow in the forearm. However, when eNOS is inhibited, inhaled NO significantly increases regional forearm blood flow (73).
- Infusions of NO solutions into the human forearm are associated with measurable increases in blood flow in the opposing arm (74).

- In a feline model of mesenteric ischemia–reperfusion, inhaled NO increases blood flow following reperfusion and decreases leukocyte adhesion. In this model, inhaled NO also increases blood flow to the intestine during NO synthase inhibition (75,76).
- Mean systemic arterial pressure and systemic vascular resistance are decreased in sheep breathing 80 ppm NO gas (77).
- Inhaled NO (80 ppm) increases renal blood flow, urinary flow, and glomerular filtration rate in anesthetized pigs (78).
- In a recently completed, randomized, placebo-controlled trial of NO therapy for premature newborns with respiratory failure, NO treatment significantly reduced the combined end point of intracranial hemorrhage, periventricular leukomalacia, or ventriculomegaly, an effect consistent with endocrine transport of an NO intermediate in the blood to the central nervous system (79).

In many of these studies, the observed vasodilation was associated with increases in plasma levels of S-nitrosated, N-nitrosated, and iron-nitrosylated proteins as well as  $\text{NO}_2^-$ . These data suggest that NO might be stabilized in the circulation in the form of a higher oxidation product (nitrite) or as an NO-modified protein, peptide, and/or lipid (S-nitrosothiol, N-nitrosamine, or nitrated lipid) and released later at distal sites to act as an NO-dependent signaling molecule.

Although support for the concept of a circulating NO store has advanced in the last few years, much controversy surrounds the identity of the circulating species, how it forms, and its mechanism of action. The principle that NO may be stabilized in blood, and that the inactivation reactions with hemoglobin may thus be limited, was first proposed by Loscalzo and Stamler. They hypothesized that NO (after a required abstraction of an electron) could form a covalent bond with cysteine residues on albumin to form S-nitrosated albumin (SNO-albumin) (80,81). This paradigm was later extended by the Stamler group to SNO-hemoglobin (82). This field is extremely controversial, largely because of major questions about the concentrations and function of SNO-albumin and SNO-hemoglobin in the human circulation (reported values range from 7  $\mu\text{M}$  to undetectable, with more modern methodologies documenting levels of less than 10 nM) (66,82–88). However, it is likely that a number of intravascular species are capable of endocrine-mediated vasodilation, including S-nitrosothiols (76,81),  $\text{NO}_2^-$  (89), N-nitrosamines (29,86,90), iron-nitrosyl (83), and recently identified nitrated lipids (91). Figure 62.2 illustrates the putative pathways involved in the formation and stabilization of NO in blood as an endocrine vasodilating species. In the following sections, we briefly review the SNO-Hb hypothesis, the major challenges to this theory, and then focus on the emerging role of the nitrite anion as a storage molecule of NO that is activated during physiological blood and tissue hypoxia and acidosis.

Figure 62.2. Pathways for the formation of potential circulating NO species. The majority of NO produced by the endothelium is metabolized by the erythrocyte. NO reacts with oxyhemoglobin to form nitrate or with deoxyhemoglobin to produce iron-nitrosyl hemoglobin (HbNO). The mechanisms of S-nitrosated hemoglobin (SNOHb) formation are not entirely clear, but both SNOHb and iron-nitrosyl-hemoglobin (HbNO) have been hypothesized to deliver NO to distal sites. A minor portion of endothelium-derived NO escapes erythrocytic scavenging and is converted to potential endocrine mediators (nitrite, nitrated lipids, plasma nitrosothiols, N-nitrosamines) by the plasma. The plasma component ceruloplasmin oxidizes NO to nitrite. Nitrite enters the erythrocyte, where it is oxidized to nitrate by oxyhemoglobin or is reduced to bioactive NO by deoxyhemoglobin. The mechanism for NO escape from this reaction is still unclear, but may involve an intermediate NO species (unknown intermediates denoted by question mark). (Reprinted with permission from Dejam A, Hunter CJ, Pelletier MM, et al. Erythrocytes are the major intravascular storage sites of nitrite in human blood. *Blood*. 2005;106:734–739. Epub 2005 Mar 17.) For color reproduction, see Color Plate 62.2.

### The S-Nitrosated Hemoglobin Hypothesis

The SNO-hemoglobin hypothesis suggests the formation of a covalent modification of the cysteine-93 residue on the  $\beta$ -chain of the hemoglobin protein by NO (82,92). In this model, NO first binds cooperatively to a vacant heme on the oxygenated hemoglobin molecule to form iron-nitrosyl hemoglobin (93). This requires a preferential binding of NO to a deoxyheme on 99% oxygenated hemoglobin. A subsequent transfer of the NO group from the heme to the  $\beta$ -93 cysteine, to form SNO-hemoglobin occurs (94). This NO

group is then delivered to tissues as an “X-NO” intermediate by a mechanism linked to the allosteric structural transition of hemoglobin between the oxy (R) state and deoxy (T) state (95). The SNO-hemoglobin concept was initially supported by data showing relatively high ( $2.5 \mu\text{M}$ ) levels of SNO-hemoglobin in the blood and an arterial-to-venous gradient of this species (38,96). In addition, SNO-hemoglobin and NO-treated erythrocytes could vasodilate aortic rings as well as blood vessels in vivo (92,94). However, data generated by several different labs seriously challenge essential elements of the SNO-hemoglobin hypothesis (38). The cooperative or preferential binding of NO to the deoxyhemes of oxygenated hemoglobin has not been reproduced by other laboratories and has been ascribed to an artifact of bolus NO addition (82,97–99). A recent study monitoring the position of NO on the hemoglobin molecule using electron paramagnetic resonance (EPR) during oxy-to-deoxy cycling did not show a transfer of NO between the heme and the thiol on the protein (100,101). The levels of SNO-hemoglobin measured in the human circulation by other groups are one to two logs lower than the  $2.5 \mu\text{M}$  concentrations obtained using photolysis-based assays, and significant artery-to-vein gradients of SNO-hemoglobin have not been detected by other laboratories (83,102,103). A resolution to this controversy will likely require carefully performed physiological studies of hypoxic vasodilation in a cysteine 93-substituted mouse model. Although the specific mechanisms of the SNO-hemoglobin model remain controversial, the principle of endocrine transport of an NO species in blood and the possibility that red cells contribute to hypoxia-dependent NO homeostasis has driven a field of research attempting to identify novel mechanisms by which NO may act as an endocrine mediator.

### Nitrite as a Circulating Store of Nitric Oxide

It has recently been proposed that nitrite ( $\text{NO}_2^-$ ) serves as a circulating storage pool of bioactive NO in the human blood stream (20,104–107). The small circulating anion, found at high nanomolar (300–600 nM) concentrations in blood, is generated in the body by the oxidation of NO (104). The circulating plasma metalloprotein ceruloplasmin has been shown to be responsible for oxidizing NO to nitrite in the plasma (108). In addition, plasma nitrate ( $\text{NO}_3^-$ ) is concentrated into saliva and reduced to nitrite ( $\text{NO}_2^-$ ) by commensal mouth bacterial flora. This nitrite is further reduced to NO in the stomach, where it regulates mucosal blood flow and mucous production (109–112). Although dietary nitrite and nitrate appears to contribute to plasma nitrite levels, studies suggest that up to 70% of plasma nitrite derives from endothelially produced NO (113). In human physiological studies, our laboratory detected arterial-to-venous gradients of nitrite in human plasma and observed increased nitrite consumption during exercise stress (106). This consumption, coupled with measured increases in plasma nitrite associated with endocrine vasodilation during NO gas inhalation in normal human volunteer studies, led to

the hypothesis that the intravascular reduction of nitrite to NO might contribute to in vivo blood flow regulation (73).

Consistent with a vasodilatory role for nitrite, early in vitro studies demonstrated that nitrite was able to mediate vasodilation and the activation of soluble guanylate cyclase when applied to aortic rings at high (micro- to millimolar) concentrations (8,114,115). However, because nitrite levels are less than 1  $\mu\text{M}$  in blood, the high concentrations of nitrite required to vasodilate aortic ring preparations appeared to preclude a physiological role for nitrite as an endogenous vasodilator (116). We were therefore quite surprised to find that infusions of near physiological concentrations of nitrite into the human forearm circulation produced vasodilation, a phenomenon associated with the rapid formation of NO-modified hemoglobin during artery-to-venous transit (89). (The chemical mechanism is described in the section "Hemoglobin as an Allosterically Regulated Nitrite Reductase: Physiological Roles for Deoxyhemoglobin and Myoglobin-Dependent Nitrite Reduction.") It is increasingly clear that nitrite is indeed a bioactive signaling molecule, generating NO under physiological levels of hypoxia and acidosis (117–121). A number of mechanisms for nitrite reduction to NO are being studied, including an enzymatic reduction by xanthine oxidoreductase (122–124), acidic reduction (disproportionation) (125), and heme-based nitrite reduction by hemoglobin, myoglobin, or other tissue heme proteins (89,105,119, 126,127).

### Nitrite and Hemoglobin – A Long History

The reaction of nitrite with myoglobin has been harnessed by man since the time of the Greeks and Romans. In the process of meat curing, the application of nitrate derived from saltpeter and ascorbic acid in the form of citrus juice results in enzymatic and nonenzymatic nitrate reduction to nitrite and subsequently to NO by bacteria and heme proteins in meat. Haldane and Hoagland demonstrated that the reduction of nitrite to NO in a reaction with hemoglobin or myoglobin produced iron-nitrosyl heme, which was responsible for the resulting red color of cured meat (105,128). Nitrosylation of the heme inhibits iron release from the porphyrin ring, preventing iron-catalyzed lipid oxidation and deleterious Fenton chemistry that is thought to contribute to the spoiling of the meat (128). In 1923, the U.S. Food and Drug Administration (FDA) authorized the use of nitrite as the curing agent in place of higher concentrations of nitrate that were previously used.

Therapeutically, the antidotal activity of nitrite for cyanide poisoning was first demonstrated in 1888, and nitrite has since become an essential component of the cyanide antidote kit used today (129). The principle of nitrite's action for cyanide poisoning derives from the ability of nitrite to oxidize hemoglobin to ferric methemoglobin. This form of hemoglobin binds cyanide with a very high affinity, causing cyanide to dissociate from its other targets and bind to hemoglobin. With all the cyanide circulating as cyanomethe-

moglobin, an agent such as thiosulfate can be given to react with the cyanide to form thiocyanate, which will be excreted in the urine. Interestingly, studies performed in 1937 clearly demonstrated that doses of nitrite comparable to those used for the treatment of cyanide poisoning produced circulatory collapse (130). However, despite the fact that the reactions of nitrite with hemoglobin have long been studied and exploited therapeutically, the physiological role of this reaction and the fate of any by-products, such as NO, generated from this reaction has been reappraised only recently.

### HEMOGLOBIN AS AN ALLOSTERICALLY REGULATED NITRITE REDUCTASE: PHYSIOLOGICAL ROLES FOR DEOXYHEMOGLOBIN AND MYOGLOBIN-DEPENDENT NITRITE REDUCTION

In 1981, Doyle and colleagues characterized the reduction of nitrite by purified deoxyhemoglobin in a reaction yielding NO and methemoglobin (Equation 3) (131).

NO formed from this reaction can then bind vacant deoxyheme sites to form NO-modified hemoglobin, as shown in Equation 2.

The kinetics of this reaction have been re-examined with particular emphasis on the physiological role of hemoglobin as a nitrite reductase, able to produce bioactive NO and potentially other NO<sub>x</sub> intermediates (132,133). Three important ideas emerge from these studies: (a) the reduction of nitrite by deoxyhemoglobin is allosterically regulated by the quaternary structure of hemoglobin; (b) the reduction of nitrite generates measurable quantities of NO gas and likely other NO<sub>x</sub> intermediates; and (c) the reduction of nitrite by deoxyhemoglobin by the above reaction possesses both pH and O<sub>2</sub> sensor chemistry with increased rates of reduction at low Pao<sub>2</sub> and low pH (132).

From a physiological standpoint, consider that this reaction requires deoxyhemoglobin and a proton – providing O<sub>2</sub> and pH sensor chemistry – and generates NO, a potent vasodilator. Methemoglobin formed during the reaction will not autocapture and inactivate the NO formed. These conditions provide a chemistry that has the potential to generate NO and mediate vasodilation under hypoxic and acidic physiological stress.

We recently re-examined the reaction of excess nitrite with cell-free deoxyhemoglobin and found that the products of the reaction are met- and iron-nitrosyl hemoglobin in equimolar concentrations. In addition, the kinetics of the reaction deviated from second order and demonstrated a surprising sigmoidal reaction profile, characterized by a maximal reaction rate when 50% of the heme was ligated (with NO or oxidized to methemoglobin) (132,133). This sigmoidal profile

Figure 62.3. Allosteric regulation of nitrite reductase rate. The rate of hemoglobin-dependent nitrite reduction (*black dashed line*) depends on the number of available heme sites for reaction and the amount of R state tetramers. As  $O_2$  saturation of hemoglobin increases, the number of available heme sites for nitrite binding decreases, decelerating the reaction. However, the R-state tetramer is increasingly stabilized, which accelerates reaction rate. The maximal reaction rate occurs at an optimal balance of these two subprocesses, which occurs when 50% of the hemoglobin is saturated with oxygen. The partial pressure at which this occurs is the  $P_{50}$  of hemoglobin. For color reproduction, see Color Plate 62.3.

is the result of the allosteric quaternary structural transition of the hemoglobin tetramer from the T (deoxy) to R (oxy) state during the course of the reaction. Over the course of this anaerobic reaction of nitrite with deoxyhemoglobin, the concentration of T-state deoxyhemoglobin decreases as the deoxyheme is converted to metheme and NO-heme; the depletion of deoxyheme has an effect of decelerating the reaction, because fewer heme sites are available for nitrite to react with. This is counterbalanced by an increasing concentration of R-state hemoglobin, produced by the R-state stabilizing effects of NO-heme and metheme, which are formed in this reaction (Equation 2 and Equation 3). R-state hemoglobin tetramer has a lower heme reduction potential (i.e., is a better electron donor to nitrite), which accelerates the reduction reaction of nitrite to NO. The balance of these two opposing subprocesses results in a sigmoidal reaction profile in which the maximal rate occurs when the majority of tetramers switch from the T to R state, a point that coincides with approximately 50% heme ligation (Figure 62.3; for color reproduction, see Color Plate 62.3).

Physiologically,  $O_2$  is the major regulator of allosteric conformation and is the predominant ligand for hemoglobin. Consistent with the chemistry described earlier, the measured rate of nitrite reduction by hemoglobin is maximal at a hemoglobin- $O_2$  saturation between 40% and 60%, around the hemoglobin  $P_{50}$  (132). A maximal nitrite reductase activity at the hemoglobin  $P_{50}$  is biochemically consistent with a potential role in hypoxic vasodilation. Hypoxic vasodilation is a highly conserved physiological response in which blood flow

and  $O_2$  delivery increases in proportion to tissue  $O_2$  consumption. This response requires the ability to detect changes in  $O_2$  concentration or pH in the tissue, and to couple this sensing to the rapid elaboration of a vasodilator (134). Although the exact mechanism of this response is not yet known, it occurs when hemoglobin  $O_2$  saturations fall between 40% and 60% (20–40 mmHg  $O_2$ ), a value approximating the  $P_{50}$  of hemoglobin and the point of maximal nitrite reduction (135). Studies investigating the gradients of hemoglobin  $O_2$  saturation across the vasculature show that arteriolar  $O_2$  concentration drops from A1 to A4 caliber arterioles. In skeletal muscle, this drop is substantial, resulting in hemoglobin saturation values of less than 40% ( $P_{O_2}$  of 20 mm Hg) in A4 level arterioles (136). These data demonstrate that conditions ideal for maximal nitrite reductase activity occur within resistance vessels, consistent with a potential physiological role for nitrite-dependent hypoxic vasodilation. In addition to  $O_2$  unloading and NO production occurring within the arterioles and arteriolized precapillaries, it is possible that NO generation at the capillary level could modulate NO-dependent hypoxic vasodilation by retrograde propagation, as characterized by Duling and Segal (137,138). A role for nitrite, hypoxia, and the red cell in hypoxic vasodilation is supported by aortic ring bioassay experiments in which precontracted vessels were exposed to nitrite in the presence and absence of red blood cells over a range of  $O_2$  concentrations. In these studies, vessels exposed to both nitrite and red blood cells vasodilated maximally at a  $P_{O_2}$  approaching the intrinsic hemoglobin  $P_{50}$  (89,139).

Within tissues, the reduction of nitrite by deoxyhemoglobin or myoglobin may contribute to the regulation of mitochondrial respiration and tissue O<sub>2</sub> gradients. Owing to the low redox potential of the heme group of myoglobin, the rate of reaction of nitrite with myoglobin is approximately 50-fold faster than with deoxyhemoglobin; hence, the rate of NO production is also greater (132). Under hypoxic conditions, nitrite (present in the tissue between 1 and 10 μM) has the potential to react with myoglobin to produce NO and inhibit local mitochondria by binding to cytochrome *c* oxidase (139,140,141). NO-dependent inhibition of mitochondrial respiration has been proposed to facilitate O<sub>2</sub> diffusion. Alternatively, hypoxia-dependent inhibition of respiration may generate a protective response to subsequent ischemic challenge (ischemic preconditioning), a concept that is discussed more thoroughly in the next section.

### **THERAPEUTIC IMPLICATIONS: NITRITE AS A NOVEL NITRIC OXIDE DONOR TARGETING ISCHEMIC AND ACIDIC TISSUES**

#### **Pulmonary Hypertension**

Neonatal pulmonary hypertension is a condition associated with NO deficiency, right-to-left shunting of blood, profound hypoxemia, and low hemoglobin O<sub>2</sub> saturations (arterial hemoglobin O<sub>2</sub> saturations of approximately 55%). In a newborn sheep model of pulmonary hypertension, nitrite delivered as a nebulized aerosol produced a 50% reduction in hypoxia-induced pulmonary hypertension (119). Consistent with the conversion of nitrite to bioactive NO by hemoglobin, the vasodilation was accompanied by the formation of iron-nitrosyl hemoglobin and an increase in exhaled NO gas. Furthermore, the magnitude of decrease in pulmonary artery pressure in response to nitrite was dependent on blood pH, with decreased pulmonary pressures as pH was lowered, a chemistry consistent with the reduction of nitrite to NO by the deoxyhemoglobin reaction (119).

#### **Subarachnoid Hemorrhage–Associated Cerebral Artery Vasospasm**

Nitrite may also have therapeutic potential for conditions in which hemolysis plays a role in pathogenesis. In subarachnoid hemorrhage-induced cerebral vasospasm, the vasospasm of large intracranial arteries is thought to occur secondary to hemolysis of clotted erythrocytes within the subarachnoid space. In addition to free deoxy- and oxyhemoglobin scavenging NO, eNOS is inhibited, resulting in decreased regional NO bioavailability (120). In a well-characterized nonhuman primate model of subarachnoid hemorrhage-induced cerebral vasospasm, 14 animals were observed for 14 days, with half receiving a continuous infusion of nitrite and the others receiving saline. All animals in the control group developed cerebral vasospasm 7 to 14 days after aneurysm rupture, whereas vasospasm was prevented in all animals who received

continuous intravenous infusions of nitrite (120). Furthermore, the concentration of nitrite in the cerebrospinal fluid of these animals correlated inversely with the degree of vasospasm (120).

#### **Ischemia–Reperfusion Injury**

In addition to pathologies involving the vasculature, nitrite may be beneficial in preventing ischemia–reperfusion injury in tissues (118,121). Tissue injury induced by ischemia and subsequent reperfusion is characterized by an increased production of ROS, leading to protein modification, mitochondrial damage, an inappropriate inflammatory response, and tissue death by both apoptosis and necrosis. In a model of ischemia–reperfusion in a Langendorff heart, nitrite at concentrations as low as 10 μM reduced infarct size (121). In a mouse model of hepatic ischemia–reperfusion, infusion of nitrite in doses as low as 1.2 nmol (blood levels of less than 200 nM) during the 45-minute ischemic period protected the liver from tissue death. This protection was replicated in a mouse model of myocardial infarction, in which 2.4 to 48 nmol of infused nitrite in the left ventricle reduced infarct size by 50% in comparison with control animals that did not receive nitrite. Interestingly, tissue protection was accompanied by the formation and maintenance of NO-modified proteins after reperfusion. In control animals, the concentration of plasma nitrosylated species (RXNOs; including nitrosamines and iron-nitrosyl) was maximal 1 minute after reperfusion and decayed thereafter, whereas in nitrite-treated animals, these species remained elevated 30 minutes after reperfusion (118). Although the mechanism of this nitrite-dependent tissue cytoprotection has not yet been elucidated, and the identity of these modified proteins is unknown, several potential targets exist, including soluble guanylate cyclase and proteins within the mitochondrion.

#### **KEY POINTS**

- The endothelium and red blood cells interact to regulate NO-dependent blood flow and vascular homeostasis. The reactions of NO and hemoglobin largely determine the paracrine and endocrine properties of NO. Scavenging reactions control the paracrine properties of NO, and nitrite reductase reactions contribute to an endocrine hypoxic bioactivity. Disruption of this balance during intravascular hemolysis severely limits NO bioavailability, whereas the therapeutic amplification of these reactions with therapeutically delivered nitrite increases regional NO bioavailability.
- Intravascular hemolysis disrupts vasomotor tone through the release of hemoglobin from the red blood cell into plasma, which is then able to scavenge

endothelial-derived NO 600-fold faster than compartmentalized erythrocytic hemoglobin, thereby disrupting NO homeostasis.

- In addition to providing an NO scavenging role in the physiological regulation of NO-dependent vasodilation, hemoglobin and the erythrocyte may deliver NO as the hemoglobin deoxygenates. Recent data suggest that deoxygenated hemoglobin reduces blood nitrite to NO, leading to vasodilation along the physiological O<sub>2</sub> gradient.
- The endothelium can be considered a signaling organ that generates both paracrine NO and endocrine nitrite NO<sub>2</sub><sup>-</sup> and other NO-modified protein species.

#### Future Goals

- To establish and further characterize the role of hemolysis as a mechanism for endothelial dysfunction that leads to proliferative vasculopathy and pulmonary hypertension in human disease such as the hereditary hemolytic anemias, iatrogenic hemolytic states such as cardiopulmonary bypass and red cell alloimmunization, and during infections such as malaria and hemolytic uremia syndrome
- To develop hemoglobin or red cell-based blood substitutes that bypass NO scavenging reactions (19,137)
- To determine the mechanisms by which nitrite formation and function is regulated physiologically, particularly the role of enzyme systems in this balance
- To determine the therapeutic effects of nitrite on the vasculature in the setting of hemolytic disease as well as other vascular dysfunction

## Leukocyte–Endothelial Cell Interactions

Volker Vielhauer, Xavier Cullere, and Tanya Mayadas

*Brigham and Women’s Hospital, Harvard Medical School, Boston, Massachusetts*

Pathologists of the 19th century were aware that leukocytes migrate from the blood across the wall of microvessels and accumulate in inflamed tissue. The purpose of this migration, a process called *diapedesis*, remained enigmatic until the discoveries of Elias Metchnikoff in 1901. He demonstrated that leukocytes attack and kill bacteria, and he recognized diapedesis as a fundamental mechanism of host defense (1). Indeed, any immune response relies on the well-coordinated trafficking of leukocytes from the circulation into lymphoid tissue (homeostatic immune surveillance) and sites of tissue injury (inflammation). The emerging model is that leukocyte adhesion and extravasation are guided by a series of well-choreographed interactions between leukocytes and endothelial cells (ECs). These interactions are supported by temporally controlled and spatially restricted engagement of receptor–ligand pairs between cell types. This triggers bidirectional signaling events that lead to changes in cellular phenotype and function. The extravasation of a specific subset of leukocytes at selective sites during inflammation is achieved through expression of specific adhesion molecules and cell-type–selective chemoattractants (2,3).

The function of recruited neutrophils is to control and eliminate infection and to promote tissue repair. To achieve these ends during an inflammatory response, the lifespan of transmigrated neutrophils is extended, compared to circulating counterparts, partially through endothelial-derived factors. The endothelium also provides cues to those phagocytes that result in their locally contained release of cytokines, chemokines, growth factors, proteinases, and reactive oxygen species (ROS). Clark and Clark (4) recognized the importance of changes in the “consistency” of the endothelium in initiating an inflammatory response. Furthermore, they noted that a spatially localized and graded physiologic response to inflammatory stimuli was important for maintaining the integrity of the endothelium (4). It is now well accepted that excessive leukocyte accumulation contributes to the initiation and progression of a number of diseases including atherosclerosis, vasculitis, meningitis, ischemia–reperfusion injury, and autoimmune disease. Because the inflamed endothelium is responsible for coordinating the recruitment and function of

phagocytes, and is also potentially the most proximal target of leukocyte-mediated signals, it is not surprising that endothelial dysfunction has been linked to the pathogenesis of multiple vascular diseases. The thesis of this chapter is that the cross-talk between leukocytes and ECs during an inflammatory response has short- and long-term effects on the functional phenotype of the vasculature. In one direction, endothelial-derived effectors modulate leukocyte activity and their survival. In the other direction, activated phagocytes release cellular factors that can moderate EC function and viability in physiological and pathophysiological settings. The bidirectional communication between leukocytes and ECs is essential for host defense and physiologic inflammation (Figure 63.1). Understanding the molecular basis of this cross-talk will provide insights into how its dysregulation can provide a nidus for endothelial dysfunction.

### LEUKOCYTE ROLLING

The first step in leukocyte recruitment comprises initial tethering followed by reversible rolling. Rolling is mediated by molecules that are specialized for adhesion under shear stress, namely the selectins. The selectin family consists of leukocyte- (L-selectin, CD62L), platelet- (P-selectin, CD62P), and endothelial selectin (E-selectin, CD62E) (5). L-selectin is constitutively expressed on nonactivated neutrophils, monocytes, and eosinophils, and on the majority of lymphocytes. L-selectin is important in T-cell rolling and homing to secondary lymphoid organs as well as leukocyte rolling on inflamed endothelium. P-selectin and E-selectin are induced on the surface of the vascular endothelium activated by inflammatory stimuli. P-selectin also is expressed on the surface of activated platelets. Both P- and E-selectin support rolling of all leukocyte subsets in various inflamed tissues and are essential for rolling and homing of hematopoietic progenitor cells to the bone marrow after bone marrow transplantation (6,7). Selectins recognize and bind to specific carbohydrate moieties – the posttranscriptionally modified sialylated, fucosylated lactosamine-type glycans that decorate core molecules

Figure 63.1. Leukocyte-derived inputs that modulate the phenotype of the endothelium. Phagocyte interaction with the endothelium occurs through adhesion molecules: PSGL-1/P- and E-selectin, and  $\beta 2$  or  $\beta 1$  integrin/ICAM-1 and VCAM-1, respectively. These interactions increase intracellular  $\text{Ca}^{+2}$  and ROS, and lead to changes in the actin cytoskeleton and gene transcription in the endothelium. After phagocytes undergo firm adhesion, they transmigrate. PECAM-1, constitutively recycling at the endothelial borders, is targeted to areas of leukocyte transmigration, where homophilic interactions with PECAM-1 on the leukocyte promote leukocyte egress. PECAM-1 engagement activates the antiapoptotic kinase Akt in ECs. Adherent leukocytes release superoxide and proteinases. Superoxide ( $\text{O}_2^-$ ) is converted to hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), which penetrates the endothelium and has effects on NF- $\kappa$ B activation, intracellular  $\text{Ca}^{+2}$  levels, and actin dynamics. Elastase has proteolytic functions that result in cleavage of surface adhesion receptors and chemokines, as well as nondegradative signaling functions that promote PDGF release. High and/or prolonged exposure of the endothelium to leukocyte-derived products leads to EC injury. GM-CSF produced by activated ECs extends the lifespan of migrating neutrophils and thus the pool of functional neutrophils at sites of inflammation.

(mainly mucins) as a result of post-translational modification by specific glycosylation enzymes. An important receptor on leukocytes that contain these selectin ligands is the P-selectin glycoprotein ligand (PSGL)-1, originally identified as a ligand for P-selectin but subsequently shown also to bind E-selectin. Consistent with this, PSGL-1 supports both P- and E-selectin-mediated leukocyte rolling (8–12). Notably, the rolling phase is not mediated exclusively by selectins and their glycosylated ligands. The integrin  $\alpha 4\beta 1$  (very late activation antigen-4, VLA-4) can support T-cell tethering and rolling on vascular cell adhesion molecule (VCAM)-1, an integrin ligand expressed on activated endothelium (13,14). CD44, a transmembrane glycoprotein present on activated T cells, facilitates leukocyte rolling on endothelial-bound hyaluronan (15,16). CD44 also associates physically with VLA-4 on T cells to facilitate VLA-4-mediated slow rolling and subsequent firm adhesion of T cells (17). Interestingly, fractalkine, a transmembrane mucin-chemokine chimeric molecule induced on the surface of activated ECs, mediates rapid capture (without rolling) and integrin-independent firm adhesion of free flowing monocytes, T cells, and NK cells through interaction with its receptor CX3CR1 (18).

One of the earliest responses of leukocyte contact with the endothelium is an elevation of intracellular free calcium

that is accompanied by cytoskeletal changes in the endothelium. Mounting evidence suggests that “rolling” receptors contribute to these changes by serving a signaling function in ECs (19). For example, E-selectin engagement promotes its linkage to the cytoskeleton and results in the dephosphorylation of its cytoplasmic tail (20). Also, clustered E-selectin redistributes to caveolin-1-containing lipid rafts, where it activates signaling molecules such as phospholipase  $\text{C}\gamma$  (21,22). E-selectin activates the immediate early response gene *c-fos* through the mitogen-activated protein kinase (MAPK) pathway (23), suggesting that leukocyte-EC interactions may modulate the transcriptional profile of the endothelium. Further studies are needed to demonstrate that signaling through E-selectin has functional consequences for the endothelium during an inflammatory response. Studies evaluating P-selectin-mediated signaling in the endothelium are limited, but suggest that it too may serve a signaling function. P-selectin serine and threonine phosphorylation of its cytoplasmic tail has been documented in activated ECs and platelets (24), and histidine phosphorylation is noted in stimulated platelets (25). Because the cytoplasmic tails of E- or P-selectin are not necessary for leukocyte adhesion per se (26), the role of their intracellular domains may indeed be primarily to modulate downstream biologic events that affect the phenotype of the endothelium.

Endothelial engagement by rolling leukocytes has functional consequences for the leukocyte. Transient interaction with P- and E-selectin leads to the induction of an intermediate state of leukocyte integrin activation that reduces the velocity of the rolling leukocytes. This provides an opportunity for leukocytes to sample the microenvironment for additional cues required for leukocyte arrest (27–29). On the leukocyte, occupancy of PSGL-1 induces tyrosine phosphorylation and activation of MAPKs (30), cytokine release (31–34), activation of  $\beta 2$  integrins (29,35,36), and serum response factor (SRF)-mediated transcriptional activation of immediate early genes (37). The pathways by which PSGL-1 triggers such intracellular signals include its association with and phosphorylation by the syk tyrosine kinase. This association is mediated by ezrin and moesin, proteins that link to the actin cytoskeleton (37). PSGL-1 also is expressed on platelets and could possibly serve similar signaling functions in these cells (38). Finally, although a bona fide ligand for L-selectin on the inflamed endothelium has not been identified, L-selectin engagement triggers various cellular events in leukocytes, including ionized calcium mobilization, increases in protein tyrosine phosphorylation, and rearrangements of the cytoskeleton (39–41).

## LEUKOCYTE ARREST

The arrest of leukocytes on the activated endothelium is a prerequisite for subsequent leukocyte spreading, transendothelial migration, and diapedesis into the subendothelial tissue. Neutrophil arrest is signaled by soluble factors released by the endothelium and/or membrane-bound signaling molecules on the endothelium. The cues for arrest are provided by a class of chemotactic cytokines, the chemokines that are secreted by activated ECs, activated platelets, and subendothelial parenchymal cells (42). During inflammation, activated ECs produce inflammatory chemokines including macrophage inflammatory proteins (MIPs) CCL3 and CCL4; monocyte chemotactic proteins (MCPs) CCL7, CCL8, and CCL13; RANTES (Regulated on Activation, Normal T-cell Expressed and Secreted)/CCL5; interleukin (IL)-8/CXCL8; and fractalkine/CXCL1. Moreover, chemokines generated in the subendothelial tissue have been shown to cross the endothelium via caveolar transcytosis following binding to glycosaminoglycans and/or Duffy receptor and be selectively presented on the apical microvilli. The activated endothelium also upregulates structures such as heparin-sulfate proteoglycans, which retain and present these chemokines to circulating leukocytes (43). These immobilized chemokines on the apical surface of the endothelium are then poised to locally stimulate the rolling leukocytes that express the relevant receptors. This ensures spatially localized activation and transmigration of leukocytes during an inflammatory response. Thus, expression of a chemokine in a tissue, and the presence of its receptor on a circulating leukocyte, contribute to the selectivity of the local leukocyte recruitment.

Chemokine signaling through specific leukocyte-expressed 7-transmembrane G-protein-coupled receptors converts the low-affinity, selectin-mediated leukocyte–EC interaction into a high-affinity, integrin-mediated interaction that leads to the firm arrest of the leukocyte on the endothelial surface. Several chemokines have been described that mediate integrin-dependent firm adhesion to activated endothelium, accordingly described as “arrest” chemokines (44). The CXC chemokine IL-8/CXCL8, produced by tumor necrosis factor (TNF)-activated endothelium activates  $\beta 2$  integrins and leads to the arrest of rolling neutrophils (45). More recently, RANTES and KC (the mouse chemokine resembling human IL-8) were identified as arrest chemokines for rolling monocytes (44). Interestingly, L-selectin stimulation on the leukocyte induces surface redistribution of CXCR4, the receptor for the chemokine SDF-1 from intracellular vesicles (46). Thus, in addition to selectins mediating activation of  $\beta 2$  integrins and leading to slow rolling, selectin-mediated leukocyte rolling may prime the cell for subsequent chemokine-mediated integrin activation.

Chemokine-induced integrin activation, known as *inside-out signaling*, is particularly relevant in leukocytes. In these cells, the integrin heterodimers (one  $\alpha$ - and one  $\beta$ -subunit) are present in a low-affinity, low-avidity state on the cell surface but are induced to rapidly bind ligand upon chemokine stimulation (47). Activation of integrins is mediated by GTPases of the Ras and Rho family and associated signaling cascades, which are well-described and reviewed elsewhere (48,49). Increased integrin affinity and avidity are achieved through conformational changes, association of integrins with the cytoskeleton, and integrin clustering. Integrin binding to their ligands brings about the third step of the adhesion cascade, the tight adhesion of the leukocyte to integrin ligands presented on the activated endothelium. The major integrins required for this adhesion are the  $\beta 2$  integrins lymphocyte function-associated antigen (LFA)-1 ( $\alpha L\beta 2$ ) and Mac-1 ( $\alpha M\beta 2$ ), the  $\alpha 4\beta 1$  integrin VLA-4, and the  $\alpha 4\beta 7$  integrin. The endothelial ligands to which the integrins bind are members of the IgG superfamily that are upregulated on the activated endothelium. Intercellular adhesion molecule (ICAM)-1 and ICAM-2 are counter-receptors for the  $\beta 2$  integrins LFA-1 and Mac-1, whereas VCAM-1 interacts with VLA-4 (50) and  $\alpha 4\beta 7$  additionally binds MAdCAM, which is important in lymphocyte homing to intestinal tissue (51).

Similar to the rolling receptors, engagement of the IgG superfamily of ligands on the endothelium also generates intracellular signals in ECs (52). Engagement of ICAM-1 on the endothelium induces calcium signaling, cytoskeletal rearrangements (53–54), activation of Rho GTPase, and phosphorylation of several proteins including focal adhesion kinase, paxillin, and p130Cas (55). Crosslinking of VCAM-1 also induces increases in intracellular calcium and stress fiber formation (19) as well as Rho-dependent Rac activation and ROS generation (56–58). Interestingly, inhibition of downstream signaling by Rac1 was shown to reduce the migration of leukocytes across endothelial monolayers (57). Thus,

ICAM-1-induced Rac activity may promote the opening of endothelial cell-cell contacts, thus allowing leukocytes to transmigrate. ICAM-1 and VCAM-1 clustering induces their association with the Ezrin/Radixin/Moesin (ERM) proteins moesin and ezrin (59) in a Rho-dependent manner, providing docking structures for adherent leukocytes to transmigrate. These data indicate that both RhoA and Rac1 in ECs are activated by adhesion receptors and may signal changes in the endothelium that facilitate leukocyte egress. ICAM-1-mediated signaling events during neutrophil adherence also were shown to activate xanthine oxidase in ECs, which in turn mediated the production of ROS. This led to cytoskeletal remodeling and cell stiffening, steps that may influence both neutrophil migration as well as EC permeability (60). ROS production stimulated by lymphocyte binding to VCAM-1 has been shown to result in actin coalescence in ECs and activation of EC-associated matrix metalloproteinases, with the latter being required for lymphocyte transmigration (61). Thus, leukocyte adhesion to the endothelium may result in locally generated signals that prime the endothelium for subsequent transmigration.

Shortly after arrest, most leukocytes spread and begin to migrate laterally over the apical surface of the endothelium prior to transmigration. The outside-in signaling that occurs through ligand-bound integrins leads to cell polarization and forward movement of the leukocyte, driven by the combination of leading-edge protrusion and contractility at both the front and the back of the cell. A large number of focal adhesions, as well as structural and regulatory proteins, are located at the leading edge of the migrating cell. These include chemokine receptors, integrins like VLA-4 (but not LFA-1), and regulators of the actin cytoskeleton assembly, such as the small GTPase Rac1, its effector PAK1, and the Arp2/3 complex (49,62). During movement over the endothelium, leukocytes have to form new adhesion contacts at protruding sites while breaking down old ones at the retracting end of the cell. The turnover of focal adhesions involves intracellular interactions between integrins, adapter molecules, and microtubules. For example,  $\alpha 4$  integrins use paxillin to regulate the attachment and detachment of the leading edge (63). LFA-1 signals through myosin light-chain kinase and through p160ROCK, which regulates cell contraction and detachment (64). Binding of LFA-1 to endothelial ligands also induces actin polymerization at the leading edge of the leukocyte, possibly through the Rho family exchange factor Vav1 (65,66). Thus, the dynamic exchange of information between the migrating leukocyte and endothelium is required for directed leukocyte movement.

## LEUKOCYTE TRANSMIGRATION

Usually within minutes, firmly arrested leukocytes, which spread and migrate over the endothelium, extravasate. Proactive roles for the endothelium in facilitating diapedesis of leukocytes, the final step of the adhesion cascade, have been suggested by a variety of studies. A testament to this is the early demonstration by Huang and colleagues that a rise in intra-

cellular calcium levels in ECs, induced by leukocyte contact, was required for efficient transendothelial migration (67). The majority of transmigration occurs at junctions present at endothelial cell-cell contacts, and this is referred to as the *paracellular route*. The endothelial junctions consist primarily of two types of complexes: the adherens junctions and the tight junctions, which remodel to facilitate various endothelial processes (68). These structures transiently disassemble during leukocyte transmigration and after stimulation with growth factors and inflammatory stimuli. For example, transmigrating leukocytes induce a focal and transient redistribution of junctional vascular endothelial (VE)-cadherin. Although no role for VE-cadherin in leukocyte transmigration has been established, the dynamic changes in the location of this protein during diapedesis does suggest that active endothelial junctional remodeling occurs during the transmigration process. Molecules at endothelial cell-cell contacts that are indeed required for paracellular leukocyte transmigration include platelet-endothelial cell adhesion molecule (PECAM)-1, a member of the immunoglobulin superfamily (69,70), and junctional adhesion molecule (JAM)-A, a component of the tight junctions (71,72). The mechanisms by which these two proteins facilitate transcellular migration, and the signals that they generate upon their engagement, will be discussed.

PECAM-1 is concentrated at the intercellular junctions of ECs. It is also expressed on the surface of platelets and most leukocytes. PECAM-1 is essential for leukocyte diapedesis, and supports cell-to-cell adhesion by homophilic and heterophilic interactions. Recently, Mamdouh and colleagues found that PECAM-1 constitutively recycles evenly along EC borders (73). However, during transendothelial migration across human umbilical vein EC (HUVEC) monolayers, PECAM-1 is targeted to areas of the interendothelial junction where monocytes transmigrate (73). This may provide a source of endothelial PECAM-1 for the leukocyte PECAM-1 to engage via homophilic interactions. The continuous addition of PECAM-1 into the junction may create a gradient of cellular adhesion sites through the junction, forming a molecular zipper that provides traction to drive diapedesis at these locations. Following stimulation of ECs with various stimuli, PECAM-1 is tyrosine- and serine/threonine-phosphorylated, resulting in its interaction with catenin family members (70). Engagement of PECAM-1 modulates EC migration through its interaction with the tyrosine phosphatase SHP-2 (74) and through the small GTPase Rho (75). During leukocyte transendothelial migration, ECs are protected from apoptosis, and this may be attributed to PECAM-1-mediated activation of survival signals in the endothelium (76). The engagement of PECAM-1 with monoclonal antibodies in ECs also results in an increase in intracellular calcium (77). Whether the engagement specifically of PECAM-1 during leukocyte transmigration evokes similar effects on the endothelium is not known. Notably, PECAM-1 has been shown to transduce EC responses to hydrogen peroxide, potentially derived from neutrophils, by generating cation currents and a transient rise in intracellular

calcium flux (78). Finally, engagement of PECAM-1 by migrating neutrophils results in a negative feedback on nuclear factor (NF)- $\kappa$ B activity in ECs (79). This could potentially provide a mechanism by which leukocyte transmigration could limit the amplification, or aid in the resolution of, the inflammatory response at the level of endothelial gene expression (79).

JAM-A is a member of the immunoglobulin superfamily proteins expressed at endothelial and epithelial cell junctions, but it also is present on leukocytes and platelets (80). In vivo studies have demonstrated an important role for this protein on neutrophils in neutrophil diapedesis (72,81). Insight into the role of this molecule on ECs has come from in vitro work. Endothelial JAM-A has been shown to bind LFA-1 and support leukocyte adhesion through this receptor (82), although the relative contribution of this interaction to transmigration in the presence of other adhesion molecules present on the inflamed endothelium has not been demonstrated. Interestingly, neutrophil LFA-1, which is evenly distributed upon neutrophil arrest on TNF-activated HUVECs, rapidly redistributes to form a ring-like structure at the neutrophil-endothelial junctional interface that coclusters with endothelial ICAM-1 and JAM-A as the neutrophil transmigrates (83). In this system, endothelial ICAM-1, but not JAM-A, appeared to contribute to LFA-1-dependent transmigration. These studies illustrate the complex roles played by junctional molecules during leukocyte recruitment, being possibly involved in both adhesion and diapedesis. JAM-A signaling has been reported to affect EC motility and fibroblast growth factor (FGF)-induced tube formation in ECs (84). Another member of the JAM family, JAM-C, has been shown to interact with the  $\beta$ 2 integrin Mac-1 (85) and promote leukocyte transendothelial migration in vivo and in vitro (86). Thus, JAM molecules on the endothelium have the potential to significantly alter the inflammatory response and serve as a possible conduit for leukocyte signaling into ECs.

Transmigration through adjacent ECs is not the exclusive pathway for leukocyte diapedesis. Mounting evidence suggests that leukocytes can pass through the body of an EC (i.e., the transcellular route) and does not require mechanisms for the separation of adherence junctions. Indeed some of the first electron microscopy studies on transendothelial migration provided in vivo evidence for the predominance of the transcellular route of diapedesis (87,88). Recently, a cuplike trans migratory structure was described using high-resolution fluorescence imaging techniques. This endothelial structure is composed of vertical microvilli-like projections that surround trans migrating leukocytes and induce redistribution of leukocyte integrins (LFA-1 and Mac-1) into linear tracks oriented parallel to the direction of diapedesis (89). These structures are highly enriched in ICAM-1 and VCAM-1, whereas PECAM-1 or VE-cadherin seem to be excluded. The disruption of these projections inhibited leukocyte transmigration, which suggest that this trans migratory cup represents an important mechanism of directional guidance during transendothelial migration (89). Interestingly, both trans- and paracellular diapedesis by neutrophils, monocytes, and lymphocytes were

associated with trans migratory cup formation, suggesting that this endothelial structure represents a more general mechanism fundamental to transendothelial migration (89). Consistent with this concept, endothelial ICAM-1 was identified as essential for both paracellular and transcellular neutrophil transmigration in in vitro flow assays. Interestingly, interfering with ICAM-1 cytoplasmic tail function preferentially reduced transcellular transendothelial migration. Moreover, ICAM-1 endothelial surface density and distribution as well as TNF-induced changes in EC shape contributed to transcellular transendothelial migration (90). Apparently, the proper adhesive function of ICAM-1 (and VCAM-1) during leukocyte adhesion and transendothelial migration depends on the presence of endothelial tetraspanin microdomains. Tetraspanins relocalize to the contact site with trans migrating leukocytes and associate laterally with both ICAM-1 and VCAM-1. Interference with tetraspanin microdomains prevented lymphocyte transendothelial migration and increased lymphocyte detachment under shear flow (91).

In summary, leukocyte transmigration requires complex, overlapping cellular and molecular interactions between leukocytes and ECs at all stages of leukocyte transmigration. Recent studies emphasize that the engagement of adhesion molecule-ligand pairs on leukocytes and ECs results in signal transduction in both cell types, which can impact functional outcomes. The importance of the carefully choreographed interaction between leukocytes and ECs to human physiology is highlighted in human leukocyte adhesion deficiency (LAD) syndromes. These patients have missing or dysfunctional surface adhesion molecules such as the  $\beta$ 2 integrins and selectin ligands that are required for leukocyte egress from the vessel into tissues. The LAD syndromes result from failures of leukocytes, primarily cells of the innate immune system including neutrophils and monocytes, to transmigrate which leads to compromised host defense (92).

#### ROLE OF ENDOTHELIUM ON THE LIFESPAN OF LEUKOCYTES

During inflammation, the lifespan of normally short-lived peripheral blood neutrophils is prolonged in the circulation and that of trans migrated neutrophils is further delayed compared to circulating cells. This delay may serve to increase the pool of functional neutrophils at sites of inflammation. Importantly, activated ECs play a pivotal role in modulating leukocyte apoptosis. Under in vitro conditions, transmigration of neutrophils through a cytokine-activated endothelial monolayer was shown to delay neutrophil apoptosis through adhesive interactions between the two cell types, as well as endothelial-secreted cytokines such as granulocyte monocyte colony stimulating factor (GM-CSF) (93). In contrast, resting ECs may induce leukocyte apoptosis by expressing functional Fas ligand, which triggers cells death in cells carrying its receptor Fas. Fas ligand is constitutively expressed in nonlymphoid cells of the eye and testis, which may render these tissues immune-privileged by eliminating infiltrating lymphocytes

and granulocytes (94). Interestingly, TNF stimulation leads to downregulation of Fas ligand, which may promote the survival and accumulation of extravasating leukocytes during the inflammatory response in these tissues (94). In conclusion, ECs present at the interface of circulating blood cells and tissue modulate the accumulation of leukocytes at sites of inflammation by potentially two mechanisms: the control of leukocyte egress and regulation of the lifespan of these cells.

### LEUKOCYTE-DEPENDENT ENDOTHELIAL SIGNALING AND INJURY

As discussed, leukocyte adhesion-induced calcium signaling in ECs occurs at various stages of leukocyte transmigration and is functionally important under homeostatic conditions. However, it also may have pathophysiologic relevance in certain disease states, such as transplant rejection. Monocyte adhesion to xenogeneic but not syngeneic ECs results in calcium signals and reorganization of the F-actin cytoskeleton in the endothelium, with an associated increase in endothelial permeability (95). Earlier studies also showed that leukocyte interactions with the normal vasculature during an inflammatory response leads to tissue edema, although the mechanism involved remained undetermined (96). A key contractile event in ECs leading to barrier disruption is the phosphorylation of regulatory myosin light chains by calcium/calmodulin-mediated activation of myosin light-chain kinase and/or through the activity of the Rho/Rho kinase pathway (97–101). Thus, the location and extent of calcium release in ECs may facilitate transmigration, or provide a cue for endothelial permeability and dysfunction.

In addition to leukocyte adhesion-induced calcium signaling, leukocyte-derived soluble factors can potentially have deleterious consequences for the endothelium. Reactive oxygen and nitrogen species are formed in neutrophils following particle uptake and are normally targeted intracellularly to phagolysosomes. However, ROS are released extracellularly in response to stimuli such as cytokines and chemoattractants or following a process referred to as *frustrated phagocytosis*, wherein the target is too large to ingest. ROS are both labile and reactive, and the majority of superoxide released extracellularly is converted to  $H_2O_2$  via xanthine oxidase (found in neutrophils and ECs) or to hypochlorous acid through the action of myeloperoxidase.  $H_2O_2$  is highly membrane-permeable and may contribute to EC dysfunction associated with ischemia–reperfusion (102), hypertension (103,104), and sepsis (105). Although leukocyte-derived ROS and nitric oxide (NO) radicals are traditionally viewed as cytotoxic and causing frank injury to ECs, they have now gained recognition as molecules that may contribute to EC oxidant stress signaling. Neutrophil-derived ROS increase microvessel permeability and intracellular calcium levels in the endothelium (105,106). HUVECs treated with ROS exhibited increased actin stress fibers, which was associated with phosphorylation of focal adhesion kinase, paxillin, and p130cas

tyrosine (107,108). ROS treatment also resulted in enhanced neutrophil adhesion (109), and the neutrophil NADPH oxidase was required for the TNF-induced NF- $\kappa$ B activation and ICAM-1 expression in the endothelium *in vivo* (110). The described ROS-mediated increases in endothelial adhesion receptor expression and change in redox state could enhance cell–cell interactions. These actions may contribute to the progression of atherosclerosis or plaque rupture in acute myocardial infarction. The CD18-dependent adhesion of neutrophils to the endothelium also results in the transmission of neutrophil NADPH oxidase-dependent signals that leads to enhanced expression of the Toll-like receptor 2 (TLR2) in the endothelium (111). This latter report suggests the intriguing possibility that leukocyte-derived inputs into the endothelium result in local amplification of innate immune responses against pathogens. Finally, oxidative stress might alter signal transduction and transcription factor activity through glutathiolation of thiol residues in proteins involved in these pathways or through  $H_2O_2$ -mediated depletion of cellular GSH reserves (103).

Neutrophils have an abundance of proteinases, which are stored in three different classes of intracellular granules (primary, secondary, and tertiary). Proteinases released from primary and secondary granules may cleave EC surface adhesion receptors, chemokines, and extracellular matrix molecules and result in a change in the endothelial phenotype at sites of inflammation. Elastase also serves a nondegradative signaling function by significantly promoting platelet-derived growth factor (PDGF) release from activated ECs (112). On the other hand, proteinases may promote EC injury. Studies to date suggest that serine proteinases, such as elastase released from neutrophils, promote EC injury in various diseases. For example, neutrophil elastase has been reported to decrease endothelial production of NO and prostaglandin  $I_2$ , thereby contributing to the development of ischemia–reperfusion-induced liver injury (113). The toxic effects of neutrophil elastase are greatly enhanced by increased oxidative stress because ROS inhibit the naturally occurring neutrophil elastase inhibitor, alpha-1-proteinase inhibitor. In addition to cell proteolysis resulting in gross changes in the endothelial integrity, elastase could also indirectly impact leukocyte transmigration, since it has been shown to cleave endothelial junctional molecules, adhesion molecules, and surface-retained chemokines (104). Furthermore, the neutrophil proteinase-mediated release of spatially restricted signaling molecules and chemokines at the endothelial surface may result in activation of leukocytes in blood and/or at remote tissue targets. This may occur in sepsis, acute respiratory distress syndrome (ARDS), and ischemia–reperfusion syndromes.

### BLOCKING LEUKOCYTE-ENDOTHELIAL CELL INTERACTIONS: THERAPEUTIC IMPLICATIONS

Inflammation is a fundamental response to tissue injury and infection, but is detrimental in clinically important

inflammatory disorders. The phenotypic changes in the endothelium that often occur in chronic inflammatory sites can fundamentally change the rheostat of the inflammatory response. A striking example of this is the adoption of a unique plump or tall appearance reminiscent of high endothelial venules (HEVs, specialized for recruitment of lymphocytes in secondary lymphoid organs) in ECs in many chronic inflammatory settings. These ECs express unique epitopes for L-selectin ligands, MECA-79, which are normally largely restricted to expression in HEVs (114). The implication is that lymphocyte traffic may be increased at these sites; this has ramifications for the cellular immune response and the ensuing inflammation. Blocking leukocyte recruitment through inhibition of leukocyte–endothelial interactions is an attractive therapeutic approach that could yield benefits in disease states like autoimmune disease, atherosclerosis, and ischemia–reperfusion injury. Indeed, the effect of many anti-inflammatory drugs, such as nonsteroidal anti-inflammatory agents (NSAIDs) and corticosteroids, can be ascribed, in part, to inhibition of adhesion molecules. Inhibiting either IL-1 $\beta$  or TNF through the use of antibodies or their respective soluble receptors reduces the expression of adhesion molecules on activated ECs. Moreover, NSAIDs, corticosteroids, and antioxidants also decrease the expression of inflammatory adhesion molecules and chemokines, in part by down-modulating the function of the inflammatory transcription factor NF- $\kappa$ B. In the search for more selective and potent drugs, the leukocyte and EC adhesion molecules emerged as direct targets for therapeutic interventions (115).

In many experimental models, inhibiting leukocyte rolling by blocking selectin activity affects the accumulation of leukocytes. However, although initial preclinical studies were promising, in clinical trials, antibodies against all selectins, either individually or in combination, and recombinant ligand for P- and L-selectin (rPSGL-1-Ig) did not protect against inflammation induced by ischemic conditions (115). Similarly, clinical trials blocking  $\beta$ 2 integrin or its ligand ICAM-1 were unsuccessful in reducing either myocardial or cerebral ischemic injury (116–118). By contrast, inhibition of LFA-1 is successful in the treatment of graft-versus-host disease, transplant rejection (119), and psoriasis (115).

In contrast to the limited success of blocking the selectins and  $\beta$ 2 integrins, targeting  $\alpha$ 4 integrins (such as VLA-4) with monoclonal antibodies has been beneficial in several human diseases, such as multiple sclerosis and inflammatory bowel disease (120,121). This success might relate to the principal leukocyte subtype targeted in these autoimmune diseases. Whereas trials of selectin and  $\beta$ 2 integrin antiadhesion therapies have primarily involved inflammatory conditions in which neutrophil infiltration predominates, the beneficial effect of antagonizing  $\alpha$ 4 integrins was achieved in disease in which macrophages and lymphocytes play crucial roles. An advantage of selectively targeting mononuclear leukocytes by  $\alpha$ 4 integrin inhibition also can be that, at long-term therapy, serious adverse effects with regard to increased susceptibility to infections may not occur. By contrast, blocking selectins and

$\beta$ 2 integrin adhesion pathways, which strongly affect adhesion of neutrophils, mimics the clinical LAD-I and LAD-II syndromes and could compromise innate immune responses.

## CONCLUSION

In the last three decades, it became increasingly clear that leukocyte extravasation from the blood into the tissues, both under physiologic and pathologic conditions, is not a passive phenomenon, but a highly regulated and selective process. As discussed, this process involves adhesive interactions between leukocytes and ECs, resulting in the generation of intracellular signaling events in both cell types. These events are required for the temporal and spatial regulation of leukocyte diapedesis into the tissues critical for inflammation and host defense. Leukocyte-derived inputs into the endothelium may serve to modify subsequent leukocyte recruitment and responses to inflammatory stimuli. Taken a step further, repetitive leukocyte–EC cross-talk could lead to aberrant endothelial responses that contribute to chronic inflammation. Thus, one may argue that a multipronged approach is required to prevent the leukocyte–endothelial cross-talk that leads to leukocyte diapedesis and associated endothelial phenotypic alterations. A better understanding of the inputs and outputs of both cell types will provide a framework to design targeted therapeutics to achieve this objective.

## KEY POINTS

- Cross-talk between leukocytes and the activated endothelium, which occurs locally via adhesive interactions and soluble mediators, results in short- and long-term modifications of the endothelial phenotype.
- Regulated phagocyte adhesion signals changes in the endothelial actin cytoskeleton, secondary messengers, and gene transcription.
- The timed, limited, and low exposure of ECs to inflammatory mediators generated by phagocytes leads to homeostatic signaling, whereas excessive concentrations of these mediators leads to EC injury.
- Blocking of leukocyte-generated inputs in the endothelium represents an attractive therapeutic target for treatment of inflammatory diseases.

## Future Goals

- To develop techniques to detect spatially localized intracellular signals in the endothelium generated by leukocyte–EC interactions
- To elucidate specific intracellular signaling molecules critical for relaying particular leukocyte mediated inputs into the endothelium. This will aid in identifying therapeutic targets for inflammatory diseases

## Platelet–Endothelial Interactions

---

Patricia B. Maguire, Orina Belton, Niaobh O’Donoghue, Sandra Austin,  
and Judith Coppinger

*Conway Institute, University College Dublin, Ireland*

Platelets are anucleate, discoid cell fragments measuring 1.5 to 3.0  $\mu\text{M}$  in diameter. They are derived from bone-marrow megakaryocytes that are normally maintained in a nonadhesive state, whereby they circulate freely in blood. Anucleate platelets are unique to mammals, with nonmammalian vertebrates (such as zebrafish) possessing nucleated thrombocytes. In 1865, a German anatomist Max Schultze (1825–1874) first described platelets as “spherules” much smaller than red blood cells. A few years later, in 1882, Giulio Bizzozero (1846–1901) found that platelets played a role in coagulation because they could clump and form a blood clot at the site of vessel wall injury. It was not until 1961, however, that the platelet aggregating effect of adenosine diphosphate was discovered (1) and, in the following year, that a machine for measuring aggregation (an aggregometer) was developed (2). The most important breakthroughs surrounded the discovery of proaggregatory platelet thromboxane A<sub>2</sub> (TXA<sub>2</sub>) and antiaggregatory endothelial cell (EC) prostacyclin (PGI<sub>2</sub>), both discovered in the 1970s, along with the finding that aspirin inhibited prostaglandin synthesis and platelet activation. Indeed, finding inhibitors to platelets was exciting because it established the therapeutic possibility of preventing arterial thrombosis and ultimately vessel occlusion (the precipitating event in most myocardial infarctions and many strokes) by means of antiplatelet therapy.

The activation of platelets to arrest bleeding at sites of vascular damage results in platelet adhesion to the vessel wall, where they convert from passive, small discs into larger, flattened structures with extended pseudopods that act as a surface for the propagation of the clotting cascade. Activated platelets secrete and synthesize further platelet agonists, inflammatory mediators, and vasoactive substances. Through conformational changes in the major integrin  $\alpha\text{IIb}\beta\text{3}$ , these platelets “stick” to other platelets via fibrinogen (a process termed *platelet aggregation*) to form a hemostatic plug. Platelets, however, can inappropriately undergo activation and aggregation as a consequence of vascular disease, leading to thrombosis and ultimately vessel occlusion. In addition to this classical role in thrombosis, studies have shown that acti-

vated platelets also are involved (along with other products) in the development of atherosclerotic lesions, heparin-induced thrombocytopenia (HIT), antiphospholipid antibody syndrome (APS), and thrombotic thrombocytopenic purpura (TTP).

A critical facet of the normal and pathological platelet response is the regulatory effect that activated platelets and ECs exert on each other and on other cells in the microenvironment. As well as their primary hemostatic function, platelets can serve to nourish and support the vascular endothelium. By providing a source of growth factors such as fibroblast growth factor 2 (FGF2) and vascular endothelial growth factor (VEGF), platelets can improve EC survival and potentially contribute to vessel angiogenesis (3). Alternatively, under normal circumstances, the vascular endothelium, through secretion of mediators such as PGI<sub>2</sub>, prostaglandin E<sub>2</sub>, nitric oxide, nucleoside triphosphate diphosphohydrolases, tissue factor pathway inhibitor, tissue-type plasminogen activator (t-PA), and heparan sulfate, maintains a nonadhesive, nonthrombogenic vessel lining that forms a barrier to prevent the extravasation of blood cells. The activation of ECs, for example by ischemia–reperfusion and diseases such as hypertension and diabetes, leads to a change in their surface structure, with presentation of surface receptors that allow rolling and adhesion of platelets and leukocytes. Such endothelial dysfunction is attributed as one of the initiating factors in the pathogenesis of atherosclerosis and can alter these transcellular regulatory mechanisms, thereby increasing endothelial adhesiveness to platelets and leukocytes and resulting in their subsequent adherence and activation (4,5).

The mechanisms contributing to the interaction of platelets with denuded vessel wall have been well described over the past decade. Less well defined is the process by which platelets roll along and adhere to intact, but activated, endothelium. However, several recent studies have demonstrated platelet interaction with intact endothelium *in vivo*, even under conditions of high shear stress (6,7). It is becoming clear that many similarities exist between platelet–endothelial interactions and the multistep process by which leukocytes

Figure 64.1. Schematic representation of the major platelet–EC interactions. Activation of ECs leads to presentation of surface receptors (P-selectin, vWF, ICAM-1, PECAM-1), which facilitate rolling and adhesion of activated platelets (increased surface expression of adhesion molecules, integrins, P-selectin and PSGL-1).

roll and adhere to ECs prior to extravasation. Little or no evidence as yet suggests that platelets transmigrate across the intact endothelium. Thus, platelet adhesion to ECs leads to a buildup of activated platelets on the vessel surface, providing a platform for leukocyte recruitment to the vessel wall and a mechanism for the delivery of proinflammatory cytokines to atherosclerotic sites.

Furthermore, several *in vivo* models demonstrate that platelet activation in early lesion formation contributes to the development of the lesion (8). Thus, accumulation of activated platelets on the inflamed endothelium (increased intercellular adhesion molecule [ICAM]-1, vascular cell adhesion molecule [VCAM]-1 and E-selectin expression) provides a reactive surface for the recruitment of leukocytes and additional platelets and allows the localized delivery of the platelet “releasate” on to the endothelial surface. This releasate is composed of a multitude of inflammatory and vasoactive substances and exosomes that can attract atherogenic leukocytes from the circulation, activate ECs and, by infiltrating the vessel wall, trigger vascular cell proliferation, migration, and inflammation (6,7,9,10). Thus, the participation of activated platelets in the genesis of atherosclerotic lesions centers on the products translocated to their surface and those released following adhesion and activation. It is worth noting that, in addition to an important role in atherosclerosis, platelet–EC interactions play an important role in other diseases including sickle cell disease, myeloproliferative disorders, sepsis, and nephritis.

#### PLATELET–ENDOTHELIAL ADHESION

The adhesion of platelets to the endothelium is a multistep process in which platelets are first tethered to the damaged blood vessel, then followed by rolling and both transient

and firm adhesion. In recent years, much attention has focused on understanding the molecular intermediates on platelets and ECs that promote platelet–endothelial interactions including integrins, cell adhesion molecules, and selectins. In platelets, several of these proteins are present in  $\alpha$ -granules and, on activation, are expressed on the platelet surface (Figure 64.1). Interestingly, the inhibition of platelet adhesion to the endothelium dramatically reduces leukocyte accumulation and attenuates atherosclerotic lesion progression in the cholesterol fed *ApoE*<sup>−/−</sup> mouse (10). Thus, the exact role of each receptor in mediating platelet–EC interactions must be elucidated as they may influence the progression of atherosclerosis in different ways.

Selectins, present on both platelets and ECs, mediate the initial contact between circulating platelets and the endothelium (11,12). P-selectin is stored in Weibel–Palade bodies in ECs, and is expressed on the endothelial surface in response to inflammatory stimuli. In addition, P-selectin is stored in the platelet  $\alpha$ -granules and is translocated to the surface upon activation. Surface-bound P-selectin mediates interaction of ECs and platelets with leukocytes that express the P-selectin glycoprotein ligand (PSGL)-1 (13). Falati and colleagues examined thrombus formation in wild-type, *P-selectin*- and *PSGL-1*-knockout animals using *in vivo* microscopy. Mice lacking P-selectin or PSGL-1 developed platelet-rich thrombi compared to wild types, suggesting a role for P-selectin in thrombus formation (14). Specifically, it has been shown that endothelial P-selectin is crucial for the promotion of atherosclerotic lesion growth because, in its absence, only relatively small lesions develop. However, platelet P-selectin also contributes to the lesion development because lesions in wild-type recipients receiving transplants with wild-type platelets were larger than those receiving P-selectin–deficient platelets and were more frequently calcified (15). In addition, deficiency of

P-selectin dramatically protected against neointimal lesion formation after arterial injury in *ApoE*<sup>-/-</sup> mice and significantly attenuated macrophage recruitment into the arterial wall (16). Although it is as yet unclear as to which of the phenotypes associated with the P-selectin mouse are attributed to platelet or ECs, it has been shown recently that platelet-derived, not endothelial-derived P-selectin, is required for neointimal formation after vascular injury in the *P-selectin*-knockout mouse (17). Furthermore, blood levels of soluble P-selectin, mainly derived from platelets, were found to correlate with the progression of atherosclerosis (18). These data are consistent with earlier immunohistochemical studies showing increased expression of P-selectin protein on the endothelium overlying human atherosclerotic lesions and on the endothelium of patients with unstable angina (19).

Although platelet- and EC-derived P-selectin mediates platelet rolling in inflammation, it has been suggested that the process of platelet rolling does not necessarily require previous platelet activation, because platelets from *P-selectin*-knockout mice roll as efficiently as those from wild-type animals (11). However, it is important to note that P-selectin on both platelets and endothelium is expressed on the cell surface only on activation of the cells (20). Furthermore, although PSGL-1 mediates leukocyte-endothelium interactions and leukocyte-platelet interactions in vivo, it appears that PSGL-1 is not involved in platelet-endothelial interactions, as its expression has not been detected on the platelet membrane, and platelet rolling is not inhibited by an anti-PSGL-1 antibody in vivo (21). However, this has been disputed by other groups, which have shown that PSGL-1 on platelets mediates platelet-endothelial interactions in vivo (12). Therefore it seems feasible to suggest that the interaction of platelet PSGL-1 with endothelial P-selectin may, at least in part, mediate platelet rolling. However, it should be noted that the presence of PSGL-1 on a particular cell type does not indicate its functional relevance. For example, although lymphocytes express PSGL-1, only 15% are actually able to bind P-selectin (22).

Another platelet receptor that may mediate interaction of the platelets with the endothelium is glycoprotein (GP)Ib, which is also a ligand for P-selectin (23). Although it has been shown, using antibodies against P-selectin and GPIb, that the von Willebrand Factor (vWF) mediates platelet adhesion to the subendothelial matrix and intact ECs (23), it is still not clear if GPIb interaction with P-selectin on the endothelial surface induces platelet activation similar to that observed with GPIb-vWF interaction in thrombus formation (24). Although selectins enable platelets to rapidly bind to the endothelial layer, these interactions have high dissociation rates, resulting in platelet rolling. Consequently these P-selectin-PSGL-1 interactions are not sufficient to promote firm adhesion of platelets, and thus new bonds characterized by low dissociation rates must be formed. These interactions between platelets and the vascular wall involve endothelial integrins and cell adhesion molecules.

ICAM-1 is upregulated in leukocytes and ECs and mediates adhesion by establishing strong bonds with integrins and

the firm arrest of inflammatory cells on the vascular surface. In addition, an ICAM-1 mechanism is involved in platelet adhesion and aggregation in vitro and in vivo (25). It has been shown that ICAM-2 is expressed on the surface of resting and activated platelets, and this may play an important role in leukocyte-platelet interactions in inflammation and thrombosis (26). In ICAM-1-deficient animals, reduced platelet adhesion to the endothelium is present, most likely because of decreased EC interactions with leukocytes. In addition, expression of ICAM-1 on ECs is enhanced by activated platelets via the cytokine interleukin (IL)-1 $\beta$ , which promotes neutrophil and monocyte recruitment to the endothelium.

Platelet-endothelial cell adhesion molecule (PECAM)-1, another member of the Ig family, is expressed on platelets and leukocytes, and is concentrated at the lateral junctions of ECs. In platelets, PECAM-1 is derived from  $\alpha$ -granules and is thought to play a role in leukocyte migration (27). In PECAM-1-deficient mice, there is a prolonged bleeding time and, in addition, platelets from these animals show enhanced adhesion to collagen as well as enhanced platelet aggregation (28) to negatively modulate the prothrombotic platelet collagen interactions. Therefore, PECAM-1 may play a role in preventing platelet thrombus formation. In addition, PECAM-1 expression by donor ECs attenuates the development of transplant arteriosclerosis, possibly by affecting macrophage infiltration (29).

Indeed, both platelet GPIb $\alpha$  and  $\alpha$ IIB $\beta$ 3 have been demonstrated to contribute to platelet endothelial adhesion in vitro (30). Furthermore, in vivo studies have shown that antibodies against GPIb $\alpha$  reduce both transient and firm adhesion to the endothelium the *ApoE*<sup>-/-</sup> model. In contrast, in the same model, inhibition of  $\alpha$ IIB $\beta$ 3 had only partial effects on transient platelet adhesion but almost completely inhibited firm attachment to ECs. It is important to note that a similar reduction in transient and firm adhesion was observed in the *ApoE*<sup>-/-</sup> mouse with platelets deficient in  $\alpha$ IIB $\beta$ 3 (6). This study also showed that inhibition of platelet adhesion to the endothelium in the early stages of atherosclerosis not only decreased lesion formation but also attenuated inflammatory cell accumulation. This provides strong evidence for the role of platelet-endothelial interactions in early atherosclerotic lesion formation. However, it is important to note that  $\alpha$ IIB $\beta$ 3 may not be as important in the early development of atherosclerosis. Weng and colleagues have shown that in both an *ApoE*<sup>-/-</sup> and low-density lipoprotein receptor (*LDLR*)<sup>-/-</sup> mouse models of atherosclerosis,  $\beta$ 3 integrin deficiency was associated with increased atherosclerosis (31). Increased vascular disease in the absence of members of the  $\beta$ 3 integrin family also has been previously reported. Indeed, humans with Glanzmann thrombasthenia due to deficiency of  $\alpha$ IIB $\beta$ 3 develop carotid atherosclerosis (32). In addition, despite the unquestioned efficacy of short-term intravenous inhibition of  $\alpha$ IIB $\beta$ 3, long-term oral inhibition of  $\alpha$ IIB $\beta$ 3 increases mortality in humans (33).

Although the role for vWF in the development of atherosclerosis has not fully been elucidated and remains a

Figure 64.2. Platelet granules and vesicles. Upon platelet activation, three types of preformed granules,  $\alpha$ -granules, dense granules, and lysosomes, fuse with the plasma membrane (in a process known as *exocytosis*); change their surface structure (express P-selectin); and release their contents into the external environment. This platelet releasate contains more than 350 soluble proteins and enzymes from  $\alpha$ -granules and lysosomes as well as exosomal vesicles and can exert potent biological effects. In addition, microparticles are generated from the platelet plasma membrane and are involved in hemostasis and angiogenesis.

matter of debate, it has been shown that mice deficient in vWF have decreased atherosclerosis (34). This has been suggested to be due to the lack of platelet–EC interactions; however, other possible mechanisms cannot be excluded. It also has been shown that enhanced secretion of vWF in response to inflammatory stimuli can lead to local recruitment of platelets (35). Thus, inflammatory states are associated with an increased potential for EC–platelet interactions (36). This may explain in part why the deficiency of vWF protects against atherosclerosis. Stimulated ECs recently have been shown to express long string-like multimers of von Willebrand factor, known as ultralarge vWF (ULVWF), to which platelets can adhere and support leukocyte tethering under high shear conditions (37).

## PLATELET–ENDOTHELIAL COMMUNICATION

Upon activation, platelets release a wealth of adhesive and proinflammatory substances that allow cross-talk between platelets and the endothelium. Physiologically, this releasate could be involved in many normal EC processes, including angiogenesis, due to the release of VEGF and matrix metalloproteinases (MMPs). Additionally, the effects of this releasate

are believed to be central in the initiation, development, and exacerbation of atherosclerotic lesions, and offers a direct link between platelets, inflammation, atherosclerosis, and other platelet-associated diseases.

## Platelet Granules and Vesicles

Platelets contain a number of preformed, morphologically distinguishable storage granules:  $\alpha$ -granules, dense granules, and lysosomes (9). In addition, platelets also release two distinct membrane vesicle populations during activation: exosomes and microparticles (Figure 64.2) (38).

### $\alpha$ -Granules

$\alpha$ -Granules are suggested to arise from the trans-Golgi complex in the megakaryocyte and are the most abundant granule with about 80 present per platelet. Several subclasses of  $\alpha$ -granule proteins exist: platelet-specific proteins, cationic proteins, growth factors, adhesion molecules, coagulation factors, and glycoproteins, which have a diverse range of functions including many chemokines and growth factors for ECs, smooth muscle cells, and fibroblasts. These proteins originate either from endogenous synthesis in the megakaryocyte or platelet or by endocytosis from the plasma; they are

packaged into granules through vesicle trafficking processes. Gray platelet syndrome is associated with thrombocytopenia, enlarged platelets, and a specific absence of  $\alpha$ -granules and their contents.

### *Dense Granules*

Dense granules, of which there are approximately seven per platelet, contain no secretable proteins but instead store many low-molecular-weight compounds, for example 5-hydroxytryptamine (serotonin) and the nucleotides ADP and ATP, which are potent activators of platelet aggregation and vasoconstriction. Indeed, ADP plays a role in the “second wave of platelet activation” and is essential for TxA<sub>2</sub>-induced platelet aggregation via the phosphoinositide-3-kinase (PI3K) pathway. Functional ADP receptors (P2Y and P2X1) are present on the endothelium; upon activation, these produce vasodilatation. Platelet dense granules are related to melanosomes, and such lysosome-related organelles are deficient in the autosomal recessive Hermansky-Pudlak syndrome.

### *Lysosomes*

Lysosomes are membrane-bound vesicles equipped with an ATP-dependent proton pump; they are morphologically similar to the  $\alpha$ -granule. Several glycosidal enzymes are released from lysosomes, as well as a number of acid phosphatase enzymes and proteases, such as cathepsin D and E. Lysosomes represent the post-multivesicular body (MVB) stage in the endocytic route and are the main site of protein and lipid degradation.

### *Exosomes*

Studies of platelets have shown the release of  $\alpha$ -granule membrane-derived exosomes following exocytosis (38). These membrane-bound vesicles (<100 nm in diameter) are biochemically and morphologically distinct from larger apoptotic vesicles such as microparticles (39). Exosomes are secreted by a multitude of other cells, including cytotoxic T cells and antigen-presenting cells, such as B cells and dendritic cells. No evidence as yet suggests that exosomes are released from ECs. They can be released from platelets in response to a variety of agonists and contain the lysosomal/exosomal tetraspan protein CD63; however, their function in platelet biology remains unknown (38). Indeed, platelet-derived exosomes do not readily bind annexin V, factor X, or prothrombin *in vitro*, suggesting that they do not play a procoagulant role (38). However, most cell-derived exosomes activate ECs to secrete plasminogen activator inhibitor (PAI)-1, increased levels of which are associated with an increased risk of ischemic cardiovascular events (40). Early studies suggested that exosomes served to eliminate undegraded endosomal or lysosomal proteins and membranes. Recent studies indicate, however, that in different cell types, exosomes may play an immunoregulatory intercellular role. For example, B-lymphocyte-derived exosomes have been shown to stimulate CD4<sup>+</sup> T lymphocytes *in vitro* (41). Furthermore, B cell-derived exosomes have been shown to express functional integrins on their surfaces that are capa-

ble of mediating exosome adhesion to the extracellular matrix (42). Interestingly, dendritic cell exosomes were found to stimulate antitumor immune responses and the rejection of established tumors in mice (39). Proteomic analysis of exosomes secreted from various cell types has revealed the presence of ubiquitous proteins such as tubulin, actin and actin-binding proteins, plasma membrane proteins, proteins involved in apoptosis (e.g., 14-3-3) as well as cell-type-specific proteins (39). However, the full molecular content of proteins found on the surface and within platelet exosomes has never been investigated, although they do contain  $\alpha$ -granular membrane proteins such as cellular prion protein (43). Future studies are necessary to define the role of platelet exosomes in mediating EC phenotype.

### *Microparticles*

Microparticles (MPs) are membrane-bound vesicles that are formed from the platelet surface within minutes following activation by many agonists or shear stress. Their generation seems to be a regulated process distinct from granule exocytosis, requiring an increase in cytosolic calcium and subsequent disruption of the membrane cytoskeleton. The formation of platelet MPs has been demonstrated *in vitro* in the presence of several agonists including thrombin and collagen, and *in vivo* under high shear conditions (44,45). Such MP formation is closely associated with the exposure of phosphatidyl serine on the outer membrane leaflet and provides an anionic surface for the binding of coagulation factors such as coagulation factor Va (46). The majority of circulating MPs are derived from platelets, and increased numbers of platelet MPs are found in many diseases such as diabetes, sickle cell disease, cancer, and following cardiopulmonary bypass surgery, where they cause an increased risk of thrombosis (47,48). Although their exact physiological and pathophysiological functions are unknown, MPs, independent of their origin, can transfer information, mostly at the level of ECs. Platelet MPs are involved in hemostasis and thrombosis because they aid in the initiation and amplification of the coagulant cascade. They can promote angiogenesis via extracellular-signaling-receptor kinase (ERK) and PI3K activation (49). Platelet MPs also stimulate ECs through modifications of arachidonic acid metabolism and the generation of TxA<sub>2</sub>, thereby inducing expression of cyclooxygenase (COX)-2 and the generation and release of PGI<sub>2</sub>, suggesting the involvement of platelet MPs in the development of inflammation.

Platelet MPs have a protein content similar to the activated plasma membrane containing GPIb/IX/V, PECAM-1,  $\alpha$ IIB $\beta$ 3, annexin V, and the tetraspanin proteins Peta-3, CD9, and P-selectin. It is thought that the presence of these glycoproteins on MPs may be important in their interactions with the endothelium (50). Furthermore, IL-1 $\beta$  also is present in MPs, in addition to its release in soluble form, and it can induce inflammatory gene expression in ECs (51). MPs generated from ADP-activated platelets have recently been studied using a proteomics approach (52). Using 1D sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) in

combination with mass spectrometry (MS), 578 proteins were identified, including the membrane surface proteins GPIIIa, GPIIb, and P-selectin, as well other platelet proteins such as the chemokines platelet factor 4 (PF4), neutrophil-activating peptide (NAP)-2, and RANTES (Regulated upon Activation, Normal T-cell Expressed and Secreted).

### The Platelet Releasate

Upon platelet activation, there ensues a series of graded responses (dependent on the degree of agonist stimulation) that include a change in cell shape, cell aggregation, and movement of preformed storage granules to the cell surface. Exocytosis of these granules involves the redistribution of soluble membrane proteins to the plasma membrane surface – such as the adhesion molecule P-selectin – as well as the release of their contents (soluble proteins and enzymes from  $\alpha$ -granules and lysosomes, as well as exosomal vesicles). These substances are known collectively as the platelet releasate. These releasates move into the external milieu, where they exert potent biological effects. This releasate contains a range of growth factors, coagulation proteins, adhesion molecules, cell-activating molecules, cytokines, integrins, proinflammatory molecules (transforming growth factor [TGF]- $\beta$ , PF4, RANTES), and angiogenic factors. Such proteins act in an autocrine or paracrine fashion to modulate cell signaling. Thus, they play a key role in hemostasis. Importantly, increasing evidence suggests that the platelet releasate plays a pathological role in vascular conditions such as thrombosis and atherosclerosis.

Despite the biological significance of such released chemokines and signaling factors from platelets, the full complement of proteins comprising the platelet releasate and the mechanisms by which these proteins exert their effects on other cell types, such as ECs, remain poorly defined. Recently, a method was developed to purify the secreted fraction of thrombin-activated human platelets. This has allowed researchers to establish the first extensive catalog of the molecular context of the platelet releasate, a fraction highly enriched for platelet granular and exosomal contents (53). It is expected that the secretion profile of platelets changes depending on the agonist, although this change may be more quantitative than qualitative. In this study, the platelet releasate was separated using a multilayered proteomic approach using a combination of two-dimensional electrophoresis and multidimensional chromatography, both coupled to mass spectrometry. In total, over 300 proteins were identified in the thrombin-activated platelet releasate, 81 of which were present in two or more experiments. A list of these released proteins, classified according to their main function (if known), is found in Table 64-1.

Of these 81, 37% were previously reported to be released from platelets, including PF4, thrombospondin (TSP), osteonectin, metalloproteinase inhibitor 1, and TGF- $\beta$ . Another 35% are released from other secretory cells: for example, cofilin, profilin, 14-3-3 $\zeta$ , and actin from dendritic cells;

peptidyl-prolyl-cis isomerase (cyclophilin A) from smooth muscle cells; phosphoglycerate kinase from fibrosarcoma cells; and  $\beta$ 2-microglobulin and vitamin D-binding protein from the liver. The remaining 23 (28%) recurring proteins were not reported to be released from any cell type, with several mapping to expressed sequence tags (ESTs) of unknown function. Moreover, out of the 81 proteins, 46 are detected at the mRNA level in platelets. The functions of many of these proteins, however, are consistent with the known proinflammatory role of platelets, and include the previously undescribed platelet proteins secretogranin-II and -III, monocyte chemoattractant precursors, and cyclophilin A, a vascular smooth muscle and EC growth factor and proinflammatory cytokine. Indeed, several molecules released by platelets are now known to play significant roles in platelet-to-EC communication.

### Immune Modulators

Released platelet chemokines coordinate leukocyte recruitment to the inflamed endothelium. These chemokines include PF4, platelet basic protein, and RANTES from  $\alpha$ -granules. Other proinflammatory cytokines released by platelets include those stored in the cytoplasm, such as CD40L, and those synthesized upon activation, such as IL-1 $\beta$ . Indeed, platelet-derived IL-1 $\beta$  induces EC adhesiveness by enhancing the expression of ICAM-1, with consequent leukocyte adhesion (51). Additionally, two antibacterial proteins, thrombocidin-1 and -2, which are structurally similar to chemokines such as NAP-2 and secretogranin (Sg)-II and -III, have been reported to be released from platelets (53,54).

PF4 is a lysine-rich, heparin-binding, low-molecular-weight (7 kDa) platelet-specific protein (55) that belongs to the CXC chemokine subfamily. It comprises 2% to 3% of the releasate (concentrations approaching approximately 25  $\mu$ g/mL [4  $\mu$ M] in the vicinity of the vessel wall). The biological role of PF4 is unclear; however, secreted PF4 binds to endothelial heparin sulfate proteoglycans, inhibiting the activity of antithrombin III (56). It also binds to the Duffy antigen/receptor for chemokines (DARC) on ECs and red blood cells (the consequences of which are unknown) (57,58), and to an alternatively spliced variant of CXCR3 found on ECs (59). Additionally, endothelial expression of E-selectin is induced by PF4 through low-density lipoprotein receptor-related protein (LRP) in an NF- $\kappa$ B-dependent manner (60). PF4 also may act as an anticoagulant, because it binds to thrombomodulin and, like protein S (also released from platelets), can stimulate the formation of activated protein C on the platelet surface (61). PF4 has been shown to bind to exposed subendothelium, where an internal fragment generated by proteolytic processing may function as an inhibitor of EC proliferation and angiogenesis (62). Platelets have been shown to deposit PF4 directly on the luminal surface of the endothelium in a mouse atherosclerotic model, significantly promoting leukocyte infiltration (10). Furthermore, PF4 and low-density lipoprotein (LDL) have been found to colocalize in atherosclerotic lesions, especially in macrophage-derived foam cells, because PF4 binds to oxidized LDL and may contribute to its uptake (63).

**Table 64-1: Summary of 81 Proteins from the Thrombin-Activated Platelet Release**

<i>Protein</i>	<i>Gene Name</i>	<i>Function</i>
<b>Adhesion</b>		
Thrombospondin	TSP1_HUMAN	Adhesive glycoprotein that mediates cell-to-cell and cell-to-matrix interactions; can bind to fibrinogen, fibronectin, laminin, type V collagen, and integrins $\alpha V/\beta 1$ , $\alpha V/\beta 3$ and $\alpha IIb/\beta 3$ ; upon secretion, can bind $\alpha IIb/\beta 3$ , $\alpha v\beta 3$ , and GPIV; can potentiate aggregation by complexing with fibrinogen and becoming incorporated into fibrin clots
SPARC protein (osteonectin)	SPRC_MOUSE	Upon secretion, forms a specific complex with thrombospondin; appears to regulate cell growth through interactions with the extracellular matrix and cytokines; binds PDGF and cell membranes; expressed in tissues undergoing morphogenesis, remodeling, and wound repair
Platelet glycoprotein V	GPV_HUMAN	Part of the GPIb-IX-V complex on the platelet surface; cleaved by the protease thrombin during thrombin-induced platelet activation
Von Willebrand Factor	VWF_HUMAN	Binds GPIb-IX-V
Glycoprotein Ib $\alpha$ chain	GPBA_HUMAN	Surface membrane protein of platelets that participates in formation of platelet plug by binding A1 domain of von Willebrand factor
Nidogen	NIDO_HUMAN	Glycoprotein found in basement membranes; interacts with laminin, collagen, and integrin on neutrophils
Endothelial cell multimerin precursor	ECM_HUMAN	Carrier protein for platelet factor V/Va
<b>Inflammation</b>		
Platelet basic protein	SZO7_HUMAN	Proteolytic cleavage yields the chemokines $\beta$ -thromboglobulin and neutrophil activating peptide (NAP) 2
Secretory granule proteoglycan core protein precursor	PGSG_HUMAN	Function unknown; associates and is coreleased with inflammatory mediators such as platelet factor 4
Clusterin	CLUS_HUMAN	Not clear; possibly platelet-derived apolipoprotein J participates in short-term wound repair and chronic pathogenic processes at vascular interface
Platelet factor 4	PLF4_HUMAN	Platelet-specific chemokine with neutrophil activating properties
Latent transforming growth factor (TGF)- $\beta$ binding protein isoform 1S	LTBS_HUMAN	Subunit of the TGF- $\beta$ 1 complex secreted from platelets
Latent TGF binding protein	O88349	Subunit of the TGF- $\beta$ 1 complex secreted from platelets
Platelet factor 4 variant	PF4V_HUMAN	Similar to PF4
Vitamin D binding protein	VTDB_HUMAN	Carries vitamin D sterols; prevents actin polymerization; has T-lymphocyte surface association
$\beta$ 2 microglobulin	B2MG_HUMAN	The $\beta$ -chain of the major histocompatibility complex (MHC) class I molecule
Plasminogen	PLMN_HUMAN	Dissolves fibrin in blood clots, proteolytic factor in tissue remodeling, tumor invasion, and inflammation
$\alpha$ Ib glycoprotein	A1BG_HUMAN	Found in plasma; role not clear, possibly involved in cell recognition as a new member of the immunoglobulin family
Apolipoprotein A1	APO1_HUMAN	Role in high-density lipoprotein binding to platelets
$\alpha$ 1-acid glycoprotein	A1AH_HUMAN	Modulates activity of the immune system during the acute phase reaction; binds platelet surface
Gelsolin	GELS_HUMAN	Two isoforms: a cytoplasmic actin-modulating protein and a secreted isoform involved in the inflammatory response
Serotransferrin precursor	TRFE_HUMAN	Precursor to macromolecular activators of phagocytosis (MAPP), which enhance leukocyte phagocytosis via the Fc $\gamma$ RII receptor; may stimulate cell proliferation
Secretogranin III	SG3_MOUSE	Unknown; possibly involved in secretory granule biogenesis; may be cleaved into active inflammatory peptide-like secretogranin II
Cyclophilin A	CYPH_MOUSE	Cellular protein with isomerase activity; secreted vascular smooth muscle cell growth factor and endothelial activator

(continued)

**Table 64-1 (continued)**

<i>Protein</i>	<i>Gene Name</i>	<i>Function</i>
<b>Actin Binding</b>		
$\alpha$ -actinin 1	AAC1_HUMAN	Actin-binding and actinin cross-linking protein found in platelet $\alpha$ -granules; interacts with thrombospondin on the platelet surface; plays a role in monocyte/macrophage maturation
$\alpha$ -actinin 2	AAC2_HUMAN	Actin-binding and actinin cross-linking protein found in platelet $\alpha$ -granules; interacts with thrombospondin on the platelet surface
$\alpha$ -actinin 4	AAC4_HUMAN	Actin-binding and actinin cross-linking protein found in platelet $\alpha$ -granules; interacts with thrombospondin on the platelet surface
Actin	ACTA_HUMAN	Major cytoskeletal protein; external function unknown
Actin	ACTB_HUMAN	Major cytoskeletal protein; external function unknown
14-3-3 protein $\zeta/\delta$	14-3-3Z_MOUSE	External function unknown; involved intracellularly in signal transduction; however, may have a role in regulating exocytosis
Adenylyl cyclase associated protein 1	CAP1_HUMAN	Contains a WH2 actin-binding domain (as $\beta$ -thymosin 4); known to regulate actin dynamics; may mediate endocytosis
Tubulin	TBA_HUMAN	Cytoskeletal protein involved in microtubule formation
Cofilin	COF_HUMAN	Actin depolymerization/regulation in cytoplasm
Profilin	PRO1_HUMAN	Actin demolymerization/regulation in cytoplasm
Filamin	FLNA_HUMAN	Actin-binding protein; essential for GPIb- $\alpha$ anchorage at high shear; substrate for caspase-3
Talin	TAL1_HUMAN	Actin-binding protein that binds to integrin- $\beta$ 3 domain
Zyxin	ZYX_HUMAN	Associates with the actin cytoskeleton near adhesion plaques; binds $\alpha$ -actinin and VASP
Transgelin	TAG_HUMAN	Actin-binding protein; loss of transgelin expression important in early tumor progression; may serve as a diagnostic marker for breast and colon cancer
Thymosin $\beta$ 4	TYB4_HUMAN	Intracellularly: G-actin binding protein; functions as an antimicrobial peptide when secreted; increases the rate of attachment and spreading of ECs on matrix components and migration of HUVECs
Vinculin	VINC_HUMAN	Actin-binding protein
WD-repeat protein FKS30	WDRI_HUMAN	Actin-binding protein
Titin	Q8WZ42	Actin binding protein
Titin	Q8WZ42	Anchoring protein of actomyosin filaments; role in secretion of myostatin
<b>Protease</b>		
Metalloproteinase inhibitor 1	TIM1_HUMAN	Interacts with metalloproteinases and inactivates them; stimulates growth and differentiation of erythroid progenitors, dependant on disulfide bonds
Amyloid $\beta$ -A4 protein (Protease nexin II)	A4_HUMAN	Exhibits potent protease inhibitor and growth factor activity; may play a role in coagulation by inhibiting factors XIa and IXa
$\alpha$ 1-antitrypsin precursor	A1AT_HUMAN	Acute phase protein, similar to complement, inhibits proteinases
$\alpha$ 2-Macroglobulin	A2MG_HUMAN	Acute phase protein, similar to complement, inhibits proteinases
<b>Coagulation</b>		
Vitamin K-dependant protein S	PRTS_HUMAN	Anticoagulant; cofactor to protein C in the degradation of coagulation factors Va and VIIIa secretion; downregulated by TNF- $\alpha$ ; deficiency associated with thrombosis; also released by endothelial and vascular smooth muscle cells
Coagulation factor V	FA5_HUMAN	Cofactor that participates with Factor Xa to activate prothrombin to thrombin
Coagulation factor XIIIa chain	F13A_HUMAN	Coagulation protein involved in the formation of the fibrin clots
Complement C3	CO3_HUMAN	Activator of the complement system; cleaved to $\alpha$ , $\beta$ , and $\gamma$ chains normally prior to secretion, and is a mediator of the local inflammatory response
Complement C4	CO4_HUMAN	Activator of the complement system; cleaved normally prior to secretion; its products mediate the local inflammatory response
78kDa glucose related protein	GR78_MOUSE	Chaperone in the ER involved in the inhibition of secreted coagulation factors
Prothrombin	THRB_HUMAN	Converts fibrinogen to fibrin and activates coagulation factors including factor V
Fibrinogen $\alpha$ -chain	FIBA_HUMAN	Cofactor in platelet aggregation; endocytosed into platelets from plasma
Fibrinogen $\beta$ -chain	FIBB_HUMAN	Cofactor in platelet aggregation; endocytosed into platelets from plasma

<i>Protein</i>	<i>Gene Name</i>	<i>Function</i>
Fibrinogen $\gamma$ -chain Calumenin	FIBG_HUMAN CALU_MOUSE	Cofactor in platelet aggregation; endocytosed into platelets from plasma; an inhibitor of the vitamin K epoxide reductase-warfarin interaction
<b>Tumor</b>		
Similar to hepatocellular carcinoma- associated antigen 59	Q99JW3	Tumor marker
<b>Mitochondrial</b>		
Glyceraldehyde 3-phosphate dehydrogenase	G3P_HUMAN	Mitochondrial enzyme involved in glycolysis; may catalyze membrane fusion
Phosphoglycerate kinase	PKG_MOUSE	Glycotic enzyme; secreted from tumor cells and involved in angiogenesis
Superoxide dismutase	SODC_HUMAN	Involved in cellular oxygen metabolism, role for SOD-1 in inflammation
Pyruvate kinase M2 isozyme	KYP2_HUMAN	Involved in final stage of glycolysis; presented as an autoantigen by dendritic cells
Fructose bisphosphate aldolase	ALFA_MOUSE	Glycolytic enzymes that converts fructose 1,6-bis phosphate to glyceraldehyde 3-phosphate and dihydroxy acetone phosphate
<b>Exocytosis</b>		
Calmodulin	CALM_HUMAN	Known to regulate calcium-dependent acrosomal exocytosis in neuroendocrine cells
Rho GDP-dissociation inhibitor 2	GDIS_MOUSE	Regulates the GDP/GTP exchange reaction of Rho proteins; regulates platelet aggregation; involved in exocytosis in mast cells
<b>Hypothetical</b>		
Filamin fragment (Hypothetical 54-kDa protein)	Q99KQ2	Unknown
Hypothetical protein	Y586_HUMAN	Unknown
Hypothetical protein	Q9BTV9	Unknown
Fibrinogen type protein	Q8VCM7	Similar to fibrinogen
<b>Lysosomal</b>		
Proactivator polypeptide	SAP_HUMAN	Activator proteins for sphingolipid hydrolases (saposins) that stimulate the hydrolysis of sphingolipids by lysosomal enzymes
<b>Miscellaneous</b>		
RNA-binding protein	Q9UQ35	RNA binding protein
Hemoglobin $\alpha$ -chain	HBA_HUMAN	Oxygen transport; potentiates platelet aggregation through thromboxane receptor
Hemoglobin $\beta$ -chain	HBB_HUMAN	Oxygen transport
Hemopexin	HEMO_HUMAN	Heme-binding protein with metalloproteinase domains
Transthyetin	TTHY_HUMAN	Thyroid hormone-binding protein secreted from the choroid plexus and the liver in to CSF and plasma, respectively
Pleckstrin	PLEK_HUMAN	A substrate for protein kinase C; its phosphorylation is important for platelet secretion
Intracellular hyaluronan- binding protein p 57	Q9JKS5	Unknown
Bromodomain and PHD finger- containing protein 3	BRF3_HUMAN	Unknown

(continued)

**Table 64-1 (continued)**

<i>Protein</i>	<i>Gene Name</i>	<i>Function</i>
Rho GTPase-activating protein	Q92512	Promotes the intrinsic GTP hydrolysis activity of Rho family proteins; involved in regulating myosin phosphorylation in platelets
Albumin	ALBU_HUMAN	Major plasma protein secreted from the liver into the blood; endocytosed into platelets from plasma

Proteins identified by Coppinger and colleagues, 2004, categorized according to their main function. Eighty-one proteins were identified using a proteomics approach from the thrombin-stimulated platelet supernatant fraction. Mass spectrometric spectra were identified using the SEQUEST program and a composite mouse and human database (NCBI July 2002 Release) in three replicate experiments. Gene name and known functions are provided.

Finally, heterophilic interactions of PF4 and RANTES promote monocyte arrest on the endothelium (64). HIT, a thrombotic disorder related to the administration of heparin, involves the formation of antibodies to a complex of PF4 with heparin. The pathogenesis of this disease is believed to be associated with excessive secretion of PF4. Resulting antibodies can directly activate ECs and, through Fc $\gamma$ RII receptors, lead to platelet activation and subsequent thrombosis and inflammation (65).

Platelet basic protein has neutrophil-activating properties. It is a platelet-specific protein that is part of the chemokine protein family. Platelet basic protein is converted by proteolysis to connective tissue activating protease (CTAP-III), and by N-terminal cleavage to  $\beta$ -thromboglobulin ( $\beta$ TG), whose proteolytic products include NAP-2. NAP-2 is a potent activator of neutrophils, stimulating neutrophil chemotaxis, calcium mobilization, and exocytosis (55). Moreover, NAP-2 reacts with IL-8 receptors on neutrophils, causing degranulation and secretion of elastase. Neutrophils also release cathepsin G, which exerts a positive feedback effect by causing platelets to release and degrade CTAP-III to NAP-2, thereby activating additional neutrophils (66). Furthermore,  $\beta$ TG is a potent activator of smooth muscle cell proliferation and platelet-leukocyte adhesion, and its levels previously have been found to be significantly elevated in deep vein thrombosis.

The CC chemokine RANTES, first purified as a product of activated T cells, is a powerful chemoattractant for memory T lymphocytes and monocytes. This proinflammatory factor is deposited by activated platelets on the surface of monocytes and the endothelium of atherosclerotic arteries, mediated by EC P-selectin (10,67). The deposition of RANTES in vivo was shown to trigger shear-resistant monocyte arrest on inflamed or atherosclerotic endothelium, as well as the potent chemotaxis of eosinophils (10,64,68). Interestingly, antagonism of RANTES receptors with the CC chemokine antagonist Met-RANTES reduces the progression of atherosclerosis in a hypercholesterolemic mouse model (69).

Secretogranins (Sg)-II and -III are members of the chromogranin family of acidic secretory proteins and have recently been found in the platelet releasate (53). These proteins were previously shown only to be localized to storage vesicles of neuroendocrine cells (70) and are not known to be present in

ECs. Upon release from these cells, SgII is proteolytically processed to yield the 33-amino acid polypeptide secretoneurin, which has a tissue distribution and function similar to the proinflammatory neuropeptides substance P and neuropeptide Y (70). In fact, secretoneurin may itself modulate inflammatory reactions, because it has been shown to increase the chemotactic migration of monocytes and eosinophils, deactivate neutrophil chemotaxis, and stimulate EC migration (71). This effect of secretoneurin to stimulate monocyte adhesion to arterial and venous ECs in vitro, followed by their transendothelial migration, was comparable to that of tumor necrosis factor (TNF)- $\alpha$ , lipopolysaccharide (LPS), or IL-1 under the same experimental conditions (72). Furthermore, secretoneurin stimulates proliferation and exerts antiapoptotic effects on ECs, where it activates intracellular PI3K/Akt and mitogen-activated protein kinase (MAPK) pathways (73). Whether cleavage products of SgIII play a similar role is unknown. Nevertheless, although absent in normal vasculature, SgIII was widely expressed in human atherosclerotic lesions (53). Therefore, secretoneurin and cleavage products of SgIII, such as substance P, may be implicated in expanding the inflammatory response of atherosclerosis by stimulating the replication of monocyte-derived macrophages and the entry of new monocytes into lesions.

CD40 ligand (CD40L, CD154) is a 33-kDa type-II transmembrane protein of the TNF family. It was originally identified as a surface molecule expressed on activated T cells. Although present on several cells of the vasculature (including ECs), platelets are the primary source, and following their activation, CD40L rapidly translocates from the cytoplasm to their surface. Surface-expressed CD40L can be cleaved to an 18-kDa soluble form, sCD40L; however, unlike  $\alpha$ -granule secretion, in which the substances are fully released within 5 to 10 minutes, this is a long-lasting process that takes at least 90 minutes to reach the maximal level of extracellular sCD40L concentration. CD40L is prothrombotic. It binds to  $\alpha$ IIb $\beta$ 3 and is involved in the recruitment of inflammatory cells at the vessel wall by ligating CD40 on ECs (no evidence for subsequent rolling mediated by CD40L-CD40). It induces the endothelial expression of adhesion molecules (ICAM-1, VCAM-1, and E-selectin) and chemokines (such as tissue factor, monocyte

chemoattractant protein [MCP]-1 and IL-8) (74,75). Interaction of membrane-bound or sCD40L with CD40 also may inhibit the re-endothelization of an injured vessel, thereby enhancing restenosis (76). Furthermore, CD40L appears to be particularly relevant in the pathogenesis of acute coronary syndromes, percutaneous coronary interventions, and cardiopulmonary bypass, because enhanced circulating levels of soluble and membrane-bound CD40L are found, and elevated levels of sCD40L are a reliable predictor of cardiovascular events (77). Moreover, inhibition of CD40L reduces the development of atherosclerosis in mice (78).

### Growth Factors

Growth factors that derive from platelets stimulate cell proliferation and have very important roles in growth, development, wound repair, and inflammatory reactions. Growth factors released from  $\alpha$ -granules include the smooth muscle cell mitogens platelet-derived growth factor (PDGF), TGF- $\beta$ , epidermal growth factor (EGF), as well as bone-derived growth factor (BDGF) and hepatocyte growth factor (53,79). The overexpression of factors such as PDGF has been linked to diseases such as atherosclerosis and cancer (4). Normal vessels express low levels of the protein and its receptors; however, a marked increase of PDGF has been observed in the eccentric lesions of atherosclerosis (80). Additionally, the role of PDGF as a transforming and angiogenic growth factor has been demonstrated (81). VEGF also is released from platelets and plays a principal role in EC migration and proliferation, promoting angiogenesis in normal (e.g., embryonic vascular development and clotting/wound healing) and pathological conditions (e.g., thrombosis/cardiac ischemia and tumor progression/metastasis). Evidence exists that angiopoietin 1 (Ang1) is also released from platelets. Ang1 binds to Tie2 receptor-like tyrosine kinase receptors located on ECs and is essential for normal vascular development and maintaining the quiescence and stability of mature vasculature (82). This interplay between VEGF and angiopoietin is essential for vessel wall stabilization. Plasminogen also is released from platelets, and it can be proteolytically cleaved to angiostatin, a negative regulator of angiogenesis (53).

Cyclophilins are peptidyl-propyl *cis-trans*-isomerases. They are members of the immunophilin family and act intracellularly both as catalysts and chaperones in protein folding. They have extracellular signaling functions, such as the induction of chemotaxis and adhesion of memory CD4 cells. Cyclophilin A is secreted by vascular smooth muscle cells in response to oxidative stress, where it acts in an autocrine manner to stimulate ERK1/2 and vascular smooth muscle proliferation (83). Recently, cyclophilin A has been found to be secreted by ECs, and also was found to act in an autocrine manner to stimulate EC proliferation, migration, and invasive capacity and induce the expression of several genes, including CD147 (84,85). Furthermore, endothelial-derived cyclophilin A was found to have proinflammatory cytokine properties, upregulating the expression of E-selectin and VCAM-1, stimulating MAPKs, and inducing apoptosis similar to the proapoptotic effect of

TNF- $\alpha$ , indicating the multifunctional role of cyclophilin A in the vascular system (86). Interestingly, cyclophilin A also is released from activated platelets and thus may stimulate the activation, migration, and proliferation of ECs and smooth muscle cells (53). Indeed, although absent in normal vasculature, cyclophilin A also was identified in human atherosclerotic lesions, which may be partially derived from incorporated platelets (53,86).

### Adhesive Glycoproteins

The platelet releasate is rich in adhesive glycoproteins such as P-selectin (as mentioned earlier), TSP, vWF, and multimerin. As well as being present in the subendothelium, vWF is stored and secreted from platelet  $\alpha$ -granules and EC Weibel-Palade bodies, because it is involved in binding to the GPIb-IX-V receptor under high shear. Multimerin, a carrier protein for platelet (but not plasma) factor V/Va, resembles vWF in its repeating, homomultimeric structure; it also is expressed in  $\alpha$ -granules and Weibel-Palade bodies.

TSP is a 450-kDa  $\text{Ca}^{2+}$ -binding, disulphide-linked trimeric glycoprotein that constitutes 25% of the  $\alpha$ -granule content; however, it is not exclusively a product of platelets and megakaryocytes, because it is present also in ECs, fibroblasts, monocytes, and macrophages. TSP can dictate the formation of multiprotein complexes at the vessel wall through specific interactions with growth factors, cytokines, other matrix components, and membrane proteins, including fibrinogen, P-selectin, osteonectin, and CD47 (87). Indeed, complexing with fibrinogen can potentiate platelet aggregation and the formation of the fibrin clot. TSP1 can modulate angiogenesis through its role in regulating EC apoptosis, protease expression, and VEGF expression by interacting with EC surface receptors such as CD36, proteoglycan receptors, or the integrins  $\alpha\text{V}\beta3$  and  $\alpha3\beta1$  (88). Furthermore, TSP also plays a role in the modulation of EC PECAM-1 expression and function during vascular development and angiogenesis (89). TSP1 has been linked to a role as an inhibitor of tumor progression; a putative tumor cell binding protein, angiocidin, has been identified (90). Additionally, secreted TSP1 regulates the multimeric size and hemostatic activity of vWF (91).

### Actin-Binding Proteins

Actin-binding proteins  $\alpha$ -actinin and thymosin- $\beta4$  (a 4.9-kDa polypeptide) have been documented as secreted from platelet  $\alpha$ -granules (92), where they bind TSP and exhibit antimicrobial properties, respectively (93). Indeed, several released platelet proteins have antimicrobial properties, including PF4, RANTES, CTAP-III, platelet basic protein, and fibrinopeptide A and B (93). Following the release of thymosin- $\beta4$ , it is cross-linked to fibrin mediated by factor XIIIa, thereby increasing its local concentration near sites of clots and tissue damage, where it may contribute to wound healing, angiogenesis, and inflammatory responses. Furthermore, thymosin- $\beta4$  increases the rate of attachment and spreading of ECs on matrix components and stimulates the migration of ECs, inducing the synthesis of PAI-1 and increasing its extracellular

expression (94). Many of the other actin-binding proteins identified in the platelet releasate are released from other cells; these releasates include profilin, cofilin, actin, and tubulin from the exosomes of dendritic cells (39,53).

### Proteases

In addition to lysosomal enzymes, several enzymes have been reported to be released from platelets, such as Adam-TS-5 and MMP-2 and -24 (53), which could support physiological processes such as angiogenesis as well as pathologically promote plaque instability or rupture through extracellular matrix remodeling and cell infiltration or migration. This ability to produce proteolytic enzymes as well as growth factors may be critical in the role that these cells play in the damage and repair that ensues as the lesion progresses.

## THERAPEUTIC AND DIAGNOSTIC IMPLICATIONS

The prevention of platelet activation or the disruption of platelet–EC or platelet–leukocyte interactions by neutralizing adhesion receptors or soluble extracellular released products may be a means of therapeutic intervention in atherosclerosis. Indeed, the inhibition of platelet-derived proteins such as CD40 ligand and the blockade of chemokine receptor–ligand interactions reduces the development of atherosclerosis in mice (69,78). Thus, the targeting of selected secreted platelet proteins or their surface receptors may provide a novel means of modifying atherosclerosis without the risk associated with the direct inhibition of platelet adhesion. In addition, these secreted proteins could potentially be used as diagnostic markers, because no currently identified single marker is ideal for the ex vivo detection of in vivo platelet activation.

### KEY POINTS

- Adhesive and signaling interactions between platelets and the endothelium play a pivotal role in vascular homeostasis and pathological conditions.
- Selectins and cell adhesion molecules mediate adhesive interactions between platelets and the endothelium.
- The platelet releasate is comprised of a multitude of inflammatory and vasoactive substances and vesicles that can attract atherogenic leukocytes from the circulation, activate ECs and, by infiltrating the vessel wall, stimulate vessel growth and repair.
- Future in vivo studies, in which certain secreted platelet proteins are enhanced or eliminated in transgenic animal models, are necessary to fully determine

the biological function of these factors and their relevance to the initiation and progression of atherosclerotic lesions. Furthermore, comprehending the full complement of the platelet releasate will significantly improve our understanding of cell–cell interactions, coagulation, vessel growth, and remodeling.

- Neutralization of these platelet-derived proinflammatory factors may become an interesting means for therapeutic or preventative intervention in diseases such as atherosclerosis.

## Cardiomyocyte–Endothelial Cell Interactions

Jian Li and Frank W. Sellke

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The vascular system delivers blood containing oxygen (O<sub>2</sub>) and nutrients to tissues according to their local needs. In the finest branches of the vascular tree, capillaries consist of little more than a monolayer of endothelial cells (ECs) surrounded by an extracellular matrix and occasional pericytes. At these sites, microvascular endothelium is in intimate contact with underlying parenchymal cells.

In the heart, capillary ECs lie in close proximity to cardiomyocytes. As a result, significant cross-talk occurs between these two cell types, which involves reciprocal gene regulation, signal transduction, and energy supply (1). Changes in endothelial–myocyte cross-talk may contribute to and/or arise from numerous cardiac pathologies. In this chapter, we review *in vitro* and *in vivo* studies that provide mechanistic insight into the nature of this cell–cell communication.

### MORPHOLOGICAL CONSIDERATIONS

The endothelium serves as the interface between the circulation and the vascular wall, integrating local and systemic events that regulate vascular function. During embryogenesis, the vascular endothelium is the first cardiovascular cell type to differentiate. These cells provide critical cues to all stages of cardiovascular development, and they are critically involved in myocardial trabeculation and the formation of primitive nutrient vessels.

In the normal heart, the ratio of the number of ECs to cardiac myocytes is approximately three to one (1). Three types of ECs have been identified in the heart based on their location: (a) endocardial ECs, which line the ventricles and atria; (b) myocardial microvascular ECs that line the arterioles, venules, and capillaries of the myocardium; and (c) ECs of epicardial arteries and veins (2–5). Of these, endocardial and microvascular ECs are in closest contact with cardiomyocytes.

Although the various EC types in the heart share certain common phenotypes, growing evidence suggests that they are not identical. For example, they differ in their embryological origin, cytoskeletal organization, and electrophysiological properties (6). The endocardium is formed by the process of

vasculogenesis and is uniquely poised to sense and respond to cardiac performance and to circulating blood entering and leaving the heart. Endocardial (and coronary vascular) ECs release substances that modify the contraction of cardiac myocytes, most notably endothelin (ET)-1 (discussed in the next section) (7). ECs lining the coronary blood vessels and capillaries are formed by angiogenesis and receive less than 5% of cardiac output, yet they comprise the vast majority of surface area of the cardiac circulation and play a primary role in supplying the myocardial muscle mass with O<sub>2</sub> and nutrients (8). Endocardial and microvascular ECs are likely to signal via cell-type–specific mechanisms with underlying cardiomyocytes.

### SIGNAL INPUT TO ENDOTHELIAL CELLS FROM CARDIAC MYOCYTES

#### Regulation of Hemostatic Balance

Previous studies have demonstrated that cardiac myocyte-derived signals are capable of modulating the expression of hemostatic genes in cardiac microvascular ECs. For example, cardiac myocytes, but not fibroblasts or hepatocytes, induce endothelial expression of endogenous von Willebrand factor (vWF) as well as *vWF* promoter activity under both *in vitro* and *in vivo* conditions (9). Expression of the endogenous gene and promoter was restricted to a minority of the cardiac microvascular ECs, suggesting the existence of a subpopulation of ECs capable of transducing the cardiomyocyte–derived signal(s).

Further studies demonstrated a role for the platelet-derived growth factor (PDGF) pathways in mediating the effect of cardiomyocytes on the expression of vWF (in addition to other genes) in microvascular ECs. In the absence of cardiomyocytes, cultured cardiac microvascular ECs were shown to constitutively express the PDGF-A isoform, leading to formation of the PDGF-AA homodimer. However, in the presence of cardiomyocytes, the microvascular ECs expressed PDGF-AB. PDGF-AB–mediated activation of the PDGF- $\alpha$  receptor was reported to induce the expression of vWF in ECs (10,11).

### Regulation of Inflammation

In a study of graft failure in heart transplantation, Wang and colleagues reported that local expression of leukocyte adhesion receptor intercellular adhesion molecule (ICAM)-1 results in an explosive cascade of inflammatory events within the reperfused graft. The authors provided evidence for a positive-feedback loop in which local endothelial expression of ICAM-1 and myocardial expression of interleukin (IL)-1 leads to an amplification of the inflammatory response (12). IL-1 receptor blockade inhibited the expression of ICAM-1 in both the graft and remote organs, and improved graft survival, suggesting that the ICAM-1–IL-1 axis plays a pathophysiological role in primary cardiac graft failure (12,13).

### Regulation of Angiogenesis

Vascular endothelial growth factor (VEGF) is involved in the growth and maintenance of blood vessels (14,15). In myocardium, VEGF expressed in cardiac myocytes is a predominant factor in controlling EC survival, proliferation, and angiogenesis. Studies have indicated that mouse embryos heterozygous for *VEGF* die around embryonic day (E)11 with malformations of the heart and major vessels. Cardiomyocyte-specific deletion of VEGF results in increased mortality between E14 and E17 (16). ECs express three endothelial-specific receptor tyrosine kinases: VEGF receptor 1 and -2 (VEGFR1 and VEGFR2) and Tie2, which bind to VEGF and angiopoietins 1 and -2 (Ang1 and Ang2), respectively. Several studies have suggested that the VEGF receptor pathway and the Tie2 pathway are independent and essential mediators of angiogenesis (17,18), leading to the hypothesis that simultaneous inhibition of both pathways should result in additive effects on angiogenesis. Indeed, blockage of both VEGFR2 and Tie2 pathways simultaneously resulted in a significant inhibition of angiogenesis (19).

The induction of VEGF expression by cardiac myocytes occurs via a hypoxia-inducible mechanism. Once released by the myocyte, VEGF activates its cognate receptors on the surface of ECs, inducing angiogenesis in ischemic myocardium. In a mouse model of myocardial ischemia, VEGF levels were shown to accumulate in the peri-infarct area (20). Under these conditions, *VEGF* mRNA expression was localized in cardiac myocytes and was associated with the formation of new capillaries that invade the infarcted myocardium. Thus, paracrine-mediated VEGF signaling may have evolved as an adaptive mechanism to improve deficient blood supply to ischemic myocardium.

Ischemic cardiac myocytes secrete other mediators that may engage in paracrine signaling pathways. In a recent study, conditioned medium from hypoxic myocytes was added to monolayers of human umbilical vein ECs (HUVECs) (21). DNA array analyses revealed more than 200 endothelial genes that were significantly induced or downregulated in the presence of conditioned medium (Table 65-1), including two widely studied markers, cyclooxygenase (COX)-2 (21), and

syndecan-4 (22). COX-2 has been implicated in inflammation and angiogenesis (23,24). Syndecan-4 plays an important role in the regulation of EC growth and migration and in fibroblast growth factor 2 (FGF2) dependent signaling (25–27). Increased syndecan-4 expression augments the ability of ECs to migrate, proliferate, and form vascular structures in Matrigel in response to FGF2 (28). Further studies demonstrated that hypoxic cardiac myocytes induce endothelial expression of COX-2 (and its products, PGI<sub>2</sub> and PGE) by a VEGF-dependent pathway, whereas hypoxic myocyte-mediated induction of syndecan-4 involves tumor necrosis factor (TNF)- $\alpha$  (21).

The angiopoietin/Tek/Tie growth signaling pathway also plays an important role in the communication between cardiac myocytes and ECs. Tek/Tie receptors are expressed in ECs receiving the angiopoietin signal from cardiac myocytes and support the maturation, maintenance, and survival of ECs (29–31). Other growth factors that are involved in the angiogenic process are transforming growth factor (TGF)- $\beta$  and FGF2 (32). These are also expressed abundantly in cardiac myocytes. The pathways through which these growth factors operate need further confirmation.

### Mechanical Forces

Myocardial ECs are constantly exposed to mechanical forces resulting from blood flow and transmural pressure. Mechanical forces have been shown to stimulate capillary growth under conditions that produce mild-to-moderate vessel wall stretch (33). Mechanical stimulation leads to altered K<sup>+</sup> conductance in ECs, resulting in increased Ca<sup>2+</sup> influx and the release from the ECs of vasoactive substances such as nitric oxide (NO), ET-1, and prostaglandins (34). In addition, increases in K<sup>+</sup> channel density are important in mediating endothelium-dependent responses to stimulating agents such as histamine and thrombin (34).

## SIGNAL OUTPUT FROM ENDOTHELIAL CELLS TO CARDIAC MYOCYTES

### Regulation of Myocardial Contractility

ECs within the heart may release a number of substances that modulate myocardial function. The paracrine modulation of cardiac myocyte function by EC-derived factors is likely to be an important mechanism contributing to the overall regulation of cardiac contractile function, both in physiological and pathological states. Endothelial-derived mediators include NO (35,36), ET-1 (37,38), angiotensin converting enzyme (ACE), prostanoids (6,39), adenylypurines (38), and many other substances. A notable feature of many of these agents is that they influence contractile behavior by modifying cardiac myofilament properties rather than alternating cytosolic Ca<sup>2+</sup> transients (7).

There are three isoforms of ET (40,41). Endothelium-derived ET-1 is a major determinant of cardiac contractility.

ET-1 is known to have potent effects on contractile function and gene expression in cardiac myocytes (42,43). In addition to promoting contraction, ET-1 also induces myocyte proliferation (44,45). Expression of ET-1 is stimulated by hypoxia, shear stress, and various pharmacological receptor-dependent agonists (46–49). The role for EC–cardiomyocyte communication in mediating ET-1-dependent cardiac function is supported by many studies (50–52). For example, cardiomyocyte-derived paracrine mediators have been shown to regulate the abundance of precursor transcripts for *ET-1* in cardiac microvascular ECs (47,51,52). In another study, TGF- $\beta$  was shown to induce expression of *ET-1* precursor mRNA in cardiac microvascular ECs, suggesting a potential autocrine and paracrine role for this growth factor (53).

ACE is located on the luminal surface of ECs (54,55), whereas other components of the angiotensin system exist locally in both cardiac microvascular ECs and cardiac myocytes (56,57). Moreover, a substantial ACE-independent conversion of angiotensin (Ang)-I to Ang-II occurs in the ventricles of the heart and may occur through cardiac chymase, a large proportion of which is localized in cardiac ECs (1).

Chronic ACE inhibition, initiated after acute myocardial infarction, can reduce ventricular dilatation and improve patient survival. ACE inhibition enhances coronary blood flow at the time of reperfusion and can prevent impairment of endothelium-dependent arteriolar responses and improve microvascular endothelial function and augmented postischemic coronary blood flow for ischemic myocardium (58). Therapeutically, ACE inhibitors have beneficial effects on ventricular remodeling and diastolic dysfunction in heart failure. Therefore, both cardiac myocytes and ECs are involved in mediating the effects of ACE inhibitors.

The endothelium of the heart releases several chemical mediators that influence cardiac regulatory pathways. Endothelial NO synthase (eNOS) is expressed predominantly in coronary vascular and endocardial ECs (59). NO synthesized by the activity of eNOS in the cardiac ECs directly modulates myocardial contractility (60,61). eNOS expression is followed by specific stimuli, for example, hypoxia. Shear

stress and the mechanical deformation that occurs during the cardiac cycle also are relevant physiological stimuli for the release of eNOS from ECs. The fact that an increase in shear stress leads to an increase in  $\text{Ca}^{2+}$ , which in turn leads to NO release, suggests that the signal transduction is similar to that of receptor-dependent activation. Ischemia–reperfusion injury of the heart is not limited to cardiomyocytes but also extends to coronary vascular cells.

Mechanical forces modulate a number of signal transduction pathways in ECs in myocardium. These pathways include the heterotrimer G-proteins (62), cyclic adenosine monophosphate (cAMP) (63), protein kinase C (PKC) (64), and mitogen-activated protein kinases (MAPKs) (65). In addition to the direct modulatory effects on cardiac function, stimulation of these pathways leads to the activation of multiple transcription factors involved in mediating cross-talk between ECs and cardiac myocytes. The balance between NO and  $\text{PGI}_2$  is important in regulating myocardial cAMP–cGMP ratios (NO and  $\text{PGI}_2$  have opposing effects on myocardial relaxation) (66). eNOS activation in cardiac myocytes may suppress ouabain-induced arrhythmias through increased cGMP (67). Cultured ECs produce abundant  $\text{PGI}_2$  and  $\text{PGE}_2$ . Interestingly, expression levels vary between endocardial ECs and coronary ECs (68). NO and  $\text{PGI}_2$  release from ECs is coupled via cross-reaction between the NOS and COX-2 pathways (69,70).

Others have demonstrated that endothelium promotes cardiomyocyte survival, increases synchronized contraction of cardiac myocytes, and modulates expression of connexin-43 (71). These findings emphasize the functional importance of communication between ECs and cardiac myocytes and underscore the potential advantages of targeting both cell types in cardiac disease.

### Regulation of Energy Supply

Two principal EC-dependent systems regulate contractile efficiency of cardiac myocytes: (a) endothelial-derived ET-1, which optimizes contraction efficiency by increasing isometric force and decreasing actomyosin ATPase activity (43,72,73);

and (b)  $\beta$ -adrenergic agonists, which increase ATPase activity through an EC-dependent mechanism, optimized for power of energy (6,74). The relative amounts of up- and downregulating EC-released substances are related to tissue  $O_2$  tension (7). The advantage of a ceiling may be the prevention of increased formation of free radicals as  $O_2$  tension rises.

The results observed with isolated cardiac myocytes confirm that these cells operate as  $O_2$  sensors and secrete substances that induce ECs to release contractility-enhancing mediators (e.g., ET-1) and possibly an unidentified relaxant (75,76). This cross-talk mediates cardiac contraction and vascular tone. For example, endothelial-derived ET-1 enhances myofilament intracellular  $Ca^{2+}$  transients (77), decreases actomyosin ATPase activity, and decreases the velocity of unloaded shortening (43). In addition, increased ET-1 also may promote vascular tone and thereby decrease energy used by the cardiac myocytes (78).

Substances released from ECs in response to various stimuli may cause changes in several ion channels in cardiac myocytes. These substances regulate  $Ca^{2+}$  concentration, which is an important step in cellular signal transduction. Following a stimulus, the increase in  $Ca^{2+}$  occurs in two phases: (a) release of  $Ca^{2+}$  from the intracellular sources, resulting in an initial transient increase; and (b) sustained influx of  $Ca^{2+}$  from the extracellular space. This influx causes the  $Ca^{2+}$  to remain elevated and depends on the electrochemical gradient of  $Ca^{2+}$ ; therefore, it is dependent on the resting membrane potential of the cardiac myocytes (6,79).

## CONCLUSION

In this chapter, we have summarized some of the newer concepts regarding physiological and pathophysiological communication between ECs and cardiac myocytes. We have focused on studies that have directly examined the input of ECs, such as VEGF from cardiac myocytes targeting ECs, and output of ECs, including ET-1 from ECs affecting the myocardial contractibility of surrounding cardiac myocytes. Accordingly, the cardiovascular system is one system governing blood supply and circulation, and the cross-talk between vascular ECs and cardiac myocytes takes place consistently in almost every aspect. In reviewing the literature, it is clear that, during the last three decades, many investigators have found that there are mutual effects of these two cell types. Among these studies, the differences between endocardial ECs and myocardial capillary ECs with regard to their interactions with cardiac myocytes have been recognized and emphasized. However, because there are limitations of the techniques used, the direct experimental evidence from in vivo animal studies is less convincing than the data from cocultured cells in vitro. Nevertheless, as vascular biological research examines more fundamental questions, it will be important to consider the modulating role of ECs to their surrounding cellular environment. It is a complex system in which signaling and gene regulation pathways cross-react with one another. Future studies may discover

the fundamental mechanisms that can be examined in the intact heart, including myocardium, coronary circulation, and capillaries.

## KEY POINTS

- The cross-talk between vascular ECs and cardiac myocytes takes place consistently in almost every aspect of their function. Thus, we may need to consider the effect of this communication when studying gene regulation and protein alteration in either ECs or cardiac myocytes, especially in therapeutic manners.
- Signal input to ECs from cardiac myocytes: Regulation of ECs in homeostasis and angiogenesis is mediated by induction of PDGF and VEGF from cardiac myocytes. Endothelial COX-2, vWF, and TNF- $\alpha$  are involved in the communication as targets of the factors from cardiac myocytes.
- Signal output from ECs to cardiac myocytes: Endothelial-derived mediators including NO, ET-1, ACE, and many other substances, influence contractile behavior by modifying cardiac myofilament properties and alternating cytosolic  $Ca^{2+}$  transients.

## Future Goals

- To identify and analyze novel factors that are involved in the input and output of ECs and their effects on cardiac myocytes
- To examine the cross-talk between ECs and cardiac myocytes in vivo to understand fundamental mechanisms of the cell–cell dialogue in the intact heart, including myocardium, coronary circulation, and capillaries

## Interaction between Hepatocytes and Liver Sinusoidal Endothelial Cells

---

David Semela and Vijay Shah

*Mayo Clinic, Rochester, Minnesota*

The liver is the largest organ in the body and, in humans, weighs between 1,400 and 1,600 g (2.5% of total body weight). It receives 25% of the total cardiac output, which arrives via the hepatic artery (one-third of hepatic blood flow) and the portal vein (two-thirds of hepatic blood flow). Blood flows through liver sinusoids, a unique microvasculature that consists of plates of liver sinusoidal endothelial cells (LSECs) between plates of hepatocytes, before coming in contact with the liver parenchyma. LSECs account for 20% of total liver cells (an estimated  $1 \times 10^8$  cells) whereas hepatocytes represent the majority of liver cells (estimated 60% or  $3 \times 10^8$  cells). The remaining cell populations are (a) hepatic stellate cells (HSCs) (5%–8%), which are liver-specific pericytes; (b) biliary epithelial cells, also known as cholangiocytes, which line the bile ducts; and (c) macrophages called *Kupffer cells*. LSECs are unique in comparison to other organs in that they possess multiple fenestrae (pores) arranged in sieve plates (Figure 66.1) and lack an organized basement membrane. LSECs lie in close proximity to hepatocytes, and the interaction of these two cell types has been the subject of intense study. Cellular cross-talk between LSECs and hepatocytes plays an important role in homeostasis and physiologic processes such as liver organogenesis and liver regeneration. Moreover, abnormalities in intercellular communication underlie virtually every disease of the liver, including acute and chronic inflammatory liver disease, liver fibrosis, and hepatocarcinogenesis. Of these physiological and pathological states, liver regeneration is the most studied and best understood. Thus, this chapter focuses primarily on the latter model as a means to explore the biology of hepatocyte–endothelial cell (EC) interactions. LSECs interact with many other cell types in the liver, including HSCs, Kupffer cells, and circulating blood cells. These interactions are discussed elsewhere in this volume (see Chapters 67 and 133).

### LIVER REGENERATION AFTER PARTIAL HEPATECTOMY

The extraordinary capacity of the liver to regenerate was first described in the Greek myth of Prometheus (Table 66-1). According to this tale, Prometheus was chained to a rock as punishment for stealing fire from Zeus and giving it to man. Zeus' eagle would come and eat part of Prometheus' liver every day, but it would grow back overnight. Today, surgeons routinely carry out partial resections of the liver for purposes of living donor organ transplantation or during the process of tumor excision. Following partial hepatectomy (up to 70% removal of the organ), the liver will completely regenerate and reach its original functional mass with normal microscopic architecture within weeks. This contrasts with other organs, which have no or only limited regenerative capacity. The phenomenon of liver regeneration has been described in mammals, birds, fish, reptiles, and amphibians. It has been suggested that this remarkable capacity for regeneration evolved as a means to protect the mammalian liver against food toxin–induced fulminant hepatic failure (1).

Experimental partial hepatectomy involves the removal of two-thirds of the liver, typically from rodents. Within 8 to 10 days, the liver remnant enlarges until the previous functional liver mass is restored (2). This process represents a hyperplastic response of the remaining liver, leading to a new lobar anatomy rather than true regeneration with restoration of the initial anatomy. Hepatocytes in the normal liver are quiescent, with only 0.01% to 0.001% undergoing mitosis at any given time. Partial hepatectomy activates numerous transcription factors, induces the expression of more than 70 genes, and promotes cell cycle entry with synchronous proliferation of almost all hepatocytes (2). The initial wave of hepatocyte proliferation is followed by a second wave of replication involving

Figure 66.1. Scanning electron microscopy of normal fenestrated hepatic sinusoids. (Reproduced with permission from Motta P, Muto M, Fujita T. *The Liver: An Atlas of Scanning Electron Microscopy*. New York: Igaku-Shoin Medical Publishers, 1978:129.)

nonparenchymal liver cells, including HSCs, Kupffer cells, and LSECs, which start to proliferate on day 3 after partial hepatectomy and reach a peak on day 5 (3).

Ross and coworkers have detailed the timing and stages associated with post-partial-hepatectomy liver regeneration in mice (3) (Figure 66.2). The initial proliferation of hepatocytes leads to the formation of avascular islands of cells. Hepatocyte signaling induces the activation and proliferation of neighboring LSECs, resulting in their migration into the avascular islands (4,5). LSECs continue to proliferate and form three-dimensional structures, ultimately leading to recanalization and formation of patent sinusoids. Eight to 10 days following partial hepatectomy, liver mass is fully reconstituted, and the architecture is restored to normal. Recent evidence suggests that endothelial progenitor cells (EPCs) (mobilized from bone marrow by systemically circulating growth factors and chemokines produced in the regenerating liver) participate in this process by homing to sites of neovascularization in the liver and committing to sinusoidal ECs (6). Bone marrow cells also have been shown to commit to HSCs, which are liver-specific pericytes supporting LSECs during liver regeneration (7).

Several key signaling molecules have been implicated in the process of liver regeneration. These include the cytokines interleukin (IL)-6 and tumor necrosis factor (TNF), which play a role in the  $G_0/G_1$  transition, and the growth factors hepatocyte growth factor (HGF) and transforming growth factor (TGF)- $\alpha$ , which are involved in cell cycle progression after the cells reach  $G_1$  (2). With the exception of TGF- $\alpha$  (which is produced by hepatocytes), all the above mediators are secreted by nonparenchymal cells (including LSECs) but act on hepatocytes as well as on nonparenchymal cells in an autocrine and paracrine way to orchestrate the regenerative response (2,8).

**Table 66-1: Milestones in the Field of Liver Regeneration/Angiogenesis**

700 BC	Hesiod's <i>Theogony</i> depicts the phenomenon of liver regeneration in the myth of Prometheus.
1880–1900	The principles of liver regeneration and liver hemostasis were first studied by Ponfick, Mayer, Kousnetzoff, Pinsky, and Pringle (36).
1931	Higgins and Anderson describe the now widely used partial hepatectomy model involving removal of two-thirds of the liver in rats for the study of liver regeneration (37).
1967	Moolten and Bucher show that a circulating mitogen (later identified as HGF) is present after hepatectomy inducing liver regeneration (9).
1975	Peak mitotic activity of LSECs after partial hepatectomy is found to occur on day 4, only after hepatocyte proliferation (38).
1984	Michalopoulos and Nakamura identify a serum protein from hepatectomized rats by gel permeation chromatography which is a potent stimulator of hepatocyte proliferation in vitro (39,40).
1990	Gherardi and coworkers characterize this protein as HGF (41).
1991	c-MET is found to be the transmembrane receptor for HGF (42).
1994	Yamane proposes HGF and VEGF with its receptors as a reciprocal communication system between hepatocytes and LSECs (43).
1996	Expression of VEGF in hepatocytes and of VEGF receptors on LSECs are shown to occur after partial hepatectomy (16).
2001	Ross and colleagues describe the spatiotemporal expression of angiogenic growth factor receptors during liver regeneration in different liver cell populations (3).
2003	LeCouter and Ferrara demonstrate that HGF is one of the liver sinusoidal EC-derived paracrine mediators promoting hepatocyte growth. VEGF receptor 1 is shown to stimulate hepatocyte but not EC proliferation in vivo and reduces liver damage in mice exposed to a hepatotoxin (15).

In 1967, Moolten and Bucher demonstrated that a circulating mitogen following hepatectomy in one rat causes regeneration of an intact liver in a second rat when the circulations of both animals were connected (9). During the 1980s and 1990s, this factor was identified and characterized, and ultimately named HGF (also known as scatter factor or hematopoietin A). HGF is an 80-kDa disulfide-linked heterodimeric protein with

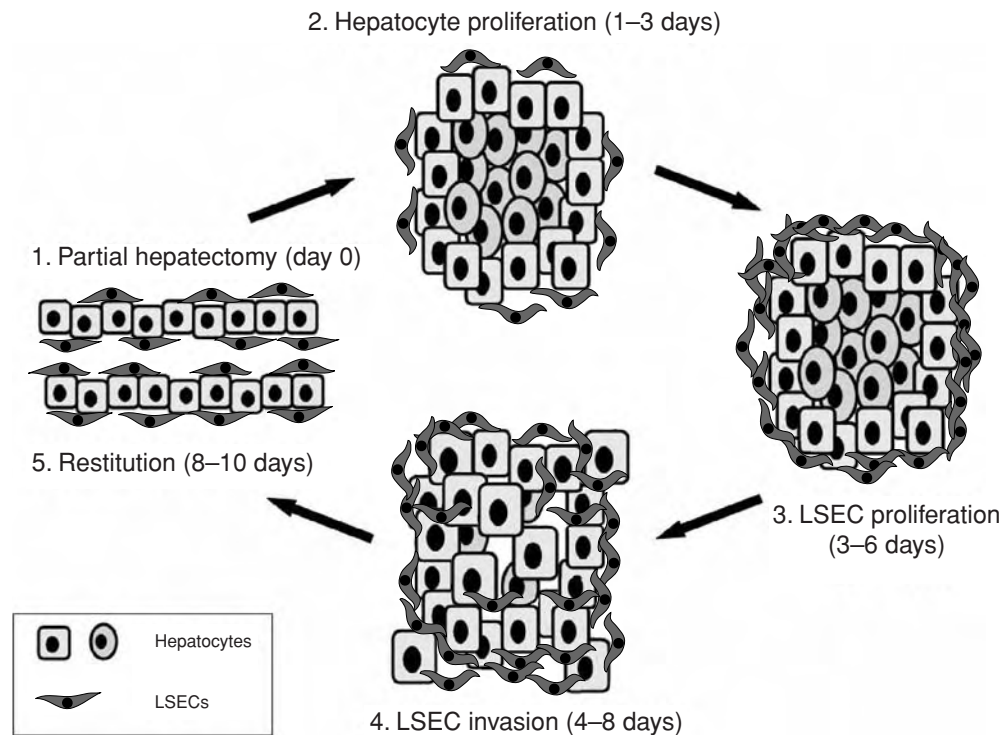

Figure 66.2. Spatiotemporal representation of proliferation and migration of LSECs and hepatocytes during liver regeneration. 1. Normal liver architecture with LSECs lining sinusoids and adjacent hepatocytes before partial hepatectomy. 2. Hepatocytes proliferate and form avascular islands composed of cell clusters of 10 to 14 hepatocytes (see Ref. 5). 3. LSECs proliferate in a second wave after hepatocytes. 4. LSECs migrate into the avascular islands of hepatocytes. 5. Reconstitution of the normal liver architecture 8 to 10 days after partial hepatectomy in rodents. (Adapted with permission from Ross MA, Sander CM, Kleeb TB, et al. Spatiotemporal expression of angiogenesis growth factor receptors during the revascularization of regenerating rat liver. *Hepatology* 2001;34:1135–1148; and Martinez-Hernandez A, Amenta PS. The extracellular matrix in hepatic regeneration. *FASEB J* 1995;9:1401–1410.)

mitogenic and motogenic properties for a number of cell types including hepatocytes and ECs. HGF, which is the most potent stimulator of hepatocyte proliferation, is produced during liver regeneration by LSECs as well as HSCs, and it signals through the tyrosine kinase receptor *c-Met* by activating mitogen-activated protein kinase (MAPK), phosphoinositide 3-kinase (PI3K)/Akt, Rac/Pak, and Crk/Rap1 pathways in hepatocytes (Figure 66.3). HGF/*c-Met* signaling is essential for hepatic recovery after partial hepatectomy or after exposure to a hepatotoxin ( $\text{CCl}_4$ ), as conditional *Met* mutant mice show severe impairment of liver regeneration under these conditions (10,11).

Vascular endothelial growth factor (VEGF) is the most important growth and survival factor for endothelium. VEGF is a 45-kDa homodimeric glycoprotein that is constitutively expressed in hepatocytes at low levels in hepatocytes of the normal liver (12). VEGF production by hepatocytes and HSCs rapidly increases during liver regeneration. Upregulation of VEGF might be triggered by hypoxia in the center of the regenerative and avascular hepatocyte islands (13). Hypoxia activates the transcription factor hypoxia-inducible factor (HIF)-1, which in turn induces the expression of downstream tar-

get genes including *VEGF* and VEGF receptor (*VEGFR*) 1. Hepatocyte production of VEGF peaks 48 to 72 hours after hepatectomy and is detected mainly in periportal hepatocytes (5,12). The administration of VEGF in hepatectomized rodents increases hepatocyte and sinusoidal EC proliferation (12,14), accelerates gain in liver mass (15), and improves functional hepatic recovery (13). Neutralizing antibodies against VEGF inhibit hepatocyte and EC proliferation after partial hepatectomy (12).

VEGF production is accompanied by an increase in the expression of the VEGFR1 on hepatocytes and of VEGFR1 and VEGFR2 on LSECs (3,4,13,16). Activation of VEGFR2 stimulates LSEC proliferation. On the other hand, binding of VEGF to VEGFR1 on LSECs induces the secretion of growth and survival factors such as HGF and IL-6 from LSECs, which in turn stimulate hepatocyte proliferation (15). The role of VEGFR1 in hepatocytes is not clear.

In addition to VEGF and HGF, other angiogenic growth factors (and their receptors) are upregulated during liver regeneration, including angiopoietins (Angs), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF) (Table 66-2) (17).

**Table 66-2: Expression of Growth Factors and Their Receptors in Hepatocytes, Liver ECs, Cholangiocytes, and Hepatic Stellate Cells after Partial Hepatectomy**

Growth Factor/Receptor	Expressing Cells	Increase after Partial Hepatectomy
VEGF	Hepatocytes, HSCs	48–72 h
VEGFR1 (FLT-1)	LSECs, HSCs	72 h to 12 d
VEGFR2 (FLK-1/KDR)	LSECs	72 h to 10 d
HGF	LSECs	Immediate, peak 12–24 h
c-Met	LSECs, hepatocytes, cholangiocytes	No change in LSECs
Ang1	unknown	72–96 h (mRNA)
Ang2	unknown	72–168 h (mRNA)
Tie1	LSECs	Start at 48 h, peak at 96 h
Tie2	LSECs	Start at 48 h, peak at 96 h
PDGF	LSECs, HSCs	48 h
PDGF-R $\beta$	LSECs, HSCs	3–12 d
aFGF	HSCs	24 h (mRNA)
bFGF	HSCs	Unchanged
FGF-R1 (Flg)	Hepatocytes	Unchanged
FGF-R2 (Bek)	Hepatocytes	Not determined
EGF	Hepatocytes	Immediate, peak 12–24 h
TGF- $\alpha$	Hepatocytes	12–24 h (mRNA)
EGF-R	LSECs	Constitutive, 3–14 d

EGF, epidermal growth factor.

Figure 66.3. Cellular cross-talk between LSECs and hepatocytes during liver regeneration. 1. Injury of the liver leads to liver regeneration, as described in Figure 66.2, with formation of avascular hepatocyte clusters. 2. In response to local hypoxia, hepatocytes in these clusters activate the transcription factor HIF-1, which induces the expression of downstream target genes including VEGF. 3. Hepatocytes secrete VEGF. 4. Activation of VEGFR2 stimulates LSEC proliferation. 5. Activation of VEGFR1 induces the secretion of survival and growth factors such as HGF and IL-6 from LSEC. 6. These secreted factors stimulate hepatocyte proliferation (c-Met is the receptor for HGF).

**Table 66-3: Liver Organogenesis in VEGF and HGF Knockout and Knockdown Mice**

Gene (Refs.)	Survival of Mutant	Phenotype
<i>VEGF</i> (23, 24)	Lethal at E12	Vessel malformation and abnormal organ development
<i>VEGF</i> (liver only) (25)	Viable	Abnormal sinusoidal network, lack of LSEC fenestrae, impaired lipoprotein intake in hepatocytes
<i>VEGF</i> (neonatal) (26)	Increased mortality	Small liver with immature hepatic sinusoids, reduced number of LSECs with high apoptosis index
<i>VEGFR1</i> (27, 28)	Lethal at E8.5	Abnormal vasculature, excessive angioblast proliferation
<i>VEGFR2</i> (19)	Lethal at E9.5–10.5	Lack of mature ECs, fails to form a liver bud
<i>HGF, c-Met</i> (20–22)	Lethal at E13.5–16.5	Small liver, loss of hepatocytes

## LIVER ORGANOGENESIS

Similar to their role in liver regeneration, HGF and VEGF signaling are required for liver organogenesis by mediating signal exchange between hepatocytes and LSECs during mouse development. Hepatic cells are induced within the endoderm by embryonic day (E)8.5 of mouse gestation (18). Interaction between these cells and surrounding ECs or angioblasts induces outgrowth of the liver bud into the septum transversum mesenchyme at E9.5 (Figure 66.4) (19). This stage is then followed by the de novo formation of a local vascular network from hemangioblasts (vasculogenesis) and the recruitment of hematopoietic cells (19). Knockout mice for HGF (20,21) or *c-Met* (22) fail to complete development and die in utero between days E13.5 and E16.5 (Table 66-3). These mutations affect the embryonic liver, which is reduced in size and shows extensive loss of parenchymal cells. The impor-

Figure 66.4. Model of liver bud formation during liver organogenesis. Hepatic endoderm cells are induced within the endoderm by day E8.5 of mouse gestation (A). Interaction between hepatic endoderm cells and surrounding ECs induces outgrowth of the liver bud into the septum transversum mesenchyme at E9.5 (B), which is followed by the generation of an extensive local vascular network with formation of the future sinusoids. (Adapted with permission Matsumoto K, Yoshitomi H, Rossant J, Zaret KS. Liver organogenesis promoted by endothelial cells prior to vascular function. *Science* 2001;294:559–563.)

tance of VEGF signaling during embryonic development is highlighted by the fact that lack of a single *VEGF* gene allele results in abnormal blood vessels, abnormal organ development, and embryonic lethality in mice by E12 (23,24). Carpenter and coworkers studied the development of the hepatic vasculature using an elegant liver-specific conditional VEGF-knockdown system (25). Downregulation of VEGF during liver organogenesis resulted in an abnormal hepatic microvascular network with incomplete lining of the sinusoidal lumen, partially collapsed sinusoidal channels, lack of LSEC fenestrae, and impaired lipoprotein uptake in hepatocytes (25). But VEGF also is required during the neonatal development of the liver. The inactivation of the *VEGF* gene in newborn mice leads to a small liver with an immature hepatic sinusoidal network, focal loss of integrity of the space of Disse, and a reduced number of LSECs with high levels of apoptosis (26). The liver parenchyma in these mice shows small and rounded hepatocytes that fail to produce the typical plate architecture surrounding the sinusoids (26). Knockout of the *VEGFR1* gene in mice results in the formation of abnormal vascular channels and excessive angioblast proliferation in embryonic and extra-embryonic regions, causing lethality by day E8.5 (27,28). Homozygous loss of *VEGFR2* results in lack of ECs, impaired liver organogenesis (19), and embryonic lethality at day E9.5 to E10.5, whereas heterozygous mice are normal (29). Mice with homozygous deficiency in *VEGFR2* lacking mature ECs and blood vessels show normal thickening of the hepatic endoderm but absence of liver bud emergence (19). Vasculogenic ECs with intact signaling through *VEGFR2* are therefore critical in the earliest stages of liver organogenesis, even prior to blood vessel function (19).

## DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Studies in patients undergoing liver resection (for example, for liver metastasis), show increased serum levels of IL-6 and HGF, which is in line with Molton and Bucher's early observations in the animal regeneration model explained earlier (30). Similar studies with HGF and VEGF have been carried out in

patients undergoing living donor liver transplantation (31,32). To recover, both donor and recipient rely on liver regeneration after the transplantation.

Could liver regeneration and recovery in such patients be accelerated if growth factors would be administered? Several animal studies confirm faster recovery and accelerated liver regeneration after partial hepatectomy if growth factors such as HGF and/or VEGF are administered intravenously or via recombinant adenoviral vectors 48 hours before or at the day of surgery (12–14). No clinical studies have been carried out so far. However, a recent study has investigated whether extracorporeal liver support systems, which have been developed to remove metabolites and facilitate recovery or as a bridge to liver transplantation in patients with liver failure, can influence liver regeneration. It has been shown that when not only metabolites and toxins, but also various hepatic growth factors, were simultaneously removed by the artificial liver support it potentially retarded liver regeneration (33,34).

Several proteins involved in the regulation of angiogenesis, such as VEGF and HGF, have been investigated as biomarkers and potential therapeutic targets in patients with hepatocellular carcinoma and chronic inflammatory liver disease (17,35).

#### KEY POINTS

- Molecular cross-talk between LSECs and hepatocytes regulates organogenesis, regeneration, and homeostasis of the liver.
- Partial hepatectomy as a model to study cellular and humoral interaction within the liver has identified intense and timely regulated paracrine cross-talk between liver sinusoidal ECs and hepatocytes during hepatic regeneration.
- VEGF secreted by hepatocytes stimulates LSEC proliferation and angiogenesis by signaling through VEGFR2, whereas activation of VEGFR1 on LSECs induces secretion of liver-specific growth factors such as HGF.
- HGF secreted by LSECs in conjunction with other growth and survival factors provides the main stimulus for hepatocyte proliferation during liver regeneration.
- HGF and VEGF signaling are also fundamental for normal liver organogenesis by mediating signal exchange between the mesenchyme and epithelium during development.

#### Future Goals

To develop diagnostic and therapeutic strategies for patients with liver disease based on insight from the recent molecular discoveries in the field of liver regeneration

## Stellate Cell–Endothelial Cell Interactions

Haruki Senoo

*Akita University, School of Medicine, Japan*

The hepatic lobule consists of parenchymal cells (epithelial cells) and nonparenchymal cells associated with the sinusoids: endothelial cells (ECs), Kupffer cells, pit cells, dendritic cells, and stellate cells (also known as vitamin A-storing cells, lipocytes, interstitial cells, fat-storing cells, Ito cells) (1–3) (Figure 67.1). ECs (4,5) express lymphocyte costimulatory molecules (6) and form the greater part of the extremely thin lining of the sinusoids, which are larger than ordinary capillaries and more irregular in shape. Kupffer cells are tissue macrophages and components of the diffuse mononuclear phagocyte system. They usually are situated on the endothelium, with cellular processes extending between the underlying ECs. The greater part of their irregular cell surface is exposed to the blood in the lumen of the sinusoid. Pit cells are natural killer cells. Dendritic cells (located in the portal triad in human, and in periportal and central areas in rats) capture and process antigens, migrate to lymphoid organs, and secrete cytokines to initiate immune responses (7). Hepatic stellate cells (1–3,8–11) lie in the space between sinusoidal ECs and parenchymal cells (perisinusoidal space or space of Disse) and, like ECs, are mesenchymal in origin. Recently, retinoid-storing stellate cells have been reported to exist in extrahepatic organs including the kidney, intestine, lung, and pancreas (2,12,13). The goal of this chapter is to review the structure and function of the hepatic stellate cell and to discuss its interactions with neighboring ECs.

### HEPATIC STELLATE CELL

Hepatic stellate cells distribute regularly within hepatic lobules. The cell consists of a spindle-shaped or angular cell body and long, branching cytoplasmic processes that encompass the endothelial tubes of sinusoids (14,15). Some processes penetrate the hepatic cell plates to reach the subendothelial space of neighboring sinusoids. Accordingly, a single stellate cell wraps two, three, or sometimes four sinusoids along its processes. The total length of sinusoids surrounded by a single stellate cell is 60 to 140  $\mu\text{m}$  in the rat liver.

The subendothelial processes are flat and have three cell surfaces (relative to the EC): inner, outer, and lateral. The inner

surface is smooth and adheres to the abluminal (basal) surface of the sinusoidal endothelium. Intercalated between the stellate cell and EC is the basement membrane, consisting of components such as type IV collagen and laminin. The outer surface faces the space of Disse and is decorated with short microvillous protrusions. The lateral edges of the subendothelial processes are characteristically studded with numerous spike-like microprojections, the tips of which make contacts with the microvillous facets of the hepatic parenchymal cells (see Figure 67.1). Although the stellate cells are closely connected to the sinusoidal ECs through basement membrane components, they make only spotty contacts with parenchymal cells. Recently, the hepatic stellate cells have been demonstrated at molecular and morphological levels to adhere to each other through adherens junctions (16).

### Retinoid Storage and Metabolism

Retinoids (vitamin A and its metabolites) are known to regulate diverse cellular activities such as cell proliferation, differentiation, morphogenesis, and tumorigenesis (17). Under physiological conditions, hepatic stellate cells store 80% of the total body retinoids in the form of retinyl palmitate contained within lipid droplets in the cytoplasm.

Hepatic stellate cells play a critical role in retinoid homeostasis. These cells regulate both transport and storage of retinoids, maintaining the concentration of retinoids in the bloodstream within physiological range. Retinoids circulate as a complex of retinol and a specific binding protein called retinol-binding protein (RBP) (Figure 67.2). Stellate cells take up retinol from the blood via receptor-mediated endocytosis (17). Once inside the cell, free retinol has several fates, one of which is to recomplex with RBP and return to the bloodstream (17–19).

More than 50 years ago, Rodahl reported that mammals in the Arctic were able to store a large amount of retinoids in the liver (20). More recently, Higashi and colleagues investigated the cellular and molecular mechanisms underlying the transport and storage of retinoids in Arctic animals inhabiting the Svalbard archipelago (situated at 80° N, 15° E) (21). These

Figure 67.1. Structure of hepatic lobule. Hepatic cords of the lobule consist of parenchymal cells (PC). Endothelial cells (EC) form the thin lining of the sinusoids (S). Kupffer cells (KC) are tissue macrophages and belong to the monocyte-macrophage cell lineage. Pit cells (P) have natural killer activity. Stellate cells (SC) lie in the space between parenchymal cells and ECs, and store 80% of retinoids of the whole body as retinyl palmitate in the lipid droplets in the cytoplasm. The classical definition of the perisinusoidal space (space of Disse) was the space between PCs and ECs. However, the new concept of the perisinusoidal space (PS) is the space between PCs and the complex of SCs and ECs. BM, Basement membrane components; ECM, extracellular matrix.

animals were found to store retinoids predominantly in hepatic stellate cells, with only a small amount present in other organs such as kidney, spleen, lung, and jejunum. Top predators among Arctic animals store 6 to 23  $\mu\text{m}$  retinyl ester per g liver, which is 20 to 100 times higher than the levels normally found in other animals, including humans. Thus, the hepatic stellate cells in these animals have an unusually high capacity for uptake and storage of retinoids.

Xenobiotics (such as polychlorinated biphenyls and dioxins) may reduce the threshold of retinoid toxicity (17), and both retinoids and fat-soluble xenobiotics have a tendency to accumulate in the food chain (22). Total kidney retinol, which may be used as a biomarker for retinoid-related toxicity or excess, in polar bear and bearded seal was below 1% of their liver value, which is in the normal range for most animals (22). Arctic fox and glaucous gull, however, had kidney levels of about 9% and 42% of the liver values, respectively (23). This increased kidney concentration and decreased capacity for storage in hepatic stellate cells of total retinol in Arctic fox and glaucous gull are most likely signs of retinoid-toxicity that deserve attention. This observation is alarming and has not been observed previously in free-living animals.

Figure 67.2. Major pathway for retinoid transport in the body. Dietary retinyl esters (RE) are hydrolyzed to retinol (ROH) in the intestinal lumen before absorption by enterocytes, and carotenoids are absorbed and then partially converted to retinol in the enterocytes. In the enterocytes, retinol reacts with fatty acid to form esters before incorporation into chylomicrons (CM). Chylomicrons then reach the general circulation by way of the intestinal lymph, and chylomicron remnants (CMR) are formed in blood capillaries. Chylomicron remnants, which contain almost all the absorbed retinol, are mainly cleared by the liver parenchymal cells (PC) and, to some extent, also by cells in other organs. In liver parenchymal cells, retinyl esters are rapidly hydrolyzed to retinol, which then binds to retinol-binding protein (RBP). A complex of retinol-RBP (RBP-ROH) is secreted and transported to hepatic stellate cells (SC). Stellate cells store retinoids mainly as retinyl palmitate and secrete retinol-RBP directly into the blood. Most retinol-RBP in the bloodstream is reversibly complexed with transthyretin (TTR). The uncomplexed retinol-RBP is presumably taken up in a variety of cells by cell surface receptors specific for RBP. RA, retinoic acid; 9-cis RA, 9-cis retinoic acid; RARs, retinoic acid receptors; RXR, retinoid X receptors; lipoprotein R, lipoprotein receptor; RBPR, retinol-binding protein receptor.

In pathological conditions such as liver cirrhosis, hepatic stellate cells lose retinoids, proliferate vigorously, and synthesize and secrete a large amount of extracellular matrix (ECM) components such as collagen, proteoglycan, and glycoprotein (24). The appearance of the cell changes from star-shaped

to fibroblast-like or myofibroblast-like, with well-developed rough-surfaced endoplasmic reticulum and Golgi apparatus (25). The dysregulation of collagen gene expression in hepatic stellate cells is a central pathogenetic step during the development of hepatic fibrosis (10).

Matrix metalloproteinases (MMPs) and tissue inhibitor of metalloproteinases (TIMPs) were reported to be synthesized by hepatic parenchymal and stellate cells (26). Recent reports indicate that the substratum used for culturing hepatic stellate cells is an important determinant of MMP activity, hence ECM remodeling (27). The three-dimensional structure of ECM can reversibly regulate hepatic stellate cell morphology, proliferation, and function (28–30). Stellate cells can take up collagen fibrils by endocytosis (31) and phagocytosis (32). Thus, hepatic stellate cells play pivotal roles in sinusoidal blood flow retinoid homeostasis, remodeling, fibrosis or cirrhosis of the liver, and so on. Additional studies have implicated a role for this cell type in liver regeneration (33).

### SINUSOIDAL ENDOTHELIAL CELL

The sinusoidal wall of the liver is covered with a layer of ECs that enclose the perisinusoidal space (space of Disse) (4). The hepatic sinusoids differ from other capillaries in the body in that the ECs possess fenestrae lacking a diaphragm (5), and their basal lamina is discontinuous, even beneath the nonfenestrated regions of the cell. Fenestrae are grouped into clusters called *sieve plates*. Mean fenestration diameter in the rat is 150 to 175 nm, occupying 6% to 8% of the endothelial surface area (4,5). The fenestrae can change in size and number in response to various stimuli; agents that disrupt actin filaments can almost double the number of fenestrae within minutes (4,5).

On the basis of morphological and physiological evidence, it was reported that the grouped fenestrae act as a dynamic filter. Fenestrae filter fluids, solutes, and particles that are exchanged between the sinusoidal lumen and the perisinusoidal space, allowing only particles smaller than the fenestrae to reach the parenchymal cells or to leave the perisinusoidal space.

Another functional characteristic of the hepatic sinusoidal ECs is their high endocytic capacity (4,5). This function is reflected by the presence of numerous endocytic vesicles and by the effective uptake of a wide variety of substances from the blood by receptor-mediated endocytosis.

### INTERACTIONS BETWEEN STELLATE CELLS AND SINUSOIDAL ENDOTHELIAL CELLS

Cross-talk between stellate cells and sinusoidal ECs plays a key role in homeostasis (14,15). The stellate cells are closely associated with ECs in a manner similar to that of the pericytes and ECs in the capillaries of other organs. In the normal rat liver,

basement membrane components are interposed between the two cell types. In lower vertebrates, sinusoidal walls are not as well organized as they are in mammals; the stellate cells are often found in close contact with thick bundles of collagen fibrils. Interestingly, a similar phenotype is observed in fibrotic livers of mammals (25). It seems likely that the degree of stellate cell–EC communication has increased during the course of vertebrate evolution (14,15).

In mammals, stellate cells are organized into a sheath encompassing the sinusoids. Because the processes of these cells are long and branching, they are difficult to observe under light and electron microscopy. As a result, many studies underestimate the true size of stellate cells. The interactions between hepatic stellate cells and sinusoidal ECs occur via extracellular components. It is clear that the ECM plays an active and complex role in regulating the behavior of the cells they contact, influencing morphology, development, migration, proliferation, and function.

Conventionally, the perisinusoidal space has been defined as the space that lies between the sinusoids and the liver parenchyma, and which contains hepatic stellate cells. However, in the normal mammalian liver, the endothelial tubes are intimately wrapped by stellate cells. Virtually no space exists between ECs and the stellate cells. Together, these two cell types form an inseparable entity that borders the sinusoidal lumen on one side and the liver parenchyma on the other. Viewed from this perspective, the perisinusoidal space represents the limited space between the EC–stellate cell complex and parenchymal cells (14,15). Within this region are found nerve fibers, collagens (type I, III, V, and II), glycoproteins, and proteoglycans.

#### KEY POINTS

- Hepatic stellate cells that lie in the space between parenchymal cells and ECs play pivotal roles in the regulation of retinoid homeostasis in the whole body.
- Hepatic stellate cells are principal cells for induction of hepatic fibrosis and liver cirrhosis.
- The stellate cell consists of a spindle-shaped or angular cell body and long and branching cytoplasmic processes that encompass the endothelial tubes of sinusoids.
- The interactions between hepatic stellate cells and sinusoidal ECs occur through basement membrane components.

#### Future Goals

- To elucidate mutual functional regulation between ECs and stellate cells
- To develop therapies for hepatic fibrosis and liver cirrhosis

## Podocyte–Endothelial Interactions

---

Susan E. Quaggin

*Mt. Sinai Hospital, University of Toronto, Ontario, Canada*

The glomerular filtration barrier (GFB) separates the blood from the urinary space. It consists of two cell types: glomerular visceral epithelial cells, also known as podocytes, and glycocalyx-coated, fenestrated endothelial cells (ECs) that form the glomerular capillary system. They are separated by a glomerular basement membrane (GBM), which is produced by both cell types (Figures 68.1 and 68.2) and consists of laminins, collagens, and heparan sulfate-containing moieties such as perlecan and agrin. In humans, each kidney contains approximately 600,000 to 1 million individual glomeruli that produce 180 L of filtrate per day. Mesangial cells sit between the capillary loops; they provide support and produce the extracellular matrix (ECM) molecules and growth factors required for proper formation of the developing capillary system. The structure of the GFB was first appreciated in electron micrographic (EM) studies that were performed during the 1970s (1–3). Using EM, it was possible to visualize fenestrations in glomerular ECs and specialized intercellular junctions between the foot processes of podocytes known as slit diaphragms (SDs), which are electron-dense structures resembling the teeth of a zipper. Until very recently, it was believed that the major function of the SD was to form the ultimate structural barrier to the blood to prevent loss of critical proteins into the urine.

The identification of human nephrin (NPHS1; nephrosis 1) by Karl Trygvasson's group in 1998 (4) led to an explosion in our understanding of the molecular basis of the SD and the biology of the podocyte (5,6). Nephrin molecules from adjacent foot processes span the SD space and, through homophilic interactions, make up a major structural component of the SD. In addition, the slit proteins reside in lipid raft microdomains of the podocyte cell membrane and function as signaling centers that relay inputs from the glomerular microenvironment to the cytoskeleton and intracellular environment of the podocyte. Nephrin interacts with the actin cytoskeleton through phosphorylated tyrosines in its cytoplasmic tail. Recruitment of Nck adaptor proteins to phosphorylated nephrin leads to actin reorganization in vitro, whereas podocyte-selective loss of Nck leads to failure of podocyte foot process formation (7,8). Three nephrin homologues have been

identified in mammals: NEPH1, -2, and -3 (9); at least one of these proteins, NEPH1, is known to form both homo- and heterodimers with nephrin in vitro (10). On the heels of the discovery of nephrin, several other components of the slit and/or cytoskeleton were identified, including podocin (NPHS2),  $\alpha$ -actinin 4 and CD2AP (11–14). Human mutations in each of the *NPHS1*, *NPHS2*, and  *$\alpha$ -actinin 4* genes are associated with steroid-resistant forms of congenital nephrosis or focal segmental glomerulosclerosis (FSGS), emphasizing the role of the SD and cytoskeleton in podocyte and glomerular biology. Recently, mutations in the transient receptor potential cation channel, *TRPC6*, which is expressed by both podocytes and glomerular ECs, and *PLCe1*, which is expressed by podocytes, have been found to underlie other familial forms of FSGS and mesangial sclerosis, respectively (15–17). Several additional proteins have been shown to coprecipitate with nephrin in a large multimeric complex; these include ZO-1, p120 catenin, CASK (18), and IQGAP1, but their functional role is less clear (19). Still other proteins required for SD function have been identified by knockout studies, although their exact subcellular localization and interacting partners remain unclear. One example of this latter group includes the cadherin FAT (20); *FAT*-null mice die prior to birth with no foot processes or SDs.

In addition to its role in filtration, the glomerulus is a specialized high-flux capillary bed, as large volumes of water and small solutes pass from the blood to the urinary space. In this context, the podocyte may be considered as a vascular supporting cell. What is the evidence that they function as vascular supporting cells? They are in close association with adjacent ECs, and produce ECM proteins that are required for the podocyte–endothelial interface. However, most importantly, they express a number of vascular growth factors known to be essential for endothelial migration, differentiation, survival, and activity. These factors include vascular endothelial growth factor (VEGF)-A, VEGF-C, angiopoietin 1 (Ang1), and ephrinB2 (21–24). Adjacent ECs express the major receptors for each of these ligands, although the Eph receptor responsible for ephrinB2 signaling within the glomerulus has not yet been identified. Reciprocal signals from the endothelial to podocyte

Figure 68.1. Electron micrographs of the renal glomerulus. (A) Scanning electron micrograph shows an isolated whole mouse glomerulus. The cells seen on the outer surface represent podocytes. (B) Scanning electron micrograph at higher power shows the cell body of a podocyte (*po*) with its primary processes (*pr*) and secondary foot processes (*unlabeled arrows*) that wrap around glomerular capillaries. (C) Transmission electron micrograph shows foot processes (*fp*) of a podocyte. The slit diaphragms (*SD*) are specialized intercellular junctions between interdigitating foot processes. Fenestrations (*f*) are present in the glomerular endothelium. Podocytes and ECs are separated by an intervening glomerular basement membrane (*GBM*). Urine is formed as it passes through the fenestrations and SDs.

compartment also likely exist, although their identities are not known.

Despite the advances that have been gained in our understanding of the molecular components of the filtration barrier, some controversy exists regarding the role of each of the components and cell types—including the podocytes, ECs, glycocalyx, glomerular basement membrane, and SDs—in providing the permselective qualities that permit high flux and loss of small solutes and water into the urine, but prevent the loss of larger molecules, including albumin and blood clotting factors. Evidence from clinical medicine and the laboratory suggests that each of these components plays a role. Loss of SD proteins alone, as occurs in congenital nephrosis of the Finnish

type due to mutations in *NPHS1*, results in nephrotic range proteinuria. These findings illustrate the important role that the SD plays in the barrier. Yet, how the SD prevents loss of protein in the basal state is still debated. Electron tomographic studies can resolve images of the SD to 5 to 10 nm and permit three-dimensional reconstruction (25). Together with computer modeling, these data led Wartiovaara and colleagues to argue that albumin is excluded from urine based on size exclusion within the slit. Oliver Smithies proposes a different model, in which the width of the SDs and foot processes determines the gel properties of the filtration barrier (26). In contrast to podocytes and the SD, the role of the glomerular endothelium in filtration is less well appreciated. In addition to the fenestrations, a glycocalyx is observed on the blood side of the endothelium; this is believed to provide some barrier to filtration (27). A body of evidence supports a critical role for ECs in the permselectivity of the GFB: Both the loss of fenestrations that occurs in preeclampsia and both the under- and overproduction of vascular growth factors that function at the level of the endothelium lead to rapid increases in permeability and loss of proteins into the urine (28,29). Furthermore, in several experimental models nephrotic-range proteinuria occurs with preservation of foot processes and SDs, at least ultrastructurally (30). Several interesting reviews and hypothetical argument papers have been published recently regarding these models (31).

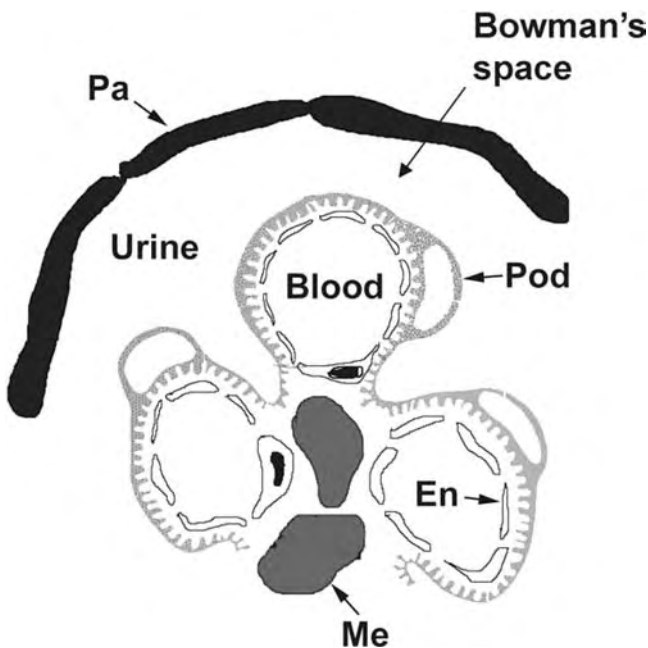

Figure 68.2. Schematic diagram of the renal glomerulus. Podocytes (*Pod*) are shown in light gray and overlie the fenestrated ECs. Mesangial cells (*Me*) sit between the capillary loops. Pa, parietal epithelial cells.

### DEVELOPMENTAL CONSIDERATIONS

Glomeruli arise from metanephric mesenchymal cells that, in turn, derive from the intermediate mesoderm (32). At approximately embryonic day (E)10.5 in mice and 4.5 to 5 weeks in humans, the ureteric bud (UB) develops from the caudal end of the Wolffian duct and grows into the metanephric mesenchyme (MM). Metanephric mesenchymal cells are induced by the adjacent UB and undergo a series of well-defined morphological changes including condensation and then epithelialization to produce a vesicle, comma-shape, S-shape, capillary

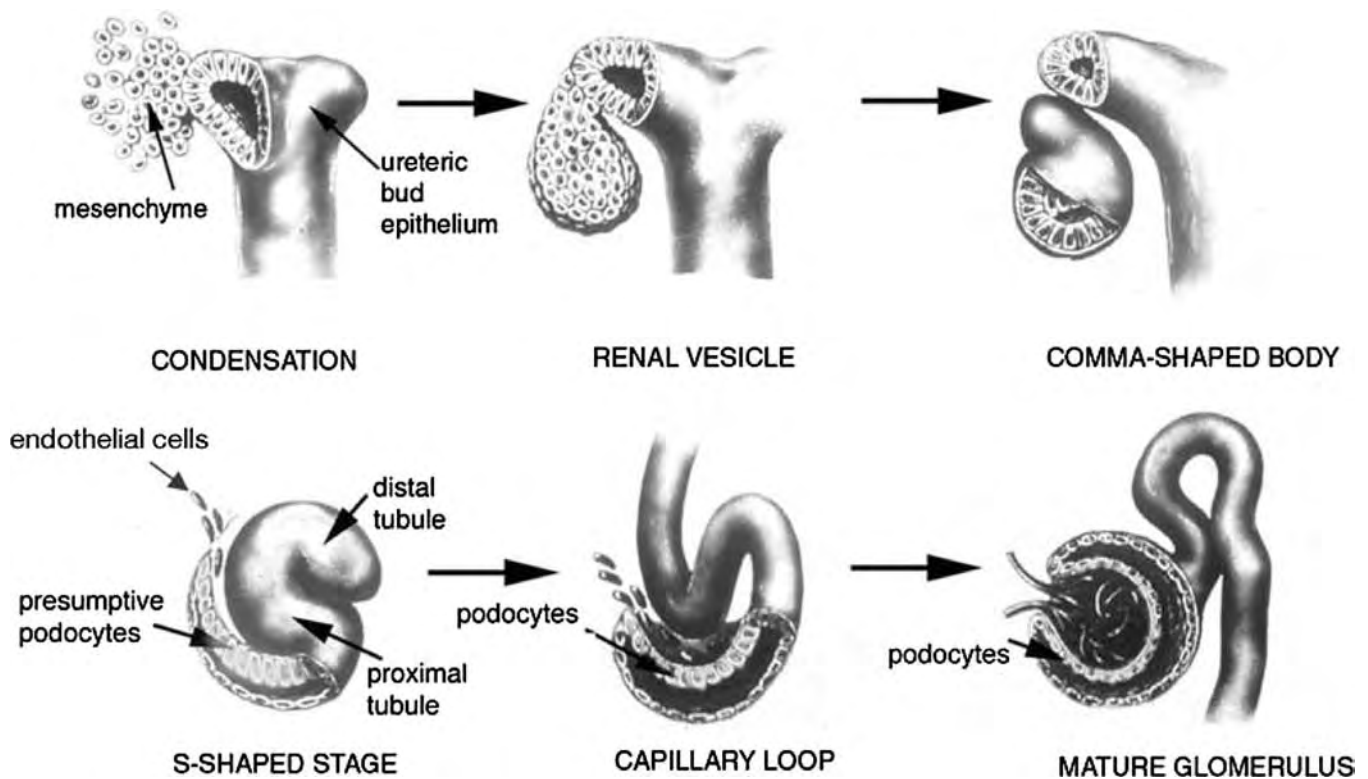

Figure 68.3. Development of the glomerular filtration barrier. Glomeruli develop from metanephric mesenchymal cells that are induced to condense and epithelialize by the adjacent ureteric bud epithelium. Presumptive podocytes are first observed at the S-shape stage of development as columnar epithelial cells. A vascular cleft forms immediately adjacent to the podocyte precursors that express VEGF-A. The VEGF receptors (VEGFR1 and VEGFR2) are expressed by incoming ECs. At the capillary loop stage, ECs develop fenestrations, and capillaries form in direct apposition to podocytes. The functional filtration barrier is seen in mature glomeruli. (Adapted with permission from Saxen L. *Organogene of the kidney*. Cambridge University Press, 1987.)

loop, and finally mature glomerulus (Figure 68.3). Podocyte precursors are first evident at the S-shape stage of development. A vascular cleft develops immediately adjacent to the columnar-shaped podocytes, which already produce high levels of the vascular mitogen VEGF-A (see Figure 68.3). FLK-1-positive ECs migrate into this cleft from the MM and set up the glomerular capillary system in direct apposition to the podocytes. By the capillary loop stage of development, fenestrations are observed within the endothelium. The mature capillary loop structure depends on the migration of mesangial cells into the center of the developing glomerulus to provide support and produce the “flowerlike” structure of the system. Interactions between glomerular ECs and mesangial cells require platelet-derived growth factor (PDGF) receptor (PDGFR)- $\beta$  and PDGF-B signaling. Loss of either the PDGF- $\beta$  receptor or its ligand PDGF-B in knockout mice prevents mesangial cell migration and, as a result, glomeruli form with a single ballooned capillary loop only (33,34).

#### LIGAND-RECEPTOR INTERACTIONS: VASCULAR ENDOTHELIAL GROWTH FACTOR-A SIGNALING

During glomerular development and in the mature glomerulus, podocytes produce high levels of VEGF-A. During this

time, VEGF receptors are expressed by adjacent endothelium, suggesting a tightly regulated paracrine system for the development and maintenance of the filtration barrier. In addition, podocytes express the VEGF coreceptors – neuropilin 1 (NRP1) and NRP2 – in vivo, and immortalized podocyte cell lines express high levels of VEGFR1, NRP1 and NRP2, leaving open the possibility that an autocrine loop for VEGF-A signaling exists in the glomerular podocytes as well (21,35). In vitro, inhibition of tyrosine kinase signaling leads to apoptosis of podocytes (36). In some laboratories, these podocyte cell lines also have been shown to express VEGFR2 (37); however, to date no one has been able to demonstrate expression of this receptor by podocytes in vivo.

The angiotensin ligand-receptor pairs are expressed by podocytes and glomerular ECs, respectively. Chimeric mouse studies demonstrated a cell-autonomous requirement for the Ang1 receptor (Tie2) in glomerular ECs, because *Tie2*-null embryonic stem cells can contribute to many vascular beds, but never to glomerular ECs (38).

Similar to other fenestrated vascular beds in the body, the adjacent vascular supporting cells – the podocytes – continue to constitutively express VEGF-A in the postnatal and adult periods. Although hypoxia-inducible regulation of VEGF-A is well established and is believed to play a major role during

Figure 68.4. Exquisite dosage sensitivity for VEGF-A exists in the developing glomerulus. A wild-type mouse glomerulus is shown for comparison (+/+). Loss of all VEGF-A production by podocytes (-/-) results in failure of the filtration barrier to form; removal of one VEGF-A allele (+/-) in podocyte-specific haploinsufficient mice results in endotheliosis, whereas an intermediate dose (hypomorphic and one null allele) leads to massive mesangiolytic and death at 3 weeks. By contrast, marked upregulation of VEGF-A (+++++) in podocytes leads to collapsing glomerulopathy, similar to the lesion observed in acquired immune deficiency syndrome (AIDS)-related nephropathy.

glomerular development (39), these mechanisms appear to be less important in the adult kidney, suggesting the presence of alternative, nonhypoxia-mediated regulatory pathways for VEGF-A production, such as integrin-mediated regulation (40).

#### VASCULAR ENDOTHELIAL GROWTH FACTOR-A SIGNALING AND THE GLOMERULUS

Numerous clinical studies have demonstrated an association between dysregulation of the VEGF-A protein or gene expression, and glomerular disease (41). Given the nature of association studies, it was not clear whether this dysregulation was primary or secondary. Elegant studies by Karumanchi and colleagues have identified elevations in circulating levels of soluble VEGFR1/FLT-1 (sFLT-1) and patients with preeclampsia (28,42) (see Chapter 161). Furthermore, injection of sFLT-1 into rats led to endotheliosis – the classic renal lesion observed in preeclampsia, in which ECs become swollen and lose their fenestrations. Injection of a mouse antibody to VEGFR2/FLK-1 led to redistribution of the SD protein, nephrin, and proteinuria in mice (43), suggesting a possible podocyte-dependent mechanism for proteinuria in addition to direct effects on the endothelium.

Conditional gene targeting in mice has provided additional support for the pivotal role that VEGF-A signaling plays in all aspects of glomerular endothelial function. Using the Cre-loxP system, a series of transgenic mice were generated that carried different “doses” or copy numbers of the VEGF-A allele (29,44–46). Deletion of all VEGF-A from podocytes led to perinatal death and failure of GFB formation because of defects in EC migration into the vascular cleft, decreased survival, and failure of fenestrations to form. Mice that were hemizygous for the VEGF-A gene within their podocytes (one wild-type copy only) developed endotheliosis similar to patients with preeclampsia. Because systemic VEGF-A levels were presumably normal in this genetic model of VEGF-A reduction,

it suggests that circulating levels of VEGF-A are unable to rescue the local paracrine requirement for VEGF-A signaling. This endothelial defect led to global deterioration of glomerular function and glomerulosclerosis by 3 months of age. Further reduction of VEGF-A (one hypomorphic allele and one null allele in the podocyte) led to a phenotype intermediate between the null and haploinsufficient mice (Figure 68.4). Although EC migration occurred normally into the glomeruli of hypomorphic VEGF mice, they rapidly disappeared, leaving capillary ghosts devoid of all endothelium (Figure 68.5). This led to mesangiolytic (dissolution of mesangial cells), presumably due to defects in signaling from the endothelium to mesangium.

Figure 68.5. Podocyte-selective deletion of VEGF-A leads to loss of ECs. (A) Podocytes (po) and fenestrated endothelial (en) cells are shown in a wild-type mouse glomerulus. (B) In mice with podocyte-selective deletion of one VEGF-A allele and one remaining hypofunctioning allele, only capillary ghosts devoid of ECs are seen. Podocyte foot processes (po) and glomerular basement membrane (GBM) are present. (Adapted with permission from Eremina V, et al. VEGF-A signaling in the podocyte-endothelial compartment is required for mesangial cell migration and survival. *J Am Soc Nephrol.* 2006;17: 724–735.)

By contrast, upregulation of the major VEGF-A<sub>164</sub> isoform in developing podocytes led to collapsing glomerulopathy and death from renal failure at 5 days of age (44). Taken together, these results emphasize the critical role for VEGF-A signaling from podocytes to ECs during glomerular development.

However, this requirement does not end after development. Although VEGF-A production by podocytes occurs against the “flow of urine” from capillaries to urinary space, it is still required by the endothelium in the adult. Podocyte-specific induction of the VEGF-A<sub>164</sub> isoform using a tetracycline-inducible gene-targeting system in mice (47) leads to rapid changes in glomerular EC permeability and nephrotic-range nonselective proteinuria within 48 hours (29,47). In this situation, podocyte foot processes are intact, consistent with a central role for the endothelium in glomerular permselectivity. Deletion of VEGF-A from adult podocytes also leads to glomerular injury, disease, and renal failure with major defects observed in glomerular endothelia (29).

## CLINICAL IMPLICATIONS

Only recently have podocytes come to be viewed as vascular supporting cells. A large body of work in murine models demonstrates the intimate nature of interactions between podocytes and glomerular ECs and highlights the role of vascular signaling pathways in glomerular development and disease (29,45,46).

Is this relevant to our patients in the clinic? In the simplest interpretation, it is paramount that we recognize potential safety issues for drugs and inhibitors that target these vascular pathways in diseases such as cancer and vasculopathies. Of note, the most common adverse effects observed in patients treated with VEGF-inhibitory drugs is the development of proteinuria and/or hypertension (48). Whether circulating levels of VEGF-A in these patients influence the glomerular endothelium to produce symptoms is not yet clear, but increased awareness of possible adverse events in patients treated with these drugs is required. By contrast, the emergence of prolyl hydroxylase inhibitors to stabilize hypoxia inducible factors (HIFs) will lead to increased local levels of VEGF-A; in theory, these drugs also may affect the glomerular endothelium to cause proteinuria. Future studies will be needed to determine if this is a consideration in the clinic.

Given the embryonic lethality of VEGF-A-knockout and haploinsufficient mice (49), it is unlikely that such major mutations underlie human disease. However, more subtle defects that alter gene expression or affect the storage and/or delivery of VEGF-A are likely to be involved in glomerular disease. Studies to determine the role of VEGF-A signaling within the glomerulus are providing new insights into glomerular filtration. For example, the upregulation of VEGF-A within podocytes rapidly leads to nonselective nephrotic-range proteinuria (45), and proteinuria in clinical medicine portends serious renal disease and is the surrogate marker used to predict progression. A lower level of proteinuria, termed

microalbuminuria (albumin <300 mg/24 hour), is a prognostic indicator not only for diabetic nephropathy and glomerular disease but also for cardiovascular disease; its presence is associated with poorer clinical outcome. Given the central role of VEGF-A and glomerular endothelia in glomerular permselectivity and function, it follows that VEGF-A may contribute to microalbuminuria. The fact that microalbuminuria is associated with systemic vascular disease may reflect a more generalized endothelial defect that can be detected through urinalysis. This is simplified due to the accessibility of the glomerular capillary bed to the external environment, and suggests that urinalysis may be extended to include biomarkers of endothelial function.

## KEY POINTS

- Podocyte–endothelial cross-talk is essential for the development and maintenance of the GFB – a specialized capillary bed.
- Podocytes function as vascular support cells within the glomerulus.
- Paracrine signaling from the podocyte to EC is critical for glomerular function; VEGF-A is an important example of one such signaling pathway.

## Future Goals

- To identify additional signaling pathways that are important for podocyte–endothelial interactions
- To determine how VEGF-A pathway is altered in human glomerular disease and proteinuric states

# Coupling

## Introductory Essay: Endothelial Cell Coupling

---

Michael Simons

*Dartmouth Medical School, Hanover, New Hampshire*

Endothelial cells (ECs), by virtue of their location at the interface between the bloodstream and the vessel wall, must integrate bidirectional signaling inputs and generate appropriate responses. These responses in turn can affect both EC interaction with the flowing blood and the circulating blood cells, as well as affect the function of the vessel wall. Thus, these deceptively simple looking cells are charged with a highly complex task of responding to and modifying the behavior of the liquid phase (plasma) and the solid phase (vessel wall) environments.

This integrative signaling function performed by the endothelium includes a number of components, including sensors of the physical environment such as the rate of blood flow (shear stress), of the circulating growth factors and cytokines, and of the circulating cells. In addition, the type of matrix the EC rests on, and cells it is in contact with, including other ECs, provide additional inputs into the complex integration matrix. As a practical example of this challenge, let us consider that, under certain circumstances, an EC may be called on to deal with a variety of inputs, including signals from multiple soluble ligands binding to tyrosine kinase receptors (e.g., vascular endothelial growth factor [VEGF], fibroblast growth factor [FGF], platelet-derived growth factor [PDGF]); serine/threonine kinases (e.g., epidermal growth factor [EGF]); G-protein-coupled receptors (e.g., thrombin); input from binding circulating cells via cellular adhesion molecules; signals from the extracellular matrix via integrins, syndecans, and other adhesion molecules; and signals from other adjoining ECs via tight junctions. All this input is integrated to yield a variety of responses including the initiation of migration or cell division and changes in production of nitric oxide and other EC-derived vasoactive substances, such as prostaglandins. Processing of these signals thus results in the endothelium altering its own properties – such as changes in its shape, expression of various receptors, and production of signaling molecules – as well as potentially altering the appearance of the blood vessel at the site where

the signal was applied or even affecting the overall state of circulation.

Thus, the endothelium is a key component of a complex signaling network operating over several orders of magnitude on the spatiotemporal scales (1). Some of the examples of these scales of operation include the endocrine signaling provided by circulating growth factors and cytokines, the paracrine interaction with smooth muscle cells directed by the production of nitric oxide, and the autocrine signaling generated by secretion of FGF1.

Shifting next to the intracellular scale of endothelial signaling, one observes multiple individual signaling networks, such as VEGF receptor or  $\alpha_v$  integrin signaling cascades, that are typically tightly compartmentalized. We have a tendency to think of these signaling cascades in linear terms and to ascribe a change in cell phenotype resulting from an alteration in function of one of the signaling cascade proteins (e.g., inhibition of Akt-1 phosphorylation) to the particular signaling cascade interfered with. Yet this hardly can be correct. It is quite clear that various signaling cascades interact and modify one another, with resulting output from signaling cascade X being dependent on the presence or absence of signals from cascades Y and Z (2). This is a very important issue that is usually ignored in discussions of individual signaling pathways.

The interactions between different signaling networks typically lead to the appearance of new functionality, described by the term *emergent properties*. One example of such emergent properties is the effect of the EGF receptor signaling cascade cross-talk with other cellular processes. A thorough analysis of these interactions demonstrates several emergent properties, including extended signal duration, activation of feedback loops, changes in thresholds for stimulation of biological processes and, perhaps most importantly, multiple signaling outputs (2).

The chapters in this section of the book discuss various microdomains and signaling pathways in ECs. As these chapters illustrate, we clearly have and continue to gain very

detailed understanding of individual organelles and pathways. The section begins with a chapter that summarizes the differences and similarities between endothelium and epithelium (Chapter 70). Dvorak provides us with an overview of the seminal advances related to ultrastructure during 1950s and 1960s (Chapter 71). As discussed in chapters by Lowenstein, Schnitzer, and Stan, the last decade has witnessed remarkable progress in understanding the signaling functions and molecular basis of EC microdomains (e.g., caveolae) and organelles (e.g., Weibel-Palade bodies) (Chapters 72–74). Other structural elements discussed in this section, which contribute to signaling, include the glycocalyx (Chapter 75) and the cytoskeleton (Chapter 76). The field of water channels and ion channels has gained significance over the past years, as evidenced by the awarding of Nobel prizes in Medicine for discoveries in these areas. In this volume, Verkman and Yao apply principles of water and ion transport to an understanding of endothelial function in health and disease (Chapters 78 and 79). Finally, McCarty and Hynes discuss the critical interaction between integrins and the extracellular matrix (Chapter 77).

At the level of signaling pathways, many important intermediates occur, only some of which are discussed here. These include chapters on phosphoinositide 3-kinase (PI3K)-Akt (Chapter 80), mitogen-activated protein kinases (MAPKs) (Chapter 81), protein kinase C (PKC) (Chapter 82), Rho GTP-binding proteins (Chapter 83), phosphatases (Chapter 84), and Wnt signaling (Chapter 85).

Activation (or repression) of signaling pathways in ECs may lead to changes in proteins (posttranscriptional) or mRNA (posttranscriptional and/or transcriptional). Changes in gene expression are mediated by DNA binding proteins. Interestingly, few if any transcription factors (or for that matter target genes) are truly specific to ECs (one exception may be *Vezf1*, which is discussed in Chapter 95). It seems likely that EC-specific gene expression is mediated by the coordinate action of nonspecific transcription factors and coactivators. However, as recently discussed in a comprehensive review of EC gene regulation (3), there is far more to learn about the endothelium by focusing on those transcription factors and target genes whose activity is modulated by the microenvironment, regardless of their lineage specificity. Examples of transcription factors that serve as signal transducers that couple changes in the extracellular milieu to alterations in gene expression include nuclear factor (NF)- $\kappa$ B (Chapter 86), peroxisome proliferator-activated receptors (PPARs) (Chapter 87), GATA (Chapter 88), Ets (Chapter 89), early growth response (*Egr*)-1 (Chapter 90), Krüppel-like factor 2 (KLF2) (Chapter 91), nuclear factor of activated T cells (NF-AT) (Chapter 92), forkhead (Chapter 93), MEF (Chapter 94), Sox (Chapter 96), and Id (Chapter 97). As detailed in these chapters, many of these transcription factors have been implicated not only in homeostasis, but also in the pathogenesis of vascular disease states.

Yet the question remains whether this knowledge of individual components on endothelial signaling is sufficient to

gain a thorough understanding of how the endothelium functions as an organ, or whether the emergent picture is more complex than the sum of its parts and cannot be deduced from the first principles – in this case, the knowledge of individual signaling pathways.

As an illustration of this complexity, let's consider two examples. A simple matter of two-pathway interaction is illustrated by endothelial expression of the  $\alpha v\beta 5$  integrin. ECs expressing it are far more sensitive to VEGF stimulation, and may demonstrate an entirely different phenotypic response than those that do not (4). Another example is that of transforming growth factor (TGF)- $\beta$  which, when studied in a conventional in vitro culture, produces results quite different from those obtained in a three-dimensional (3D) collagen matrix (5). This presumably occurs because the cellular inputs from a 3D matrix differ from those of the two-dimensional (2D) matrix, and this difference is enough to dramatically alter cellular response to TGF- $\beta$ . It is hardly necessary to note that in vivo response is frequently, if not always, different from the effects observed in vitro.

Thus, the endothelium itself can in some sense be considered an emergent system in which the total system demonstrates functionality not obviously evident from its parts. Although the concept of emergent systems has gained much popularity lately, with everything from consciousness to Newton laws being viewed as emergent, the implication of such a nomenclature is not clear. In some cases, the underlying message is that studying constitutive components is not particularly useful to the overall understanding of the system, because the emergent nature cannot be accounted for by its individual parts. This, of course, runs counter to a reductionist approach firmly ingrained in science in general and biological science in particular. The other implication, to paraphrase Samuel Johnson, is that “one does not criticize the way endothelium functions, it is sufficient that it functions at all.”

Thus, we will need new tools and new ideas to better understand the role of endothelium and the function of its numerous signaling networks. Various simulation approaches have been advanced to study the network–network interactions (6,7), and several in silico methods have been developed to study the computational properties of protein networks (8). But more traditional biological techniques will also play an important role. A better understanding of the compartmentalization of individual network components, including the roles played by caveolae, lipid rafts, and endosomes; the function of various scaffold proteins that assemble the network components together; and the organization of signaling inputs into reaction channeling (9), will be critical to a sophisticated understanding of signaling.

Furthermore, as with any complex system, stability is the key question. How stable is the phenotype being studied, and how easily can it be perturbed by changes in individual parameters or by outside influences? Remarkably, molecular biology provides wonderful tools for dealing with these issues: In vivo manipulations of individual and multiple gene expression changes in desired cell types is a routine of daily life in

vascular biology laboratories. Now we need to systematically and comprehensively apply these tools to study of endothelial function under a variety of normal and abnormal conditions.

Although we have a pretty good idea how the individual signaling components mentioned here work, we have a rather incomplete understanding of how the various signals are integrated and harnessed into a coherent response. The understanding of this integration, occurring under a variety of conditions from normal to pathologic, is the next big challenge facing vascular biology. A successful solution to this riddle will provide not only the intellectual satisfaction of understanding a complex system but will allow us to design more effective treatments for a variety of illnesses – for rare is the illness that does not involve endothelium.

A practical example of this can be seen in the field of therapeutic angiogenesis. Multiple studies in vitro and in a variety of simple animal models have convinced us that a single exposure to an angiogenic growth factor such as VEGF or FGF is sufficient to induce a meaningful growth of new vasculature (10). Yet, when applied to humans or even to atherosclerotic mice, this approach utterly failed, thus demonstrating that new inputs generated by the altered disease environment have so altered the endothelium as to make it unresponsive to the stimuli to which it was responsive before (11).

To understand signal integration at the level of the individual EC, a layer of ECs and, indeed, an organ, will require new thinking and new experimental approaches. But the payoff will be worth it.

# Endothelial and Epithelial Cells

## General Principles of Selective Vectorial Transport

Rolf Kinne

*Max Planck Institut für molekulare Physiologie, Dortmund, Germany*

One of the major prerequisites for the existence of biological organisms is compartmentalization. This process is an important early step in biological evolution, when the first organisms dissociated themselves from the surrounding medium by the generation of a selectively permeable membrane. In more and more complex organisms, not only are cells separated from their environment but also organs, such as the brain, are protected from changes in the interstitial fluid. Ultimately, the whole organism generates a *milieu interieur* whose composition is monitored with great precision and kept within narrow limits that optimize body function. Compartmentalization in complex organisms, such as mammals, is achieved by specifically organized cells, such as endothelial cells (ECs) and epithelial cells. On the one hand, both cell types act as barriers that separate compartments. On the other hand, they both mediate the vectorial transport of solutes and macromolecules. The predominance of the “wall function” versus the “gate function” varies from the blood–brain barrier endothelium to the sinusoidal endothelium and from “tight” epithelia to “leaky” epithelia. The underlying cellular and molecular mechanisms appear, however, to be quite similar. The current chapter reviews these biophysical and biochemical similarities and attempts to delineate common principles of structure and function in endothelial and epithelial cells.

Special emphasis is thereby placed on the relation between asymmetry and net movement of small solutes. Asymmetry (i.e., polarity) of cell membrane transport properties is found in both epithelial and EC layers, and provides the basis for transcellular transport. Furthermore, the asymmetry of membrane transporters is discussed with regard to their different properties at the extra- and intracellular face. These molecular asymmetries play an important role in the efficiency, direction, and regulation of transport processes across the plasma membranes in endothelial and epithelial cells.

### PERMEABILITY OF ENDOTHELIA AND EPITHELIA

The pathways used in endothelia and epithelia for the penetration of cells, macromolecules, organic nutrients, inorganic salts, and water are summarized in Table 70-1. In both cell layers, para- and transcellular pathways are used, with the size of the permeating compounds spanning from cells permeating through discontinuous endothelia in liver and spleen, for example, to water permeation through the tight endothelium of the blood–brain barrier (1). Epithelia, although also categorized into leaky, intermediate, or tight, are much more restrictive with regard to their permeability to cells and macromolecules. Selectivity appears at the level of organic solutes, inorganic ions, and water. This selectivity is reflected in their transepithelial resistance and transepithelial voltage, as well as in their hydraulic conductivity (2).

Thus, the degree of similarity in transendothelial and transepithelial pathways increases with the tightness of the cell layer, with the blood–brain barrier and the tight epithelia becoming most similar in their basic transport properties.

### GENERAL PRINCIPLES OF TRANSPORT THROUGH CELL LAYERS

#### Energetic Considerations

The net transport of any electrolyte  $i$  across a cell layer is the sum of the passive transport by solvent drag (similar to heat convection) and electrochemical potential difference, and of the active transport. This is expressed in Equation 1:

$$J_i = (1 - \sigma_i) \bar{c}_i J_v - P_i \left( \Delta c_i + \frac{zF}{RT} \Delta \varphi \bar{c}_i \right) + J_{act}, \quad (\text{Equation 1})$$

**Table 70-1: Gateways in Endothelia and Epithelia**

<i>Permeating Compound</i>	<i>Occurrence of Permeation</i>	
	<i>EC</i>	<i>Epithelial Cell</i>
Cells	Frequent, in particular in sinusoidal endothelium	Rare, more frequent in intestinal epithelium
Macromolecules (< albumin)	Frequent, except at blood–brain barrier	Rare, selective uptake in renal and intestinal epithelia
Organic nutrients	Paracellular pathways rare; transcellular pathways predominate	Paracellular pathways rare, predominantly transcellular transport
Inorganic salts	Paracellular pathways predominate, except at blood–brain barrier	Paracellular pathways predominate in leaky epithelia, transcellular pathways predominate in tight epithelia
Water	Paracellular pathways predominate; transcellular pathway in nonfenestrated endothelia	Transcellular pathways predominate

Compiled from Refs. 106–118.

where  $\sigma$  represents the reflection coefficient,  $c$  the mean concentration of  $i$  in the two compartments,  $J_v$  the volume flow,  $P$  the permeability coefficient,  $\Delta c$  the concentration difference,  $z$  the charge of the molecule,  $F$  the Faraday constant,  $R$  the gas constant,  $T$  the temperature in Kelvin degrees,  $\Delta\varphi$  the electrical potential difference, and  $J_{act}$  the active transport component. This active transport component is by definition the transport observed when all physical driving forces are zero, and it is coupled to a chemical reaction (3–5).

The flux of a nonelectrolyte is described by Equation 2.

$$J_i = (1 - \sigma_i) \bar{c}_i J_v - P_i \Delta c_i + J_{act} \quad \text{(Equation 2)}$$

The volume flow  $J_v$  can be formulated according to Starling (6) as:

$$J_v = L_p A \cdot [p - P] \quad \text{(Equation 3)}$$

where  $L_p$  represents the hydraulic conductivity,  $A$  the effective cell layer surface,  $p$  the osmotic pressure difference, and  $P$  the hydrostatic pressure difference. Therefore, solute movement by solvent drag also depends on the osmotic and hydrostatic pressure differences that cause water movement across the cell layer (for a more extensive treatment of water flow across a cell layer see Ref. 7).

Active transport across a cell layer usually involves transcellular transport and, at one point or another, the coupling of an exergonic (i.e., energy yielding) chemical reaction to a vectorial flux (5). The transport across the membrane can be either primary active or secondary or even tertiary active (8). Primary

active transport is mediated by ATP-dependent pumps such as the inorganic ion translocating  $\text{Na}^+\text{-K}^+\text{-ATPase}$ ,  $\text{Ca}^{++}\text{-ATPases}$  (PMCA),  $\text{H}^+\text{-ATPase}$ , and the like, or the organic anions ABC transport systems. Secondary active transport systems use ion gradients established by primary active pumps across the plasma membrane as driving force. Typical examples in mammalian cells are the sodium ( $\text{Na}^+$ )-solute cotransport systems for sugar, amino acids, organic metabolites, and similar substances (8). Tertiary active transport systems use the gradients established by the secondary active transport as driving forces for transfer across the membrane. The latter systems are mostly antiport or exchange systems, such as the PAH/ $\alpha$ -ketoglutarate antiporter (9) localized in the basolateral plasma membrane of the proximal tubule, which exchanges with a broad substrate specificity organic anions with  $\alpha$ -ketoglutarate accumulated by a  $\text{Na}^+\text{-}\alpha$ -ketoglutarate cotransport system (8,9). Secondary active and tertiary active transport also can be combined in one translocation step, such as the  $\gamma^+\text{L}$  amino acid transport system in which a neutral amino acid (together with  $\text{Na}^+$ ) is taken up into the cell by secondary active transport and, at the same time, arginine is transported out of the cell against its electrochemical gradient by tertiary active transport (10,11).

### Paracellular Transport

The transport of molecules between cells is governed by passive driving forces such as differences in concentration, electrical potential, pressure, or temperature in the two compartments that are separated by the cell layer (5). The rate of transfer also

depends on the physical and chemical properties of the paracellular pathway, such as effective pore size, geometry, surface charges, and presence of binding sites, to name a few (12–14). Paracellular transport thus can be selective but only to a limited extent. Across leaky cell layers, in general, no significant concentration differences between compartments are established. However, in the presence of even small differences in electrochemical potential, the paracellular pathway is the predominant route for the bulk flow of salts in leaky epithelia and discontinuous endothelia (14,15).

It is important to note at this point that significant differences exist in the cell-to-cell contact between epithelia and endothelia. In the former, desmosomes are found, specialized cell junctions that are formed by desmosomal cadherins and additional associated proteins into which intermediate filaments are inserted. They are also known as macula adherens junctions, and they link the intermediate filament network of one cell to its neighbor (16). Although mainly considered as imparting tensile strength and resilience to the epithelium, they also may limit the size of molecules able to pass through the paracellular pathway. Similarly, paracellin, a paracellular protein that confers specificity for paracellular calcium and magnesium permeability has also thus far only been observed in epithelial cells (in the renal thick ascending limb of Henle's loop and duct cells in salivary glands).

## Transcellular Transport

### *Hydrophobic Molecules*

The plasma membrane surrounding the endothelial and epithelial cells is composed mainly of membrane proteins and phospholipids. The latter provide an ideal solvent for small hydrophobic molecules; these molecules can be translocated from one cell side to the other (called luminal-to-abluminal translocation in endothelia and apical-to-basolateral translocation in epithelia). Thereby, diffusion of the translocated molecules within the hydrophobic solvent (17) flip-flop between the two monolayers (18), and the mobility of the inner layer of the phospholipid bilayers aid their migration (19). These pathways are known both for endothelial and epithelial cells, and they are characterized by a specificity based on the oil/water partition coefficient (20,21). The net transport across the cell layer depends strongly, however, on the mode of delivery to the one cell surface and mode of removal from the other cell surface. In this context, the role of plasma proteins and interstitial tissue in providing a reservoir and/or "sink" for hydrophobic molecules is of particular importance.

### *Hydrophilic Molecules*

Passage of hydrophilic molecules such as inorganic salts, sugars, and amino acids through the plasma membrane requires the presence of specific mediators. When the electrochemical potentials of the transportates are equal at both sides of the cell (i.e., luminal and abluminal sides in endothelia; apical and basolateral sides in epithelia), net transcellular transport can occur only if the transport properties of the two

membranes facing the *cis* and *trans* compartments are different (22). Thus, an asymmetry of the cell must exist to allow for vectorial transcellular transport (5). Such a cellular *asymmetry* has been clearly demonstrated in endothelial (blood–brain barrier) and epithelial cells (kidney tubules) for example, using indicator dilution techniques *in vivo* (15,23–27) and in uptake studies employing isolated capillaries or tubules or cultured cells *in vitro* (10,28–33). Thereby, the two transporting surfaces of the cell were functionally defined, and striking differences could be observed. The blood–brain barrier showed a strongly asymmetric behavior for the movement of potassium ( $K^+$ ), glycine, and glutamate, whereas much less asymmetry was evident for sugars and large neutral amino acids (34–37). In the proximal tubule, the apical cell side avidly absorbed sugars and amino acids; at the basolateral side, p-aminohippuric acid (PAH) entered the cells most rapidly (25,26). The physiological significance of these findings is evident. In the blood–brain barrier, substances that interfere with the electrical activity of the neurons or act as neurotransmitters, such as  $K^+$ , glycine, and glutamate, are removed from the extracellular fluid, whereas in the kidney, the secretion of metabolic waste products or xenobiotics (PAH as representative) is initiated at the basolateral cell side. Both in the blood–brain barrier and in the proximal tubule, the first steps of nutrient transfer take place at the luminal cell side.

## CELLULAR ASYMMETRY AS BASIS OF VECTORIAL TRANSCELLULAR TRANSPORT

As pointed out earlier, an asymmetry of the transport properties of the two cell membranes arranged in series is required to achieve transcellular vectorial transport. The basis for this idea was laid by Forster and Taggart in 1950, when they proposed that the coupling of metabolic energy to the active transport of organic solutes occurs only at one cell membrane – leading to a "push" mechanism when the intracellular concentration of the transported solute was higher than the concentration in the luminal medium, or to a "pull" mechanism when the concentration gradient was established across the contraluminal membrane (38). This sequence of events in molecular terms is realized in the active transcellular movement of sugars, amino acids, and phosphate, for example, where one membrane contains a secondary-active  $Na^+$ -cotransport system for the solute and the other membrane a  $Na^+$ -independent uniporter (8). In 1958, Koefoed-Johnsen and Ussing postulated an asymmetry for the frog skin to explain the active  $Na^+$  transport across the epithelium, which involves a  $Na^+$  channel in the cell membrane facing the outside and an active  $Na^+$  pump at the inside (39). This is one of the typical arrangements observed, for example, for the transcellular movement of calcium and protons. A small modification for bile acids, xenobiotics, and other substances is the presence of a diffusive pathway in one membrane and an ABC transporter in the other cell membrane (see the next section).

The cellular and molecular basis of such asymmetry has been elucidated successfully mainly by two techniques. In vesicle transport studies, the transport properties of the two membranes have been determined under well-defined driving forces *in vitro* after their separation from the intracellular space and from each other (40–42). The other technique uses immunohistochemistry, which localizes particular transport systems based on their antigenicity. Highly specific antibodies directed against distinctive epitopes of transporters can be generated to allow the identification and localization of transport molecules. Both methods have their advantages and disadvantages. In the former, the interaction with other membrane-associated and/or modifying proteins might be lost (43–47), and transport rates (and sometimes also affinities and substrate specificities) might vary from the situation in intact cells. In the latter, only the *presence* of a transport system is observed – no information about its current state of activity is provided. Sometimes antigenic sites might also be inaccessible, as observed, for example, for the glucose transporter-1 (GLUT1) in bovine blood–brain capillaries (48).

Another major step forward in defining the transport properties of the different cell poles was the development of the patch-clamp technique, which allows the identification and characterization of channels for inorganic and organic ions (49,50).

More recently, it has been realized that the degree of cellular polarity can, however, be modified. Modification may occur via two mechanisms. First, new transporters may be inserted into one cell pole after a particular stimulus – best exemplified by aquaporin water channels (51) or the insulin-responsive

GLUT glucose transporter (52). This phenomenon is increasingly realized to be of major importance in regulating the rate of transfer and also occasionally the net direction of translocation (53). Second, a modification may occur by the activation or inactivation of transporter *in loco*; that is, at the membrane in which they are residing in. In brain capillaries, recent studies on the regulation of the  $\text{Na}^+/\text{K}^+ / 2\text{Cl}^-$  cotransporter (NKCC) revealed such a modification *in loco*. Ischemia activates a basal lateral NKCC; this may lead to a reversal of chloride fluxes and the removal of electrolytes released by damaged cell (54). Such regulatory phenomena also are affected by drugs, such as nicotine – demonstrating the flexibility of the cells generated by the possibilities of intracellular trafficking of regulatory members of the signal transduction pathways (such as protein kinases and phosphatases) or the transporters themselves (54). This kind of “flexible” polarity should always be taken into account when considering epithelial and endothelial polarity.

**DISTRIBUTION OF TRANSPORT SYSTEMS IN ENDOTHELIAL CELLS**

Figure 70.1 compiles data obtained by a combination of techniques on the distribution of transport systems in ECs at the blood–brain barrier. Some of the transport systems, such as those for D-glucose (GLUT1) and L-leucine (system L), are present both in the luminal and contraluminal membrane (10,55–58). Others, such as the  $\text{Na}^+/\text{K}^+$ -ATPase are present only in the abluminal membrane. This enzyme, in combination with a luminal  $\text{K}^+$  channel, is probably mainly involved

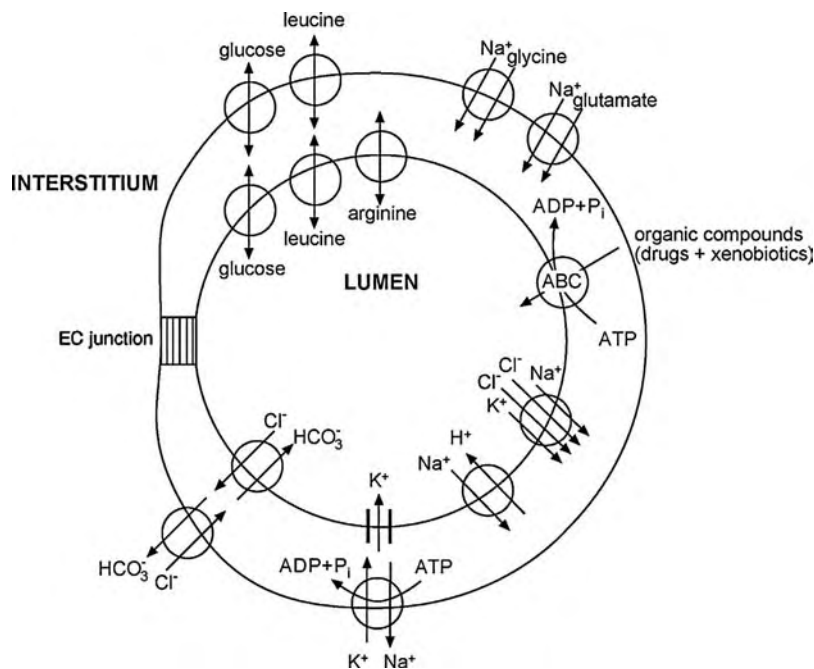

Figure 70.1. Distribution of transport systems in the EC of a brain capillary. (Modified after Risau W. Differentiation of blood–brain barrier endothelium. *News Physiol Sci.* 1989;4:151–153.)

in  $K^+$  removal from the brain tissue into the blood. In addition a  $Na^+/K^+/2Cl^-$  cotransport system has been shown to be present in the luminal membrane (54,59). Thus, the luminal  $K^+$  channels (60,61) also may be involved in recycling of  $K^+$  after its uptake via the  $Na^+/K^+/2Cl^-$  cotransporter. The arrangement of these transporters is very similar to the one found in the distal part of the nephron (see later section), where secretion of  $K^+$  is observed (62,63). In addition, the  $Na^+,K^+$ -ATPase maintains the electrochemical potential difference for  $Na^+$  across the plasma membrane that is employed for the uptake of glycine, glutamate, and taurine into the cells. As mentioned earlier, the former two transport systems are apparently present only in the abluminal membrane.

The molecular identity of the transport systems in ECs for amino acids can be summarized as follows (10): System L1 (for "large" amino acids) expressed both in the luminal and abluminal membrane, is a heterodimeric transport system and transports (and exchanges) alanine, leucine, glycine, serine, and glutamine (64). The abluminal membrane contains three  $Na^+$ -dependent amino acid transport systems: the system A (65) and  $B^{0,+}$ , and one for anionic amino acids. System A is the major  $Na^+$ -dependent transport systems for neutral amino acids such as alanine and proline; its hallmark is that it interacts

with the nonphysiological  $\alpha$ -(methylamino)isobutyric acid (MeAB). System  $B^{0,+}$  appears to be of minor importance. At the abluminal cell side, anionic amino acids such as glutamate are probably translocated both by the  $Na^+$ -dependent  $X^-_{AC}$  system and the  $Na^+$ -independent  $X^-_C$  transport system that exchanges cystine and glutamate. Depending on the ECs investigated, one or the other transport route prevails. At the luminal membrane of ECs, cationic amino acids such as arginine, which plays a crucial role in the nitric oxide production of ECs (66–69), are taken up via a  $Na^+$ -independent transport system  $\gamma^+$  (probably CAT1 similar). Another major luminal pathway for amino acids in some ECs is the  $\gamma^+L$  system. This heterodimeric transport system mediates the exchange of a cationic amino acid for  $Na^+$  and a neutral amino acid – a particularly intriguing combination.

### DISTRIBUTION OF TRANSPORT SYSTEMS IN EPITHELIAL CELLS

In most epithelial cells, the asymmetry of the cell membranes is more striking than that of endothelia. For any particular transported solute, the transport systems in the apical and

Figure 70.2. Distribution of transport systems in the epithelial cell of the renal proximal tubule.

basolateral membrane are very often completely different. Sugar entry into the cells of the proximal tubule and intestine, for example, is mediated by a  $\text{Na}^+$ -dependent cotransport system, SGLT (Figure 70.2) (8), whereas cell exit occurs via the  $\text{Na}^+$ -independent transport system, GLUT2 (70). The same holds for a large number of other organic solutes that are retrieved from the lumen of the tubule and small intestine, respectively (8). PAH is taken up at the contraluminal membrane by a specific exchange system with  $\alpha$ -ketoglutarate (9) and released at the luminal membrane by another transporter that bears similarities to a channel. Therefore, the entry steps for these solutes are driven directly or indirectly by the electrochemical potential difference of  $\text{Na}^+$  across the cell membrane, which is maintained by the primary active  $\text{Na}^+$  pump, the  $\text{Na}^+, \text{K}^+$ -ATPase. As a consequence, the transport systems in the two membranes are set up in such a way that the *active* transepithelial transport of sugars and PAH is possible.

In the distal tubule,  $\text{K}^+$  is secreted by a similar mechanism as in the brain capillary (62,63). Organic solutes, however, are taken up almost exclusively from the contraluminal side and subserve cellular metabolism. This latter phenomenon is observed for all epithelia whose luminal membranes are in contact with fluids that do not contain the appropriate metabolic substrates; other examples are the urinary bladder, the colon, and other organs.

#### MOLECULAR ASYMMETRY AT THE MEMBRANE LEVEL AS BASIS FOR VECTORIAL TRANSPORT

Similar to the requirement that vectorial transport across the cell requires an asymmetry of the two cell surfaces, such an asymmetry also must be postulated at the membrane level. Indeed, all transport systems cloned thus far exhibit such an asymmetry when the amino acid sequence and the (in most cases computer-predicted) topology of the transport system is considered. The asymmetry also is reflected in different properties of the two sides of the molecule. Classic examples are  $\text{Na}^+, \text{K}^+$ -ATPase, with its different accessibility of ion-binding sites and the active center for ATP hydrolysis from the two membrane surfaces (71) and ion channels that show rectification of current (i.e., a different conductivity depending on the direction and strength of the electric field applied to them) (49,72). Also,  $\text{Na}^+$  cotransport systems have been shown to exhibit a strong functional asymmetry. In general, the affinity for  $\text{Na}^+$  at the domains facing the inside of the cell is much lower than at the outside, allowing for a rapid dissociation of both the  $\text{Na}^+$  and the cotransported solute. In addition, regulation of transport systems occurs mainly by modification of internally located phosphorylation, methylation, or prenylation sites. Also, uniporters for amino acids and carbohydrates show marked differences in substrate affinity and specificity when investigated in the *cis* or in the *trans* conformation.

One example that has been studied in our laboratory is the L-glutamate transport system present in the kidney as well

as in the endothelium (73,74). For these experiments, brush border membrane vesicles were isolated from hog kidney. The isolated membranes are oriented right side out (i.e., in influx experiments, the properties of the transporter exhibited at the extracellular face are studied, whereas in efflux experiments the properties of the transporter at the cytoplasmic face are examined). In influx experiments,  $\text{Na}^+$  stimulates L-glutamate influx into the vesicles. In efflux experiments, it becomes obvious that the cytoplasmic face of the transporter lacks the  $\text{Na}^+$  dependence. This asymmetry increases strongly the efficiency of the transmembrane translocation by minimizing back leak that would reduce energetic coupling (75). Similar observations have been made with the  $\text{Na}^+$ -D-glucose cotransporter. When expressed in inside-out vesicles of yeast, the uptake of D-glucose is  $\text{Na}^+$  independent and has a very low affinity for sugars. In addition, it lacks the sensitivity to phlorhizin found when testing the extracellular face of the carrier (76).

The  $\text{Na}^+$ -dependent glutamate transporter in the kidney also exhibits a strong asymmetry with regard to its sensitivity to changes in the intra- or extraventricular pH. L-glutamate transport is strongly stimulated when the pH of the extraventricular medium is reduced from 7.4 to 5.4 (77). A similar reduction of the intravesicular pH does not change the L-glutamate influx significantly. Furthermore, the stimulatory effect of protons at the extraventricular face is not due to an increased driving force provided for  $\text{H}^+$ -glutamate cotransport, because the identical stimulation is found when both the intra- and extracellular pH are lowered at the same time.

It can, therefore, be expected that a functional asymmetry exists for probably all transporters – including the  $\text{Na}^+$ -independent uniporters. Its characterization will have important consequences on how transmembrane and transcellular transport across endothelial and epithelial cell layers can be described.

#### DIRECTION OF TRANSCELLULAR ORGANIC SOLUTE TRANSPORT IN ENDOTHELIAL CELLS

##### D-Glucose Transport across Endothelial Cells

The consequences of the apparent cellular asymmetry of the GLUT1 distribution for transcellular transport of D-glucose depend on several assumptions concerning the kinetic properties of the transport systems in the two membranes and the glucose concentrations in the various compartments. With regard to the latter, we can assume that, under normal physiological conditions, the glucose concentration is highest in the blood, intermediate in the EC, and lowest in the brain tissue. If, under these circumstances, the two glucose transport systems behave identically, the rate-limiting step for the transport across the cell would be the transport across the luminal membrane. The basolateral transporters then could be a functional reserve that acts, in concert with an increased insertion of transporters from an intracellular pool into the luminal membrane, to increase glucose supply to the brain in

case of increased demand. Such regulation of transendothelial D-glucose transport has been discussed in the literature (43,78). Another explanation for the asymmetry in the distribution of GLUT1 could, however, be a functional asymmetry of the transporter itself. For the human erythrocyte glucose transporter and GLUT1, it has been described that the affinity of the transporter for the mediation of efflux of D-glucose is much lower than for the mediation of influx (79,80). If this difference holds also for the situation in the ECs, the greater number of transporters at the basolateral membrane would compensate (at least partially) the kinetic disadvantage for the permeation of D-glucose across this cell pole.

### Amino Acid Transport across Endothelial Cells

With regard to the transport of amino acids the situation is rather complex. This complexity stems from the fact that amino acid transporters often exchange one amino acid against another; therefore, the direction of the translocation across one membrane can be reversed at the same membrane when exchange systems are arranged in parallel. In this instance, the functional and kinetic data obtained in isolated capillaries, membranes, and cell cultures can be helpful. Thus, for glutamate, the basal-lateral localization can explain the observed avid uptake at the brain-oriented cell pole. Together with the high stoichiometry of the system (2 to 3 Na<sup>+</sup> ions per glutamate), a reversal of the direction appears to be improbable.

With regard to arginine, Na<sup>+</sup>-independent uptake is driven by the membrane potential and the low intracellular arginine concentration. This uptake could be, however, counteracted by the exchange of arginine for Na<sup>+</sup> and a neutral amino acid entering the cell via the  $\gamma^+L$  system at the same luminal cell pole.

For the large amino acids, the presence of the same transport system at the luminal and the abluminal side allows only for vectorial transcellular transport when the transporters are in the right location (81), the driving forces are in the proper direction, and the exchangeable amino acids are in the proper concentration.

### TRANSPORT OF DRUGS AND XENOBIOTICS ACROSS ENDOTHELIAL CELLS

The expression and activity of transporters in the endothelium of the blood-brain barrier also critically determine the bioavailability of drugs essential for treating neurological diseases, including brain tumors and epilepsy (82,83). Similarly, the removal of neurotoxins and glutathione-S-conjugates from the ECs and/or xenobiotics from the brain into the blood depends on the presence of appropriate transport systems in the cells. In both instances, the directionality of transcellular transport is very clearly defined, as indicated by the strong unidirectional, energy-dependent efflux observed in brain capillary cell lines and isolated capillaries (84–86). The

molecular bases for this transport are the ABC transporters multidrug resistance-associated protein (MRP or ABCB1), P-glycoprotein encoded by MDR1 (or ABCC1), and a homologue of the human breast cancer resistance protein breast cancer resistance protein (BCRP) (or ABCG2), which are exclusively located at the luminal pole of the ECs in the brain (87,88). The lipophilic organic compounds presented to the ECs either from the brain or blood side enter the cells via simple diffusion according to the oil partition coefficient or by the flip-flop mechanism (18) mentioned earlier. They are then, often after conjugation within the cell for detoxification, extruded across the luminal membrane into the blood. Thus, one function of the endothelium is to act as an effective barrier against the entry of these substances from the blood into the brain due to the recycling of the compounds across the luminal membrane. For substances conjugated in the cells or entering the ECs from the brain side, an effective removal from the brain into the blood takes place (89,90).

It is interesting to note that similar systems operate in a variety of epithelial cells such as the liver hepatocytes, renal proximal tubule cells, and secretory cells such as the mammary glands (91).

### CONCLUSION

Since I reviewed this topic several years ago (92), the knowledge of the transport properties of the endothelium has increased significantly. Interestingly, the methods that helped in the past to decipher the chain of events comprising transcellular transport in epithelia-isolated tubules and in particular cell cultures (93–95) and isolated membranes (8,40) have now found their way to the endothelium (10). An additional gain came from the cloning of transporters and the possibility of generating specific antibodies for use in immunohistochemistry. In general, it has become clear that epithelia and endothelia are quite alike – histology defines the endothelium as “flat epithelium in contact with lymph or blood.” The main differences prevail when the tight junctions become fenestrations.

Another major difference is the reactions of the ECs engendered by blood cells interacting with them (96–101). In classical epithelia such as kidney and liver, such phenomena are rare. Mechanical stress also is a potent modifier of endothelial function (102–104). Another point of difference is that the surface of the endothelium is exposed to signaling molecules present in the bloodstream more frequently than is the epithelium, although even there luminal messenger systems are becoming more and more elucidated (105). If, for example, wound healing is considered, such factors – particularly the interplay between endothelium and epithelium – are important. This mutual interplay is one area in which the specific, differing properties of both cell types become dominant over the similarities pointed out in this chapter. This is particularly important when disease states, such as inflammation and cancer, are considered (105).

**KEY POINTS**

- Both endothelia and epithelia fulfill wall and gate functions in simultaneously separating and connecting various body compartments. The basic principles by which the cells achieve this function are, despite their different evolutionary origins, very similar. This holds in particular for the transcellular transport pathways, in which the two membranes facing the *cis* and *trans* compartments (i.e., the luminal and abluminal side) of the endothelium are crossed in series. The paracellular pathways differ more in their composition and properties, but the same physical principles are at work to drive solutes across the cell layer.
- Cellular polarity and membrane asymmetry are the basis for vectorial transcellular transport. This polarity is generated by the different composition of the luminal and contraluminal cell membrane with regard to transport systems.
- These transport systems are either primary active transport systems, in which the translocation of the solute is directly coupled to ATP hydrolysis, or secondary or even tertiary active transport systems, in which (electrochemical) gradients of inorganic ions (mostly Na<sup>+</sup>) or organic molecules (mostly metabolites) are coupled to the symport or antiport of other solutes.
- The membranes also differ in the presence and activity of channels for inorganic anions, inorganic cations, and organic molecules.
- The polarity between the two membranes is more evident in epithelia than in endothelia, although similar transport systems are involved.
- Transport through the paracellular pathway is governed by passive driving forces.
- The paracellular pathway exhibits major differences between endothelia and epithelia; those most evident are the fenestrae in endothelia, as contrasted to the tight junctions in epithelia, and the presence of desmosomes in the latter.
- The prediction of the direction of flow in endothelia is complicated by the low asymmetry of the cells, the presence of multiple transport systems (in particular for amino acids), the lack of knowledge concerning the chemical and electrical driving forces, and the occurrence of significant paracellular movements.

**Future Goals**

- To study all these parameters in parallel at the same point in time and space to make possible predictions on the transport rates and transport routes

- To understand the mechanisms of transfer of organic compounds across EC layers – in particular therapeutic drugs in the brain – which could lead to important progress in the treatment of disease

# Electron Microscopic–Facilitated Understanding of Endothelial Cell Biology

## Contributions Established during the 1950s and 1960s

---

Ann M. Dvorak

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The application of electron microscopy to biological research initially required intensive investigation directed toward improvements in instrumentation and specimen preparation. As these investigations progressed, ultrastructural descriptions of the cell, different cells, and subcellular organelles common to cells and those which are distinctive of specific cell lineages emerged. Application of ultrastructural studies to the endothelium facilitated understanding of endothelial cell (EC) biology. In this chapter, we review the contributions of electron microscopy to this understanding, which was established during the 1950s and 1960s.<sup>1</sup>

### CONTRIBUTIONS ESTABLISHED DURING 1950–1959

The endothelium provides a physical barrier between the vascular lumen and the extravascular tissue space. All blood vessels are lined by interconnected ECs that comprise the endothelial layer. Before the electron microscope was developed, knowledge of EC structure and function was based primarily on physiological and light microscopic studies. One of the primary uses of the electron microscope was to confirm or deny the prevalent theories and findings obtained with these methods. Thus, by the late 1940s, physiologists had modeled the necessity for pores of small and large sizes in the endothe-

lium to explain permeability data (1), and light microscopic studies proposed an intercellular cement to account for the connection between adjacent ECs (2). As well as re-examining such issues with the electron microscope, studies proceeded on the anatomic organization, heterogeneity of different vascular beds, classification of types of microvessels, and description of individual cellular components of small vessels and of the organelle content of microvascular endothelium (3). Early studies using tracers to probe permeability possibilities began during the 1950s, as well as studies of the mediator-induced leaking vessels characteristic of inflammatory changes involving small vessels (4).

### Ultrastructural Description of the Endothelium

Defining *capillary* to include any small blood vessel, *endothelium* to refer to the lining of any blood or lymphatic channel, and *EC* to be the cell lining such channels (3) set the operational parameters for ultrastructural studies during the 1950s. Further refinement of these definitions included the size of vessels and their investiture with smooth muscle cells, pericytes (5), and elastic tissue, thus separating the thin-walled, small, smooth muscle cell-free capillaries from the larger, smooth muscle- and elastica-encased arterioles. Large venules with variable areas of thin and thick endothelium and pericyte investiture were also distinguished by electron microscopy.

Electron microscopists examined vessels from multiple organ sites and established that the microvasculature was of several characteristic types. These were classified as continuous (with or without large fenestrae) or discontinuous (3). These characterizations have held up over time, and such vessels typically can be found in different vascular beds. For example, discontinuous endothelium has large openings between individual ECs and is typified by sinusoid endothelium in the liver; continuous fenestrated endothelium is found in endocrine

<sup>1</sup> This review covers two decades (1950–1969) that were instrumental to defining the ultrastructural anatomy of ECs. These studies provided the background for an explosion of information made possible by the ultrastructural studies regarding EC biology spanning 1970–2005, which are not covered here. Some later electron microscopic studies done in the author's laboratory during the past 10 years directly answer questions raised by the early studies and are referenced here. The apparent gap in citations of ultrastructural work (1970–2005) reflects only the assignment and space constraints. Electron microscopists continue to enrich our knowledge of EC biology and will certainly continue to do so in the future.

Figure 71.1. EC plasmalemmal vesicles. (A) Mouse skin capillary EC shows PVs attached to the luminal (*L*) and abluminal plasma membranes. Free and membrane-bound ribosomes and a mitochondria (*M*) fill in the central cytoplasm. Some PVs display elongated, narrow necks that connect them to the surfaces of this EC (*arrows*). (B) Guinea pig skin capillary PV (intravenous anionic ferritin) shows a thin diaphragm closing the luminal (*L*) aspect of this flask-shaped structure attached by a narrow neck to the plasma membrane. Ferritin is plentiful within the vessel lumen; several ferritin particles have entered the PV through a stoma (*s*) (*outlined with a dotted line in this unstained image*). (C) Mouse skin capillary PV (intravenous cationized ferritin, sample obtained 30 minutes after local exposure to serotonin) shows numerous electron-dense cationized ferritin particles bound to the luminal surface of a PV diaphragm, which restricts entry of the tracer into the PV. (D) Mouse skin microvessel EC in an induced angiogenic site and prepared with an immunogold method shows silver-enhanced gold particles indicating vascular endothelial growth factor receptor 2 (VEGFR2) in a PV attached to the luminal plasma membrane. A large coated pit is also similarly attached but is not labeled (*arrow*). *L*, lumen. (A)  $\times 109,000$ ; (B)  $\times 210,000$ ; (C)  $\times 137,000$ ; (D) Bar = 140 nm. (A, B, and C are reproduced with permission from Feng D, Nagy JA, Dvorak HF, Dvorak AM. Ultrastructural studies define soluble macromolecular, particulate, and cellular trans-EC pathways in venules, lymphatic vessels, and tumor-associated microvessels in man and animals. *Microsc Res Tech.* 2002;57:289–326. Figure D is reproduced with permission from Feng D, Nagy JA, Brekken RA, et al. Ultrastructural localization of the vascular permeability factor/vascular endothelial growth factor (VPF/VEGF) receptor-2 (FLK-1, KDR) in normal mouse kidney and in the hyperpermeable vessels induced by VPF/VEGF-expressing tumors and adenoviral vectors. *J Histochem Cytochem* 2000;48:545–556.)

organs and continuous nonfenestrated endothelium lines skin vessels.

The increased resolution afforded by the electron microscope allowed a description of EC organelles. Thus, the first description was possible of EC plasmalemmal vesicles (caveolae) (Figure 71.1) attached to luminal and abluminal sur-

faces and apparently free in the cytoplasm of ECs (6,7). Other organelles described included mitochondria, Golgi apparatus, dense bodies, endoplasmic reticulum, and intracellular fibrils (6). A basement membrane composed of a feltwork of 10-nm fine fibrils was shown to encase the abluminal endothelial surface (6).

Areas of contact between adjacent ECs were described as specialized attachments that served as barriers between the vessel lumen and the perivascular space (6), heralding future studies that definitively describe EC junctions (discussed in the next section).

### Where Is the Cement?

Starling (8) thought that “cracks between ECs filled with cement” were probable leakage sites for fluid escaping from the vascular lumen. During the 1940s, intercellular cement between ECs was in vogue (2), and changes in this cement were implicated as a mechanism for vascular leakage. Electron microscopists working during the 1950s, however, did not find any intercellular cement (9), thus refuting the idea of filtration slits between ECs.

### Where Are the Holes?

During the late 1940s, physiologists modeled capillary permeability and proposed a “pore theory” for capillary leakage (1). This model stipulated that endothelia, of necessity, must be perforated by pores of essentially two sizes, termed *large pores and small pores* (1). Enter the new field of electron microscopy during the 1950s, and a considerable effort to find these pores ensued. Pores of the dimensions postulated were not found by electron microscopists to perforate endothelium (3). Subsequent efforts by electron microscopists began to investigate further the possible role(s) of plasmalemmal vesicles and/or interendothelial attachments within the controlled, known permeability properties and barrier functions of the endothelium.

### What about Inflammation?

As electron microscopists examined the microvasculature in search of static holes in the endothelium, to prove physiological principles and implicate the endothelium as an inert barrier to fluid exchange dictated by pore size, and failed to do so, others used the electron microscope to investigate the role of endothelial changes in inflammation typified by increased permeability (4). These early electron microscopic studies used colloidal particles (mercuric sulfide variably sized from 5 to 25 nm) as a tracer for permeability pathway(s) across dermal capillaries topically exposed to histamine (4). Although the image quality was hampered by primary osmium fixation, embedment in methacrylate, and sectioning with glass knives, some conclusions were possible. Thus, a transendothelial cell pathway for leakage of colloidal particles was found, rather than a paraendothelial cell pathway, and those EC organelles

Figure 71.2. Weibel-Palade body. An elongated WPB (*closed arrowhead*) oriented at a right angle to the EC apical plasma membrane and vascular lumen (L) of a tumor-associated venule in a human diaphragm sample. Note that the WPB is enveloped by a membrane and is filled with small tubules. Most of the tubules are located longitudinally; a few are seen in cross-section. Also evident in this photo is a VVO (*open arrowhead*) attached to the plasma membrane. This cluster shows four vesicles connected by knobbed diaphragms, necks, and stomata,  $\times 95,000$ . (Reproduced with permission from Dvorak AM. Weibel-Palade body. *Blood* 1996;87:409.)

in the cytoplasm containing tracer were all membrane-bound, including vesicles, folds, clefts, and caveolae (plasmalemmal vesicles). Of particular interest, despite exposure to histamine and the rapid onset of edema at the injection site, electron microscopic examination of inter-EC attachments showed no widening or gap formation in kinetically acquired samples (4). Moreover, no holes were found in the continuous endothelium lining these vessels.

However, complex intracytoplasmic membrane-bound structures honeycombed the endothelial cytoplasm in histamine-treated vessels. Some of the vesicles comprising these structures were as large as 200 nm in diameter. Rarely, perforating channels containing tracer were noted and interpreted to be cytoplasmic membranous structures rather than altered intercellular junctions, because no thickenings of the membrane, contacts, or attachment belts were associated with them (4). During the 1950s, these early electron microscopic descriptions of permeability pathways in inflammation involving skin microvessels served as a prelude to the electron microscopic studies of the 1960s, which discovered tracer-filled plasmalemmal vesicle transport across ECs (10). During the 1990s,

Figure 71.3. Fenestrated endothelium. In A, fenestrated endothelium lines a tumor-associated microvessel from the same sample imaged in Figure 71.2. Note that the thin endothelium is periodically perforated by large diaphragm-guarded fenestrae (*arrows*). By contrast, the capillary in B, from a mouse peritoneal sample, is not fenestrated. The EC contains numerous PVs, most of which are attached to the abluminal plasma membrane. Note the short, closely apposed lateral endothelial borders, which also show focal adherens junctions. C, a sample similar to B, shows a venule, also from a nonfenestrated microvessel, that has a thicker endothelium than that in panels A and B, filled with a VVO between two adherens junctions involving three ECs. L, lumen. (A)  $\times 66,000$ ; (B)  $\times 53,000$ ; (C)  $\times 70,500$ .

discoveries were made, using sophisticated instrumentation, ultrathin serial sections, tracer technology, and computer-assisted three dimensional reconstructions to clarify EC cytoplasmic vesiculo-vacuolar organelles (VVOs) as a permeability pathway between the blood vascular space and the extravascular compartment (11,12).

#### CONTRIBUTIONS ESTABLISHED DURING 1960–1969

By the end of the 1950s, electron microscopic studies had largely established the ultrastructural components and organization of capillaries, arterioles, and venules. The array of endothelial organelles identified in the microcirculation included the first description of plasmalemmal vesicles (see Figure 71.1) (6), and early tracer experiments of allergic inflammation defined a transcellular pathway for leakage through ECs (4) and, as proposed earlier (6) possible transcellular transport via plasmalemmal vesicles (4). Importantly,

Figure 71.4. EC lateral borders. Mouse skin samples imaged using routine ultrastructural methods after intravenous injection of colloidal carbon. (Note, in all three panels, carbon particles are present in the vessel lumen but not in ECs or in extravascular tissues). The lateral plasma membranes of ECs are closely apposed and, in these medium-magnification images, areas of occludens and adherens junctions show enhanced electron density and are located in the apical one-third of the lateral borders (*open arrowheads*). In **A**, a coated vesicle is attached to the lateral plasma membrane (*straight arrow*) of one EC beneath the specialized junctional complexes and the widened intercellular cleft (*curved arrow*). In **B**, elongated EC flaps (also called marginal folds) guarding the lateral border of two ECs protrude into the vessel lumen (*closed arrowhead*). In **C**, an interconnected cluster of vesicles (*closed arrowhead*) spans the cytoplasm of one EC from immediately below the occludens junction (also called the tight junction; *open arrowhead*) from the lateral plasma membrane to the abluminal (also called basilar) plasma membrane. This structure has been termed the EC VVO. (See text and Ref. 11). L, lumen. (A)  $\times 37,000$ ; (B)  $\times 22,000$ ; (C)  $\times 28,000$ .

the new imaging capabilities definitively denied the existence of intercellular cement (2) and static EC pores (1). During the 1960s, these findings in aggregate fueled the search (and development of tools to facilitate this search) for permeability pathways in the microcirculation (13–41). The extensive morphological studies of the 1960s also provided the first description of a new EC-specific organelle, the Weibel-Palade body (Figure 71.2) (42), a more complete description of inter-EC junctions (3,15–18,43–47) and EC suborganellar characteristics that define plasmalemmal vesicles (see Figure 71.1) (19–23,44,48), and EC fenestrae (Figure 71.3) (23,48,49). In addition, both the fluid phase and the cellular phase of acute inflammation were probed by electron microscopists to better understand possible pathways of egress from vessels during acute inflammatory reactions (24–26,50–55).

#### More about the General Anatomy of Endothelial Cells

As the electron microscopes of the world were turned on, more and more cellular organelles and specializations were

Figure 71.5. Lateral borders of unstained ECs processed using a potassium ferrocyanide-reduced osmium postfixation step. Mouse (**A**), guinea pig (**B**, **D**), and rat (**C**). Skin samples were taken after anionic ferritin was given intravenously in animals receiving skin injections of saline (**A**), histamine (**B**, **D**), or VEGF (**C**). With this method and magnification, the lateral plasma membranes are electron dense, allowing visualization of the closeness of membranes in the occludens junctions (**A**, **B** *arrowheads*). The subadjacent cytoplasmic densities associated with adherens junctions are poorly visible with this method, thus allowing better imaging of the tight junctional areas. Ferritin is visible in the lumens of vessels (**A–C**). In **A**, a single PV (*arrow*) is attached to the lateral membrane of one EC. In **B**, two clusters of vesicles (*arrows*) are similarly attached. In **C**, PVs contain ferritin—one has fused with the lateral border of one EC, and extravasated ferritin lies in the extravascular space below. In **D**, a vesicle cluster (VVO) connected to the lateral border of one EC shows diaphragms, stomata, and necks. The stomata and necks contain ferritin, and the entire structure connects the lateral and basilar (also called abluminal) plasma membranes of this EC. (A)  $\times 107,000$ ; (B)  $\times 99,000$ ; (C)  $\times 155,000$ ; (D)  $\times 120,000$ .

defined generally. Many of these also were recorded in ECs. Thus, in addition to those described during the 1950s, EC structures defined during the 1960s included an endocapillary layer stained with ruthenium red (56,57); EC flaps or marginal folds, guarding primarily the luminal introit to the aligned lateral EC borders (Figure 71.4) (37,44,46,47,58,59) (structures found to contribute to ingestion by ECs [17,51]); coated vesicles (Figures 71.1 and 71.4) (22,44,47); membrane-bound lysosome-like dense bodies (56,58,60–64); multivesicular bodies (37,38,47,56,61–66); mitochondria (61,62); Golgi

apparatus (61,62); endoplasmic reticulum (61,62); ribosomes (61,62); centrioles (62); cytoplasmic filaments (60,65,67,68); microtubules (47,69,70); and lipid droplets (56,71,72).

### Identification of a New Endothelial Cell-Specific Organelle by Electron Microscopy

The high-resolution analyses made possible by electron microscopy allowed electron microscopists to peer inside EC organelles and, in so doing, to describe an entirely new organelle that is unique to ECs (42). This organelle, an elongated, tightly membrane-bound, small, tubule-packed structure was named the Weibel-Palade body (Figure 71.2) for its discoverers (42). Several other early microscopists also noted differences between the Weibel-Palade body and other EC organelles (47,56). This EC-specific organelle has become the ultrastructural gold standard for the identification of ECs and is now known to play a key role in EC biology (73).

### Inside the Fenestra

The term *fenestra* was initially used to define the unique opening in the type of thin endothelium that obtained its name from the presence of these fenestrae – that is, fenestrated endothelium (see Figure 71.3) (14,17,20,22,23,28,33,35,39,47–49,62,74). These relatively large endothelial openings were found generally to be guarded by a single, thin electron-dense membrane called a diaphragm and to display an electron-dense knob in the center of this diaphragm (49). Some microvascular beds were said to have open fenestrae (no diaphragms) (28) but, as technology improved, most microvascular beds (including those in the kidney, which displayed fenestrated endothelia) were shown to have fenestrae closed by diaphragms (17,22,48,49). Good preparations imaged en face at high magnification showed radial striations proceeding from the central knobs to fenestral edges (23).

### Inside the Plasmalemmal Vesicle

EC plasmalemmal vesicles (PVs), also known as pinocytotic vesicles and caveolae, could well be called Palade vesicles in recognition of Dr. Palade's original description of them in 1953 (6). These small, flask-shaped structures are located attached to all three borders of ECs, as well as apparently free in the cytoplasm (Figures 71.1 and 71.3) (6,14–23,29,33,35,44,46–49,59–62,65,75). These locations and their anatomy inspired the hypothesis that they could participate in the transfer of material from the vascular lumina to the extracellular space (6) (discussed in the next section). Ultrastructural studies have defined those unique characteristics of PVs (see Figure 71.1) (14–23,29,35,44,46–49,56,59,61) that have proven useful in the recognition of PVs as participants in chain and cluster formations with permeability properties (76,77). PVs attached to luminal, lateral, or abluminal plasma membranes show constrictions at these attachments where a thin single membrane, also called a diaphragm, closes the vesicle opening. These

Figure 71.6. Colloidal carbon-filled trans-EC pores in a venule of rat cremaster muscle. Colloidal carbon was injected intravenously and tissue was harvested 1 min after local injection of 50 ng VPF/VEGF. *Left*, A–G illustrate sections 29 through 35 from a series of 41 consecutive 100-nm thick serial sections. *Right*, corresponding tracings of EC plasma membranes. Two transcellular pores are encompassed in these seven serial sections. The left and smaller pore illustrated only in C (*small star*) passes through a single EC (labeled 2). The diameter of this pore was <100 nm, and it was encompassed entirely within a single section (C); therefore, the tracing of section C (*right panel*) does not indicate a complete transendothelial opening because it traces plasma membrane superficial and deep to the pore. The larger pore (*large star*, C) crosses through portions of two overlapping ECs (labeled 1 and 2) in C and D. A VVO (V) that extends across EC 1 is followed in sections A–F; in D, carbon particles are present in a portion of this structure that opens to the endothelial ablumen (*open arrow*). The intercellular cleft and occludens-type junctions (*arrows*) joining the two ECs are closed normally at all levels. Note that, in the course of these serial sections, EC 1, which is luminal in A–C, dips beneath EC 2 in D–G; i.e., peripheral portions of the two ECs interdigitate, forming a woven pattern. L, lumen; P, pericyte. Scale bar (applies to A–G), 0.6  $\mu$ m. (Reproduced with permission from Feng D, Nagy JA, Hipp J, et al. Reinterpretation of EC gaps induced by vasoactive mediators in guinea-pig, mouse and rat: many are transcellular pores. *J Physiol*. 1997;504:747–761.)

Figure 71.7. Computer-generated 3-D reconstruction of the pores illustrated in Figure 71.6. Panels represent successive rotations toward the viewer around a horizontal axis at the angles indicated. 0 degrees (not shown) corresponds to a vascular cross-section taken at right angles to the direction of blood flow and a 90-degree view looking down on the luminal surface; views  $\geq 240$  degrees illustrate the abluminal surface. ECs 1 and 2 represent cells correspondingly numbered in Figure 71.6. Left panel includes extravasating carbon, which is represented in black. Middle panel illustrates views corresponding to those in left panel, except that carbon was deleted from the reconstruction to facilitate visualization of the pore interior. In the right panel, the overlapping ECs are viewed separately. Two trans-EC pores are illustrated. The smaller (*left*) pore extends to the albumen by passing through only EC 2 and corresponds to the pore marked by the smaller star in Figure 71.6C; background is visible from both luminal (e.g., 90-degree) and abluminal (e.g., 240-degree) views. The larger pore passes through overlapping portions of both ECs 1 and 2 and corresponds to the pore designated by the large star in Figure 71.6C. Abluminal views (*left panel*, 240 degrees and 300 degrees) illustrate carbon present within abluminal portions of cell 1, corresponding to the carbon-containing VVO illustrated in Figure 71.6D. Note (*middle panels*, 240- and 300-degree views, here and for Figure 71.6D) that carbon does not extend through the entire thickness of cell 1. L, lumen. (Reproduced with permission from Feng D, Nagy JA, Hipp J, et al. Reinterpretation of EC gaps induced by vasoactive mediators in guinea-pig, mouse and rat: many are transcellular pores. *J Physiol.* 1997;504:747–761.) For color reproduction, see Color Plate 71.7.

diaphragms (also discussed in Chapter 72) also show central electron-dense knobs and radiating striations from the knobs to the vesicle edges. Various elongated narrow necks attach vesicles to the plasma membranes.

The openings to PVs have variously been called *mouths*, *stomata*, *fenestrae*, and *apertures* (Figure 71.1). The unfortunate use of the term *fenestrae* to indicate these narrow, circular openings into PVs provides for possible confusion with their larger counterpart, also termed *fenestrae*, which typify fenestrated endothelium (see Figure 71.3) (as discussed earlier). We prefer to designate the openings into PVs as *stomata* and call attention to their similarity to the fenestrae of fenestrated endothelia, which also are guarded by knobbed diaphragms. An interesting property of PV stomata is their multiplicity. That is, individual PVs may display single, double, or many stomata, thus providing necessary connection points for the formation of small chains or large clusters of interconnected PVs in the endothelium (76,77).

This electron microscopic definition of the substructure of PVs during the 1950s and 1960s facilitated the recognition

of interconnected chains of PVs during the 1970s (76) and clusters of PVs and larger vacuoles (VVOs) during the 1990s (11,77).

### Junctionology

Originally, cells were thought to be surrounded by a cement that bound them together (2). The use of electron microscopy showed this not to be true and, early on, microscopists used a number of terms to allude to inter-EC connections. ECs are polarized cells with apical, basilar, and lateral borders. Intercellular connections populate the lateral borders, which in simple capillary endothelia are short, straight, and easier to study than the complex interdigitating and overlapped lateral borders of ECs in venules (78). Some of the terms used to describe lateral-border EC anatomy (see Figures 71.3 through 71.5) include attachment belts (2,3,28,59,62,79), adhesion plates (28,29), intercellular clefts (15,17,35,41,47), intercellular junctions (not otherwise specified) (39), interlocking inter-EC processes (78), quintuple-layered membrane junctions at

Figure 71.8. Control mouse skin venule. Numerous collections of cytoplasmic vesicles and vacuoles constitute the vesiculo-vacuolar organelle (VVO) (*open arrowheads*). Note that the inter-EC lateral borders show complex interdigitations; electron-dense tight and adherens junctions are located near the luminal aspect of the lateral borders of ECs (*closed arrowheads*),  $\times 21,500$ . (Reproduced with permission from Feng D, Nagy JA, Dvorak HF, Dvorak AM. Ultrastructural studies define soluble macromolecular, particulate, and cellular trans-EC pathways in venules, lymphatic vessels, and tumor-associated microvessels in man and animals. *Microsc Res Tech.* 2002;57:289–326.)

terminal bars (43), occludens junctions (tight junctions), and adherens junctions (15,16,23,44,46,47,61–63,65,67). Of these terms, the originally described quintuple-layered membrane junctions of Muir and Peters (43) also are known as occludens junctions and as tight junctions in EC lateral borders. They generally are located nearer to the apical surface than to the basilar surface, and they can be recognized by closely apposed membranes of variable lengths. The adherens junction, also seen between the lateral borders of ECs, has an intercellular space; straight, apposed membranes; and a dense condensation of the subjacent cytoplasm in each cell. The ultrastructural nomenclature for these specializations of EC lateral borders follows that originally defined for epithelial cells (45). The occludens (tight) and adherens junctions of ECs are structurally resemble those in epithelia. ECs (like some simple epithelial cells) do not display desmosomes.

Because inter-EC junctions (generally in capillaries) were studied using high magnifications and with a few partial series of sections, some favored that the junctions were closed by fused membranes, and others that they were narrowly open between the apposed lateral membranes (15,17,43,44). In fact, images reflecting both these situations are available that demonstrate the actual “tightness” of tight junctions.

Although electron microscopists have made great contributions to our understanding of inter-EC junctions, one should keep in mind that most studies were done in capillaries, not in the more complex venular lateral borders (78). Also, because the correct terminology has been provided for these specialized attachments, these terms should be used appropriately. That is, either an occludens (tight) (Figures 71.4 and 71.5) or adherens (Figure 71.4) junction can be called an inter-EC junction and both (as well as multiples of each) can be

Figure 71.9. Control mouse skin venule EC shows portions of a VVO near the lumen (L). Individual vesicles and vacuoles are connected by thin diaphragms (*closed arrow*) and display electron-lucent stomata, many of which contain a central electron-dense knob (*arrowhead*). Numerous ribosomes fill the cytoplasm.  $\times 109,000$ . (Reproduced with permission from Feng D, Nagy JA, Dvorak HF, Dvorak AM. Ultrastructural studies define soluble macromolecular, particulate, and cellular trans-EC pathways in venules, lymphatic vessels, and tumor-associated microvessels in man and animals. *Microsc Res Tech.* 2002;57:289–326.)

found separated by wider spaces between any given pair of ECs. These spaces have been referred to correctly as clefts, intercellular spaces, and sometimes as “gaps” (see Figures 71.4 and 71.5) (15,17,35,41,47). However, since the classic papers appeared (15,17,43–45), a vast literature has emerged that misuse the term *EC junction*. That is, *cell junction* is all too often used to refer to any portion or all of the EC lateral border (Figures 71.4 and 71.5). Based on the contributions of electron microscopy carried out during the 1960s, it is appropriate to use the terms *lateral borders* and *intercellular clefts*, reserving the usage of *junction* to indicate only the focal, specialized areas of adherens and occludens junctions regularly present between ECs at their lateral borders (see Figures 71.4 and 71.5).

### Vesicular Transport

Plasmalemmal vesicles (also termed *pinocytotic vesicles*, *Palade vesicles*, or *caveolae*) are uniquely constructed and located to fill, fuse, and move between the three cell surfaces that comprise ECs (Figure 71.5) (6,21,22,29,34,44). Most reports of capillary endothelium find them attached to the plasma membranes of the basilar, apical, lateral borders. Some appeared to be free in the cytoplasm in the standard 70- to

Figure 71.10. Two consecutive ultrathin (12 nm) sections, from a series of 61, of a control mouse skin venule. The mouse had been injected intravenously with ferritin 5 min prior to sacrifice and intradermally with HBSS 1 min prior to sacrifice. Together these sections demonstrate direct, open communication between VVOs present in adjacent ECs. A vesicle (A) in the left-hand cell connects with the intercellular cleft which, in turn, connects successively with vesicles and vacuoles (B–G) in the right-hand cell. Diaphragms close the stomata, linking some adjacent vesicles/vacuoles (for example, B–C, C–D, and D–F in panel B). Closed arrows indicate area of tight junction near the luminal surfaces. Scattered FE particles are present in the vascular lumen (L) and in the vesicle (open arrow) immediately above vesicle labeled B. R, red blood cell; BL, basal lamina. (A, B)  $\times 88,000$ , scale bar =  $0.2 \mu\text{m}$ . (Reproduced with permission from Feng D, Nagy JA, Hipp J, et al. Reinterpretation of EC gaps induced by vasoactive mediators in guinea-pig, mouse and rat: many are transcellular pores. *J Physiol.* 1997;504:747–761.)

80-nm single sections used for viewing by electron microscopy during the 1960s.

The utility of PVs for transendothelial transport first envisioned by Palade (6) was also first tested by Palade using 3- to 25-nm gold particles (27). He showed that colloidal gold injected intravenously entered vesicles attached to the luminal front, increased with time after injection, and later was found in the perivascular space. Gold particles were not present free in the cytoplasm of ECs and did not enter intercellular spaces (27).

Palade's group used another electron-dense tracer, ferritin ( $\sim 11$  nm), to image vesicle transport in capillary ECs (see Figures 71.1 and 71.5) (14). As with the gold tracer, PVs on both luminal and abluminal EC borders contained ferritin. Ferritin did not traverse interendothelial junctions (14). In an attempt to better understand vesicle connection possibilities in endothelia, Bruns and Palade (44) made a three-dimensional (3D) model in plastic of a short segment of capillary EC cytoplasm. The model was based on photographs of seven serial 50-nm sections. In this model, the authors found five vesicle pairs that were apparently fused. One set opened to the luminal front, another set to the abluminal front, and two sets did

not open to either surface in this model. From this, the authors concluded that vesicles were not interconnected in chains or clusters from surface to surface (44). Later studies have, however, demonstrated such interconnectedness (11,76).

The 1960s showed numerous efforts by electron microscopists to model vesicles in their transport roles across endothelia. Thus, vesicles were said to be capable of motion by random Brownian movement (21,31,36). Others noted that another EC vesicle system – coated vesicles (Figure 71.4) – avidly took up ferritin in tracer experiments, and that multivesicular bodies in the cytoplasm of ECs stored ferritin (56,63,64).

All together, the ultrastructural tracer experiments done during the 1960s provided evidence for the vesicular transport of macromolecular colloids and electron-dense enzymes into and through capillary ECs (14,15,17–19,23,35,41). As such, the suggestion that the vesicular transport properties imaged using tracers fulfilled the criteria for the large pore system of physiologists (1) gained favor (14). Some (14,23) envisioned future studies in which interconnected chains (76) and clusters (11,77) of vesicles would be demonstrated to have constrictions corresponding to diaphragm insertions at PV-like

Figure 71.11. Computer-generated 3-D reconstruction of portion of a venular VVO from mouse skin injected 5 min earlier with 50 ng VPF. The interior volumes of VVO vesicles and vacuoles in successive electron micrographs were traced onto transparent overlays with reference marks to retain register. Tracings were digitized at a resolution of 5.9 nm/pixel. Because section thickness (15 nm) was greater than in-plane resolution, bicubic interpolation was performed between sections, and convolutions were used to smooth surfaces. (A–F) Portion of a VVO (15 consecutive serial, ultrathin EM sections illustrating 25 individual vesicles-vacuoles) reconstructed using Advanced Visual Systems (Waltham, MA) Software, here viewed in successive rotations around a horizontal axis at intervals of 30 degrees (except 15 degrees, [C–D]). There are two openings (E, F) to the vascular lumen and four to the abluminal surface (A). (Reproduced with permission from Feng D, Nagy JA, Hipp J, et al. Vesiculo-vacuolar organelles and the regulation of venule permeability to macromolecules by vascular permeability factor, histamine and serotonin. *J Exp Med.* 1996;183:1981–1986.) For color reproduction, see Color Plate 71.11.

necks (11,76,77). These constrictions within the fused vesicles and vacuoles could account for the small pore system of physiologists (1).

### Junctional Transport

During the 1960s, a new era of ultrastructural studies was ushered in by the development of smaller probes for the investigation of EC permeability pathways (32,33). These studies made use of injected enzymes (horseradish peroxidase [HRP] was the prototype) that are rendered electron dense by an enzyme reaction and an affinity for osmium (32,3). Use of this approximately 4- to 5-nm probe with timed collection of samples after intravenous injections provided a potential probe for the physiologist's small pores. All together, this probe clearly entered the intercellular clefts, permeated the ~4-nm gaps in the EC tight junctions, and filled PVs in capillaries of muscle origin

Figure 71.12. Electron microscopic tracer studies of trans-EC leakage through VVOs of mouse tumor microvascular ECs. (A) At 10 sec after IV injection of HRP, the electron-dense tracer fills the vessel lumen and a cytoplasmic VVO, which has released a small amount to the basal lamina focally (*open arrowhead*). The inter-EC junction (*closed arrowhead*) does not contain HRP. Bar = 260 nm. (B) A tumor EC VVO connected to the abluminal surface shows an open, HRP-containing stoma. The abluminal surface of the EC plasma membrane is focally stained with HRP beneath this cell; the basal lamina (*arrow*) remains unstained. Bar = 80 nm. (C) At 10 sec after IV HRP, several vesicles in this VVO contain electron-dense HRP, similar in intensity to the overlying HRP-filled vessel lumen. One HRP-loaded vesicle (*arrowhead*) is fused with the abluminal plasma membrane and has released a cloud of HRP focally into the underlying basal lamina and surrounding connective tissue. Bar = 154 nm. (D) At 30 min after IV injection of anionic ferritin, a VVO vesicle stoma at the basilar EC front is filled with ferritin particles. Individual ferritin particles (*arrows*) have dispersed widely in the extracellular matrix beneath this EC. Bar = 63 nm. (Reproduced with permission from Dvorak AM, Kohn S, Morgan ES, et al. The vesiculo-vacuolar organelle (VVO): a distinct endothelial cell structure that provides a transcellular pathway for macromolecular extravasation. *J Leukoc Biol.* 1996;59:100–115.)

Figure 71.13. Mediator-induced VVO leakage demonstrated with FE in control skin venules. (A) Extravasation of FE by way of VVOs in guinea pig skin venules 20 min after intradermal injection of VPF/VEGF or (B) 10 min later in response to an intradermal injection of histamine. (A) Note FE particles entering VVO vesicles-vacuoles that open to the vascular lumen (V); (B) FE has progressed to mid-cytoplasmic VVO components. A few FE particles have spilled into the subendothelial spaces in (A, B). (A)  $\times 109,000$ ; (B)  $\times 111,000$ . (Reproduced with permission from Feng D, Nagy JA, Pyne K, et al. Pathways of macromolecular extravasation across microvascular endothelium in response to VPF/VEGF and other vasoactive mediators. *Microcirculation*. 1999;6:23–44.)

(15,17,19,41). Similar studies of brain microvessels, which are normally poorly permeable, showed tracer in a vastly reduced PV population and none in tight junctions between ECs (16). In neither location in brain endothelium did HRP pass to the interstitium through the endothelial barrier (16).

During the 1960s, new tracer studies done using the prototypes ferritin and HRP lent credibility to the concept of endothelial holes that are important for permeability purposes. They also, however, drew further attention to the heterogeneity of vascular beds within an organ and between different organs, and to the necessity for future studies to probe these differences carefully.

## More about Inflammation

### Humoral Phase

Electron microscopists working during the 1960s tended to discount the earliest ultrastructural examination of the humoral phase of inflammation (4). In the early studies, changes involving the lateral endothelial borders or hole development through the cytoplasm of ECs were not found after direct exposure to histamine (4). Complex membrane-bound cytoplasmic intracytoplasmic structures were thought to supply a trans-EC pathway for stimulated macromolecular leakage in acute inflammation (4). Although a tracer (colloidal mercury) was used in the early study (4), during the 1950s, general technical considerations in electron microscopy sam-

Figure 71.14. Transmigration of a neutrophil (*n*) across a thinned portion of venular endothelium at 60 min after local intradermal injection of  $10^5$  M FMLP. Twelve sections (numbers 13, 14, 16, 19, 21, 24, 25, 27, 29, and 30–32) of a series of 74 consecutive serial sections are illustrated. Portions of the neutrophil's nucleus (E–G) are included within the pore. The pore passes through a single EC (*e1*), but a junction of *e1* and with a second EC, *e2*, is indicated (arrow); this junction is intact and maintained a distance of  $>1\mu\text{m}$  from the pore margin at all levels of sectioning. L = lumen. Bar =  $1\mu\text{m}$ . (Reproduced with permission from Feng D, Nagy JA, Pyne K, et al. Neutrophils emigrate from venules by a trans-EC pathway in response to FMLP. *J Exp Med*. 1998;187:903–915.)

ple preparations did not allow for the production of excellent images of skin. In 1961, another group initiated ultrastructural studies of acute inflammation and stated for the first time that histamine induced “dissecting aneurysms of the vessel wall,” otherwise referred to as *gap formation* (20). (These gaps are not to be confused with the use of this term to describe spaces that occur normally between the lateral borders of apposed ECs.) In inflammation, the newly developed gaps are said to develop as stimulated ECs pull apart, thus providing a gap for the egress of plasma (20).

At this point, the use of colloidal carbon as a tracer for vascular injury was applied to electron microscopy (Figures 71.4, 71.6, and 71.7; for color reproduction, see Color Plate 71.7) (24–26,40). In inflammation, these particles are sufficiently

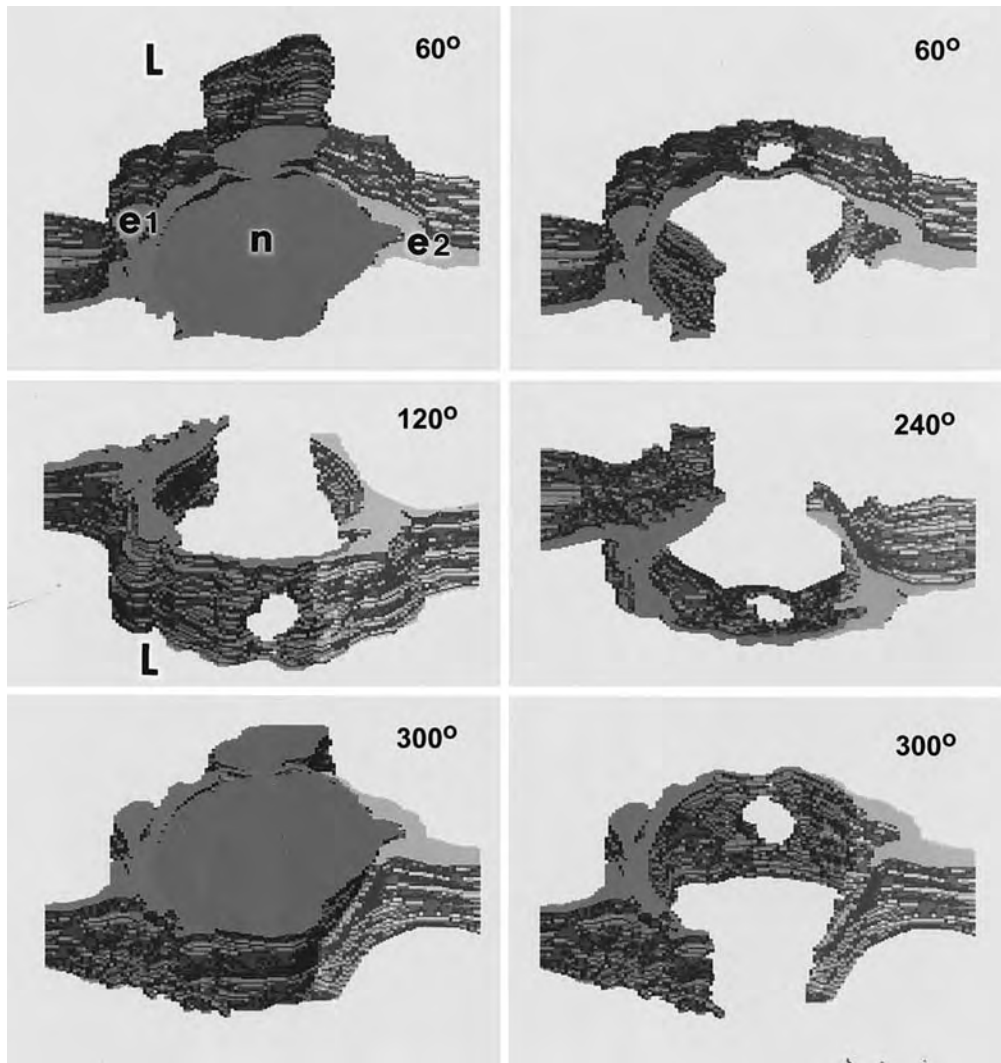

Figure 71.15. Computer-generated 3-D reconstruction of the transmigrating neutrophil illustrated in Figure 71.14. The panels portray successive rotations toward the viewer around a horizontal axis at angles of 60, 120, 240, and 300 degrees as indicated. 0 degrees (*not shown*) would represent a vascular cross-section at right angles to the direction of blood flow, and 90 degrees (*also not shown*) would represent a view looking directly down the luminal surface. Emigrating neutrophil (*n*) is in *upper and lower left*; in the other panels, the neutrophil was subtracted electronically to visualize the pore that passes cleanly through the cytoplasm of EC e1 distinctly apart from the junction of e1 with e2. Cytoplasmic arms of both e1 and e2 embrace the neutrophil luminally and, to a lesser extent, abluminally. L, lumen. (Reproduced with permission from Feng D, Nagy JA, Pyne K, et al. Neutrophils emigrate from venules by a trans-EC pathway in response to FMLP. *J Exp Med.* 1998;187:903–915.) For color reproduction, see Color Plate 71.15.

large that they accumulate at basement membranes after leaking from the vascular compartment. The carbon accumulations produce blackened vessels that are easily seen by light microscopy and can be selected for higher magnification studies by electron microscopy.

Electron microscopists, looking either at standard preparations or following intravenous injections of carbon, became convinced that ECs developed large gaps at their junctions through which carbon-containing macromolecular leakage occurred in inflammation (20,24–26,50). Use of the term *junction* in these cases generally referred to a separation at lateral

EC borders, not permeation through tight junctions. However, the mechanism of such gap formation remained obscure and, in some of the published studies, visible adherens and occludens junctions nearby are not leaking carbon. Clearly another approach was necessary. One group noted that nuclear pinches formed in the reactive ECs stimulated by histamine, and they postulated that the active contraction of ECs pulled them apart at “junctions,” thus allowing for the escape of vascular fluid (26). In one study, colocalized leaks of carbon and silver nitrate staining at cell “junctions” by light microscopy were said to provide proof of gap formation at intercellular junctions (24).

Figure 71.16. Neutrophil trans-EC migration in acute inflammation in guinea pig skin. The image represents section 19 of a consecutive series of 45 100-nm sections that encompassed the luminal pore through which the neutrophil is migrating in its entirety. Maximum pore size was  $0.75\ \mu\text{m}$ , 60 minutes after  $10^5\ \text{M}$  FMLP exposure. The nearest inter-EC junctions (*arrows*) are closed and are remote from the pore through which the neutrophil (*n1*) is transmigrating. A short, thin process projecting from *n1* is in contact with a second neutrophil (*n2*, below), which, beyond the area of this micrograph, has progressed through the basal lamina and underlying pericyte (*p*). Note pinches of EC (*e*) nucleus that appear to result from the compressing bulk of the adjacent neutrophil, not from gap formation at junctions. The thin rim of EC cytoplasm overlying *n1* and the bulging EC nucleus is relatively smooth, in contrast to surface endothelium to the right of the figure, which exhibits extensive wrinkling with extension of cytoplasmic processes into the vascular lumen and abluminally into the basal lamina. L = lumen. Bar =  $1\ \mu\text{m}$ .

The silver nitrate method, however, identifies the lateral borders of ECs, not just junctions. And, in the electron microscopic study, whereas nuclear pinches were quantifiably more numerous in histamine-stimulated samples than in controls, no convincing photographs of carbon-filled gap formation and nuclear pinches in the same cell were presented (26).

By the end of the 1960s, the electron microscopic studies seemed to be solidly accepted regarding the mechanism of mediator-induced vascular leaking (20,24–26,50). The ultimate resolution of where and how the leakage sites develop in ECs in acute inflammation would require large sets of serial sections and 3D computer reconstructions. These were done during the 1990s (Figures 71.6 and 71.7) and showed that carbon leaked through parajunctional and cytoplasmic trans-EC membrane-bound structures adjacent to unaltered lateral borders and adherens and occludens junctions (12,80). Also, exact replication of the cremaster model for examining histamine-induced vascular leakage (24,26) using ferritin as

a tracer and numerous large series of 12- to 14-nm sections allowed for 3-D reconstructions that showed macromolecular leakage through interconnected vesicles and vacuoles spanning endothelial cytoplasm, structures newly termed VVOs (Figures 71.3 through 71.5, and Figures 71.8 through 71.13; for color reproduction, see Color Plate 71.11) (11,12,81). Closed junctions were present and were not passing ferritin in this well-known model of acute inflammation (see Figure 71.5).

### Cellular Phase

Acute inflammation is typified by the enhanced leakage of plasma proteins followed by the diapedesis of circulating inflammatory cells through the wall of venules (24,68). The cellular phase of this process was the subject of electron microscopic studies during the 1960s. Numerically, polymorphonuclear cells (PMNs) dominate the cellular migration process in acute inflammation, and therefore their traffic route was the primary study objective in these studies (51–55). The question that was framed, but not answered completely, was: Did PMNs pass through the cytoplasm of ECs, or did they travel between ECs? In the early studies, virtually everybody suggested that PMNs might pass through the cytoplasm, but that this route was unproven in the absence of serial sections. One study was based on serial sections, although neither the thickness of sections nor the completeness of the series was given (53).

In this study, it was decided, based on one serial set, that PMNs could “pry open the ‘intercellular junction’ with an extended pseudopod and travel down the junction” (53). Upon this evidence, and since the 1960s, future investigations claim, but do not prove, that PMNs migrate down intercellular junctions. The important body of work during the 1960s (51–55) served to stimulate re-examination of this issue using extensive ultrastructural sets of serial sections and computer-assisted 3-D reconstructions (Figures 71.14 through 71.16) (12,82). In one model, the new studies established a trans-EC traffic route for PMNs through EC cytoplasm in acute inflammation. Nearby intercellular junctions and lateral EC borders were intact (Figures 71.14 through 71.16; for color reproduction, see Color Plate 71.15).

### CONCLUSION

Ultrastructural studies during the 1950s and 1960s greatly advanced the understanding of EC biology, including the correction of ideas developed earlier, without the use of the magnifications and resolution made possible by electron microscopes. The general anatomy of the microvasculature, described during the 1950s and 1960s, still stands today, and the identification of new organelles in ECs provided the rationale for future work. Vascular permeability routes through the endothelium in health and disease were probed with newly developed or applied tracers for electron microscopy. In all, a large body of work was accomplished with ever-improving instruments and methods, all of which provided powerful

stimuli for new electron microscopic studies of the endothelium that are still in progress.

## Weibel-Palade Bodies

### Vesicular Trafficking on the Vascular Highway

Charles J. Lowenstein, Craig N. Morrell, and Munekazu Yamakuchi

*The Johns Hopkins University School of Medicine, Baltimore, Maryland*

Edward Weibel and George Palade made a remarkable discovery in 1964. Surveying human lungs with an electron microscope, they saw a “hitherto unknown rod-shaped cytoplasmic component . . . in endothelial cells of small arteries” (1). These rods, measuring 0.1  $\mu\text{m}$  thick and 3  $\mu\text{m}$  in length, contained dense material organized as fibers running parallel to the long axis (Figure 72.1; for color reproduction, see Color Plate 72.1A). Weibel and Palade concluded that the “nature and significance of these cytoplasmic components are yet unknown.”

Over the last four decades, we have learned an enormous amount about these endothelial-specific organelles, now called Weibel-Palade bodies (WPBs). WPBs are regulated secretory granules. Within seconds of vascular injury, endothelial cells (ECs) activate the internal exocytic machinery, driving fusion of the WPBs with the cellular membrane. WPBs contain a variety of compounds that, once released into the blood, activate vascular inflammation and thrombosis (Figure 72.2). WPB exocytosis is the initial response of the vasculature to injury.

However, a number of intriguing questions about WPBs remain unanswered. Why are specific proteins targeted to enter the WPBs, whereas other cargo is excluded? How are WPBs directed to fuse with the plasma membrane and not with other organelles? Which vascular beds contain the most endothelial granules, and why? Finally, are endothelial granules capable of plasticity? Do the contents of these WPBs change as their environment changes, giving the ECs the ability to alter their response as their own environment changes, thus reflecting a vascular memory?

#### CONTENTS OF WEIBEL-PALADE BODIES

WPBs contain molecules that regulate thrombosis and inflammation, as well as other vascular regulators (Table 72.1). The predominant component of WPB is von Willebrand factor (vWF) (2). Within the EC, vWF forms dimers in the endoplasmic reticulum, multimers in the Golgi apparatus,

and then is either secreted from the cell via the constitutive pathway or stored in WPBs for subsequent secretion (3,4). The highest molecular weight vWF are preferentially incorporated into WPBs. Parallel bundles of vWF form the striations within endothelial granules first seen by Weibel and Palade (4). WPB exocytosis releases multimeric vWF into the blood, where it is cleaved by the metalloproteinase ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin type 1 repeats 13) (5). vWF mediates platelet adherence to collagen in the subendothelial space through its interactions with the platelet glycoprotein (GP) complex GPIb-IX-V; vWF also mediates platelet aggregation by interacting with activated GPIIb/IIIa on platelets (6). Humans and mice lacking vWF have defects in hemostasis (7). Although WPBs also may contain fibrinolytic mediators such as tissue-type plasminogen activator (t-PA) (8), activation of endothelial exocytosis induces immediate platelet adhesion to the endothelium mediated by vWF and its interaction with platelet P-selectin and platelet GPIb-IX-V (9,10). Thus, secretion of the WPB contents is prothrombotic.

WPBs also contain inflammatory mediators. P-selectin, the major endothelial receptor mediating leukocyte rolling, is stored in WPBs (11,12). P-selectin is a transmembrane protein, stored inside WPBs with its amino-terminal domain inside the granule, and its carboxy-terminal cytoplasmic tail in the cytoplasm. During exocytosis, P-selectin translocates from the granule to the external cellular surface. Its carboxy-terminal tail remains cytoplasmic, but its amino-terminal domain becomes extracellular, where it interacts with its ligand P-selectin glycoprotein ligand (PSGL)-1 on the surface of leukocytes, triggering leukocyte rolling along blood vessels. However, within 20 minutes of its externalization, P-selectin is removed from the cell surface by endocytosis, recycles to the lysosome or Golgi apparatus, and returns to the WPBs (13). Mice lacking P-selectin have decreased leukocyte recruitment to sites of injury (14). (In contrast to vWF release through both constitutive and secretory pathways, P-selectin is only released through granule exocytosis.) Exocytosis of WPBs is thus proinflammatory.

Figure 72.1. Weibel-Palade bodies in ECs. (A) Immunofluorescent images of ECs with nuclei stained blue and vWF stained green. (B) Electron microscopy of a human EC with boxed region expanded below. Bar = 200  $\mu$ m. (C) Electron microscopy of a WPB within a human EC (arrow shows WPB; bar = 200 nm). For color reproduction, see Color Plate 72.1A.

Additional molecules in WPBs regulate inflammation. Interleukin (IL)-8 is a C-X-C chemokine stored within WPBs (15,16). Stimulation of ECs with IL-1 $\beta$  or tumor necrosis factor (TNF)- $\alpha$  causes the accumulation of IL-8 within WPBs. Once released by exocytosis, IL-8 can activate neutrophil adhesion. WPBs thus contain separate molecules that activate distinct stages in leukocyte trafficking: P-selectin, which mediates leukocyte rolling; and IL-8, which induces leukocyte adhesion.

Another component of WPB is a member of the tetraspanin superfamily, CD63 (17). Tetraspanins are transmembrane proteins that promote a diverse array of neuronal and immune functions. The precise role of CD63 in WPBs is unknown. CD63 may play a role in the biogenesis of WPBs, fusion of WPBs with the plasma membrane, or extracellular signaling.

### PLATELET $\alpha$ -GRANULES VERSUS ENDOTHELIAL GRANULES

Because both platelet  $\alpha$ -granules and endothelial WPBs contain vWF and P-selectin, it is tempting to speculate that both granules contain similar components. However, platelet  $\alpha$ -granules may contain more types of proteins than do. WPBs. Approximately 15 proteins have been identified within WPBs (see Table 72-1). In contrast, a proteomic analysis described at

least 81 proteins released from thrombin stimulated platelets—although these proteins may be components of  $\alpha$ -granules, dense granules, lysosomal granules, or exosomes (18). The diversity of  $\alpha$ -granule proteins may be accounted for in part by the ability of platelets to take up various compounds from the blood and store them in granules. Nonetheless, a comparison of the components of endothelial and platelet granules will not be possible until a precise proteomic description of isolated granules is performed. Until such experiments are performed, additional clues to the composition of these granules can come from understanding how cargo is selected and loaded into granules.

### CARGO LOADING AND BIOGENESIS OF WEIBEL-PALADE BODIES

The earliest model for molecular sorting of specific proteins into WPBs suggested that WPBs are pre-existing organelles to which proteins are directed by signal sequences. This model was supported by studies showing that the 742-amino acid residue propeptide of vWF is necessary for the targeting of vWF to WPBs (4,19–24). In contrast, expression of the 2,050-amino acid residue mature vWF lacking the propeptide sequence leads to a cytoplasmic localization of vWF. Coexpression of the vWF propeptide and the mature vWF *in trans* leads to localization of the latter in granules. Furthermore, the vWF propeptide can direct a chimeric protein, consisting of the vWF propeptide fused to complement C3, into granules (23). In fact, expression of the vWF propeptide alone, without the mature vWF, also leads to granule localization of the propeptide (4). Thus, in the revised model, vWF propeptide directs vWF into WPBs.

The model for cargo sorting into WPBs has been extended by observations suggesting that cargo loading of WPBs and formation of WPBs are linked: The process of sorting proteins into the granule drives formation of the granule itself. Coat proteins play a dual role in granule biogenesis, not only

Figure 72.2. A variety of agonists trigger resting ECs to release the contents of WPB into the bloodstream.

**Table 72-1: Contents of WPB.**

<i>WPB Contents</i>	<i>Vascular Function</i>
vWF	Thrombosis
Factor XIIIa	Thrombosis
t-PA	Fibrinolysis
P-selectin (PADGEM, GMP-140)	Inflammation
IL-8	Inflammation
Eotaxin	Inflammation
$\alpha$ -1,3-fucosyltransferase VI	Inflammation
CD63 (Lamp3)	Unknown
Endothelin-1	Vasoconstriction
Endothelin converting enzyme	Vasoconstriction
Calcitonin gene-related peptide	Vasodilation
Angiotensin 2	Angiogenesis

catalyzing the budding of granules from donor trans-Golgi-derived membranes, but also sorting cargo proteins into granules. Coat proteins select diverse proteins for inclusion into granules through interactions between specific cargo proteins and multiple cargo-binding sites on the coat proteins (25–27). This model is supported by studies that show the vWF propeptide is necessary for formation of WPBs; however, the coat proteins associated with WPBs have not been identified. Ectopic expression of vWF propeptide leads to the formation of novel WPB-like granules in AtT-20 neuroendocrine cells that contain adrenocorticotropin secretory granules but normally lack WPBs (21). Conversely, WPBs are absent from mice deficient in vWF (28). In contrast, the *P-selectin*-knockout mice contain WPBs in their ECs (14). Collectively, these data imply that an unidentified coat protein in the trans-Golgi of ECs interacts with the vWF propeptide, simultaneously forming the WPBs while loading vWF into the nascent granule.

What determines the distribution of WPBs throughout the vascular tree? WPBs have been found in the vascular ECs of all organs, and throughout the vascular tree in arteries, capillaries, and veins (29). Because leukocyte trafficking often is detected in postcapillary venules, it might be expected that more WPBs are found here. However, a precise description of the distribution of WPBs is not available. The factors that initiate the biogenesis of WPBs or that regulate the number of WPBs within an individual EC are unknown.

What is the molecular basis for localizing WPBs within ECs? Presumably, WPBs are transported to specific subcellular locations, as are other cellular organelles, along microtubule tracks by a kinesin isoform. Although another molecular motor, dynein, may play a role in the subcellular localization of WPBs, the specific mechanisms of WPB transport are not well defined (30). In fact, the distribution of WPBs within ECs is not well characterized. However, the secretion of WPBs appears to be polarized. Approximately 90% of vWF is released through the basolateral surface of human umbilical vein ECs (HUVECs) *ex vivo* (31). We have also visualized the basolateral release of vWF during acute rejection of allografts *in vivo*

(32). The release of vWF and other components of WPBs into the subendothelial space is surprising, because many of these factors are thought to regulate leukocyte and platelet interactions with the endothelium. This polarized release of WPBs suggests that unknown mechanisms deliver WPBs to both the apical and the basolateral surfaces of ECs.

## THE EXOCYTIC MACHINERY OF ENDOTHELIAL CELLS

During endothelial exocytosis, the membrane of the WPB fuses with the cellular plasma membrane, releasing the contents of the granule out to the extracellular space. The endothelial proteins that drive fusion of the WPB with the cellular membrane are a subset of the vesicular trafficking proteins conserved in yeast, *Drosophila*, and mammalian cells. Granule exocytosis is a type of vesicle trafficking that involves a series of discrete stages: loading of cargo into the nascent vesicle, vesicle budding, targeting of the vesicle to its fusion partner, priming of the vesicle, membrane fusion, and, finally, vesicle recycling (Figure 72.3) (33–36). The families of proteins that mediate these steps include the Rab and Rab effectors, soluble N-ethylmaleimide sensitive factor receptor (SNARE) proteins, members of the Sec1/Munc18 protein family, and N-ethylmaleimide sensitive factor (NSF).

Rab proteins regulate vesicle tethering to target membranes. The Rab family member RalA associates with WPBs and is phosphorylated following activation of exocytosis (37–39). Rab27a associates with mature WPBs that contain vWF, but not with nascent WPBs lacking vWF (40). However, the

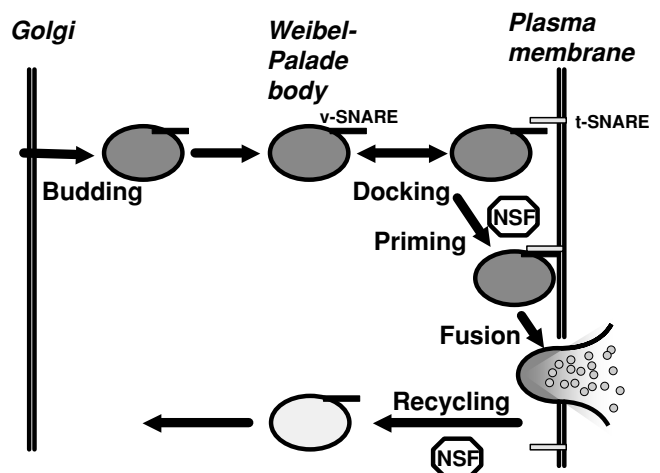

Figure 72.3. WPB and the cycle of vesicle trafficking. Granules bud off from the Golgi. Vesicle-SNARE (v-SNARE) proteins on the granule membrane interact with target-SNARE (t-SNARE) proteins on the plasma membrane, specifying the destination of the granule. An influx of calcium then triggers fusion of the granule and cytoplasmic membranes, causing exocytosis. NSF either primes the granule for fusion, facilitates empty granule recycling, or mediates both processes.

precise role that RalA, Rab27a, and other Rab family members play in WPB exocytosis is unknown.

SNAREs are transmembrane proteins localized to granule and target membranes. They play a role in directing granules to the appropriate target membrane prior to membrane fusion. SNAREs in granule membranes can interact with SNAREs in cellular membranes, forming a stable SNARE complex and placing the two membrane fusion partners in apposition prior to fusion. Experiments using RNA silencing or antibody interference have demonstrated that syntaxin-4 is one of the three SNARE molecules that targets WPBs to the plasma membrane (41,42). The identity of the other two SNARE partners of syntaxin-4 on WPBs are unknown, but are probably SNAP-23 and synaptobrevin-3 (VAMP-3), which interact with syntaxin-4 to direct granule exocytosis in other secretory cells. Syntaxin-4 is found predominantly on the inner surface of the plasma membrane; synaptobrevin-3 and SNAP-23 are usually associated with granule membranes (34). The Sec1/Munc18 family members are negative regulators of SNARE interactions that separate from the SNARE complex prior to membrane fusion. Although Munc18 is phosphorylated prior to WPB exocytosis, its precise role in EC exocytosis is unclear (42).

NSF is a critical component of the exocytic machinery in ECs. NSF associates with the SNARE complex via an accessory protein,  $\alpha$ -soluble NSF attachment protein ( $\alpha$ -SNAP), hydrolyzes ATP, and disassembles the SNARE complex (43–47). Precisely how NSF converts the chemical energy of ATP into physical energy to separate the three SNARE molecules is unknown. Although chemical or genetic inactivation of NSF blocks vesicle trafficking, the precise step at which NSF mediates vesicle trafficking is controversial. NSF was originally thought to prime vesicles for fusion, but subsequent studies suggested that NSF is necessary for vesicle recycling after fusion. Inhibiting NSF in ECs with intracellular antibodies blocks WPB exocytosis; adding recombinant NSF back to these cells restores exocytosis (41). Thus NSF is the molecular motor that drives endothelial exocytosis in WPBs.

### TRIGGERS OF WEIBEL-PALADE BODY EXOCYTOSIS

Two aspects of WPB exocytosis are particularly notable: WPB release is both rapid and stereotypical. Agonists trigger endothelial exocytosis within seconds to minutes. WPB release is thus an immediate early response of ECs – a rapid response to injury independent of gene transcription (48). (In contrast, vascular injury also can activate a delayed endothelial response that involves transcription of genes, but this response may take hours.) The endothelial response to thrombin is immediate: Thrombin activates WPB exocytosis within minutes, leading to the rapid externalization of P-selectin, which mediates leukocyte rolling along the endothelium (49). In contrast, the endothelial response to hypoxia is both immediate and delayed. Hypoxia not only triggers WPB exocytosis within

**Table 72-2: Triggers of WPB Exocytosis**

<i>Class</i>	<i>Agonist</i>
Physical	Hypoxia
	Radiation
	Trauma
	Shear stress
Endogenous chemicals	ATP
	ADP
	Reactive oxygen species
	Leukotrienes
	Histamine
	Epinephrine
	Serotonin
Polypeptides	Thrombin
	Fibrin
	Oxidized LDL
	Complement
	VEGF

minutes, leading to rapid externalization of P-selectin, but also activates the transcription of intercellular adhesion molecule (ICAM)-1 within hours, which eventually leads to leukocyte adherence to the vessel wall (50,51). Thus, WPB exocytosis is an immediate endothelial response to injury.

WPB exocytosis is also a stereotypical response to a wide variety of agonists, physical, chemical, and biological (Table 72-2). Physical injury, such as hypoxia, ischemia, radiation, and trauma activates WPB secretion (50,52–57). Endogenous chemicals, including ADP, ATP, epinephrine, serotonin, and histamine, also trigger endothelial exocytosis (12,58–62). Proteins such as thrombin, fibrin, complement, vascular endothelial growth factor (VEGF), and oxidized low-density lipoprotein (LDL) induce WPB release (49,63–65). All these diverse agents not only activate unique receptors and specific signal transduction cascades, but also trigger WPB exocytosis, leading to vascular inflammation and thrombosis. WPB exocytosis is thus a final common pathway by which ECs respond to injury.

### NEGATIVE REGULATORS OF ENDOTHELIAL EXOCYTOSIS

Although many activators of WPB exocytosis have been identified, the only inhibitor of exocytosis identified thus far is nitric oxide (NO). Several lines of evidence suggest that NO inhibits exocytosis by regulating NSF (41). First, NO chemically modifies recombinant NSF, S-nitrosylating three of its nine cysteine residues. Second, S-nitrosylated NSF cannot disassemble the SNARE complex. Third, exocytosis can be restored by adding NSF back to ECs previously inhibited with NO. Finally, inhibition of NO production by pharmacologic or genetic tools increases endothelial exocytosis and platelet adherence in vivo

(41,66). NO thus inhibits vascular inflammation in part by blocking endothelial exocytosis.

If NO inhibits endothelial inflammation, then lack of NO permits excessive vascular inflammation. This may explain why endothelial dysfunction is a risk factor for atherosclerosis. The hallmark of endothelial dysfunction is the inability of the endothelium to produce NO. In healthy patients, NO may limit endothelial exocytosis in response to vascular injury. However, in patients with endothelial dysfunction and decreased NO production, perhaps NSF is not inhibited, thus permitting an exaggerated endothelial response to injury, excessive release of inflammatory and thrombotic mediators, and vascular inflammation.

### ENDOTHELIUM AS VASCULAR MEMORY

If memory is the ability to store and retrieve information, then ECs function as a vascular memory. Just as neurons integrate presynaptic signals and secrete neurotransmitters from neurovesicles, so do ECs respond to external agonists by exocytosis of vascular messengers from WPBs. Neurons and ECs share components of the exocytic machinery: Both cell types rely on SNAREs and NSF to regulate exocytosis. Furthermore, the strength of the exocytic response of both neurons and ECs can be modulated. Long-term potentiation (LTP) and long-term depression (LTD) describe the ability of neurons to increase and decrease, respectively, exocytosis of neurotransmitters in response to repetitive stimulation. The EC response to agonists is also plastic: ECs modulate exocytosis in response to the external environment. For example, WPBs normally do not contain IL-8. However, prolonged treatment with TNF- $\alpha$  or IL-1 $\beta$  induces ECs to synthesize IL-8 and store it inside WPBs. Thus, ECs alter the contents of WPBs in response to inflammatory stimuli. After exposure to cytokines, ECs can release IL-8 from WPBs, modulating neutrophil activation. ECs also modulate exocytosis in response to anti-inflammatory signals. NO inhibits endothelial exocytosis for 6 hours. However, after exposure to NO ceases, ECs gradually recover the ability to activate exocytosis (41). ECs thus exhibit both LTP and LDP. Proinflammatory and anti-inflammatory signals modulate endothelial exocytosis – in a sense, ECs “remember” their inflammatory environment.

#### KEY POINTS

Upon discovering the rod-shaped organelles that now bear their name, Weibel and Palade noted that these granules “must be a structure of some functional significance which for the moment remains obscure . . . It is hoped that further . . . studies may shed some light on the nature of the rods and their components.”(1) In

the decades since the discovery of WPB, investigators have learned that:

- Endothelial exocytosis of WPBs is a rapid response to vascular injury.
- WPB exocytosis activates vascular inflammation and thrombosis.
- NO inhibits vascular inflammation by regulating WPB exocytosis.

#### Future Goals

- To identify WPB coat proteins that simultaneously direct granule budding and select proteins for inclusion in WPB
- To define the molecular components of the exocytic machinery in ECs
- To invent novel drugs that inhibit endothelial exocytosis for the treatment of inflammatory diseases

#### ACKNOWLEDGMENTS

Supported by grants from the NIH (R01 HL63706–04, R01 HL074061, P01 HL65608, P01 HL56091), the Ciccarone Center, and the John and Cora H. Davis Foundation to CJL; and by grants RR07002 and HL074945 from the NIH to CM.

## Multiple Functions and Clinical Uses of Caveolae in Endothelium

Lucy A. Carver and Jan E. Schnitzer

*Sidney Kimmel Cancer Center, San Diego, California*

Caveolae were first identified half a century ago by electron microscopy (EM) as small, flask-shaped, smooth plasmalemmal invaginations. They are most abundant in certain endothelial cells (ECs) and adipocytes but exist in many other cell types. For the next 40 years, exploration into these mysterious organelles was limited primarily to morphological study by EM, including transendothelial transport studies using electron-dense tracers. Until recently, when caveolae were considered at all, they were thought at best to function only in fluid-phase endocytosis (the uptake of small molecules and/or fluids surrounding the cell, also known as *pinocytosis*) and thus were frequently called *pinocytic* or “drinking” vesicles. During the last decade, the development of new molecular tools, markers, and purification techniques that permit selective functional and architectural analysis of caveolae has led to a renaissance in the research of caveolae and to new insights into their structure, composition, physiology, and function. This renewal has been fueled further by key fundamental discoveries of their role in important cellular processes, including signaling and mechanotransduction, cholesterol trafficking, cell growth, and membrane trafficking. Selective targeting of caveolae in vivo can mediate tissue-specific delivery of substances to the endothelium and even across the endothelial layer (via transcytosis) into underlying tissue. In this chapter, we discuss the structure, purification, and composition of caveolae, their relation to lipid rafts, and their role in trafficking and signaling, with emphasis on functions pertinent mostly to ECs, such as acute mechanotransduction and transcytosis. The possible clinical utility of caveolae in the vascular targeting of drugs, genes, and nanomedicines also is presented.

### DEFINING CAVEOLAE

Initially, the terms *noncoated plasmalemmal invagination* and *caveolae* referred to the smooth invaginations at the plasma membrane with bipolar-oriented, thin striations around the bulb observed by EM (1,2) (Figure 73.1). These structures

were noted to be distinct from the thick, electron-dense coat characteristic of clathrin-coated vesicles (Table 73-1). Caveolae are most abundant (up to 60% of the plasma membrane) in the continuous microvascular endothelia of the lung, skeletal muscle, and heart; moderate in endothelia of large blood vessels; relatively rare in the highly restrictive continuous microvascular endothelia of brain and testes; and apparently absent in sinusoidal endothelia (3), such as in liver (where ECs express abundant clathrin-coated vesicles). They are most abundant in the arteriolar and capillary segments of the microvasculature and less so in the postcapillary venules.

Caveolae appear to require for their existence the expression of caveolin-1 (also called VIP21) (4,5). The caveolin gene family has three members in mammals. Caveolin-1 is a 21-kDa integral membrane protein that exists as two isoforms produced by alternative initiation,  $\alpha$  and  $\beta$ , and which oligomerize to form the structural coat of the caveolar bulb (5,6). Caveolin-1 is an integral membrane protein whereby both the NH<sub>2</sub> and COOH termini face the cytoplasm with the intervening hydrophobic domain forming a hairpin loop embedded within the membrane bilayer (5,7). Caveolin-2 is a 20-kDa protein that can form stable hetero-oligomeric complexes with caveolin-1 in the caveolar bulb (8). Both caveolin-1 and -2 are expressed in some ECs, adipocytes, epithelial cells, smooth muscle cells, and fibroblasts (8). Caveolin-3 appears to be expressed mainly in muscle cells, including smooth, skeletal, and cardiac myocytes, and is present in the caveolae of these cell types (9).

Caveolin-1 appears to be a major structural component of caveolae. The expression of caveolin-1 is both sufficient and necessary to drive the de novo formation of caveolae under in vitro and in vivo conditions (10–14). In human umbilical vein ECs (HUVECs), the reduction of *caveolin-1* mRNA expression levels using antisense oligonucleotides ablates caveolae formation at the cell surface (14). Caveolin-2 requires caveolin-1 for proper membrane targeting and for protein stability (11,15), but caveolin-1 may not necessarily rely on caveolin-2 for the formation of caveolae, its overall protein stability, and/or its

Figure 73.1. Electron micrograph of cross-section of a capillary in mouse myocardium. A red blood cell (RBC) is cramped in the middle of the capillary and next to the very attenuated ECs, with the luminal and abluminal surfaces less 100-nm apart in some regions (box). Arrowheads point to some of the caveolae in the EC. Arrow points to EC junction (route for paracellular transport). Beyond the EC is basement membrane (extracellular matrix), some perivascular cells (PVC), and the main tissue cell of the heart, a cardiomyocyte (rich in mitochondria and myofibrils). Mito, mitochondria.

localization in the plasma membrane (13,16). Yet, the coexpression of both caveolin-1 and -2 appears necessary for the formation of stable, deep, plasma membrane-attached caveolae (16). Recent studies have shown that caveolin-2-regulated caveolae biogenesis is dependent on the phosphorylation state of caveolin-2 (16). In addition, the formation and maintenance of caveolae seems to require the presence of cholesterol, which binds tightly to caveolin-1 (17,18). The depletion or removal of membrane cholesterol using cholesterol binding agents, such as filipin, results in the disassembly of caveolae, dispersal of caveolar proteins diffusely across the plasma membrane, and loss of specific trafficking and signaling functions (4,17,19–23).

Caveolin-1 was initially discovered by analysis of the material comprising the caveolar structural coat. Antibodies recognizing VIP-21, a 22-kd substrate for *v-src* tyrosine kinase in virus-transformed chick embryo fibroblasts, bound the filaments that comprise the striated coat, and the substance was named the caveolin (4). With the discovery of caveolin-1 as a marker for caveolae (4), many methods were introduced to isolate caveolin-containing membranes by subcellular fractionation. The earliest methods were unidimensional, relying on detergent-resistance and buoyant density or solely on buoyant density for isolation of caveolar membranes after cell fragmentation (24). It soon became clear that both detergent and detergent-free methods were problematic. First, caveolin-1 can exist in other locations in the cell, including Golgi appa-

ratus (25) and endoplasmic reticulum (ER) (6,18), leading to questions about its specificity as a sole marker for following caveolae isolation. Second, these preparations are heavily contaminated with low-density, detergent-resistant membranes derived from other intracellular organellar structures, such as nuclei (26,27). The isolation of plasma membranes from fragmented cells using Percoll gradients first, before detergent or sonication treatment, can help but, at least so far, the isolates still contain ample markers for Golgi and ER membranes (24). Such contamination is expected for unidimensional isolation based almost solely on buoyant density for the separation of membrane compartments.

In addition to nuclei, Golgi, and ER, unidimensional isolation of low-density membranes also yields lipid rafts. Lipid rafts are thought to exist as very small plasma membrane microdomains that share certain biochemical properties with the canonical, invaginated caveolae. Because lipid rafts cannot be visualized by light or EM techniques, they are defined biochemically as dynamic, detergent-resistant regions of highly saturated sphingolipids that self-assemble with cholesterol to pack into a highly ordered lipid phase and which are enriched in a wide variety of glycosylphosphatidyl inositol-anchored proteins (GPI-AP) (28). Caveolae and lipid rafts may be found on the cell surface as discrete entities, but they also can be closely associated with each other so that, in some cases, lipid rafts are essentially attached to a caveola at the annulus (26).

### Using Nanotechnology to Improve Microdomain Isolation

The development of more rigorous, higher-dimension separation techniques for isolating caveolae has resulted in a greater understanding of the relationship between caveolae and lipid rafts by permitting purification of caveolae from tissue or cultured cells (26,29). One technique perfused positively charged colloidal silica nanoparticles (NPs) to selectively coat the cell surface membrane before crosslinking to form a stable, strong membrane pellicle, then employed tissue/cell homogenization to break the cells or tissue into subcellular components. Because the NP has a density greater than any component of the cell or tissue, a series of centrifugations through high-density gradients yields silica-coated plasma membranes as a membrane pellet. Intracellular membranes or membranes of other cell types (when processing tissue) are not NP-coated so they float on the gradient and are nearly eliminated from the pellet. For example, biochemical and EM analyses show that, in rat organs, this technique provides reasonably purified EC plasma membranes ( $\geq 20$ -fold enrichment of key EC surface marker proteins) with minimal contamination ( $\geq 20$ -fold depletion of markers of other tissue cells as well as nuclei, Golgi, ER, and other intracellular membranes).

As depicted in Figure 73.2, caveolae have been purified from silica-coated luminal EC plasma membranes isolated from rat lung either by physical homogenization (26) or by physiological GTP induction of caveolae budding (30). The silica coating serves to stabilize the flat parts of the plasma

**Table 73-1: Comparison of Properties between Caveolae and Lipid Rafts**

	<i>Caveolae</i>	<i>Lipid Rafts</i>
<b>Other names</b>	Pinocytic vesicles; noncoated plasmalemmal invagination	
<b>Distribution</b>	Continuous microvascular endothelia of the lung, skeletal muscle, and heart; moderate in endothelia of large blood vessels; relatively rare in the highly restrictive continuous microvascular endothelia of brain and testes. Absent in liver sinusoids; presence in lymphatic ECs not yet verified	All ECs
<b>Constituent proteins/enriched constituents</b>	Caveolin-1, -2, and -3; G-protein G <sub>q</sub> ; PDGF-R; eNOS; Ras, Raf, dynamin, SNAP, vSNARE, VAMP-2, small and large GTP binding proteins; select calcium-dependent, lipid binding annexins; NSF; intersectin; albumin binding proteins	Immunoglobulin E receptors, T-cell receptors, and GPI-AP; G-proteins G <sub>i</sub> and G <sub>s</sub>
<b>Abrogation</b>	Caveolin-1 deficiency; removal of membrane cholesterol	
<b>Description</b>		Dynamic, detergent-resistant regions of highly saturated sphingolipids that self-assemble with cholesterol to pack into a highly ordered lipid phase and which are enriched in a wide variety of glycosylphosphatidyl inositol-anchored proteins (GPI-APs)
<b>In vivo:in vitro abundance</b>	10–100:1	
<b>Enriched</b>	Caveolin, Ca <sup>2+</sup> -ATPase, the glycolipid GM <sub>1</sub> , VAMP, eNOS, dynamin, and the IP <sub>3</sub> receptor	
<b>Trafficking</b>	Cholera toxin; albumin-gold complexes; SV40, ebolavirus, and polyomavirus.	

membrane, so that the invaginations can be detached selectively from the plasma membrane, leaving behind the plasma membrane proper (including lipid rafts, pits coated by clathrin, or other microdomains) still attached to the silica NPs. The buoyant caveolae are collected at a specific low density after being floated away from the high-density silica membrane pellicle by sucrose gradient centrifugation. Other possible invaginations include clathrin-coated structures, which must be fully developed as invaginations rather than large pits to avoid silica coating. These are much fewer at the lung EC surface *in vivo* than are caveolae, and, regardless, are bigger and much more dense than caveolae. More than 95% of the caveolae on the silica-coated plasma membranes can be removed to yield a homogeneous population of morphologically distinct, smooth, flask-shaped vesicles of 60 to 80 nm in diameter as visualized by EM (26) (Figure 73.2). This reasonable homogeneity is confirmed biochemically by caveolin antibodies binding >95% of the isolate to magnetic beads. Biochemical analysis also reveals that the isolated caveolae represent specific microdomains of the cell surface with their own unique molec-

ular topography (26,31). They are enriched in seven caveolar markers established by immunogold EM: caveolin-1, calcium (Ca<sup>2+</sup>)-ATPase, the glycolipid GM<sub>1</sub>, vesicle-associated membrane protein (VAMP), endothelial nitric oxide synthase (eNOS), dynamin, and the IP<sub>3</sub> receptor (26,29,31–35). By contrast, clathrin, angiotensin-converting enzyme (ACE), Band 4.1, and  $\beta$ -actin are not detected or at least markedly depleted ( $\geq 15$ -fold) from the isolated caveolae, despite ACE, Band 4.1, and  $\beta$ -actin being amply present in the silica-coated plasma membranes. Alternatively, caveolae also can be isolated from low-density membrane subfractions by immunoaffinity techniques using magnetic nanoparticles and select caveolin antibodies (29).

Once free of caveolae, the stable attachment of silica particles to the remaining silica-coated plasma membranes provides a means to isolate the remaining flat detergent-resistant membranes, the so-called lipid rafts, away from both caveolae and the plasmalemma proper (26). After a high-salt wash to remove the silica beads, most of the remaining flat plasma membrane subjected to Triton solubilization will be “melted

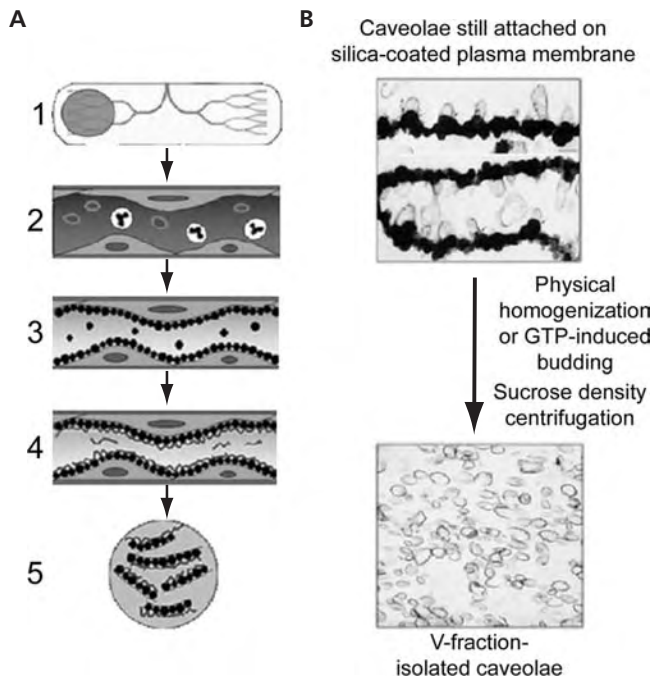

Figure 73.2. Subcellular fractionation to isolate luminal EC plasma membranes normal or tumor tissue in vivo. (A) The vasculature of an organ or solid tumor (1) is flushed free of blood, then perfused with a positively charged colloidal silica solution to (2 → 3) coat specifically the luminal EC surface membrane directly exposed to the circulating blood. The monolayer of silica particles stably adherent to this plasma membrane of interest are cross-linked with polyacrylic acid to establish intraparticle cohesion and to neutralize excess positive charges (4). This coating increases the density of the plasma membrane significantly above any other tissue component, so that after tissue homogenization, large sheets of silica-coated luminal EC plasma membranes (5) with their attached caveolae are readily isolated away from other membranes and debris by ultracentrifugation through a high-density medium. Further subcellular fractionation to isolate caveolae (V-fraction) can be performed by homogenization or GTP-induced budding (both of which release the caveolae from the silica-coated plasma membranes), followed by flotation via sucrose density centrifugation. (B) Electron micrographs of silica-coated rat lung EC plasma membranes (*top*) and caveolae (*bottom*) after isolation.

away” to leave behind the detergent-resistant microdomains, which vesiculate and can be isolated by sucrose density centrifugation as a homogeneous population of rather large vesicles (very similar to those described next). These new NP-based preparations reveal molecular distinctions between caveolae and putative lipid rafts, both isolated from the same EC plasma membranes (26). Caveolae appear concentrated in caveolin-1 but not so for several GPI-APs, which instead exist quite concentrated in lipid rafts devoid of caveolin-1 (26,29).

**Lipid Rafts**

In contrast to the multidimensional silica NP-based methods for isolating caveolae, unidimensional methods isolate

caveolin-rich fractions containing lipid rafts, the obvious smaller, omega-shaped caveolae, and even intact large vesicles with a caveola attached (26). The attached caveola usually is oriented inside the larger vesicle but also can be seen sometimes with the bulb oriented outside. Immunogold EM reveals GPI-AP and carbonic anhydrase on the larger vesicles but not the free or attached caveolae, suggesting that these larger vesicles are, or contain, lipid rafts (26). This finding of coisolation using unidimensional methods is underscored by studies showing that similar, large, detergent-resistant vesicles rich in GPI-AP are isolated from cells lacking caveolin or caveolae (36,37). Moreover, only approximately 40% of these isolates can be bound to, and isolated by, magnetic beads coated with caveolin antibodies (much less than the 98% binding observed for the silica-based preparations) (29). Thus, it is quite apparent that unidimensional methods based primarily on physical separation by membrane buoyant density are unable to discriminate caveolae from lipid rafts. This heterogeneity is compounded further by the presence of additional microdomains (of similarly low buoyant density and usually detergent-resistant) derived from contaminating membranes of intracellular organelles (as discussed earlier).

In retrospect, it is not surprising that, as a consequence of early reports showing that caveolin-containing, detergent-resistant membrane fractions were rich in both GPI-AP and caveolin, many investigators concluded that caveolae constituted the GPI-AP-enriched lipid rafts in the plasma membrane. This notion was supported further by the findings that antibodies to GPI-AP can be found in caveolae using immunocytochemistry (38) and EM (23,39), and that GPI-AP can be internalized via caveolae (39). Later, however, it also was reported that several GPI-APs are not normally clustered in caveolae but rather artifactually induced to localize in caveolae by antibody sequestration resulting from crosslinking by secondary reporter antibodies (40). These early conflicting data led to confusion about the exact definition and composition of caveolae that remains to this day.

It was even proposed that caveolin interacts with and traps GPI-AP in caveolae (41), but this seems unlikely given the structural nature of caveolin and the opposite orientation of these proteins in the bilayer. This does not mean that some GPI-AP may not exist concentrated in caveolae in some cell types. Many GPI-APs, when sequestered, may move into caveolae. Thus, natural crosslinking ligands to GPI-APs, yet to be identified, could potentially sequester select GPI-APs and concentrate them in caveolae. Alternatively, an intermediate linker between caveolin and select GPI-APs eventually may be found. But for now it is apparent that GPI-APs appear to reside preferentially as a group in rafts. Also note that clathrin-coated vesicles can endocytose GPI-APs (42), so the relationship between the molecular inventory of caveolae and lipid raft is not a simple continuum.

In the end, caveolae and lipid rafts (as defined by detergent-resistant low-density membranes) appear to be distinct microdomains containing a unique set of proteins, including signaling molecules. For example, caveolae contain

growth factor receptors (e.g., platelet-derived growth factor receptor) whereas lipid rafts contain immunoglobulin E receptors, T-cell receptors, and GPI-APs (43). In cells expressing caveolin and caveolae, the heterotrimeric G-protein,  $G_q$ , tends to concentrate in caveolae but not in lipid rafts, whereas  $G_i$  and  $G_s$  exist in lipid rafts preferentially over caveolae (44). The apparent ability of caveolin-1 to form a complex in the plasma membrane with  $G_q$ , but not  $G_i$  or  $G_s$ , appears to trap  $G_q$  effectively in caveolae and minimize its presence in lipid rafts (44). In cells that don't normally express caveolae,  $G_q$  partitions into lipid rafts with other G-proteins (44). These findings discovered by tissue/cell subfractionation were confirmed by immunofluorescence microscopy on intact cells (44).

If they exist, lipid rafts are probably very small, flat, plasmalemmal microdomains (<50 nm) enriched in GPI-AP. As such, they lack a distinct morphology easily detected by EM and thus require sophisticated biophysical detection that, to date, has not definitively established their existence. They currently are defined most often operationally through biochemical isolation and detergent resistance (45). Such analysis is complicated by the fact that many cellular components can be detergent-resistant and have low buoyant densities, including cytoskeletally tethered membrane proteins, protein-protein complexes, and adhesion sites. Also, one must not forget that, during the 1980s, nonionic detergent insolubility of a protein was considered good evidence for cytoskeletal association. In contrast to rafts, the existence of caveolae is certain. They have a distinct omega-shaped invaginated form easily detected by EM, are readily labeled at the cell surface with caveolin antibodies, and can be isolated to homogeneity as appropriately sized and shaped vesicles coated with caveolin. Much more research is required to buttress so far suggestive evidence and to establish clearly the existence and even proposed function of lipid rafts. Although much suggestive evidence has accumulated to support a function for rafts in signaling, until raft targeting is shown to be functionally obligatory and protein-protein interactions auxiliary, this hypothesis will remain rather speculative and unproven.

Many still wish to consider rafts and caveolae as near equivalents. Some even describe caveolae as a subset of lipid rafts. If so, then nearly all unidimensional isolation procedures become, by definition, more homogeneous. Also the lipid raft field becomes more grounded and not reliant on establishing the existence of lipid rafts, which currently appears close to impossible. In the end, it should not be forgotten that finding distinction is fundamental to the philosophy and progress of science.

## FUNCTIONS OF CAVEOLAE

### Role of Caveolae in Ligand-Based Cell Surface Signaling

The compartmentalization of key signaling molecules in caveolae appears to be necessary to provide the rapid, efficient, and specific propagation of extracellular stimuli to intra-

cellular targets. This key concept has emerged from studies performed over the last decade. Caveolae are rich in many signaling molecules including platelet-derived growth factor receptor (PDGFR) (21,46), eNOS (35,47,48), select heterotrimeric G-proteins, and nonreceptor tyrosine kinases (21). Many of these proteins appear to interact with caveolin (49,50), and may function in acute mechanotransduction (20,35) and cell surface receptor signaling (50–52). Caveolae are rich in cholesterol, and the removal of cholesterol from the plasma membrane by cholesterol binding agents such as filipin affects microdomain organization or compartmentalization (4,23). These compounds disassemble caveolae, which results in a dispersal of caveolar molecules to a more random distribution over the cell surface, thereby disrupting both transport and signaling functions (19,21). For example, filipin treatment can prevent PDGF-induced signaling downstream of the initial receptor autophosphorylation (21). Knockdown of caveolin by antisense oligonucleotides eliminates caveolae and inhibits angiogenesis (which is dependent on specific signaling factors) both in vitro and in vivo (14). *Caveolin-1*-knockout mice lack detectable cell surface caveolae and exhibit alterations in signaling, including changes in the functions of eNOS, p42/44 mitogen-activated protein kinase (MAPK), and  $M_3$  muscarinic cholinergic and insulin signaling (53–57).

G-protein-coupled receptors (GPCR) may utilize cellular localization and internalization to regulate receptor-effector signaling specificity and receptor desensitization, respectively. Upon ligand engagement, many GPCR are rapidly internalized via multiple endocytic pathways not yet fully defined. Claing and colleagues detected three distinct pathways for GPCR internalization based on their sensitivity to overexpression of  $\beta$ -arrestin and dynamin mutants and the small G-protein-coupled receptor kinase (GRK)-interacting protein, GIT1 (58). Pathway I ( $\beta_1$  adrenergic receptor,  $\beta_2$  adrenergic receptor,  $\mu$ -opioid receptor, adenosine 2B receptor, and  $M_1$  muscarinic receptor) is inhibited by overexpressed wild-type GIT1, mutant  $\beta$ -arrestin, and K44A dynamin. Pathway II mediates internalization of ETB and vasoactive intestinal peptide-1 receptor and is inhibited by K44A dynamin but not by GIT1 or mutant  $\beta$ -arrestin, whereas pathway III (angiotensin 1A receptor and  $M_2$  muscarinic receptor) is not affected by overexpression of the three proteins. Clathrin-mediated endocytosis clearly mediates pathway I, but the mechanisms underlying the others have been much less clear. It has been speculated that caveolae likely mediate pathway II (58), consistent with observed the dynamin-mediated fission of caveolae (33), but this still requires detailed experimentation and rigorous proof. Various GPCR appear to sequester in caveolae and/or lipid rafts upon activation by ligand, (e.g., endothelial differentiation gene [EDG]-1, B2 Bk, and thyrotropin receptors) (59–61). Other GPCRs, such as ETA, may constitutively reside in cell surface "caveolae-like rafts" (51). It appears likely that caveolae promote efficient signal propagation into the cell not only through effective compartmentalization but also through regulated and directed trafficking to intracellular compartments for continued signaling or desensitization. This internalization

may also facilitate subsequent desensitization of select pathways to further ligand or other stimulation.

### Role of Caveolae in Mechanotransduction

A major physiological function of the endothelium is the conversion of hemodynamic forces into a series of adaptive biological responses that minimize mechanical stress as well as injury to the blood vessel and the tissue itself. Physical forces generated by vascular blood flow appear to play a central role in the acute and chronic regulation of the structural and functional phenotype of the endothelium. By being directly exposed to the circulating blood, the vascular endothelium is constantly subjected to fluid mechanical forces, such as frictional fluid shear from blood flow parallel to the luminal EC surface and vascular pressure transmitted across the entire blood vessel surface into the tissue. These mechanical forces induce compensatory protective responses by ECs that ultimately bring about alterations in cellular structure and function, including the release of vasoactive substances that function to alter vascular tone and thus mitigate hemodynamic stress. Normal compensatory endothelial responses to mechanical stress include the rapid release of a number of vasoactive substances, such as nitric oxide (NO), prostacyclins, and coagulation factors, as well as the induction or upregulation of a number of "atheroprotective" genes including cyclooxygenase-2, superoxide dismutase, and eNOS (62). Disturbances in this process may play a significant role in the pathogenesis of cardiovascular diseases such as atherosclerosis, hypertension, diabetic microangiopathy, and coagulopathies (63). Disturbed flow is considered a dominant initiator of atherosclerotic lesions and correlates with lesion localization at vessel bifurcations. ECs in these regions exhibit an altered phenotype with enhanced proliferation, increased permeability, and impaired endothelial vasoresponsiveness. Fluid stressors with time promote EC adhesion and atherogenesis (62,64).

Because the luminal EC surface is exposed directly to blood flow and all resultant force vectors, it appears logical that acute mechanotransduction occurs at this plasma membrane. In 1995, it was proposed that caveolae may be acute mechanosensing organelles at the surface of ECs (65). Evidence in support of this hypothesis has been accumulating (20,22,35,66–68). Molecular mapping shows that caveolae are enriched in various signaling molecules known to be activated in response to shear stress, including specific G-proteins, select nonreceptor tyrosine kinases, Ras, Raf, and eNOS (20,21,35). Increased vascular flow and pressure in situ very rapidly induce the tyrosine phosphorylation of EC surface proteins located primarily in caveolae (20). Caveolae have 50-fold more kinase activity than the rest of the plasma membrane (21). Disassembly of caveolae disperses the molecular constituents of this specialized compartment and prevents acute flow-activation of cell surface tyrosine kinases as well as downstream cytosolic kinases such as extracellular signal-regulated kinase (ERK) but not c-jun N-terminal kinase (JNK) (20,22). Increased fluid stress also rapidly stimulates eNOS, which is concentrated at

the EC surface in caveolae (35). Finally, select G-proteins are highly concentrated in caveolae (44), and shear stress appears to induce G-protein activation, which in turn stimulates the production of NO and activates ERK and JNK (66). In cultured ECs, physiological levels of shear stress redistribute caveolin from the Golgi to the cell surface, induce caveolae formation, and regulate ERK and Akt activity (67).

Caveolin-1 may act as a mechanosensitive scaffold for attracting and concentrating a variety of signaling molecules to caveolae, thus forming a specialized mechanosensing compartment (20,21,35). Many laboratories have used various assays in different systems to detect an interaction between caveolin and eNOS, which may inhibit enzymatic activity and be regulated physiologically (35,49,69,70). EM has confirmed eNOS concentration in caveolae in endothelium (35). Increased flow in situ rapidly dissociates eNOS from caveolin and concomitantly increases eNOS association with key positive modulators such as calmodulin (35). *Caveolin-1*-null mice lack caveolae and provide further evidence of a regulatory role for caveolae and caveolin in eNOS (12). They exhibit an inability to respond properly to mechanostressors and thus display reduced ability to maintain steady contractile tone, as well as having defects in endothelium-dependent vasodilation and contractility (12,57).

It has been proposed that caveolin, as a highly oligomerized, proteinaceous coat anchored directly in the inner lipid membrane around the bulb of caveolae, may function like a tension-bearing spring, sensing acute changes in mechanical forces at the cell surface to regulate the activity of key signaling molecules (20,35). Caveolin, possibly through conformational sensitivities of the oligomer, may act as an inhibitory clamp for eNOS that is released to permit enzymatic activation (35). The injection of a cell-permeable caveolin scaffolding domain peptide into mice uncouples caveolin-1-eNOS complexes through competitive binding to keep eNOS inactive, thereby eliminating physiological regulation by caveolin-1, preventing activation of eNOS, and inhibiting NO-mediated vascular hyperpermeability and vasodilation (71). Other signaling molecules (G-proteins, NRTK, Ras) also may interact with caveolin to concentrate in caveolae and regulate their signaling (44,50,52). Altogether, these data strongly implicate plasmalemmal caveolae as an important component of the acute mechanosensing and signaling mechanism in the vascular endothelium.

Neutral sphingomyelinase (N-SMase), an enzyme exposed externally on the plasma membrane, is activated to produce ceramide in an acute and transient manner by increase in flow rate and pressure in rat lung vasculature. This acute mechanoactivation occurred primarily in EC surface caveolae enriched in sphingomyelin and neutral sphingomyelinase, but not acid sphingomyelinase (72). Specific inhibition of N-SMase but not acid SMase activity prevented mechanoactivation of N-SMase and downstream tyrosine and MAPKs. Cell-permeable ceramide analogues mimicked the rapid mechanoinduced tyrosine phosphorylation of cell surface proteins. Both ceramide and mechanical stress-induced mechanosignaling were inhibited by genistein, Herbimycin A, and PP2, indicating

a role of Src-like kinases in ceramide-mediated mechanotransduction. Ceramides also induced serine/threonine phosphorylation to activate the Akt/endothelial NO synthase pathway. Thus, N-SMase in EC surface caveolae may be the upstream initiating mechanosensor, which acutely triggers mechanotransduction by generation of the lipid second messenger ceramide. Further discussion of EC mechanosensation can be found in Chapter 28.

### Role of Caveolae in Transvascular Exchange and Capillary Permeability

ECs form an attenuated monolayer lining all blood vessels and creating a critical barrier to control the exchange of molecules from the tissue to the blood, as well as from the blood to the inside of each tissue (perivascular space, interstitium, tissue parenchyma, and tissue cells). The lipid membrane tends to restrict transmembrane transport—in both directions—of both small and large circulating molecules, including water, ions, and proteins because of electrostatic, steric, and/or hydrophobic exclusion forces (73,74). Highly regulated paracellular pathways through the intercellular junctions mediate the filtration of water and small solutes driven by concentration and pressure gradients (75). Caveolae can provide transcellular pathways to transport macromolecules, apparently trafficking their cargo as a vesicular shuttle from the luminal to abluminal aspect of the endothelium (76–78). They also can form transient transendothelial channels in very attenuated regions of the cell through the fusion of two or more caveolae, each located on apposing plasma membranes, to provide a direct conduit for the exchange of both small and large plasma molecules (79). These transcellular pathways may include both fluid-phase and receptor-mediated transport.

Although studied for half a century, defining the exact function of caveolae in transport has been somewhat problematic. In fact, Palade, after his discovery of caveolae in endothelium, had the insight to propose that caveolae transport molecules as quanta (specific packets of a finite number of molecules, as opposed to simply a stream of molecules.) across the EC into the tissue (80,81). Subsequent decades of research using EM show that various macromolecules such as albumin, orosomucoid, ferritin, and even gold-tagged blood proteins can enter luminal caveolae and, with time, are found in abluminal caveolae and the tissue interstitium (76,82,83). In all these cases, the labeling within caveolae, especially those apparently free in the cell, was interpreted as proof for caveolar-mediated transport. Yet, these probes may be difficult to follow under native conditions *in vivo*, and do not appear to bind in caveolae with a specificity, affinity, and level of exclusivity that rules out transport by other potentially less specific pathways. Moreover, because of the racemose structure of caveolae, wherein many vesicles link to each other in a chain to form a grape-like branching “cave” penetrating deep into the cell, conventional sections for EM can be problematic and quite misleading for interpreting transport studies with these less-than-specific markers. Conventional sections show that

about 50% of the noncoated vesicles are apparently free in the cytoplasm, and studies using serial ultrathin sectioning reveal that  $\leq 1\%$  are truly free and unattached to other membranes (84–86). That very few vesicles are found free in the cytoplasm has been interpreted as proof that caveolae are not dynamic, but rather static elements that do not bud from the cell surface to function in endocytosis or transcytosis (84–86). An alternative interpretation is that, within the time frame of specimen processing, few free vesicles are found because the caveolar budding and fusion process, once initiated, is very rapid, and the thermodynamic tendency favors fusion with cell membranes. Yet it is also possible that any observed transendothelial transport of probes to the interstitium in past studies may be primarily mediated by nonspecific paracellular transport, including retrograde entry of the probe into the abluminal caveolae (the “back-filling” model). This alternative pathway cannot be dismissed simply because the lack of both high-affinity probes targeting caveolae specifically and physically identical control probes (not targeting caveolae) precludes definitive proof that caveolae function in transport as discrete carrier vesicles capable of delivery. The idea that caveolae function in any transport (including transcytosis) has been the subject of a very contentious 40-year-old debate (63,87).

The last decade has witnessed the development of new assays for measuring endothelial transport and studying the mechanism of caveolae trafficking, including intact and permeabilized cultured cell assays, *in vitro* reconstituted cell-free systems, and immunofluorescence confocal microscopy. The development of a cell-free system that reconstituted caveolar budding *in vitro* demonstrated that caveolae fission can be induced and regulated by GTP hydrolysis (30). Simply adding GTP (but not UTP, CTP, nonhydrolyzable GTP [GTP $\gamma$ S], GDP, or ATP alone) to the isolated EC plasma membranes greatly stimulates the budding of caveolae (30). These budded vesicles are collected away from the remaining plasma membrane by centrifugation in a sucrose gradient and are concentrated in caveolin and other known caveolar proteins but not in several GPI-APs. This GTP effect has been confirmed in cultured ECs. After mild permeabilization to get the GTP into the cells, EM shows the loss of nearly all caveolae at the cell surface, and confocal immunofluorescence microscopy shows much greater internalization of probes entering caveolae. In fact, nonhydrolyzable GTP $\gamma$ S seems to “fix” at the cell surface, and prevents both caveolar fission *in vitro* and the EC endocytosis of various probes entering caveolae (30). The GTPase mediating this budding has been identified as dynamin (33) (see the following discussion). These data provided the first concrete evidence that at least some caveolae can indeed bud off the plasma membrane to form discrete carrier vesicles that participate in membrane trafficking, and thus put to rest a decades-old contention that all caveolae are fixed plasmalemmal invaginations incapable of budding.

Primarily through studying cultured cells, other evidence has been accumulating in favor of caveolae functioning as dynamic vesicular carriers. Caveolae appear to traffic select ligands, such as cholera toxin and albumin–gold complexes,

to specific destinations within the cell, such as endosomes and lysosomes, in many cell types including ECs (39,88,89). Caveolae also have been implicated in the infectious process of SV40 (90,91), ebolavirus (92), and polyomavirus (93,94). SV40 binds to cell surface major histocompatibility class (MHC) class I receptors and associates with caveolae to be internalized via a relatively slow, dynamin-dependent mechanism, with each vesicle containing a single virus to be found approximately 2 hours later in the ER (90,95,96). Polyomavirus follows a different, Brefeldin A-sensitive trafficking pathway than does SV40 (97). Furthermore, select pharmacological agents, such as filipin and N-ethylmaleimide (NEM), have been identified to inhibit the endocytosis and transcytosis of select ligands that preferentially bind within caveolae. Cholesterol-binding agents, such as filipin, reduce caveolae number and significantly decrease caveolae-mediated cellular trafficking of such molecules as albumin and insulin (4,19,98). NEM is a thioalkylating agent that inhibits the fusion of carrier vesicles to target membranes and thus reduces multiple cellular vesicular transport processes (99–102). As with other vesicular pathways, including synaptic neurotransmitter release (103), apparent caveolae-mediated transport appears to occur via NEM-sensitive vesicle-membrane fusion (104).

More recently, the ability to isolate EC caveolae to a high degree of purity directly from tissue has enabled the discovery of specific molecular machinery in caveolae that mediates the budding, docking, and fusion of transport vesicles (77). Several key proteins are concentrated in caveolae, including dynamin; SNAP; vSNARE; VAMP; small and large GTP binding proteins; select  $\text{Ca}^{2+}$ -dependent, lipid binding annexins; and the NEM-sensitive membrane fusion factor (NSF) (31,33,34). In cultured ECs, selective cleavage studies show that caveolae require intact VAMP-2 for efficient, targeted transport of cholera toxin B subunit to intracellular organelles such as endosomes (34). Immunogold EM on ultrathin frozen sections of lung tissue reveals VAMP-2 at the bulb of caveolae (34) and dynamin concentrated at the neck of caveolae (33). Overexpression of a dominant negative mutant form of dynamin, which does not hydrolyze GTP normally because of a single amino acid change (K44A), inhibits the GTP-induced budding of caveolae in the reconstituted cell-free assay and prevents caveolae-mediated internalization in both intact and permeabilized ECs (33,105). Dynamin forms an oligomer around the neck of caveolae, where it can hydrolyze GTP to drive neck extension and result in the fission of caveolae to form free transport vesicles. Recently, intersectin, a known component of the endocytic machinery in non-ECs, was found at the caveolar neck in ECs in a complex with dynamin and SNAP-23, where it may regulate caveolar fission and internalization (106). Thus, caveolae appear to have the key molecular machinery necessary to function as endocytic and possibly transcytotic vesicles.

To study in greater detail the transport function of caveolae, it is critical to have caveolae-specific probes that can target the caveolae from outside of the cell. Currently used probes, such as cholera toxin, albumin, cross-linked GPI-AP,

and even viruses such as SV40, target caveolae neither directly nor specifically. They can also be internalized by other endocytic pathways (40,98,107). Recently, a few such high-affinity probes have been created via monoclonal antibody hybridoma technology using as immunogen the isolated silica-coated EC plasma membranes and caveolae (78,108). After intravenous administration of antibody conjugated to colloidal gold NPs (Au-NPs), EM of lung tissue reveals specific and rapid targeting of caveolae followed by transendothelial transport (78). Within 3 minutes, Au-NPs appear bound at the EC surface, specifically inside luminal caveolae, with little to no Au-NPs detected in caveolae located further inside the cell nor in clathrin-coated pits or in the subendothelial space. By 10 minutes, more Au-NPs are observed inside each caveola, with more caveolae containing Au-NPs, including those obviously connected at the luminal surface as well as those further inside the cell. Perhaps more importantly, caveolae at the abluminal surface contain Au-NPs and can be captured rather frequently with Au-NPs emanating from the caveolar neck into the perivascular space. By 15 minutes, in areas where the attenuated endothelium is in close apposition to the alveolar epithelium, some of the Au-NPs accumulating in the subendothelial space percolates through the basement membrane and is even taken up by epithelial caveolae for transport across the cell to the alveolar space. Control Au-NPs conjugated to isotype-matched IgG or antibodies to GPI-AP do not accumulate in caveolae and is not transported across the endothelium into the tissue, thereby ruling out any nonspecific paracellular mechanism. Thus, caveolae can indeed mediate the transcytosis of select molecular cargo to overcome both the endothelial and epithelial cell barriers in tissue (78).

Insights into the role of caveolae in capillary permeability also have been gained from studies of *caveolin-1*-knockout mice. Normally, albumin and even albumin-conjugated to gold particles are thought to bind specific albumin-binding proteins in caveolae (88,109–112), and appear to be transported by caveolae into and even across the EC barrier into the tissue (76,83). But in *caveolin-1*-knockout mice, the caveolae in microvascular endothelium are absent, and this transport pathway is lost (113). Although albumin-gold particles bound to the EC surface *in vivo*, they did not bind caveolae and demonstrated negligible transport. However, given that *caveolin-1*-knockout mice are viable, other mechanisms must be responsible for mediating the transendothelial transport of essential nutrients and other molecules to underlying tissues. Indeed, these animals demonstrate increased paracellular transport. They have an overall increased microvascular permeability *in vivo* (12,56,57,114) resulting in the rapid, nonselective transvascular transport of both large and small molecules from the bloodstream, apparently due to significant changes to EC tight junctions (56). Because eNOS influences permeability by producing NO (56,71,115–118) that can greatly increase transvascular exchange, eNOS activity without caveolin lacks appropriate regulation and becomes sufficiently elevated to cause the vascular hyperpermeability in the *caveolin-1*-knockout mice. Injection of the NOS inhibitor

N(G)-nitro-L-arginine methyl ester (L-NAME) into *caveolin-1*-knockout mice reverses most of the microvascular hyperpermeability (56). Injection of a cell-permeable caveolin scaffolding domain peptide into mice prevents the activation of eNOS and inhibits NO-mediated vascular hyperpermeability and vasodilation (71). The physiological consequences of the apparently widespread EC dysfunction caused by a lack of cell surface caveolae are severe. *Caveolin-1*-knockout mice suffer from edematous lungs, cardiac abnormalities, low tolerance to physical stress, aberrations in lipid metabolism, and decreased life span (12,57,114,119). Future, more conclusive, experiments are needed, using inducible *caveolin* knockdown methods in adults under more acute conditions that are likely to avoid this apparently paradoxical, yet partially compensatory, effect on capillary permeability (56,71,115–118).

Recently, an interesting structure potentially related to caveolae has been discovered. Vesiculo-vacuolar organelles (VVOs) are grape-like clusters of vesicles and vacuoles found in EC cytoplasm that interconnect with each other and with the luminal and abluminal plasma membranes via stomata that may be open or closed by a diaphragm (120). VVOs extend across ECs, represent sites of transendothelial hyperpermeability in tumor microvasculature and in normal and inflammatory venules, and appear to be regulated by vascular permeability factor/vascular endothelial growth factor (VPF/VEGF), serotonin, and histamine. The possible localization of caveolin and VAMP *in vivo* suggests a close relationship between these structures and caveolae (120). Because of their large size, they cannot be present in the highly attenuated ECs normally found in most microvessels, but rather reside primarily in the thicker endothelium of postcapillary venules and tumors. It can be speculated that factors that induce caveolae internalization and reduce EC membrane tension (lower pressure) may reduce cell attenuation, decrease caveolae cell surface density, and possibly even redistribute caveolae to VVOs, thereby increasing not only their number and/or size but also nonspecific transport and overall apparent vessel permeability, while reducing the permselectivity of the EC barrier.

The current data demonstrating the presence of key molecular machinery for the budding, docking, and fusion of caveolae as vesicular carriers, and the selective transendothelial transport of probes targeting caveolae versus identical control probes, clearly establish that caveolae are capable of mediating transcytosis in endothelium. The key questions remaining are: To what degree does this occur *in vivo*? How active is this process? And, is it regulated (if so, how and what induces it)?

To get answers, we must move beyond current methods. Static imaging by EM only records data points at specific time points; this lacks continuity in the observation and thus, may miss key details. In addition, the electron-dense gold particles used to tag antibodies or other molecules for EM detection are rather large and can alter both the trafficking pathway and kinetics of trafficking (e.g., retard the rate at which the process occurs). Thus, it will be necessary to develop better imaging probes coupled to sensitive dynamic live imaging techniques to define the kinetics and degree of active transport possible

by caveolae under physiological conditions found in tissue *in vivo*. Intravital microscopy and multiphoton microscopy may be useful in this regard. Higher-intensity fluorophores and NPs, such as quantum dots, may eventually permit the trafficking of a single caveola (especially in cell culture) or at least small clusters *in vivo*. Last, a more comprehensive, detailed proteomic mapping of caveolae using mass spectrometry (see Chapter 99) to define proteins concentrated selectively in this microdomain may elucidate not only new functions but also novel targets for developing new probes to study caveolar functions.

### Other Functions of Caveolae

In addition to the functions discussed earlier for caveolae in ECs, caveolae play key roles in cellular pathways in other cell types. For example, caveolae and caveolin have regulatory roles in cholesterol metabolism and in cholesterol-dependent cell growth and adhesion, as well as in glucose metabolism and multidrug resistance. These aspects of caveolae function have been previously well-reviewed (121–123).

### CLINICAL UTILITY OF CAVEOLAE: A PATHWAY INTO TISSUE FOR DRUG AND GENE THERAPY

The design of traditional therapeutic agents has focused primarily on the immediate interaction between a drug and its intended pharmacological site of action, usually a specific tissue. For many drugs that are small molecules, accessibility into tissue normally does not pose a problem. After entering the circulation by injection or absorption, these drugs readily move across the EC barrier (primarily via paracellular transport) from the bloodstream across intercellular junctions to gain access to underlying tissue cells. The ability of drugs to nonspecifically diffuse throughout many tissues of the body can in fact be quite disadvantageous, because access to many tissues increases the effective volume of distribution within the body, which in turn results in the dilution of drug potency and unwanted pharmacological side effects. On the other hand, larger molecules, such as proteins, antibodies, NPs, or gene vectors, lack access to many organs because they are unable to readily cross the blood vessel endothelium to reach their targets (124–127). For example, although initially promising in selectively killing tumor cells in culture, monoclonal antibodies have not been very successful in targeting drugs to extravascular sites, in part because they poorly cross the blood vessel endothelium to reach their antigen targets deep inside the solid tumor tissue (126,127). In fact, dose escalation becomes necessary to achieve some efficacy but also unfortunately increases systemic toxicity. Thus, for both large and small pharmaceutical agents, the ability to rapidly target the endothelium and promote transendothelial passage to the tissue of interest may greatly improve pharmaco-efficacy at lower dosages and limit systemic side effects caused by drug uptake in healthy tissue and cells (125,128).

To achieve “site-specific drug delivery,” most drug discovery efforts have focused on designing drugs as well as NP- and antibody-based delivery systems that specifically interact with diseased or malfunctioning target cells, with little consideration for the challenges and opportunities inherent in transendothelial transport (125,128). For example, high throughput, in vitro assays that screen for pharmacological actions on the desired cell type are being used extensively in the design of new drugs. Most in vivo “omic”-based target discovery efforts are aimed at the whole tissue level, and are thus biased toward the more numerous parenchymal cell types, whose targets are poorly accessible to most biological agents injected into the circulation. Thus, these drugs frequently perform much less effectively in vivo, where the agent must reach its target cells in a tissue in sufficient quantities to be potent while sparing normal organs (126,127).

Classic gene therapy aims to deliver genetic material to a specific diseased tissue using viral and nonviral vectors to achieve the sustained expression of a specific protein product. The new and rapidly growing field of nanomedicine seeks to apply nanotechnology for the diagnosis, monitoring, and treatment of disease. A major goal of nanomedicine is to use NPs as carriers to selectively deliver, upon injection into the bloodstream, a drug, imaging agent, or gene as a probe to its site of action within specific organs or solid tumors. Most attempts to use an antibody, gene vectors, or NPs to target solid tumors or other tissues in vivo have met with modest success. NPs (e.g., pegylated cationic liposomes, latex spheres, quantum dots) and viral vectors are much larger than standard drugs and even biologics (20 to >300 nm in diameter). When injected intravenously, they show very limited uptake into most organs and tumors (129,130). They appear to enter solid tumors mostly through “passive” targeting, and their uptake is attributable mainly to tumor vessel leakiness, which occurs with considerable heterogeneity in small tumor regions. As large foreign particles, they are rapidly removed from the cir-

ulation by the reticulo-endothelial system (RES), primarily in liver and spleen. Yet, if selective targeting of gene vectors or NPs is to be effective, it will be necessary to obtain not only accessible targets but an active means to overcome the restrictive EC barrier to reach their site of action, the underlying tissue or tumor cells. Although not yet realized, active targeting is predicted to mediate the faster, more efficient targeting of specific cell types (129). The benefits of more rapid targeting are twofold: (a) by decreasing the dosages necessary to attain the desired effect, potential drug-, gene-, and NP-induced toxicities can be minimized; and (b) quick removal of the targeting gene vectors or NPs from the bloodstream may greatly reduce or avoid their destruction by scavenging macrophages or sequestration by the RES. Until these critical issues are explored and understood, the exciting promise of gene therapy and/or nanomedicine may not be attained.

Vascular targeting strategy is a new site-directed delivery strategy that seeks to facilitate tissue-, organ-, or tumor-specific drug and gene delivery by targeting the inherently accessible EC surface of blood vessels feeding the target tissue, rather than the relatively inaccessible targets sites located on the cells residing further inside the tissue (77,131). Taking this concept one step further, a selective EC caveolae targeting strategy may confer an additional advantage by providing both targeted delivery and tissue penetration (131). Caveolae at the luminal EC surface may permit access inside the EC (endocytosis) and even across the EC barrier (transcytosis) to reach the underlying cells inside the tissue, thereby providing a theoretical means for transporting molecular and functional imaging agents as well as drugs, nanomedicines, and gene vectors across the normally restrictive EC barriers to reach underlying tissue cells, the normal desired targets of pharmacotherapies (Figure 73.3). Targeting caveolae may provide additional benefits beyond just targeting the EC surface by providing greater accumulation and improved penetration throughout the tissue. In addition, caveolae-targeted

Figure 73.3. Caveolae vascular targeting strategy. The molecular heterogeneity of the EC surface caveolae may allow specific targeting of imaging agents, drugs, nanomedicines, and even viral vectors. Probes, such as an antibody, that specifically target tumor-induced EC caveolar proteins may direct linked cargo (drug/NP/virus) to enhance tumor-specific delivery into and/or across the tumor EC barrier to the underlying tumor cells (right). Blood vessels that supply normal tissue do not express tumor-induced antigens and are spared exposure to tumor-targeted cytotoxic drugs or genes (left). This novel strategy, with the discovery of reasonably specific caveolar targets for tumor endothelium, may provide the means to greatly improve tumor imaging and therapy. This obviously may extend to other organs and diseases.

molecules may exhibit relatively nonsaturable accumulation in contrast to antibodies that merely target the static EC surface to saturate available binding sites. The potential utility of caveolae in cancer therapy has been reviewed recently (132).

Proof-of-principle experiments utilizing antibodies specific for EC caveolar proteins of the lung have shown that these agents can display the adequate molecular specificity, affinity, and level of exclusivity to selectively overcome the EC barrier to deliver drugs or imaging agents to the underlying tissue cells. Gold-conjugated antibodies that specifically bind their target protein in lung caveolae have been visualized by EM after intravascular administration to specifically target the lung endothelial caveolae (78,108). As noted earlier, uptake into the lung tissue occurs within minutes, followed by rapid transport across the endothelium for release by caveolae now on the abluminal surface (78). Once at the abluminal side of the endothelial barrier, the molecules percolate through the tissue parenchyma to gain access to, and be taken up by, the tissue cells. Future efforts will no doubt focus on extending this work to live dynamic imaging in vivo and to include caveolae on other vascular beds, including tumors.

The utility of caveolar targeting need not be limited to overcoming the vascular EC barrier. The localization of select signaling and mechanotransducing molecules in caveolae creates an additional impetus to develop caveolae-targeted delivery agents. For example, caveolae-targeted small molecules, siRNAs, peptides, or NPs may be used to inhibit specific signaling components concentrated in caveolae, such as eNOS, G-proteins, N-SMase, and the various signaling kinases, to treat such diseases as atherosclerosis and hypertension. One also can imagine using such agents to induce signaling or other events, such as caveolar budding, to bring about the desensitization of specific signaling pathways. Caveolin itself may be a useful target. Sessa and colleagues have generated a chimeric peptide consisting of the caveolin-1 scaffolding domain fused to a cellular internalization sequence that, when injected into mice, selectively inhibited eNOS activity and resulted in decreased inflammation-induced vascular permeability (71). This peptide also slowed tumor growth after intravenous injection, apparently by inhibiting eNOS (and probably other EC signaling molecules), which is required for VEGF effects on vessel permeability (71). Last, it is also probable that caveolae are not homogeneous organelles that all carry the same targets and signaling constituents, so that it may be possible to selectively target specific subpopulations of caveolae.

## CONCLUSION

In the 40 years since their discovery, caveolae have undergone a renaissance in terms of interest and discovery of their unique functions in signalling and transport. New techniques to isolate them directly from ECs in vivo, new reagents that allow visualization of their activity in cells, and new methods for identifying their molecular components have led to an explosion in our understanding of their biology. Clinically, cave-

olae may represent an important pathway for realizing true site-directed delivery of antibodies, NPs, and gene vectors to the endothelium itself or to cells inside the tissue. Without the caveolae portal system to penetrate into tissue, nanomedicine and gene therapy so far lack efficient access to their sites of action within the tissue and thus may have limited clinical utility. In the coming decade, it appears interesting and potentially clinically fruitful to define all potential caveolar molecules and targets, to understand caveolar function and trafficking mechanisms, and to elucidate the potential of caveolae vascular targeting as a strategy for the site-specific delivery of drugs, NPs, gene vectors, and imaging agents. This strategy may also be applied to past drugs that can be highly effective but were tabled by significant systemic toxicity. Re-engineering such drugs to include caveolae targeting capability may improve efficacy and reduce side effects via selective delivery to the desired site of action inside one or more select tissues.

## KEY POINTS

- Caveolae are smooth invaginations at the plasma membrane with bipolar-oriented, thin striations around the bulb consisting of polymers of caveolin. They are abundant in continuous ECs, moderate in ECs of large blood vessels, relatively rare in the highly restrictive continuous ECs of brain and testes, and apparently absent in sinusoidal endothelia.
- Many methods have been used to isolate caveolin-containing membranes by subcellular fractionation. The most effective of these methods involves silica NP perfusion or antibody-based methods to isolate caveolae away from lipid rafts.
- Caveolae have key functions in ligand-activated cell surface signalling, mechanotransduction, transvascular exchange, endocytosis, and vascular permeability.
- Caveolae may be an important mediator of the site-directed delivery and penetration of antibodies, NPs, and gene vectors into the endothelium itself or to cells inside a selected tissue.

## Endothelial Structures Involved in Vascular Permeability

---

Radu V. Stan

*Dartmouth Medical School, Hanover, New Hampshire*

Vascular endothelium is a highly differentiated cellular monolayer with the organization of a simple squamous epithelium. It lines the entire cardiovascular system and thus constitutes a quasi-ubiquitous presence in organs and tissues throughout the body. One of the most significant aspects of the vascular endothelium is its diversity of phenotype and function, which endows it with the ability to regulate the exchange of myriad substances between blood plasma and interstitial fluid in all tissues of the body. The ability of the endothelium to regulate the transendothelial exchange or vascular permeability is critically important in the growth, maintenance, and survival of all tissues, as well as in the delivery of therapies to correct locations.

Within the circulation, exchanges occur across the endothelium at all levels of the vascular tree. However, two functional segments are recognized with respect to the role of the vessel wall in the transendothelial exchanges between blood and tissues served: the conduit vessels and the exchange vessels. The *conduit vessels* take blood from heart to tissues (large arteries down to the smaller muscular arterioles upstream of the precapillary sphincter) or from tissues to heart (small muscular veins collecting from venules and draining into large veins). In these vessels (with large sectional diameter but low aggregated exchange surface), the transendothelial exchanges are thought to have impact only on the vessel wall and not on the organs/tissues crossed by these vessels. The *exchange vessels* consist of capillaries and venules, and are thought to be involved in active exchanges between blood and tissues. This segment, which has low sectional surface per vessel (i.e.,  $<100 \mu\text{m}$  diameter for venules and  $<10\text{--}20 \mu\text{m}$  for capillaries) yet the largest aggregated surface, is characterized by a very thin wall consisting of endothelium (with an average thickness of less than  $0.3 \mu\text{m}$ ) overlying basement membrane and occasional pericytes (situated mostly in venules). The term *microvascular permeability* as used extensively in the literature (1) (and the current chapter), describes the transendothelial exchange of fluids and solutes.

It is generally recognized that endothelium mediates “basal” microvascular permeability, which refers to the steady, continuous transverse flow of fluid and hydrophilic solutes (both small and large molecules) across the normal healthy microvascular endothelium, and “inducible” (i.e., increased) microvascular permeability, which refers to the increase in permeability to fluid and plasma proteins that occurs in inflamed tissues or tumors. Although the mechanisms underlying basal permeability remain poorly understood, previous investigations have provided important insights into the molecular basis of inducible permeability. An interesting yet unresolved question is whether increased permeability in inflammation and tumors represents an exaggeration of the normal response or is mediated by separate pathway(s).

Compared with other epithelia, the endothelium is far more permeable – by two to three orders of magnitude – to water and solutes (both small and large molecules), with the exception of brain endothelium. The relatively high basal permeability was determined to have both a diffusive and convective component. Based on physiological studies, the best fitting model for basal permeability, known as the *pore theory*, predicted that exchange takes place through two types of patent (open), water-filled, cylindrical or slit-like channels: small pores with diameters of  $<11 \text{ nm}$  and approximately  $15.1 \text{ units}/\mu\text{m}^2$ , and large pores with diameters of approximately  $50 \text{ nm}$  and approximately  $0.2$  to  $0.02 \text{ units}/\mu\text{m}^2$  (1–3).

During the 1950s and 1960s, cell biologists employed electron microscopy (EM) alone or combined with in vivo tracers to elucidate the structural basis for fluid and solute exchange across the endothelium (4–7). The latter studies – which employ probes of variable chemical and physical properties – suggested that the paracellular pathway represents the equivalent of the physiologically defined small pores. Also in agreement with the pore theory, EM and tracer studies indicated that the transendothelial channels (TECs) and fenestrae are structural equivalents of large pores in fenestrated

Figure 74.1. Structures involved in transendothelial permeability. Caveolae with (B,D) and without (A,C) SDs. Fenestrae subtended by a FD (E–H) or kidney glomerular fenestrae without FDs (I). Vesiculo-vacuolar organelle (VVO) from the heart endothelium of a *caveolin-1*-null mouse (J).

and discontinuous endothelia (Figure 74.1).<sup>1</sup> However, ultrastructural studies failed to identify pore-like equivalents for large pores in continuous endothelia (where most of the data supporting the “pore theory” had been obtained), with the exception of vesiculo-vacuolar organelles (VVOs) in the venular endothelium (4).

The failure to identify the structural equivalent of large pores in continuous endothelium presaged a longstanding controversy between capillary physiologists and cell biologists/morphologists regarding the molecular basis for the transendothelial passage of macromolecules. In the final analysis, tracer studies have provided compelling evidence for the existence of “functional pores” that mediate transfer across endothelia (a process termed *transcytosis*). Transcytosis – which appears to be a feature of all epithelia (8) – describes the process of macromolecular transport across cellular barriers via membrane-bounded vesicular carriers, including plasmalemmal vesicles (caveolae), clathrin-mediated pathways, and nonclathrin, noncaveolar pathways (9).

## HISTORY

The earliest contributions to our understanding of the exchange of water and solutes across permselective barriers

1 Endothelia have been classically defined into three main structural types, depending on their content of specific structures: the continuous, fenestrated, and discontinuous endothelium (schematized in Figure 74-2). The *continuous endothelium* forms an uninterrupted barrier between the blood and tissues. It features a large population of caveolae or plasmalemmal, extremely few TECs, and virtually no fenestrae. In addition to relatively fewer caveolae, the *fenestrated endothelium* features pores such as fenestrae, transendothelial channels, and endothelial pockets. *Discontinuous* or *sinusoidal endothelium* lines the sinusoids in the liver and bone marrow. It has extremely few caveolae and displays sinusoidal gaps.

date from the 19th century, with the work of physiologists such as C. Bernard and E. H. Starling (10). As discussed earlier, the seminal work of physiologists in the last century led to the formulation and development of the “pore theory” of capillary permeability (11–16). The introduction of the electron microscope during the 1950s ushered in an era of elegant structure-function studies. George Palade, a pioneer in the ultrastructural field, was the first to describe what appeared by transmission electron microscopy (TEM) as “uncoated”<sup>2</sup> plasma membrane invaginations and vesicles in the cytoplasm of endothelial cells (ECs); he named these structures plasmalemmal vesicles (17). Later studies uncovered the presence of a diaphragm overlying the opening or stomata of the plasmalemmal vesicles (so-called *stomatal diaphragms* [SDs]) (18–20). Very soon after their discovery, by employing electron opaque tracers (e.g., colloidal gold, ferritin), Palade showed that macromolecules use the plasmalemmal vesicles to cross the endothelium “in quanta,” that is, in discrete vesicular carriers that shuttle between the luminal and abluminal sides (21,22). Subsequent work by Palade’s and other groups have demonstrated the vesicular transport for several physiologically relevant macromolecules in endothelium, which crystallized under the concept of *transcytosis* (term coined by N. Simionescu, one of Palade’s collaborators) (23). A few years after the description of the plasmalemmal vesicles, E. Yamada described similar uncoated vesicles in other epithelia, which he called *caveolae* (24). Until the discovery of caveolin-1 as marker of caveolae, the terms *plasmalemmal vesicles* and *caveolae* were used interchangeably based simply on similar morphology. At the beginning of the 1990s, when caveolin-1 was shown to stain most of the plasmalemmal vesicles in endothelium (25–29), it was assumed that all uncoated vesicles are

2 As opposed to the clathrin-coated vesicles that have a characteristic fuzzy coat by EM.

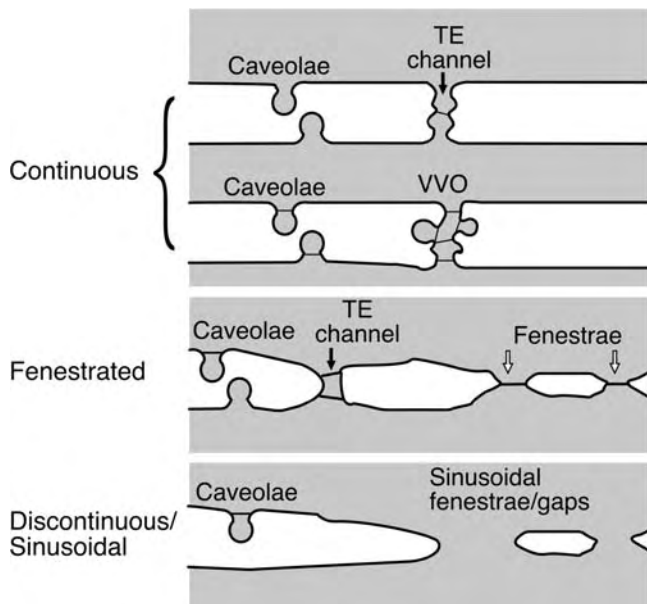

Figure 74.2. Morphological types of endothelium. Schematic cross-sections of EC segments of the continuous, fenestrated, and discontinuous type and their relevant specific organelles. Continuous endothelium has caveolae with or without SDs and few TECs. VVOs have been described in the continuous ECs of the venules. The fenestrated endothelium features caveolae, always provided with a SD, TEC, and fenestrae. A FD spans the fenestrae in all cases except kidney glomerulus. The discontinuous endothelium has extremely few caveolae provided with SDs and sinusoidal fenestrae.

the same, and the term *caveolae* became truly synonymous with *plasmalemmal vesicles*. However, during the last few years, a large number of alternative endocytotic pathways that use uncoated vesicles have been demonstrated in many cell types, endothelium included (30–33). Some of these pathways seem to participate in transcytosis, along with caveolae and clathrin-coated pits (9,34,35).

Early EM studies revealed the presence of fenestrae in certain vascular beds, giving rise to the time-honored classification of fenestrated versus nonfenestrated endothelium (Figure 74.2). Oberling first reported the existence of diaphragms in the fenestrae of kidney endothelium (36,37). Subsequent studies demonstrated fenestral diaphragms (FDs) in other types of endothelium (38–42). In 1970, E. Wisse (43) documented in the liver sinusoids an endothelial lining that lacked a basement membrane and that showed many discontinuities of varied sizes, which he named *sinusoidal fenestrae* or *gaps*. Thus, a third endothelial morphological type was recognized, namely the discontinuous (or sinusoidal) endothelium. Scanning electron microscopy (SEM) studies showed that the discontinuities of this type of endothelium are not gaps between ECs, because the intercellular junctions were fully formed, but they are circular pores through the EC (44). Thus, the term *fenestrae* is much more appropriate to describe them. However, their relationship with the fenestrae of the fenestrated endothelium (smaller, constant in size, subtended by a diaphragm) is not

clear and creates some confusion in the field. TECs were first described as “fenestrae with two diaphragms” in fenestrated endothelium, and were considered the same entity as fenestrae. Their diaphragms were later shown to have different chemical properties in terms of lectin and cationic probe binding (45–47), and were thus proposed to represent a separate structure. Also, the presence of TECs formed by a chain of interconnected vesicles with or without diaphragms was revealed by electron-opaque tracers in continuous endothelium (48). As a variant to fenestrae and TECs, in 1986, Milici and Palade described “endothelial pockets” (or “fenestrated domes”), a very little known morphological entity consisting of a vacuole-like space communicating via fenestrae with the luminal and abluminal space (49). Finally, in 1992, H. Dvorak’s group reported a novel structure in ECs, the so-called VVOs (50).

### ONTOGENETIC CONSIDERATIONS

No systematic studies have documented the appearance of caveolae, fenestrations, TECs, pockets, VVOs, or diaphragms and their specific protein components during development. Most of the data available concern the formation of the fenestrae and their diaphragms.

In the blood island and vascular plexus stage of vascular development, examination of micrographs published in various papers shows a continuous endothelium devoid of fenestrae or TECs. Unfortunately, the magnification shown is usually too low for a qualitative assessment of the presence of caveolae or VVOs and their respective diaphragms, most of the studies being more concerned with the organization of the vasculature than the ultrastructural detail of ECs.

The rat brain starts developing as an avascular mass or primordium surrounded by vascularized tissue called the perineurium, whence the developing brain will attract sinusoid-like vessels by sprouting angiogenesis between approximately embryonic day (E)12 and E16. At E12, the vessels in perineurium have fenestrated endothelia (51), but it is not known when precisely fenestrae appear in these vessels, E12 being the earliest time point reported in this paper. Interestingly, fenestrae subtended by diaphragms are present in the vessels that enter the nervous matter from E12 to E16 by sprouting angiogenesis but are lost upon the formation of the blood–brain barrier (BBB), beginning with E16 (51).

The capillaries of rat intestinal mucosa are initially continuous and express caveolae; it is not clear whether SDs are present. These continuous capillaries become fenestrated late in gestation, at E15 to E16, when they start to express fenestrae subtended by diaphragms (52,53). The reason for the delayed induction of the fenestrae in the intestine is not known. A possible explanation may be found by examining the situation in the adult, in which the vessels in the intestinal tunica muscularis are continuous, and the ECs have caveolae without SDs. As the vessels enter the mucosa (i.e., the villus), their endothelium remains continuous in the central bundle vessels but their caveolae have SDs. The capillary loops

that come in contact with the epithelium are fenestrated, and their fenestrae have SDs. The intestinal mucosa does not fully develop in the embryo but requires the postnatal establishment of the intestinal flora, which leads to the elongation of the villi and formation of fenestrated vessels by angiogenesis.

Interestingly, in rat kidney development, the fenestrae that appear first in the kidney glomerular capillaries are subtended by diaphragms. Moreover, these diaphragms bind cationic ferritin, a property common to all fenestrae in the adult embryo, conferred by heparan sulfate proteoglycans (54). It is not known, however, at which precise stage fenestrae appear in the kidney. The diaphragms of glomerular fenestrae are gradually lost within a week or two after birth, resulting in the unique phenotype of the adult glomerulus with fenestrae lacking diaphragms (37,54–56).

In the liver at E10 to E12, during the hematopoietic stage, the capillaries have a basement membrane and are fenestrated, but the fenestrae resemble those of the adult fenestrated endothelium: circular pores, regular in size (average 60–70 nm), and subtended by FDs. Starting at E17, these fenestrae are progressively replaced by larger, more size-heterogeneous fenestrae that are typical of the adult liver and other sinusoidal ECs (57,58).

In summary, it is not known when fenestrae, TECs, caveolae, VVOs, and their respective diaphragms first appear in different vascular beds. Drawing a parallel between the appearance of the glomerular fenestrae and those of the sinusoids is tempting, because both types of fenestrae lacking diaphragms seem to be preceded by fenestrae subtended by diaphragms.

Plasmalemma vesicle protein 1 (PV1) (also known as plasmalemma vesicle-associated protein [PLVAP]) is the only known marker (discussed later) of endothelial SDs and FDs. The mRNA is definitively expressed in both mouse and rat embryos by E7 (59), corresponding to the formation of blood islands. PV1 protein is detectable by E12 in most organs, and is lost by E16 to E18 in the brain at time of BBB formation (60). Moreover, the loss of PV1 expression correlates with the loss of fenestrae on BBB formation (61). In mice at E11.5, PV1 is expressed in hindlimb buds, but not forelimbs (62). PV1 also is expressed on bone marrow endothelial progenitor cells (63) as well as on the ECs that spontaneously differentiate on embryoid bodies after 5 days outgrowth (64).

## ULTRASTRUCTURE OF ORGANELLES INVOLVED IN PERMEABILITY

The transendothelial exchange of plasma and solutes takes place at intercellular junctions (paracellular pathway) and through the EC (transcellular route) via fenestrae, caveolae, TECs, and VVOs. Here, we discuss the structures, organelles, and microdomains involved in the transcellular pathway. Although their exquisite architecture has been compared to works of art (65), their molecular components have remained elusive for decades.

## Caveolae and Their Stomatal Diaphragms

Caveolae (also termed *plasmalemmal vesicles*) occur in most mammalian cell types, including ECs (for reviews see Refs. 6 and 66, and Chapter 73). They are morphologically defined as spherical invaginations of plasma membrane of regular shape and size (~70 nm) (Figure 74.1A–D) (18–20). They occur singly or in grape-like clusters attached to either the apical or basolateral domain of the endothelial plasma membrane. In fenestrated and discontinuous endothelia, and in select endothelia of continuous type (e.g., in lung, tongue, kidney vasa recta), caveolar necks are subtended by a SD, as evidenced by rapid-freeze deep-etch techniques (Figure 74.1B (67,68)). By TEM, the SD is a thin (~5–7 nm) protein barrier that bridges the neck or stoma of the caveolae at the surface of the cell or between vesicles that form part of an intracellular cluster (Figure 74.1B and D). Because of the dynamic nature of caveolae that could undergo internalization, their necks have a variable diameter, which results in variable diameter SDs (<40 nm). At the site of SD insertion, the plasma membrane forms a sharp angle. Electron-dense material usually is present on the intracellular aspect of the membrane within this angle, as shown in orthogonal TEM sections (Figure 74.1D). Both orthogonal and en face views demonstrate a central density or knob on the SDs (20,38). Favorable en face views of the SDs (e.g., in the lung capillaries) suggest the central knob to be connected to the vesicular neck by very thin fibrils. Also, in rapidly frozen deeply etched specimens, a hint of the radial fibrils pattern also is detectable (68). The diaphragm is apparently lipid-free, because it does not have the trilaminar appearance of the plasma membrane bilayer. It is destroyed by proteases (45), which implies its proteinaceous nature (66).

## Endothelial Fenestrae and Their Diaphragms

Endothelial fenestrae (Figure 74.1F–I) are circular windows resembling “boat portholes” that cut through the cell body. They are arranged in ordered linear arrays within large planar clusters called *sieve plates*. Individual fenestral pores have a remarkably constant diameter (~62–68 nm) (28,39,69). The fenestral rim delineates their circumference, where the luminal aspect of plasma membrane continues with the abluminal one under a sharp angle filled with electron-dense material, as in the case of the SD. The circumference of the fenestral pore has an octagonal symmetry (68,70,71).

With the exception of glomerular endothelium, all endothelial fenestrae possess a diaphragm (37,54–56). Compared with SDs, FDs have a slightly larger diameter. However, both types of diaphragms are structurally similar, consisting of a thin protein barrier anchored at the fenestral rim and provided with a central knob or density connected to the fenestral rim by thin fibrils (41). Bearer and Orci exquisitely demonstrated that FDs consist of radial fibrils, starting at the rim and interweaving in a central mesh, the equivalent of the central density or knob seen by TEM (Figure 74.1G–H) (68). Unfortunately, the SDs of caveolae and TECs could not be resolved

in the same detail owing to their smaller size and technical limitations (i.e., the angle of shadowing) (68). SDs of caveolae resemble those of TECs, with both featuring a central particle (68) (Figure 74.2G) and hints of FD-like radial fibrils (Figure 74.2B).

Recent studies employing special perfusion techniques have revealed an interesting difference between fenestral and SDs; FDs, but not those of caveolae or TECs, contain large (up to 400 nm) tufts (termed *fascinae fenestrae*) on the their luminal side (72). The fibers forming these tufts have been interpreted as the morphologic equivalent of the heparan sulfate proteoglycans shown to reside on the luminal surface of fenestrae (73).

### Transendothelial Channels

TECs are patent pores spanning the EC body from their apical (luminal) to the basolateral (abluminal) front (Figure 74.1E). TECs are rarely found in continuous endothelia, where they seem to be formed by the fusion of either one caveolae/plasmalemmal vesicle with both luminal and abluminal aspects of the plasmalemma or by chains of usually two to four vesicles (20,48,74). In fenestrated endothelia, TECs occur in the attenuated part of the EC and are provided with two SDs (one luminal and one abluminal) (39,69,75,76). As mentioned, TEC diaphragms display the same features as the SDs of caveolae.

### Vesiculo-Vacuolar Organelles

VVOs are morphologically defined as chains of interconnected vesicles and vacuoles of variable size that form intricate TECs, spanning the cytoplasm of the EC from the apical to the basal side of the cell (77). They normally possess SDs at the connection points between vesicles and vacuoles, as well as at the level of their stoma or point of communication with the extracellular space (78). The SDs of the VVOs closely resemble those of caveolae by TEM. VVOs have been described in post-capillary venules as well as tumor blood vessels (50,77,79). It is formally possible that VVOs represent clusters of caveolae (20,69), and thus do not represent a bona fide, novel organelle (76). However, in support of its status as a “novel organelle,” EM studies in mice null for caveolin-1 (which lack caveolae in all nonmuscle cell types) have demonstrated the presence of structures resembling VVOs in venular endothelium (Figure 74.1J) (9,80,81)]. The relationship between these structures and VVOs remains to be clarified following biochemical evaluation.

### Endothelial Pockets

By EM, these infrequently seen structures resemble a pocket or a large vacuole formed by cellular processes that contain fenestrae with the usual structure (76). The information on these is scarce (49) and, so far, they seem to occur in very low numbers only in the fenestrated endothelia.

## MOLECULAR STRUCTURE OF ORGANELLES INVOLVED IN PERMEABILITY

### Probes with Broad Specificity

The chemical components of SDs and FDs have been investigated using nonspecific probes such as lectins (46,82–84) and charged molecules (45,47,85–87). SDs bind lectins avidly and lack anionic sites, whereas FDs bind lectins poorly if at all (46,84), and have multiple anionic sites on the luminal side conferred by heparan sulfate proteoglycans (45,72,86). The presence of lectin-binding sites on SDs and FDs, together with the sensitivity of the diaphragms to protease degradation (45), suggest that these structures contain glycoproteins.

### Plasmalemmal Vesicle–Associated Protein

Recently, SDs and FDs were shown to share at least one biochemical marker, namely PV1 (PLVAP) (59,88–90). The PV1 antigen is recognized by a novel endothelial antibody (21D5 mAb) (91), which colocalizes strictly on endothelial caveolae from rat lung immunisolated with anti-caveolin-1 antibodies (92). Endothelial specificity is further supported by data obtained with two additional anti-PV1 monoclonal antibodies, MECA-32 (60,93) and PAL-E (94,95), which were shown to recognize the PV1 antigen (68). PV1 is encoded by the plasmalemmal vesicle-associated protein (*PLVAP*) gene in humans, and its presence has been clearly documented only in mammals (Homologene record #10578) (59,87–90; and R. Stan, unpublished observations). The gene or significant orthologues are absent from yeast (*Saccharomyces cerevisiae*), insects (*Drosophila melanogaster*), and nematodes (*Caenorhabditis elegans*), in which SDs and FDs are not present. No significant orthologue was found in lower vertebrates such as ascids, amphibians, or fish. Thus PLVAP genes encode for a family of proteins (Pfam 6637) that are highly conserved in mammals, consistent with a function of mammalian closed cardiovascular systems. *PV1* mRNA is expressed in most organs and tissues, with highest levels in lung, kidney, spleen, endocrine glands, and digestive tract, followed by modest levels in large vessels, heart, skeletal muscle, skin, brain, and testis (59,73,88,89).

PV1 is a 50-kDa single-span, type II membrane N-glycoprotein (88,91) that forms homodimers in situ (89). The monomer has a very basic calculated isoelectric point (pI) (~9.1), and the determined pI of the dimer in glycosylated form is still shifted to the basic (pI ~7.8). PV1 binds avidly to heparin at physiological pH (96). PV1 has a short (27-aa) N-terminal intracellular tail and a long (358-aa) C-terminal extracellular domain (73,88). Although the intracellular domain lacks known consensus motifs, it contains two short stretches of amino acids, one next to the transmembrane domain (9-aa) and the other one at the extreme N-terminus (7-aa), that are perfectly conserved across species and that may play a functional role in PV1 biology. The conserved sequence next to the transmembrane domain might contain a putative caveolin-1

interacting motif ( $\emptyset xx \emptyset xxx \emptyset$ , where x is any amino acid (aa) and  $\emptyset$  is a hydrophobic aa such as Trp, Phe, or Tyr) (97). The extracellular domain contains four N-glycosylation sites near the transmembrane domain, a proline-rich region near the C-terminus, and two large coiled-coil domains conserved in all mammals. The secondary structure is predicted to be mostly  $\alpha$ -helical (88,89), sustained by the presence of two large consensus coiled-coil domains that are obligate  $\alpha$ -helix formers (98). Every seventh amino acid of the  $\alpha$ -helix of the coiled-coil domain is hydrophobic, which results in a spiral hydrophobic interface through which one coiled-coil domain interacts with the hydrophobic interface on the cognate coiled-coil to facilitate the formation of an intermolecular superhelix (98). Moreover, seven of the cysteines are situated within the predicted coiled-coil domains. This would suggest that the coiled-coil mediated interaction between two monomers of a dimer would be “reinforced” by several disulfide bonds. All these data suggest that PV1 might adopt a rod-like shape. The fact that the PV1 dimers can be solubilized in SDS suggests that the putative protein–protein interactions between adjacent dimers and other putative interacting proteins (e.g., other PV1 dimers or other protein[s]) are noncovalent in nature.

PV1 is expressed in a subset of ECs (73, 88–90) (e.g., capillaries of the lung, choroid plexus, retina, adrenals, pancreas, intestinal villi, and peritubular capillaries in the kidney, liver, and spleen). PV1 is absent from the continuous endothelia of large vessels of the lung, aorta, and coronary artery as well as from capillaries in the heart, skin, skeletal muscle, and intestinal smooth muscle (where caveolae do not have SDs), and from the fenestrated endothelium of the kidney glomerulus (where fenestrae do not have FDs). All in all, the pattern of expression of PV1 correlates well with the pattern of expression of SDs and FDs *in situ* (73, and our unpublished data), and the observation that PV1 is present in cultured ECs that contain diaphragms (90).

By immunocytochemistry, PV1 was found to be specifically associated with the SDs of caveolae and TECs, and FDs, at both the apical and basal side of ECs (73,88,89), this being the first demonstration of a protein with such localization. The label was absent from other microdomains of the ECs (e.g., clathrin-coated pits, plasmalemma proper, intercellular junctions), as well as from any other cell type in the organs investigated, thus bolstering the claims of endothelial specificity.

### **PV1 Is Necessary and Sufficient for Formation of Stomatal Diaphragms and Fenestral Diaphragms**

PV1 could function either as a structural and/or functional component of diaphragms. Recent data from our laboratory strongly suggest that PV1 is a key structural component of SDs and FDs, and is both necessary and sufficient for diaphragm expression (90). This is based on several lines of evidence: (a) PV1 forms homodimers *in situ*, as demonstrated by cotransfection of PV1 tagged with two different epitopes, followed by immunoprecipitation and immunoblotting with anti-tag

antibodies (89); (b) several PV1 homodimers reside in close proximity within the same diaphragm, as shown by cross-linking experiments of PV1 carried out *in situ* in rat lung and kidneys (89); (c) treatment of ECs in culture, lacking both PV1 and diaphragms, with reagents that induce *de novo* formation of SDs and FDs, upregulates PV1 expression – as expected, PV1 could be found in the newly formed SDs and FDs; (d) PV1 mRNA silencing, using an siRNA approach, prevented the formation of both SDs and FDs (actually, this approach prevented the formation of fenestrae and TECs as a whole, which suggests that both TECs and fenestrae require PV1 for their biogenesis); and (e) overexpression of tagged PV1 in either ECs or non-ECs (e.g., fibroblasts, COS7, HeLa, HEK293) cell types lacking PV1 expression and diaphragms, led to the formation of caveolar SDs. This result shows that either PV1 forms the diaphragms by itself or the other components of the diaphragms are ubiquitously expressed (at least in the cell types studied), PV1 being the limiting factor (90). Based on these data, a model of PV1 integration in the diaphragms was proposed in which PV1 dimers would form or participate in the formation of the diaphragm fibrils (66).

### **FUNCTION OF ORGANELLES INVOLVED IN PERMEABILITY**

In this section, we describe the functional implications of diaphragms in caveolae, fenestrations, TECs, and VVOs. By virtue of their location in these structures, diaphragms likely act as sieves in transendothelial exchange. The passage of select molecules from the blood plasma to the interstitial fluid could be either inhibited or facilitated depending on chemical (i.e., binding to the diaphragm or not) or biophysical (i.e., size, geometry, charge) criteria.

#### **Stomatal Diaphragms of Caveolae in Continuous Endothelium**

No studies directly compare the permeability of continuous endothelium whose caveolae either possess or lack SDs. One approach to this question might be the analysis of lymph composition in different organs (99). However, because the relative contribution of the cell types present in a given organ to the lymph is not known, and the basement membrane composition is expected to be of importance in mediating permeability, differences in lymph composition may provide few clues about the function of the SDs.

Such studies also are limited by microheterogeneity in SD distribution. For example, in perfusion studies, some but not all caveolar invaginations in the microvascular endothelium of the lung are provided with SDs (R.V. Stan, unpublished observations). In EM studies of the lung microcirculation, tracers appeared to gain access to some but not all caveolae, suggesting an uneven distribution of SDs (100–105). It is formally possible that the variable presence of diaphragms in a given vascular bed may be explained on technical grounds (e.g.,

perfusion-related disruption of SDs), or on the basis of misidentification (e.g., similarly sized lipid raft-based endocytotic vesicle systems) (106,107).

Finally, endothelial caveolae have been involved in several functions (see Ref. 6 and references therein); therefore, the SDs may have other roles in addition to that of a possible permeability modulator.

**Diaphragms of Fenestrated Endothelia**

Fenestrated capillaries occur in organs that are involved in the reabsorption of water and small solutes (e.g., kidney and intestine) or hormones (e.g., endocrine glands) from the interstitium into the blood. Most of the data in the literature argue that the fenestrated capillaries are highly permeable to water and small hydrophilic solutes, but their permeability to macromolecules, including albumin, is basically the same as that of the continuous endothelium (108). The fenestrae are the structural equivalents of the large pores described by the pore theory (1). The relative contribution of other organelles, such as caveolae and their SDs, TECs, and VVOs in mediating permeability in fenestrated endothelium is not clear.

Fenestrae demonstrate low albumin penetrance. This was explained by the contribution of the proteoglycan tufts, as well as the basement membranes, to overall permeability. It has been calculated that the permeability to water and small solutes could be explained with only a fraction of the fenestrae being open, therefore the function of the proteoglycans would be that of a permeability-reducing plug (109). Tracer experiments show that all fenestrae are permeable to horseradish peroxidase (molecular diameter (Ø) 4 nm) (39), whereas only a few permit the exit of ferritin (Ø 11 nm) (39), dextrans (Ø 12.5–22.5 nm), and glycogen (Ø 22 and 30 nm) (110). As in the case of the fenestrae, all these tracers gained access to few caveolae past their SDs (53,110). As shown by Bearer and Orci (68), the pores between the fibrils of fenestrae have dimensions of 5 to 6 nm; therefore, the passage of the larger tracers must be accommodated by fenestrae with larger pores. An interpretation of these data may be that the diaphragms are dynamic structures, and the degree of their permeability could be modulated by yet unknown factors. Another possibility that cannot be discarded at present is artifact creation in perfusion experiments or during processing in experiments in which the tracers were injected into circulation.

**Vesiculo-Vacuolar Organelles**

The functions of VVOs have been extensively reviewed recently (4). They have been involved in increased permeability related to inflammation and tumors, permeability to macromolecules, and particulate and immune-cell extravasation. Interestingly, their SDs seem to play a restrictive role in the permeability of particulates (78). The results obtained in cells in culture (111) bolster the claims for VVOs as an organelle involved in the permeability induced by cytokines such as vascular endothelial growth factor (VEGF). However, it is not

clear how their restricted localization to the venular endothelium would contribute to the overall permeability in a particular vascular bed, accepting the hypothesis that the bulk of transendothelial exchanges would occur at the level of the capillaries.

**KEY POINTS**

- Two types of vascular permeability occur: “basal” and “increased.” The molecular mechanisms of these types of vascular permeability are not clearly understood.
- Several endothelial structures, such as caveolae, fenestrae, TECs, and VVOs, have been involved in different aspects of permeability. There is little information about the components and the regulation of these structures, especially of fenestrae, TECs and VVOs. PLVAP (PV1) protein is the only protein shown to specifically reside within these structures.
- Work on the components and regulation of these structures should lead to the elucidation of the molecular mechanisms of permeability.

## Endothelial Luminal Glycocalyx

### Protective Barrier between Endothelial Cells and Flowing Blood

†Academic Medical Center and University of Amsterdam, Amsterdam, The Netherlands

All cells – from single-cell microorganisms to highly organized mammalian cells – are shielded from their surrounding milieu by a membranous, carbohydrate-rich layer, or glycocalyx. The glycocalyx also is involved in nutrient uptake, and it facilitates the binding and concentrating of factors necessary for proper cell function. In the vasculature, the endothelial glycocalyx protects the vascular wall from direct exposure to flowing blood, contributes to the vascular permeability barrier and its antiadhesive properties, and stimulates the endothelial release of nitric oxide in response to fluid shear stress.

Historically, studies aimed at understanding mechanisms of endothelial permeability led to the concept that vessel walls are lined with an extracellular layer of membrane-bound substances (1,2). Danielli (1), and Chambers and Zweifach (2) hypothesized the existence of a thin, noncellular layer on the endothelial surface, termed the *endocapillary layer*. In the latter study, the perfusion of frog mesentery with an Evans blue-containing solution revealed blue-colored thin strands and sheets of translucent material on the inner surface of the capillary (2). In subsequent experiments involving intravenous injections of pontamine sky blue and intravital microscopy of the hamster cheek pouch, Copley and Staple observed an unstained plasmatic zone adjacent to the endothelial surface, giving rise to the notion that the endothelial surface is covered by a thin molecular layer (the endoendothelial fibrin lining) and an adjacent immobile plasma region (3).

To date, although both concepts, in essence, still hold true, novel data on the structural and compositional properties of the endothelial glycocalyx implicate a highly active role for this noncellular layer in vascular wall homeostasis. Like so many other properties of the endothelium, this role is likely to vary

between different sites of the vascular tree. Indeed, efforts to correlate the structure and composition of the glycocalyx with underlying physiology and pathophysiology should take into account site- and time-specific differences in vascular permeability and blood flow.

#### STRUCTURAL PROPERTIES OF THE ENDOTHELIAL GLYCOCALYX

##### Electron Microscopy

A combination of ruthenium red staining and conventional electron microscopy (EM) provided the first direct visualization of the endothelial glycocalyx (4). Ruthenium red is a cationic dye that has a high affinity for acidic mucopolysaccharides and, together with osmium tetroxide fixation, generates electron density. The electron micrographs revealed a small, irregularly shaped layer extending approximately 50 to 100 nm into the vessel lumen. Subsequent EM studies, in which varying perfusates or fixatives were used to stabilize anionic carbohydrate structures, demonstrated the presence of a glycocalyx (of heterogeneous dimension and appearance) on continuous endothelium throughout the vasculature (5–10). Fenestrated endothelium, in addition, was found to have a combination of surface-bound stained structures (50–100 nm thick) and distinct filamentous plugs (20–40 filaments, with a length of about 350 nm) on the surface of the fenestrae (11). Collectively, these investigations provided compelling evidence for a thick endothelial surface layer (ESL) throughout the vascular tree (Figure 75.1). Colocalization of lectins to the observed stained structures confirmed their saccharine nature (5,7,9).

Figure 75.1. Electron micrograph of a goat coronary capillary stained with Alcian blue.

### Intravital Microscopy

Improvements in intravital microscopy, such as the introduction of quantitative methods and fluorescence techniques, have yielded additional insights into the glycocalyx. Among the more important discoveries is that the glycocalyx is much thicker than originally believed based on EM studies. For example, using a hamster cremaster muscle model, Klitzman and Duling demonstrated dramatic differences in the microvascular and systemic hematocrit (12). Moreover, these differences were abrogated upon enzymatic treatment of the microvascular network with heparinase (13). Based on these findings, it was hypothesized that there exists a 300- to 1,000-nm thick, slow-moving plasma layer on the endothelial cell (EC) surface consisting principally of heparan sulfate (HS) proteoglycans.

As an alternative approach to characterize the glycocalyx, we labeled the free-flowing plasma using FITC-dextran. In hamster cremaster capillaries, the width of the labeled plasma column was compared with the anatomical diameter of the lumen. The anatomical diameter was consistently greater than that of the plasma column, revealing a continuous EC surface layer with a thickness of 400 to 500 nm (Figure 75.2) (14). Subsequent theoretical considerations predicted a glycocalyx thickness of 500 to 1,000 nm, accounting for the observed variations in red cell motion through the microvessels and the discrepancy between *in vivo* and *in vitro* estimates of resistance to blood flow (15–17).

The functional relevance of the glycocalyx was demonstrated in a canine model of coronary reactive hyperemia (18). Reactive hyperemia following a 15-second occlusion of the left circumflex artery was compared in dogs in which coronary arteries were infused with or without hyaluronidase. Treatment with hyaluronidase resulted in increased coronary conductance (the inverse of resistance). Heat-inactivated hyaluronidase had no such effect. Further *in vivo* evidence for the role of the hyaluronan in mediating glycocalyx properties was provided by Henry and Duling, who demon-

strated that hyaluronidase treatment of hamster microvessels in the cremaster muscle resulted in increased access of 70- to 145-kDa FITC dextrans, but not higher molecular weight FITC dextrans or red blood cells (19).

Taken together, these findings are consistent with the presence of a hyaluronan-containing glycocalyx whose volume and thickness provide normal resistance to flowing blood. Indeed, the unexpectedly large dimension of the glycocalyx exceeds – by several times – the dimensions of the endothelium and its associated receptors, including leukocyte adhesion molecules. It is tempting to speculate that glycocalyx dimension per se plays an important role in blood vessel physiology. Indeed, various studies have demonstrated a link between altered glycocalyx dimension and pathophysiology, as in ischemia–reperfusion (6), hypoxia (10), high-density lipoprotein (HDL) (20) and low-density lipoproteins (LDL) (21,22), and variations in wall shear stress (7,23).

### COMPOSITION OF THE ENDOTHELIAL GLYCOCALYX

The endothelial glycocalyx is composed of a negatively charged mesh consisting of proteoglycans (core proteins containing long, unbranched carbohydrate side-chains termed *glycosaminoglycans*), glycoproteins (proteins containing short carbohydrate side-chains), and glycolipids (24). The most common core proteins are syndecans, glypicans, and perlecan. Glycosaminoglycans include HS, chondroitin sulfate (CS), and hyaluronan. Examples of glycoproteins include selectins, integrins, and members of the immunoglobulin superfamily. In addition to cell surface-bound components, the composition of the glycocalyx also is influenced by absorption of soluble plasma components, such as albumin, orosomucoid, fibrinogen, and fibronectin. The endothelial glycocalyx also harbors a wide array of enzymes and proteins that play a role in leukocyte–EC and platelet–EC adhesion, including extracellular superoxide dismutase

Figure 75.2. Combined bright-field and fluorescence intravital microscopy. These studies reveal a gap of about 200 to 800 nm between passing red blood cells, and a fluorescent column of an infused fluorescent dye coupled to a large molecule (Dextran 70), and the EC boundary. (Reproduced with permission from Vink H, Duling BR. Identification of distinct luminal domains for macromolecules, erythrocytes, and leukocytes within mammalian capillaries. *Circ Res.* 1996;79(3):581–589.)

(ec-SOD), angiotensin-converting enzyme (ACE), antithrombin III (ATIII), lipoprotein lipase (LpL), hepatic endothelial lipase (HEL), apolipoproteins, growth factors, and chemokines.

Constituents of the glycocalyx, such as hyaluronan, have been found to be intimately involved in mediating vascular homeostasis (7,9,19). For example, the glycocalyx serves as a mechano-shear sensor for nitric oxide (NO) release (25–27). Certain enzymes present in the glycocalyx contribute to its vasculoprotective effect. In particular, ec-SOD, which dismutates oxygen radicals to hydrogen peroxide and is bound to proteoglycans within the glycocalyx, is shed upon damage to the glycocalyx and results in an unbalance in favor of a pro-oxidant state (28).

### ENDOTHELIAL GLYCOCALYX AND VASCULAR PERMEABILITY

Vascular barrier properties determine the transport of fluid between blood and interstitial space according to the Starling-Landis equation (29):

$$J_c = L_p A [(P_c - P_t) - \sigma_p (\pi_c - \pi_t)]$$

where  $J_c$  = net transcapillary fluid shift,  $L_p$  = hydraulic conductivity of capillary wall,  $A$  = capillary membrane filtration area,  $P_c$  = capillary blood pressure,  $P_t$  = tissue fluid pressure,  $\sigma_p$  = reflection coefficient for plasma proteins,  $\pi_c$  = capillary blood colloid osmotic pressure, and  $\pi_t$  = tissue fluid colloid osmotic pressure.

A continuous turnover of fluid occurs in the body. Fluid is filtered from blood to tissues at the arterial end of the circula-

tion and is reabsorbed at the venous end. This pattern is largely dictated by differences in the hydrostatic pressure between the two ends of the vascular segment. Excess fluid not taken up at the venous end is removed from the tissue by the lymphatics.

The hydraulic conductivity reflects vessel wall permeability to water. Hydraulic conductivity varies between different segments of the vascular tree (e.g., arterioles, capillaries, and venules) and between microvascular beds from different organs. These differences, which presumably reflect site-specific demands of the underlying tissue, are explained – at least in part – by the variable existence of transendothelial channels, fenestrae, and intercellular gaps.

In 1980, Curry and Michel proposed the fiber matrix concept (30). According to this model, the molecular sieving properties of the capillary wall are determined by a fiber matrix, covering all endothelial channels and filling intracellular boundaries. It was suggested that the local protein concentration gradient that generates the colloid osmotic pressure (or oncotic pressure) is localized across the glycocalyx and not between the plasma and tissue underlying the endothelium. Thus, the endothelial surface glycocalyx maintains fluid balance between blood and tissue and results in a balance between the absorption and filtration of water. This hypothesis was confirmed by the remarkable similarity of protein permeability and reflection coefficient (i.e., the rejection of molecular passage) in fenestrated and continuous capillaries despite their differences in filtration coefficient and ultrastructure (31). Recently, this was further illustrated by very similar estimates (between 34 and 45 mEq/L) of the permeability parameter related to the presence of charge-selective

properties ( $\omega$ ) between peripheral and glomerular capillaries, although the renal glomeruli are the body's most active filtration units, producing about 180 liters of primary urine per day, with a minimal loss of proteins (32).

Because glomerular capillaries consist of fenestrated ECs, whereas peripheral ECs are predominantly of the continuous type, it appears that, in most vascular beds, the capillary wall behaves as a molecular filter that allows the free exchange (by convection and diffusion) of water, ions, and small hydrophilic solutes between the plasma and tissue spaces, but limits the passage of highly charged macromolecules. These findings argue for similar selective permeability properties throughout the various vascular networks and organs, predominantly dependent on the high plasma concentration of negatively charged albumin, the main contributor to oncotic pressure.

### ENDOTHELIAL GLYCOCALYX IN MICRO-VERSUS MACROVASCULATURE

Studies in both micro- and macrovessels demonstrated similarity in glycocalyx constituents such as hyaluronan (7,9,19), the release of NO (25–27), and the presence of ec-SOD (28), which are all involved in vascular homeostasis and protection against damage. These findings are of particular interest because altered vascular permeability, attenuated NO bioavailability, and redox dysregulation are among the earliest characteristics of atherogenesis (33).

Despite these observations, it has proved difficult to show direct relevance of the glycocalyx as a vasculoprotective paradigm for larger vessels. The latter is predominantly due to the fact that glycocalyx research has traditionally focused on the microvasculature, in which atherogenesis does not occur. However, several studies have emphasized the relevance of the glycocalyx in macrovessels (6,23). van Haaren and colleagues recently visualized a thick endothelial glycocalyx in the larger arteries of rats (34). Interestingly, the reduced thickness of the glycocalyx at high-shear compared to low-shear regions of the murine carotid artery lends direct support to a potential role of glycocalyx perturbation in rendering low-shear regions more susceptible to atherogenesis (23,35). The glycocalyx in larger vessels also has been shown to decrease extravasation of LDL particles into the subendothelial space (36,37). Together, these data imply that, in addition to its functional importance in small vessels, the glycocalyx serves a vasculoprotective role in large vessels.

### ROLE OF ENDOTHELIAL GLYCOCALYX IN HEMOSTASIS

The endothelium is involved intimately in the regulation of coagulation. Under physiological conditions, the generation of thrombin is tightly regulated by the inhibitory actions of ATIII, thrombomodulin, endothelial protein C receptor, and tissue factor pathway inhibitor (TFPI), all of which are bound

to the luminal endothelium (38,39). Denudation of endothelium leads to exposure of blood to the tissue factor-rich vessel wall. Activation or dysfunction of *intact* endothelium results in downregulation of natural anticoagulant mechanisms, including reduced expression of thrombomodulin and the endothelial protein C receptor. Whether structural or functional in nature, these changes may result in a shift in the hemostatic balance toward the procoagulant side. Interestingly, a specific disruption of the glycocalyx itself results in thrombin generation and platelet adhesion as early as 10 minutes after glycocalyx removal (22). Moreover, activation agonists such as proinflammatory cytokines have profound effects on the synthesis of glycocalyx constituents, such as HS and hyaluronan, thus contributing to impaired natural anticoagulant defenses (40,41).

### ROLE OF ENDOTHELIAL GLYCOCALYX IN LEUKOCYTE ADHESION

Leukocyte trafficking is regulated by a highly orchestrated multistep pathway that involves the inducible expression of cell adhesion molecules on the surface of the endothelium (42). The dimension of the glycocalyx greatly exceeds the length of the extracellular domain of adhesion molecules such as P- and E-selectin, intercellular adhesion molecule (ICAM)-1, and vascular cell adhesion molecule (VCAM)-1.

Thus, new concepts have been developed to explain how leukocytes interact with endothelial adhesion molecules (43,44). According to one model, leukocytes develop cooperative weak interactions with hyaluronan, which exhibits electrostatic attraction properties (43). The subsequent fate of adhesion depends on modification of the glycocalyx layer such that leukocyte-bound ligands are exposed to EC surface adhesion molecules, for example, as might occur with the directed lateral diffusion of active transport of the hyaluronan and the attached membrane receptors, or the hyaluronidase-mediated degradation of hyaluronan. The second model implicates a role for long L-selectin-containing leukocyte microvilli in contacting the EC through the glycocalyx (44,45). Once the microvilli penetrate the glycocalyx, they may initiate rolling along the endothelial surface. Again, implicit in this paradigm is the subsequent modification of the glycocalyx to allow for firm adhesion, spreading, and transmigration.

It is interesting to speculate that disease-associated modification of the glycocalyx results in dysregulated leukocyte trafficking. Exposure of ECs to ox-LDL, as occurs in atherosclerosis, has been shown to decrease the amount of HS proteoglycans associated with the luminal cell surface (46). Furthermore, inflammation and ischemia-induced shedding of glycocalyx in activated endothelium may be coupled to vascular inflammation (47). Consistent with its inhibitory (barrier) role in leukocyte adhesion (48), glycocalyx preservation (via the infusion of major glycocalyx constituents) was shown to abolish leukocyte rolling to the endothelial surface in response to potent proatherogenic challenges (49).

Figure 75.3. Three-dimensional microscopic reconstruction of fluorescent tracer distributions in mouse cremaster tissue capillaries. (Reproduced with permission from Vink H, Stace TM, Damiano ER. 2003.)

**ASSESSMENT OF SYSTEMIC GLYCOCALYX DIMENSION IN HUMANS**

To date, direct visualization of endothelial glycocalyx in humans has been unsuccessful, mainly due to the fact that the endothelial glycocalyx is a very delicate structure that is critically dependent on the presence of flowing blood (24). Because the endothelial glycocalyx provides limited access to plasma macromolecules and erythrocytes, the best way to measure the endothelial glycocalyx in humans is to compare intravascular volumes using a glycocalyx-permeable tracer, such as neutral Dextran 40 (MW 40 kDa) and a glycocalyx-impermeable tracer, such as anionic sulfated dextran or labeled erythrocytes (14) (Figure 75.3). Based on the electromechanical nature of interactions of erythrocytes and anionic plasma molecules with the sulfated glycosaminoglycans, high-resolution three-dimensional (3-D) intravital fluorescence microscopy reveals a partial exclusion of intravenously injected sulfated dextran molecules (anionic) within a 1-micron thick capillary EC glycocalyx, in comparison to Texas red-labeled dextran molecules (neutral). To make this method feasible in humans, intravascular distribution of flowing blood volume can be quantified using labeled autologous erythrocytes (50). In combination with total intravascular volume measurements using the neutral tracer Dextran 40, it is possible to distinguish between flowing plasma volume and total plasma volume and hence systemic glycocalyx volume.

**CONCLUSION**

Located at the interface of flowing blood and the vascular endothelial lining, the endothelial glycocalyx displays a wide array of functions, including maintenance of interstitial fluid balance, hemostasis, leukocyte adhesion, and mechano-

transduction. Structural and/or functional disruption of the glycocalyx may arise from and/or contribute to a number of pathophysiological conditions, including atherosclerosis. Important considerations are the composition and the physical dimensions of the glycocalyx, and how these properties differ between different vascular beds in health and disease. Whereas glycocalyx disruption is accompanied by enhanced sensitivity of the vasculature toward atherogenic stimuli, glycocalyx “restoration” attenuates these abnormalities, suggesting a potential benefit of glycocalyx-based therapies. From a diagnostic standpoint, an important goal is to determine the feasibility and value of systemic glycocalyx measurement as a surrogate marker for cardiovascular disease.

**KEY POINTS**

- The glycocalyx is the carbohydrate rich matrix that lines the luminal surface of the vasculature and forms the true interface between endothelium and flowing blood.
- Novel intravital techniques indicate that the glycocalyx is considerably thicker than originally believed.
- The glycocalyx consists of endothelial-derived and plasma-derived components.
- The glycocalyx is vasculoprotective and plays an important role in homeostasis.

*Future Goals*

- To develop and test novel therapies aimed at restoring glycocalyx in disease
- To develop diagnostic tools for measuring glycocalyx dimensions and constituents

## The Endothelial Cytoskeleton

Christopher V. Carman

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The vascular endothelium represents an enormous and heterogeneous organ faced with diverse challenges. The individual endothelial cells (ECs) that make up this organ must organize a polarized and discrete monolayer, with a range of tissue-specific specializations. The endothelium must be capable of carefully balancing and dynamically regulating both barrier function and selective permeability to solutes and immune cells. ECs must resist significant, and in some settings extreme, mechanical forces including fluid shear, hydrostatic pressure, and cyclical stretch. Finally, these cells must be able to efficiently migrate and, indeed, invade tissue matrices during the formation of new vessels. The cytoskeleton of the endothelium is central to meeting all these challenges. Our growing knowledge of the roles and regulation of cytoskeletal components in endothelium provides us with an improved understanding of endothelial function in both health and disease.

### AN OVERVIEW OF THE CYTOSKELETON

The cytoskeleton is formed by three kinds of protein filaments, which together provide cells with shape, mechanical strength, spatial organization/polarity, and movement. They also serve to connect protein complexes and organelles in distinct parts of the cell, and can provide tracks for transport between them. These filaments include microfilaments (or “actin filaments”), microtubules, and intermediate filaments. Each of these is formed by the polymerization of separate sets of proteins with distinct dynamics and stability. The dynamics, stability, and function of these filaments are highly dependent on a large repertoire of accessory and regulatory proteins that control the localized assembly, connect filaments to each other and other cellular components, and provide motors that move organelles (or other filaments) along their length.

#### Microfilaments

Microfilaments are approximately 5 to 9 nm in diameter and are composed of polymers of globular ATP-binding/

hydrolyzing proteins termed *actin* (G-actin; each ~42 kDa) (1). Microfilaments are polarized, with distinct slow (*minus*) and fast (*plus* or *barbed*) growing ends, and form either as bundles of linear filaments (*fibers*) or highly branched lattices. The degree of branching is regulated by the Arp2/3 complex, which associates laterally with individual microfilaments to create branch points at a distinct 70-degree angle (2).

Basic structures formed by microfilaments include actin stress fibers, cortical actin lattices, and various distinct protrusive structures including lamellipodia, filopodia, pseudopodia, podosomes, and invadopodia (3,4). Actin stress fibers represent bundles of microfilaments that are attached to the cytoplasmic domain of cell surface adhesion receptors, such as integrins, typically arranged into clusters termed *focal contacts* and *focal adhesions* (1). Microfilaments, in combination with the actin-associated motor protein complex myosin, serve to generate centripetal contractile force. Cortical actin lattices form at the periphery of the cell underlying the plasma membrane, where they contribute to cell shape and mechanical stability. The various protrusive structures, such as lamellipodia, are critical for cell shape change, spreading, and migration. It is widely appreciated that the specific architecture and dynamics of the actin cytoskeleton are predominantly regulated by the Rho family of small GTPases including Rho, Rac, and Cdc42 (5). More recently, the small GTPase, Rap has been added as a key actin regulatory protein (6).

In endothelium, individual ECs form a monolayer stabilized by specialized interendothelial contacts – termed *adherens junctions* – rich in the homophilic adhesion molecule, vascular endothelial (VE)-cadherin (7). Actin in endothelial monolayers forms specialized dense cortical actin fibers in a Rac- and Rap-dependent manner (8). These provide peripheral bands of actin that help to organize and stabilize the adherens junctions, partly by association with VE-cadherin through the cytoplasmic adaptor proteins, the catenins (7). Actin stress fibers, stimulated by Rho signaling, function antagonistically to cortical actin fibers in endothelium, thereby weakening intercellular junctions (Figure 76.1), as discussed later (8).

Figure 76.1. Antagonistic stress fiber–dominant and cortical actin fiber–dominant endothelial phenotypes. Shown are micrographs of human umbilical vein ECs stained with phalloidin-Alexa488 to visualize actin microfilaments. The image on the left depicts an example of a strong cortical actin fiber phenotype, in which the vast majority of the microfilaments are tightly associated with the interendothelial junctions. The image on the right depicts an example of a strong stress fiber phenotype, in which stress fibers dominate the central portion of each cell, and intercellular gaps are apparent. These images show relative extremes of what is believed to be a continuum of opposing and antagonistic phenotypes (8). The lower table compares the functional consequences, signaling pathways, and signaling inputs associated with each of the two phenotypes.

**Microtubules**

Microtubules are filaments of approximately 25 nm in diameter, which are derived from the globular GTP-binding/hydrolyzing proteins termed tubulins (~55 kDa each) (9). The fundamental building block of microtubules is a stable heterodimer of single  $\alpha$ - and  $\beta$ -tubulin subunits, which undergoes both linear and lateral associations to form rigid, hollow tubes. This polymerization occurs in a polarized fashion such that the addition of new heterodimers occurs predominantly at the plus end, whereas the minus end is associated with, and stabilized by, the microtubule-organizing center (MTOC) rich in specialized  $\gamma$ -tubulin subunits. Microtubules are extremely dynamic structures, continuously alternating

between phases of growth and shrinkage at the plus end (depending on the hydrolysis of GTP to GDP) in a process termed *dynamic instability* (10). A wide range of microtubule-associated proteins (MAPs) and posttranslational modifications (including phosphorylation and acetylation) modulate the stability of microtubules in response to extracellular stimuli (11).

In cells, arrays of microtubules emanate from the perinuclear MTOC with the plus ends extending outward toward the cell periphery. Microtubules play a major role in spatial organization and polarization. A critical means by which this is achieved is through the specialized MAPs, kinesin and dynein, that serve as molecular motors to conduct movement along microtubules tracks (10). These are capable

of attaching to various cellular structures, allowing the controlled positioning of organelles and directed vesicular trafficking (10).

In endothelium, microtubules are thought to function primarily in establishing polarity and, in collaboration with the microfilament system, in providing cell shape and stability (12–14).

### Intermediate Filaments

Intermediate filaments are rope-like structures of 8 to 10 nm in diameter formed by a large and heterogeneous family of fibrous proteins, including keratins, vimentin, neurofilament proteins, and nuclear lamins (~40–200 kDa each) (15). The primary intermediate filament proteins found in ECs are vimentin and cytokeratin (16,17). Individual intermediate filament subunits form dimeric parallel coiled-coils that undergo antiparallel association with each other to form tetramers (the basic building block unit of intermediate filaments). These tetramers aggregate into helical bundles to form intermediate filaments. The antiparallel nature of the tetramers imparts symmetry to intermediate filaments, distinguishing them from microfilaments and microtubules, which are both polarized and highly dependent on polarity for their function. In general, the vast majority of cellular intermediate filament tetramers are assembled into filaments, with very little tetramer found free in the cytoplasm, suggesting relatively limited dynamics for these structures. However, their assembly is able to be regulated. For example, serine phosphorylation within the N-terminus of intermediate filament proteins, triggered by various extracellular stimuli, can induce rapid depolymerization of intermediate filaments.

In most cell types, intermediate filaments form a network surrounding the nucleus and extending throughout the cytoplasm, with a variable degree of plasma membrane interaction. In addition, the nuclear lamins provide a dense meshwork that underlies the nuclear envelope. The intermediate filaments are the most stable of the three cytoskeletal filaments, and their primary function is to provide mechanical stability and maintain cell shape (14). Indeed, intermediate filaments are most prominent in cells that are subject to significant mechanical stress, including muscle cells, epithelial cells, and ECs. Moreover, among different endothelia, the amount of intermediate filament proteins expressed tends to be proportional to the magnitude of mechanical stress experienced (18).

In addition, evidence has emerged for roles of intermediate filaments in stabilizing adhesions in endothelia. Vimentin has been shown to colocalize with  $\alpha1\beta2$  integrin- and  $\beta3$  integrin-positive focal adhesions in ECs, where they function to stabilize these structures (19,20). In addition, the laminin receptor,  $\alpha4\beta6$  integrin has been observed to form both fibrillar and hemidesmosome-like adhesions enriched in vimentin in endothelium (21).

### THE CYTOSKELETON AS AN EFFECTOR OF ENDOTHELIAL MORPHOLOGY AND HETEROGENEITY

As discussed earlier, the cytoskeleton plays critical roles in establishing cellular shape, organization, and dynamics. Endothelia in vivo are dispersed ubiquitously throughout the body, where they take on distinct morphologies and functions that suit the diverse needs of the local environments. The local environment itself provides essential contextual cues, including the specific matrix, soluble mediators, cell–cell interactions, and biomechanical forces, which drive endothelial differentiation. A wide range of signaling and adhesion receptors exist to receive and communicate this information intracellularly, as discussed in detail throughout many of the chapters of this book. Here, we focus on the cytoskeleton as a translator of this information into specific endothelial morphologies and functions.

### Matrix and Mural Cells

The minimal architecture of the endothelium consists of the ECs and the underlying matrix to which they are attached. However, in many endothelia, “mural cells” provide a third critical component that localizes in the outer (i.e., abluminal) circumference of the vessels. Mural cells include pericytes, vascular smooth muscle cells (VSMCs), and astrocytes, which are heterogeneously associated with distinct vascular structures. Pericytes predominate in the microvasculature, whereas VSMCs are associated most often with the macrovasculature, and astrocytes are restricted to the vasculature of the central nervous system (CNS) (22,23). The ECs themselves contribute importantly to their own basement membranes by secreting specific matrix components (24). However, mural cells also contribute, both directly and indirectly, to matrix composition. Pericytes secrete specific matrix components and, upon interaction with ECs, they also upregulate the production of matrix by the endothelium (23,24).

The specific composition of the resulting matrix profoundly affects the endothelial cytoskeleton and the overall EC morphology. For example, collagens and fibronectin/fibrin are recognized by endothelial  $\alpha5\beta1$  and  $\alpha v\beta3$  integrins, which in turn trigger concomitant activation of Rho and inhibition of Rac, leading to stress fiber formation, disruption of adherens junctions and, in some circumstances, the morphogenesis of new capillary sprouts (24). In contrast, laminin-1, acting through integrin  $\alpha6\beta1$  and  $\alpha3\beta1$ , stabilizes the endothelium by activating protein kinase A (PKA) and Rac1 signaling, while concomitantly inhibiting Rho and stress fiber formation (24).

In addition to matrix-dependent effects, pericytes and VSMCs also mediate direct contacts with and supply soluble factors, such as transforming growth factor (TGF)- $\beta$ , to endothelium that promote cortical actin fibers and increased adherens junction stability (22,23). Similarly, in the CNS, astrocytes as well as glial cells, secrete soluble factors that elevate

intraendothelial cyclic adenosine monophosphate (cAMP) levels, thereby inducing strong formation of cortical actin fibers and tight junctions (i.e., the blood–brain barrier) (25).

### Mechanical Stress

ECs are subjected to an extremely dynamic range of mechanical stresses, including fluid shear, hydrostatic pressure, and cyclic stretch. ECs are exquisitely sensitive to such stress, and modify their cytoskeletal composition and architecture according to the different magnitude and type of stress experienced.

Fluid shear forces range from  $<1$  dyne/cm<sup>2</sup> in the microvasculature to  $>90$  dyne/cm<sup>2</sup> in the large conduit vessels of the macrovasculature. Moreover, shear forces can be laminar, turbulent, or “disturbed,” and either steady state or pulsatile (26,27). Exposure of *in vitro* endothelial cultures (grown initially under static conditions) to acute shear force results in an almost immediate activation of Rho signaling coupled to stress-fiber formation and contraction (28). The application of long-term ( $>12$  hr) steady-state laminar shear (akin to the situation found in the microvasculature in most physiologic settings) results in an alignment of cells with the direction of shear flow and a concentration of actin into cortical fibers that stabilize the adherens junctions (26,29). In addition, steady-state laminar shear stress induces significant increases in levels of microfilament proteins, including  $\beta$ -actin, Arp2/3 complex subunit 3, and destrin (26). The nature and degree of cytoskeletal rearrangements elicited depend on the magnitude and type of the shear stress (26,27). For example, a switch from laminar to disturbed or turbulent flow alters the actin phenotypes toward distinct morphologies that are thought to contribute to the increased susceptibility to atherosclerosis (30).

Although the shear mechanosensors in endothelium are incompletely understood, evidence suggests that the integrin adhesion receptors, which link the extracellular matrix with the cytoskeleton, as well as VE-cadherin and platelet-endothelial cell adhesion molecule (PECAM)-1, which link interendothelial contacts to the cytoskeleton, function in this capacity (28,31).

Cyclic stretch is particularly important for the endocardium (the endothelium of the heart chambers), the large conduit vessels, and the pulmonary vasculature. The application of distinct cyclic stretch regimes to pulmonary artery ECs elicits distinct cytoskeletal rearrangements. Whereas physiologic regimes have been shown to induce Rac- and cortactin (an actin binding protein that stimulates Arp2/3-dependent actin polymerization)-dependent enhancement of barrier function, supraphysiologic and pathologic cyclic stretch regimes (similar to those associated with mechanical ventilation-induced lung injury) induced Rho-dependent increases in cell susceptibility to barrier-perturbing stimuli (i.e., thrombin) (32). Other studies also have shown that the amount and orientation of stress fibers induced by cyclic stretch was determined

by the interplay between the Rho pathway and the magnitude of stretch (33).

Microtubules also respond to fluid shear flow. Indeed, shear alters the planar cell polarity of ECs and causes the MTOC to orient downstream of the nucleus in the direction of flow in an integrin-, Cdc42-, and glycogen synthase kinase (GSK)-3 $\beta$ -dependent manner (28,34). Moreover, shear induces rapid and sustained stabilization in microtubules, as inferred by tubulin acetylation (34).

Similarly, the onset of laminar shear flow in bovine aortic ECs expressing vimentin-GFP was shown to induce a rapid redistribution of intermediate filaments, suggesting that they participate in mechanotransduction and play roles in shear adaptation (35,36). Vimentin also regulates focal contact size and helps stabilize cell matrix adhesions in response to flow. Shear induces thickening of vimentin intermediate filaments and growth of focal contacts (20). Moreover vimentin knock-down reduces EC adhesion to the substrate (20). Finally, *in vivo/in situ* evidence suggests that vimentin expression levels may be modulated according to the shear regime experienced by specific ECs (18).

Thus, all three elements of the cytoskeleton exhibit mechanosensitivity and adjust their architecture according to their mechanical stress regime. In many cases, the cytoskeletal arrangements seem to function in optimizing the integrity of the endothelium. However, it is likely that many more subtle consequences of such modifications also exist.

### Soluble Factors

ECs rely on a variety of soluble factors for cell formation, survival, and differentiation, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), TGF- $\beta$ , and hepatocyte growth factor (HGF). These exhibit distinct spatial and temporal patterns of expression, thereby contributing to local differences in endothelial morphology and function. Many of these do so through influences on the endothelial cytoskeleton (8). For example, VEGF, an angiogenic and survival factor, has been shown to stimulate Rho-, Rho kinase- (ROCK; a Rho effector), and myosin-dependent increases in permeability in cultured coronary venular ECs (37). Alternatively, HGF, an angiogenic and barrier-stabilizing hormone, drives the formation of cortical actin and organization of VE-cadherin in adherens junctions, through a Rac- and GSK-3 $\beta$ -dependent signaling mechanism (38).

Sphingosine-1 phosphate (S1P) has emerged as a factor with particularly important function in the formation and maintenance of vascular endothelium. S1P has been shown to bind endothelial G-protein-coupled receptors and activate endothelial Rac signaling, leading to the formation of cortical actin fibers and organization of the adherens junctions (39,40). Under basal conditions *in vivo*, S1P exists at micromolar concentrations, and a depletion of platelets, the primary producers of circulating S1P, leads to significant

vascular leak and edema (41). Thus, S1P is thought to represent a constitutive signaling input facilitating the organization and barrier function of the vascular endothelium through its effects on the actin cytoskeleton. That lymphatic endothelia, which are exposed to many-fold lower S1P concentrations (42), constitutively maintain, and are functionally reliant on, loosely organized junctions and high permeability, argues that one role for S1P is to act as a general differentiation cue helping to distinguish vascular and lymphatic endothelium.

### Heterogeneity in the Endothelial Cytoskeleton

Details of the *in vivo/in situ* architecture of the endothelial cytoskeleton are generally lacking. However, a few vascular structures are amenable to direct *in situ* analysis of the cytoskeleton; the geometry of the heart and the associated large conduit vessels provides relatively flat surfaces that allow *en face* microscopic imaging. Comparative analysis of the microfilaments, microtubules, and intermediate filament systems in various regions of the endocardium and in the vascular endothelium of the various connected large vessels provides clear demonstrations of cytoskeletal heterogeneity. For example, throughout most of the outflow tract of the left ventricle, endocardial actin forms highly organized, tightly packed cortical actin fibers, with virtually no stress fibers. However, on ridges that traverse the outflow tract, actin stress fibers dominate with few cortical actin fibers observable (43). Vimentin forms distinct perinuclear rings of density and an intricate network of intermediate filaments dispersed throughout the cytoplasm in all regions of the endocardium examined. However, in aortic endothelium, intermediate filaments are highly aligned with the direction of blood flow and lack perinuclear rings. Moreover, the levels of total vimentin expression vary dramatically in different regions of the endocardium and associated vessels (18). Microtubules also exhibit highly distinct architectures in endocardium, aortic endothelium, and pulmonary valve endothelium (43). Such studies provide a clear demonstration of local heterogeneity in endothelial cytoskeleton, with dramatic differences seen even in spatially juxtaposed regions of endothelium. Differential mechanical forces (shear and cyclic stretch) probably represent the dominant environmental differences driving specialization in this example. However, it can be envisioned that the sum of all the local environmental factors discussed together determine the specific cytoskeletal architectures of distinct endothelia.

### ENDOTHELIAL CELL PERMEABILITY

One of the most critical functions of the endothelium is balancing barrier function and selective permeability to fluids, solutes, and immune cells. A wide range of vasoactive and inflammatory mediators impinge on the endothelial cytoskeleton to dynamically modulate this property.

### Microfilaments and Endothelial Permeability

The actin cytoskeleton plays a dominant role in the modulation of EC permeability. As discussed earlier, ECs in the context of a confluent endothelial monolayer exhibit antagonistic Rho-dependent stress fiber–dominant and Rac-dependent cortical actin fiber–dominant phenotypes (see Figure 76.1) (8,29,44).

The stress fiber–dominant phenotype is stimulated by signals that elevate intracellular calcium and activate Rho. The Rho effector ROCK and myosin light chain (MLC; a component of the myosin motor complex) kinase (MLCK; a calcium-dependent kinase that phosphorylates MLC and positively regulates contractility) together promote stress fiber formation and myosin-dependent cellular contractions that weaken the intercellular junctions and increase paracellular permeability (45). In addition, Rho signals directly interfere with Rac signaling. Key inflammatory mediators that stimulate this phenotype include tumor necrosis factor (TNF)- $\alpha$ , histamine, thrombin, VEGF, lysophosphatidic acid (LPA), and endothelin (see Figure 76.1) (8).

The cortical actin fiber–dominant phenotype is stimulated by two small GTPases: Rac and Rap. Rac signaling in general is coupled to cell spreading and lamellipodia formation (5), contrasting with the contractility initiated by Rho. In endothelium, Rac stimulates p21-activated kinase (PAK), which in turn promotes cortical actin fibers, translocation of cactin to the cell periphery, and junctional assembly. PAK also functions to negatively modulate myosin-mediated contractility. The best known stimulators of this pathway in endothelium are S1P and ATP (39,46,47). It has been known for years that elevated intracellular cAMP promotes endothelial barrier function (48). cAMP is understood to act both through PKA, which inhibits Rho signaling (49), and through exchange protein activated by cAMP (EPAC)-1, a cAMP-responsive guanine nucleotide exchange factor that activates the small GTPase Rap. Rap, like Rac, enhances cortical actin fibers and reinforces adherence junctions (50,51). Barrier-enhancing agents that act through cAMP include  $\beta$ -adrenergic agonists (catecholamines), serotonin, and adrenomedullin (see Figure 76.1).

### Microfilaments and Fenestrae

Some vascular beds, such as the kidney glomerulus and liver sinusoid, are specialized for relatively high constitutive levels of permeability. These beds contain specialized transcellular pores of regulated diameters, termed *fenestrae*. Studies suggest that the actin cytoskeleton plays an important role in establishing the architecture, and therefore permeability properties, of these structures (52). Moreover, increasing evidence suggests that the permeability properties of these structures are dynamically regulated *in vivo* (53). *In vitro* studies show that disruption of actin microfilaments (54,55) or inhibition of Rho signaling (56) reduces stress fiber content and augments the number and/or diameter of endothelial fenestrae.

Moreover, the targeted delivery of the actin-disrupting agent cytochalasin B to hepatocytes also increased the number of fenestrae in vivo (57). Alternatively, activation of Rho signaling, for example with LPA (a vasoactive mediator) promotes stress fiber formation and decreases the size and numbers of fenestrae in liver sinusoidal endothelium (56). Thus, whereas Rho activation enhances paracellular permeability in many endothelia, in fenestrated endothelia transcellular permeability is attenuated by Rho.

### Microtubules and Endothelial Permeability

Microtubules have been shown to contribute to endothelial barrier function. LIM kinase (LIMK) is a Rho-activated kinase that functions, in part, to deactivate the actin-severing protein cofilin, thereby facilitating growth of stress fibers and increased paracellular permeability. Recently, LIMK also was shown to destabilize microtubules in response to thrombin, suggesting a possible role for microtubules in the modulation of permeability (58). Indeed, depolymerization of microtubules with the pharmacologic agents vinblastine and nocodazole promoted increased endothelial permeability (59,60). This effect seems to be at least partially due to the release of microtubule-sequestered RhoA and LIM kinase (58,61–68). Alternatively, cAMP-mediated barrier protective effects have been shown to act, in part, through PKA-dependent stabilization of microtubules (69). In addition, the MAP kinesis associates with p120 catenin, suggesting that trafficking of VE-cadherin could be mediated by microtubules, and implying a role for microtubules in the organization of adherens junctions (70–72). Similarly, the kinesin KIF 5 has been implicated in the trafficking of those focal adhesion components necessary for stabilizing matrix contacts (73).

In capillary endothelium, solutes such as albumin cross the endothelium transcellularly (in addition to the paracellular route) through a process of internalization and trafficking of specialized vesicles (caveolae) from the luminal to abluminal surfaces of the endothelium (*transcytosis*) (74). Although it remains to be investigated in detail, some preliminary studies suggest a role for the microtubule system in this process. For example, microtubule-disrupting agents (74) or the knockdown of specific microtubule motor proteins (kinesins HIF 3A or 3B) (75) in endothelium reduces transcytosis of albumin.

### Intermediate Filaments and Endothelial Permeability

In endothelium, the most prominent functional roles associated with intermediate filaments are the maintenance of mechanical integrity and cell shape (14). In response to shape-changing vasoactive stimuli, cytokeratin intermediate filaments undergo dynamic rearrangement in pulmonary microvascular endothelium (16). Moreover, thrombin and phorbol esters induce phosphorylation of endothelial vimentin, suggesting a potential role of protein kinase C (PKC) in the modulation of vimentin intermediate filaments (76,77). In

addition, the adherens junction protein VE-cadherin has been demonstrated, through biochemical studies, to associate with vimentin, and this interaction is modulated by the permeability-stimulating agent histamine (78). Taken together, these studies imply potential modulation of EC permeability by vimentin and cytokeratin. Yet, *vimentin*-knockout mice do not display any overt changes in EC architecture or function (79). However, responses to permeability-enhancing agents in these mice have yet to be directly investigated.

### Permeability to Immune Cells

In addition to fluid and solute, ECs interact with blood leukocytes, as well as pathogenic bacteria, that cross the endothelial barrier. The endothelial cytoskeleton plays an important role in modulating or facilitating these processes. In addition to the wide range of inflammatory and vasoactive mediators that influence these processes, as described earlier, the migrating cells themselves also significantly affect endothelial cytoskeletal dynamics.

The process of leukocyte extravasation is central to both normal and pathologic inflammatory responses. As leukocytes accumulate on the luminal surface of the endothelium, adhesion receptors, such as intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, and PECAM-1, trigger intraendothelial calcium fluxes, activation of Rho, and increased myosin contractility. These events are believed to weaken the intercellular junctions facilitating leukocyte migration at these locations (paracellular diapedesis) (80–87). Conversely, the activation of Rap-dependent cortical actin-fibers through elevated cAMP both strengthened adherence junctions and reduced monocyte diapedesis in one study (50). However, in a similar investigation, cAMP increased barrier function to solutes, but not neutrophils (51).

Recently, we and others have demonstrated that the endothelium proactively generates actin-, ICAM-1-, and VCAM-1-enriched upright microvilli-like projections that surround adherent and transmigrating leukocytes (termed *docking structures* or *transmigratory-cups*) (88–90). These are formed proactively by the endothelium through the recruitment of ezrin-radixin-moesin (ERM) family proteins ezrin and moesin (actin-binding linker proteins) to the cytoplasmic domain of clustered ICAM-1 and VCAM-1, which in turn promotes local actin polymerization (88). Additional studies demonstrate an important role for vimentin intermediate filament reorganization in the formation of transmigratory cups (91). A key function for these structures is providing a physical basis (i.e., vertical traction structures) for leukocytes to exert forces against the surface of the endothelium, thereby facilitating efficient transmigration (90,91). Another recent study demonstrates that the recruitment of the actin binding/regulator protein cortactin to sites of leukocyte diapedesis somehow functions to facilitate this process (92). Thus, the endothelium seems to respond to the presence of lumenally bound leukocytes with cytoskeletal rearrangements that act to support leukocyte trafficking.

Interestingly, certain bacteria have apparently subverted these endothelial responses to cross endothelial barriers and gain access to underlying tissues. Remarkably, the *Neisseria meningitidis* has adopted cell surface molecules (type IV pili) that engage ezrin-interacting endothelial receptors CD44 and ICAM-1. This induces actin-dependent microvilli-like structures, similar to those formed in transmigratory cups, which facilitate bacterial transcytosis across the blood brain barrier (93,94). The similarity between the *N. meningitidis*- and leukocyte-initiated structures is underscored by the finding that bacteria present on the endothelial surface can effectively “compete” for (and sequester) endothelial ezrin, thereby preventing leukocyte transmigratory cup formation and diapedesis (95).

As with solutes, leukocytes also have been found, both in vivo and in vitro, to use transcellular routes (i.e., via pores formed directly through individual ECs) for diapedesis (90,91,96–99). Very recently it was suggested that the actin-rich domains are important for this process (97). However, our studies suggest that the actin stress fiber–dominant phenotype reduced transcellular diapedesis (by creating a steric barrier to transcellular pores), whereas either directly driving the cortactin fiber–dominant phenotype or inhibiting Rho dramatically upregulated the efficiency of transcellular (but not paracellular) diapedesis (C. Carman, unpublished observations). This idea that Rho negatively modulates transcellular permeability is consistent with the findings, described earlier, that Rho activity reduces the number and diameter of fenestrae in liver sinusoid endothelium (53). Interestingly, further support for this idea is provided by the recent finding that *Staphylococcus aureus* can induce transcellular “macroapertures” (remarkably similar to the transcellular pore formed during leukocyte diapedesis) that facilitate extravasation of these bacteria via secreted Rho-inactivating toxins (100).

## ANGIOGENESIS

In healthy adults ECs, are, for the most part, highly differentiated and relatively quiescent. However, under certain settings, for example during wound healing, ECs must rapidly mobilize to form new blood vessels. This requires cell matrix degradation, cell shape change, polarization, migration, and invasion into tissue matrix, all of which depend on the endothelial cytoskeleton. Initially, in response to angiogenic stimuli, ECs begin to degrade their underlying basement membrane, exposing increased ECs to collagen I. This induces Rho signaling, actin stress–fiber formation, and myosin-dependent contraction (dissociating VE-cadherin from intercellular junctions) and supports morphogenesis of new capillary sprouts (24). In this setting, the microtubules play a critical role in establishing cell polarization (28,34). In addition to its role in maintaining barrier function, S1P represents an important and potent chemotactic agent. Stimulation of endothelium with S1P in the correct setting promotes Rac- and cortactin-dependent lamellar protrusions that form a lead-

ing edge for migration and chemotaxis (40,42). In addition, studies have revealed that novel Cdc42-dependent protrusive structures, termed *podosomes* and *invadopodia*, function in this setting. These, represent dynamic micron-scale actin-rich cylindrical protrusions found on highly migratory and invasive cells, including blood leukocytes and tumor cells (4). Such structures recently have been shown to be formed by endothelium to allow degradation and protrusion/invasion into the underlying matrix, suggesting a potentially critical role in angiogenesis (4,101,102).

## THE ENDOTHELIAL CYTOSKELETON AS A BIOMEDICAL TARGET?

As a result of many basic investigations, several potential therapeutic approaches targeting the endothelial cytoskeleton have emerged.

As outlined earlier, Rho signaling and resulting changes in the actin cytoskeleton play critical roles in barrier function, inflammation, and leukocyte extravasation. Small-molecule strategies that have been developed to disrupt these pathways show potential for therapeutic benefit in inflammatory pathology. Cholesterol-lowering drugs (statins) function to block cholesterol synthesis by inhibiting 3-hydroxy-3-methylglutaryl (HMG) CoA reductase. However, the resulting depletion of isoprenoids also prevents efficient posttranslational prenylation of Rho, which is a requirement for its proper function. Accumulating evidence suggests that the cholesterol-independent or “pleiotropic” anti-inflammatory therapeutic effects of statins likely result from inhibition of Rho signaling in endothelium, as well as in vascular smooth muscle and immune cells (103,104). Rho-dependent benefits in cardiovascular disease have been associated with the inhibition of stress-fiber formation, which leads to improved barrier function, reduced leukocyte trafficking, and increased endothelial nitric oxide synthase (eNOS) signaling (103,104). Studies also have suggested that statins may improve blood–brain barrier function in a murine model of multiple sclerosis (i.e., experimental autoimmune encephalomyelitis [EAE]) in a Rho- and actin-dependent manner, which thereby limits pathologic lymphocyte trafficking to the CNS (105). Similar anti-inflammatory and barrier-protective effects have been seen with two small-molecule inhibitors of Rho kinase, fasudil and Y-27632, that act as selective competitive inhibitors for ATP binding (104,106).

As discussed earlier, S1P acts to promote endothelial barrier function through the activation of Rac1 signaling and cortical actin fibers. Recently, Merck developed the small-molecule prodrug FTY720, which is phosphorylated in vivo to form FTY720-P, a stable circulating analogue of S1P. FTY720 has profound immunosuppressive activity and is currently in clinical trials for kidney graft rejection and multiple sclerosis. Immunosuppression results from the accumulation of lymphocytes in secondary lymphoid organs due to blocked egress from these locations. FTY720 acts partially through

direct effects on lymphocytes. However, because FTY720 has been shown to enhance cortical actin fiber formation and barrier function in vascular endothelium, it is hypothesized that enhanced barrier function of sinus-lining endothelium of lymphoid organs contributes to immunosuppression by precluding leukocyte diapedesis (107). The recent demonstration in vivo that FTY720 promotes the organization of lymphatic endothelial junctions, as evidenced by the appearance of dense accumulations of PECAM-1,  $\beta$ -catenin, and zona occludens-1 in the junctions between sinus ECs supports this idea (108). Interestingly, other studies have shown barrier protective effects of FTY720 on vascular endothelium in inflammatory settings such as acute lung injury (109).

Recently, FTY720 also was examined as an inhibitor of angiogenesis. Because S1P plays an important role in endothelial chemotaxis, it was hypothesized that FTY720 might perturb this functions in ways that alter angiogenesis. Indeed, FTY720 has proven efficacious in blocking tumor-associated angiogenesis in several models (110,111).

Like statins, the chemotherapeutic drug Taxol, commonly used to treat breast cancer, recently has been revealed to have pleiotropic mechanisms of action that involve the endothelial cytoskeleton. As a microtubule stabilizing agent, Taxol was originally developed to block tumor cell proliferation, specifically by trapping cells during the process of mitosis. However, recent studies have shown secondary effects that result from a perturbation of the EC polarization and migration necessary for angiogenesis (112–114).

#### KEY POINTS

- The major functional role of the microfilament system in endothelium is to establish and modulate interendothelial junctions.
- The major role of the microtubule system in endothelium is to establish cell polarity and facilitate trafficking.
- The major role of the intermediate filament system in endothelium is to provide structural and mechanical stability.
- Microenvironmental inputs drive distinct cytoskeletal architectures that help establish location-specific endothelial morphology and function.
- The reciprocal modulation of actin stress and cortical actin fibers is critical for the dynamic modulation of endothelial barrier function to solutes and immune cells.
- Emerging understanding of the roles and regulation of endothelial cytoskeleton in health and disease has led to several cytoskeleton-targeted therapeutic strategies.

#### Future Goals

- Endothelial morphology and function display great diversity in vivo as a consequence of distinct microenvironmental inputs. Thus, a key goal for creating new understanding of the endothelium is to develop improved approaches to study endothelial morphology and function, and especially cytoskeletal architecture and dynamics, in diverse endothelia both in situ and in vivo.

## Endothelial Cell Integrins

Joseph H. McCarty\* and Richard O. Hynes†

\*M.D. Anderson Cancer Center, Houston Texas; †Center for Cancer Research, Massachusetts Institute of Technology, Cambridge

The extracellular matrix (ECM) is an insoluble network of proteins that provides structural support to multicellular tissues and regulates a variety of cell behaviors. Most metazoan cells express transmembrane proteins, known as integrins, which serve as receptors for many ECM protein ligands (1). Integrins connect the extracellular environment to the intracellular cytoskeleton, and also regulate the signal transduction cascades leading to gene regulatory events. Integrin-mediated adhesion and signaling are essential for the proper formation of most tissues, and they play particularly important roles in vascular development and homeostasis (2).

### HISTORY OF INTEGRINS

The discovery of integrins centered around efforts to identify a cell surface receptor for the fibrillar ECM protein fibronectin (FN) (3,4). Biochemical purification of the FN receptor revealed a complex of two proteins of differing molecular weights (5). Subsequent cloning and sequencing of cDNAs encoding components of the FN receptor complex identified two transmembrane proteins, named *integrins* for their postulated role in linking the ECM to the intracellular cytoskeleton. Soon thereafter, several investigators working in areas ranging from human immunology to fly genetics published the cDNA sequences encoding other transmembrane proteins with striking homologies to the FN receptor (3). Thus, it was realized that integrins represented a multigene family with adhesive functions on diverse cell types. We now know that integrins are heterodimeric proteins consisting of two non-covalently associated subunits, termed  $\alpha$  and  $\beta$ . Most integrins recognize multiple ECM ligands, and many ECM proteins can bind to more than one integrin receptor. Integrins and their various ECM ligands play essential roles in virtually every aspect of physiological and pathological blood vessel function.

### EVOLUTIONARY AND DEVELOPMENTAL CONSIDERATIONS

Integrins are present in all metazoans, ranging from sponges to nematodes, flies, and mammals. In general, the expansion of integrin genes correlates with body plan complexity (6). For example, *Caenorhabditis elegans* contains only three integrin genes: two  $\alpha$  subunits and one  $\beta$  subunit that can combine to form two integrin heterodimers. The *Drosophila* genome has seven different integrin genes: two  $\beta$  subunits and five  $\alpha$  subunits that can yield at least five integrin heterodimers. In vertebrates, 26 integrin genes exist, 18 encoding  $\alpha$  subunits and eight encoding  $\beta$  subunits, yielding 24 distinct integrin heterodimers (Figure 77.1). Similar to flies and worms, vertebrates also contain laminin- and RGD-binding integrins, as well as an expanded set of collagen- and FN-binding integrins, and several leukocyte-specific integrins that also mediate heterotypic cell–cell adhesion (1,6).

Genetic analyses reveal important functional roles for integrins in most developmental processes (Table 77-1). Mutant screens in flies and worms reveal essential roles for integrins in cell differentiation, organ morphogenesis, and tissue homeostasis (7). Most of the 26 integrin genes have been ablated in mice, revealing a diverse range of phenotypes that reveal little, if any, functional redundancy (1,8). The phenotypes of the mouse integrin mutants range from peri-implantation defects, to lethality at various embryonic and neonatal ages, to post-natal viability with organ-specific abnormalities.

### INTEGRIN GENE REGULATION

Mechanical stress and infectious agents, as well as cytokines and growth factors, all regulate integrin expression at both the transcriptional and post-translational levels (9). A detailed description of these processes is beyond the scope of this chapter, so we refer the reader to other excellent articles that discuss

Figure 77.1. The integrin family of ECM receptors. The 26 integrin  $\alpha$ - and  $\beta$ -subunits, separated into three groups, are shown. Lines connecting subunits indicate the 24 known heterodimeric pairs. The leukocyte-specific integrins are shown in the box bordered by a double line (upper left). The  $\alpha$ v-subfamily is highlighted in the box with a solid line (lower left), and the  $\beta$ 1-subfamily is shown in the box with a dashed line (right).

these various regulators in depth (9,10). Instead, we focus here on the regulation of endothelial integrin gene expression by pro- and antiangiogenic factors.

Angiogenic growth factors and their receptors play essential roles in physiological and pathological neovascularization, and regulate these events in part via modulation of integrin expression and function. For example, vascular endothelial growth factor (VEGF) treatment of cultured endothelial cells (ECs) stimulates transcriptional upregulation of multiple integrin subunits including  $\alpha$ v,  $\beta$ 3,  $\beta$ 5,  $\alpha$ 1, and  $\alpha$ 2 (11). Additionally, the stimulation of cultured ECs with basic fibroblast growth factor (bFGF) leads to upregulation of  $\alpha$ v $\beta$ 5 expression, with little effect on the expression of other integrin gene products. Stimulation of ECs with transforming growth factor (TGF)- $\beta$ 1 also leads to upregulation of multiple integrin subunits, including  $\alpha$ v,  $\beta$ 3,  $\beta$ 5,  $\alpha$ 5, and  $\beta$ 1 (9).

Alternative splicing of exons encoding portions of the extracellular and intracellular domains also regulates integrin functions (12). For example, many  $\beta$  subunit cytoplasmic domains contain NPXY signaling motifs that play important roles in recruiting signaling proteins. Splice variants of  $\beta$ 1,  $\beta$ 3, and  $\beta$ 5 integrins that lack this motif display altered cellu-

lar localization and signal transduction. Thus, the regulation of integrin splice variants may generate functional differences in EC adhesion, migration, and survival.

## INTEGRIN PROTEIN STRUCTURE

The three-dimensional structures of integrin extracellular and intracellular portions have been solved, with the EC integrin  $\alpha$ v $\beta$ 3 serving as the prototype for many of these studies (13). Here we provide a general description of integrin structure and activation, and refer the reader to other papers for more details (1,14–16).

Unlike most transmembrane receptors, high-affinity ligand binding by integrins – termed *activation* – can be regulated via intracellular (inside-out) signals. In their inactive state, integrins recognize ECM ligands with low affinity, and the crystal structure of  $\alpha$ v $\beta$ 3 reveals the extracellular domains folded into a “bent” conformation. Inactive integrins are maintained in part by the  $\alpha$  and  $\beta$  cytoplasmic domains, which interact to form a “molecular clasp.” Inside-out activation disrupts the  $\alpha$ – $\beta$  cytoplasmic interaction and causes

**Table 77-1: Integrin Mutant Mice with Angiogenesis Phenotypes**

<i>Integrin Subunit (Refs.)</i>	<i>Mutant Phenotype</i>
$\beta 1$ (8)	Peri-implantation lethality at E6.5. $\beta 1$ -null ES cells and teratocarcinomas display a poorly developed vasculature.
$\beta 3/\beta 5$ (24)	$\beta 3/\beta 5$ double-knockout mice are viable and fertile. They display normal physiological angiogenesis, but enhanced pathological angiogenesis. Some mutants develop hemorrhage due to defects in platelet clotting.
$\beta 4$ (36)	Mutants expressing a $\beta 4$ gene product that lacks the cytoplasmic signaling portion are viable and fertile. However, mutants display defective pathological angiogenesis.
$\beta 8$ (27)	~70% of embryos dies by E11. These embryos have defective placental layering. The remaining 30% die shortly after birth owing to cerebral hemorrhage.
$\alpha 1$ (34)	Viable and fertile; reduced tumor growth owing to defective pathological angiogenesis. Elevated levels of circulating angiostatin.
$\alpha 5$ (1,30,31)	Lethality at E10.5. Defective embryonic and extraembryonic blood vessel formation. Somitic and neural crest defects.
$\alpha v$ (25,26,28)	~70% of embryos dies by E11. These embryos have defective placental layering. The remaining 30% die shortly after birth owing to cerebral hemorrhage, a cleft palate, and abnormal intestinal development.

Mouse genetic data identify several integrin subunits with roles during neovascularization. Listed are only those integrin mutants reported to display physiological and/or pathological angiogenesis defects.

a switchblade-like conformational change in the extracellular domains, leading to enhanced ECM ligand affinity. The cytoskeletal protein talin, which binds to an NPXY sequence in the integrin  $\beta$ -cytoplasmic tail, plays an essential role in inside-out integrin activation. Integrins activated by outside-in and inside-out mechanisms recruit various intracellular signal transduction molecules, which leads to protein phosphorylation cascades and gene regulatory events that cause major effects on cell behavior.

**INTEGRINS AND RECEPTOR TYROSINE KINASES**

Integrins physically associate with a variety of transmembrane receptors, including G-protein-coupled receptors, ion channels, and other cell adhesion molecules. On ECs, angiogenic growth factors and their cognate receptor tyrosine kinases

(RTKs) play well-established synergistic roles in integrin activation (17). Indeed, proper microvascular development and homeostasis depend on precise regulation of cross-talk events between integrin and RTK signaling components (18). For example, the integrin  $\alpha v\beta 3$  can physically interact with FLK-1, the VEGF-A receptor tyrosine kinase.  $\alpha v\beta 3$ -FLK-1 association augments VEGF-A-induced FLK-1 phosphorylation and enhances EC migration on vitronectin, an  $\alpha v\beta 3$  ligand. Physical association between  $\alpha v\beta 3$  and FLK-1 occurs via the  $\alpha v\beta 3$  extracellular domain, and is independent of growth factor stimulation (19). Interestingly, vascular development occurs normally in  $\beta 3$ -null mice; however, in cultured  $\beta 3$ -null ECs elevated FLK-1 phosphorylation and enhanced downstream signaling events occur, suggesting a compensatory mechanism by FLK-1 in the absence of  $\beta 3$  integrin (20).

**INTEGRINS AND THEIR INFLUENCES ON ENDOTHELIAL CELL FUNCTIONS**

Integrin adhesion to vascular basement membrane ligands regulates many intracellular signaling events, affecting EC responses such as migration and survival. ECs in multiple vascular beds and at varying developmental and postnatal time points express several integrins, including  $\alpha 1\beta 1$ ,  $\alpha 2\beta 1$ ,  $\alpha 3\beta 1$ ,  $\alpha 4\beta 1$ ,  $\alpha 5\beta 1$ ,  $\alpha 6\beta 4$ ,  $\alpha v\beta 3$ , and  $\alpha v\beta 5$  (2). Here we summarize pertinent biochemical and genetic data linking these eight integrins and their ECM ligands to various vascular events.

**$\alpha v$  Integrins**

There are five members of the  $\alpha v$  subfamily of integrins:  $\alpha v$  integrin can pair with  $\beta 1$ ,  $\beta 3$ ,  $\beta 5$ ,  $\beta 6$ , and  $\beta 8$  (see Figure 77.1).  $\alpha v\beta 3$  and  $\alpha v\beta 5$  have been implicated in various types of physiological and pathological angiogenesis.  $\alpha v\beta 3$  or  $\alpha v\beta 5$  protein expression is upregulated on cultured ECs or on angiogenic blood vessels in response to different angiogenic growth factors or cytokines (21).  $\alpha v$  Integrin-mediated neovascularization in these various systems is inhibited upon addition of function-blocking antibodies or peptide antagonists, which ultimately cause EC death (22). Hence,  $\alpha v\beta 3$  has been pursued intensely as a potential antiangiogenic target, and  $\alpha v\beta 3$  antagonists are currently being tested in human clinical trials (see next section).

Genetic ablation of the  $\beta 3$  and/or  $\beta 5$  genes does not lead to overt angiogenic abnormalities. Indeed, mice null for  $\alpha v\beta 3$  and/or  $\alpha v\beta 5$  are viable and fertile, and blood vessel development proceeds normally in these mutants (23). Physiological angiogenesis occurs normally in mice null for  $\beta 3$  or both  $\beta 3$  and  $\beta 5$ . Interestingly, pathological retinal angiogenesis as well as tumor growth and neovascularization are actually enhanced in  $\beta 3^{-/-}$  or  $\beta 3/\beta 5$ -null mice (24). Thus, the inferred significance of  $\alpha v\beta 3$  and  $\alpha v\beta 5$  in neovascularization based on the antibody and peptide inhibition results versus the genetic ablation data are quite conflicting. Interestingly, in  $\beta 3$ - or

$\beta 3/\beta 5$ -null animals upregulation of signaling events occurs, mediated by the FLK-1 receptor tyrosine kinase, suggesting that, in the absence of  $\beta 3$ - and  $\beta 5$ -integrin expression, a compensatory response occurs involving enhanced VEGF/FLK-1 signal transduction.

Lastly, mice harboring an ablated  $\alpha v$  gene, and thus lacking expression of all five  $\alpha v$  integrins, do not develop widespread vascular defects (25). Approximately 70% of  $\alpha v$ -null embryos survive to midgestation, having developed a normal vasculature, but die by embryonic day (E)11, owing to placental layering abnormalities. The remaining  $\alpha v$ -null embryos that survive beyond midgestation actually are carried to term and develop a largely normal vasculature. However, they do develop cerebral hemorrhage, a cleft palate, and die within a day after birth. The hemorrhage is not due to primary endothelial or pericyte defects, but rather involves defective associations between angiogenic cerebral blood vessels and central nervous system (CNS) glia, where  $\alpha v$  protein is expressed (26). Interestingly, the cerebral hemorrhage that develops in the  $\alpha v$ -nulls is due to the loss of one specific integrin,  $\alpha v\beta 8$ , which is a receptor for the latency-associated peptide of TGF- $\beta 1$  (27). Mice null for the  $\beta 8$  gene develop phenotypes that are very similar to those seen in the  $\alpha v$ -nulls (28). Recently, we have used Cre/lox methodology to selectively ablate  $\alpha v$  integrin expression in neural cells of the developing and postnatal CNS (29). Similar to the phenotype observed in the complete  $\alpha v$ -null mice, conditional mutant embryos and neonates also develop CNS-specific hemorrhage. Unlike the complete  $\alpha v$ -nulls, most conditional  $\alpha v$  mutants survive for several months, but develop progressive spinocerebellar neurodegeneration, leading to symptoms such as hindlimb rigidity, ataxia, and urinary dysfunction. Similar phenotypes develop in conditional  $\beta 8$ -knockout animals (30). This conditional knockout approach confirms a role for glial-expressed  $\alpha v$  integrins, particularly  $\alpha v\beta 8$ , in regulating proper blood vessel development and cerebrovascular homeostasis.

### $\alpha 5\beta 1$ Integrin

$\alpha 5\beta 1$  Integrin is a major cell surface receptor for the ECM protein FN, and various biochemical and genetic data support important functional roles for  $\alpha 5\beta 1$ -FN adhesion in blood vessel formation (2,31). Ablation of  $\alpha 5$  gene expression in mouse embryos leads to lethality by embryonic day E10.5, owing to severe embryonic and extraembryonic vascular defects. These mutants also develop posterior trunk and somitic abnormalities. Additionally, teratocarcinomas formed from  $\alpha 5$ -null embryonic stem (ES) cells form a poorly developed vasculature and display reduced tumor size. Similarly, embryoid bodies derived from  $\alpha 5$ -null ES cells also display delayed vascular differentiation and organization (32,33). In concordance with the  $\alpha 5$  genetic data, deletion of the *FN* gene leads to embryonic lethality associated with severe vascular defects, and similar angiogenic abnormalities are observed in *FN*-null embryoid bodies (34).

Other experimental models also support a necessary role for  $\alpha 5\beta 1$  and FN in angiogenesis. For example,  $\alpha 5$  integrin and FN protein levels are upregulated on angiogenic tumor blood vessels, and vascular growth factors upregulate  $\alpha 5\beta 1$  expression on angiogenic blood vessels in the chick chorioallantoic membrane (CAM). In both cases, function-blocking antibodies or peptides directed against  $\alpha 5\beta 1$  or FN reduce neovascularization (35).

### $\alpha 1\beta 1$ and $\alpha 2\beta 1$ Integrins

The collagen-binding integrins  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$  are implicated in angiogenesis. Both integrins are upregulated on angiogenic blood vessels following VEGF stimulation (2). Additionally, function-blocking anti- $\alpha 1$  and - $\alpha 2$  antibodies inhibit angiogenesis in vivo using Matrigel plugs or transplanted tumor models. Interestingly,  $\alpha 1$ -null mice are viable and fertile, yet are less susceptible to tumor growth (36). This resistance correlates with increased levels of circulating matrix metalloproteinase activity. Elevated proteolysis in  $\alpha 1$ -null mice leads to the conversion of plasminogen to angiostatin, a potent inhibitor of EC neovascularization. Mice harboring a deletion of the  $\alpha 2$  gene are viable and fertile and do not display any gross vascular abnormalities (37). A potential contribution of  $\alpha 2\beta 1$  to pathological neovascularization has yet to be reported. Obviously, analysis of mice null for both  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$  expression should be useful in understanding the exact functions of these integrins during physiological and pathological angiogenesis.

### $\beta 1$ Integrins

The  $\beta 1$  integrin subunit can pair with at least twelve  $\alpha$ -subunits (see Figure 77.1).  $\beta 1$ -containing integrins are expressed in virtually all vertebrate cells and are involved in most aspects of development. Thus,  $\beta 1$  genetic ablation leads to embryonic lethality at E7.5, which is prior to the onset of vascular development (8). However, analyses of  $\beta 1$ -null ES cells, embryoid bodies, and teratocarcinomas reveal an essential role for  $\beta 1$  integrins in blood vessel formation. Although  $\beta 1$  integrins are dispensable for vasculogenesis, they are absolutely necessary for developmental angiogenesis. Interestingly, ES cells or embryoid bodies null for  $\beta 1$  integrin,  $\alpha 5$  integrin, or FN display many strikingly similar defects. Thus, many of the  $\beta 1$ -null defects can probably be explained by loss of integrin  $\alpha 5\beta 1$ .

### $\alpha 3$ , $\alpha 4$ , and $\alpha 6$ Integrins

Endothelial laminin receptors also are involved in regulating angiogenesis. Genetic ablation of the signal transduction portion of  $\alpha 6\beta 4$  integrin leads to defects in growth factor-induced angiogenesis as well as pathological neovascularization (38). The laminin-binding integrins  $\alpha 3\beta 1$  and  $\alpha 6\beta 1$  also play cooperative roles in EC adhesion in vitro, as well as various

angiogenesis assays *in vivo* (39). Lastly, the  $\alpha 4\beta 1$  integrin binds to a variety of ECM ligands, including the vascular basement membrane proteins thrombospondin-1 and -2 (40). Disruption of  $\alpha 4\beta 1$ -mediated adhesion to the thrombospondins leads to abnormal EC functions in various *in vitro* and *in vivo* angiogenesis assays (41).

### ANGIOSTATIC PROTEINS ACT VIA INTEGRINS

The *angiogenic switch* model (42) proposes that a balance exists between pro- and antiangiogenic factors. Changes in the balance regulate whether a blood vessel remains in a quiescent state or becomes angiogenic. Many ECM proteins within the vascular basement membrane, acting via integrins, are regulators of the angiogenic switch. The pro- or antiangiogenic functions of a particular ECM protein, as well as the integrin receptor(s) it binds, can be greatly affected by proteolysis (43).

Type IV collagen, a major component of the vascular basement membrane, is normally a ligand for the integrins  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$ . Matrix metalloprotease (MMP)-9-mediated cleavage of the NC1 domain of collagen IV ( $\alpha 3$ ) yields the potent angiogenesis inhibitor tumstatin. Tumstatin binds to  $\alpha v\beta 3$  integrin and inhibits the protein translation machinery, leading to EC apoptosis and reduced tumor progression (43). Proteolysis of the C-terminal NC1 domain of collagens XV or XVIII generates the antiangiogenic factor endostatin. Murine endostatin inhibits VEGF- or bFGF-induced EC proliferation and migration *in vitro*, and also represses pathological angiogenesis in some transplantable tumor models (44). Endostatin is primarily a ligand for both  $\alpha 5\beta 1$  (45). Importantly, although the exact molecular mechanisms by which endostatin exerts its antiangiogenic effects remain unknown, it is clear that they are different from those regulated by tumstatin and do not require  $\alpha v\beta 3$  (46).

Endorepellin, an 80-kDa C-terminal proteolytic fragment of the ubiquitous basement membrane protein, perlecan, also has antiangiogenic activity (47). Endorepellin blocks EC migration and tube formation *in vitro*, and inhibits growth factor-induced angiogenesis in Matrigel plugs and the CAM assay. Endorepellin binds to  $\alpha 2\beta 1$  integrin, which leads to EC actin cytoskeletal disassembly and focal contact disruption. Interestingly, endorepellin also can bind to endostatin and counteract its antiangiogenic activity, suggesting that a balance exists between angiostatic proteins and also affects angiogenesis.

The proteolysis of many other ECM proteins also generates antiangiogenic fragments, although the mechanistic details of how they exert these effects remain unclear. For example, when proteolytically cleaved, thrombospondin-1 “cryptic fragments” bind to the scavenger receptor CD36 and serve as potent repressors of angiogenesis (40). Similarly, degradation of the proangiogenic factor FN generates the angiogenesis inhibitor anastellin (48), and degradation of plasminogen

yields angiostatin (49). Interestingly, many of these ECM cryptic fragments require the circulating forms of plasma FN and vitronectin for their antiangiogenic activities (50), thus identifying a new complexity to angiogenesis regulation.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

There is no doubt that modulating integrin function can have beneficial effects in treating human disease. For example the peptide antagonist eptifibatide (Integrilin), which targets the platelet-specific integrin  $\alpha IIb\beta 3$ , has proven efficacious in treating patients with acute coronary artery syndromes (51). Furthermore, natalizumab (Tysabri/Antegren), a humanized monoclonal blocking antibody directed against the  $\alpha 4$  integrin, has proven effective in inhibiting the T cell-mediated autoimmunity associated with multiple sclerosis and Crohn disease (52).

The fact that tumor growth and metastasis depend on neovascularization has spearheaded efforts to develop angiogenesis inhibitors to treat cancer, and some of these strategies have shown promising clinical results (53). Accordingly,  $\alpha v\beta 3$  integrin has been a target of intense focus for neovascular intervention. This integrin is highly expressed on angiogenic ECs and structural data (see the previous section) will allow for the rational design of antagonists with exquisite molecule specificities and biomimetic properties. To date, a humanized anti- $\alpha v\beta 3$  antibody has yielded varied results in human clinical trials, although approaches using small-molecule antagonists or combinatorial radiotherapy may prove more effective (54). Additionally, small-molecule inhibitors targeting  $\alpha 5$  integrin have yielded encouraging results in mouse models of colorectal cancer (55); whether these results correlate with tumor regression in human clinical trials remains to be determined.

#### KEY POINTS

- Integrin-mediated adhesion and signal transduction play important roles during physiologic and pathologic angiogenesis.
- Integrin expression is regulated at the transcriptional and post-translational levels by various angiogenic growth factors.
- Cell surface integrins form physical complexes with different endothelial receptor tyrosine kinases, which regulate EC functions.
- Many endogenous angiostatic proteins – derived from proteolysis of ECM components – are ligands for EC integrins.

### Future Goals

- To develop EC integrins as attractive targets for antiangiogenesis therapies
- To understand the molecular pathways by which different integrins regulate angiogenesis, which will prove useful in determining strategies to more effectively modulate their function and may identify other protein targets for neovascular inhibition

## Aquaporin Water Channels and the Endothelium

Alan S. Verkman

*Cardiovascular Research Institute, University of California, San Francisco*

The aquaporins (AQPs) are a family of water transporting channels that are expressed in many mammalian tissues including epithelial, endothelial, and other cell types. At least ten AQPs are present in mammals, and more exist in amphibians, plants, and lower organisms. Functional measurements suggest that mammalian AQPs 1, 2, 4, 5, and 8 are primarily water-selective, whereas AQPs 3, 7, and 9 (called *aquaglyceroporins*) also transport glycerol and possibly other small solutes. The AQPs function as pores to increase water transport across cell membranes in response to an osmotic gradient. Structural studies of AQP1 indicate a tetrameric assembly in membranes in which each monomer contains six tilted helical segments surrounding a putative aqueous pore. Human mutations exist for several AQPs. Humans with mutations in AQP0, the major intrinsic protein of lens fiber (also called MIP) develop cataracts (1). Humans with mutations in the *AQP1* gene (Colton blood group antigen) manifest a urinary concentrating defect (2), and humans with mutations in the *AQP2* gene, the vasopressin-regulated water channel, have autosomal hereditary nephrogenic diabetes insipidus (3).

AQP1 is expressed strongly throughout microvascular endothelial beds outside the brain, such as in kidney (vasa recta), lung and airways, skin, secretory glands, skeletal muscle, pleura, and peritoneum (4,5). AQP1 also is expressed in the endothelium of proliferating tumor microvessels (6) and in nonvascular endothelial cells (ECs) in cornea, trabecular meshwork in the canal of Schlemm, and central lacteals in small intestine (4,5,7). Figure 78.1A shows immunolocalization of AQP1 in ECs in a variety of microvascular and nonvascular endothelia. AQPs have not been identified in ECs in the brain, although a different AQP (AQP4) is expressed in astrocyte foot processes that comprise the blood-brain barrier (BBB) in close contact with ECs. The expression of AQP1 in various vascular and nonvascular endothelia suggests a possible role in transendothelial water movement. Our laboratory generated a series of knockout mice to examine the role of AQPs in mammalian physiology and disease. This chapter summarizes the general paradigms that have emerged from phenotype analysis of AQP-knockout mice,

followed by an analysis of AQP1 function in endothelial biology.

### NONENDOTHELIAL ROLES OF AQUAPORINS REVEALED BY KNOCKOUT MICE

Phenotype analysis of transgenic mice lacking AQPs has been useful in defining their physiological roles. The role of AQPs in transepithelial fluid transport is fairly well-understood. Mice lacking AQP1 manifest defective urinary concentrating ability (8) as a consequence of impaired isosmolar fluid absorption in the proximal tubule (9) and countercurrent multiplication (10,11). Mice lacking water channels of the kidney collecting duct, AQPs 2, 3, or 4, have variable impairment of urinary concentrating ability (12–14) because of reduced transepithelial water permeability in the collecting duct and consequent impaired lumen-to-interstitial water transport. The impaired fluid absorption in the kidney proximal tubule in AQP1 deficiency indicates the need for high transepithelial water permeability for rapid, near-isosmolar fluid transport (9). Impairment of near-isosmolar fluid transport also was found for fluid secretion in salivary (15) and airway submucosal (16) glands in AQP5 deficiency, and for AQP1-dependent secretion of cerebrospinal fluid by choroid plexus (17) and aqueous fluid by the ocular ciliary epithelium (18). High, AQP-facilitated transepithelial water permeability permits rapid, passive water transport in response to active transepithelial salt transport. However, active fluid transport in many tissues does not appear to be AQP-dependent, such as alveolar fluid absorption in AQP1 or AQP5 deficiency (19,20), and sweat secretion in AQP5 deficiency (21). The rate of active fluid absorption/secretion per unit epithelial surface area in alveolus and sweat gland is much lower than that in kidney proximal tubule or salivary gland, suggesting that high AQP-dependent water permeability is not required to support relatively slow fluid absorption or secretion.

A number of interesting, less predictable phenotypes were found for AQP deletion in nonepithelial tissues. AQP4 appears to play an important role in the central nervous system,

Figure 78.1. AQP1 expression in ECs in mice. (A) Tissues stained with purified polyclonal anti-AQP1 antibody. Arrows point to central lacteals in duodenum, corneal endothelium, pleural microvessels, and skeletal muscle microvessels. (B) Light micrographs of renal vasa recta microdissected from mouse kidney of wild-type and *AQP1*-null mice. (Reproduced with permission from Pallone TL, Edwards A, Ma T, et al. Requirement of aquaporin-1 for NaCl driven water transport across descending vasa recta. *J Clin Invest.* 2000;105:215–222; Binder D, Oshio K, Ma T, et al. Increased seizure threshold in mice deficient in aquaporin-4 water channels. *Neuroreport.* 2004;15:259–262; and Thiagarajah JR, Verkman AS. Aquaporin deletion in mice reduces corneal water permeability and delays restoration of transparency after swelling. *J Biol Chem.* 2001;277:19139–19144.)

both for fluid movement into and out of the brain, and for rapid neural signal transduction. Mice lacking AQP4 have reduced swelling in models of cytotoxic (cellular) brain edema, including water intoxication, ischemic stroke, and meningitis (22,23). However, brain swelling and clinical outcome were worse in AQP4-deficient mice in models of vasogenic (leaky vessel) brain edema, including cortical freeze injury and brain tumor, where it was concluded that the AQP4-dependent exit of water from brain tissue is impaired. *AQP4*-null mice also

have impaired evoked potential responses to sound (24) and light (25), as well as altered seizure threshold (26), which has been proposed to be related to impaired AQP4-dependent Kir4.1  $K^+$  channel activity (27) and/or altered extracellular space dynamics (28).

The aquaglyceroporins AQP3 and AQP7 transport both water and glycerol, leading to interesting phenotypes in *AQP3*- and *AQP7*-null mice involving impaired glycerol transport. AQP3 is expressed in the basal layer of epidermal keratinocytes

in skin, where its deletion in mice produces dry skin with impaired biosynthetic function as a consequence of reduced glycerol content in epidermis and stratum corneum (29). AQP7 is expressed in adipocytes, where its deletion in mice produces progressive adipocyte hypertrophy as a consequence of glycerol and triglyceride accumulation in adipocytes (30), as well as an impaired serum glycerol response to fasting and hormonal stimuli (31).

### AQUAPORIN 1 IN THE RENAL VASA RECTA ENDOTHELIUM

AQP1 is expressed in the microvascular endothelium of outer medullary descending vasa recta (OMDVR). The formation of a concentrated urine requires the trapping of NaCl and urea in the renal medulla, as well as high water permeability across the collecting duct epithelium. In portions of OMDVR, water efflux from the vascular space into the renal interstitium occurs despite the existence of Starling forces (hydrostatic and oncotic forces) that favor volume influx, suggesting that water efflux involves a water-only (AQP1) pathway in which NaCl and urea osmotic gradients drive water movement. To investigate the role of AQP1 in vasa recta function, OMDVR were perfused *in vitro* (11). Interestingly, OMDVR from *AQP1*-null mice were much larger in diameter than those from wild-type mice (see Figure 78.1B). Osmotic water permeability in response to a 200-mM NaCl gradient (bath > lumen) was reduced by more than tenfold in *AQP1*-null mice, and by approximately twofold when driven by a raffinose gradient. These data, together with mercurial inhibition measurements, suggested that most NaCl-driven water transport occurs by a transcellular route through AQP1. In a mathematical model of the medullary microcirculation, deletion of AQP1 resulted in diminished concentrating ability due to enhancement of medullary blood flow, partially accounting for the observed urinary concentrating defect. Therefore, AQP1 in OMDVR is an important component of the urinary concentrating mechanism. Mechanistically, NaCl and urea gradients drive water transport from the OMDVR lumen to the medullary interstitium across the AQP1-containing luminal and abluminal membranes, thereby shunting blood flow from descending to ascending vasa recta in the outer medulla. The reduced blood flow to the deep inner medullary portions of the vasa recta is predicted to enhance countercurrent exchange by limiting solute washout. The enlarged vasa recta in *AQP1* deficiency may be a kidney-specific effect involving chronically increased vasa recta blood flow, because neither microvascular structure nor density differ in extrarenal vascular beds, such as in skin and skeletal muscle (32).

### AQUAPORIN 1 IN LUNG MICROVESSELS

The lung and airways participate in fluid movement during airway hydration, reabsorption of alveolar fluid in the neona-

tal period, and formation and resolution of pulmonary edema resulting from heart failure or lung injury. The barriers to water movement between the airspace and capillary compartments consist of an epithelium, interstitium and endothelium. The alveolar epithelium is composed mainly of type 1 cells, that express AQP5 at their apical membrane. The microvascular endothelium expresses AQP1. AQP3 and AQP4 are expressed mainly in airway epithelia. Osmotic water transport between the airspace and capillary compartments, as measured by a pleural surface fluorescence method, was reduced approximately tenfold by deletion of AQP1 or AQP5, and by more than 30-fold by deletion of AQP1 and AQP5 together (19,20). However, there was no effect of AQP1 or AQP5 deletion on alveolar fluid absorption in the adult or neonatal lung, or on the response of the adult lung to epithelial or EC injury (33). Also, AQP1 deletion in mice did not impair airway humidification (34) or lung carbon dioxide transport (35). Together these results indicate that, although AQP1 in the lung and airway microvascular endothelium facilitates osmotic water transport, its deletion does not impair physiologically relevant lung fluid or gas transport physiology.

### AQUAPORIN 1 FUNCTION AT THE PLEURAL AND PERITONEAL BARRIERS

Fluid is continuously secreted into and cleared from the pleural space. Pleural fluid can accumulate in congestive heart failure, lung infection, lung tumor, and the acute respiratory distress syndrome. Fluid entry into the pleural space involves filtration across microvascular endothelia near the pleural surface and movement across a mesothelial barrier lining the pleural space, whereas fluid clearance occurs primarily through lymphatic drainage. AQP1 is expressed in microvascular endothelia near the visceral and parietal pleura as well as in mesothelial cells in visceral pleura (36). Osmotic water permeability was measured in anesthetized, ventilated mice from the kinetics of pleural fluid osmolality after instillation of hypertonic or hypotonic fluid into the pleural space. Osmotic equilibration of pleural fluid was rapid in wild-type mice (50% equilibration in <2 min) and slowed by approximately fourfold in *AQP1*-null mice. However, the clearance of isosmolar saline instilled in the pleural space (~4 mL/kg/hour) was not affected by AQP1 deletion, nor was the accumulation of pleural fluid (~0.035 mL/hour) in a volume overload model of congestive heart failure. Thus, although AQP1 facilitates rapid osmotic equilibration across the pleural surface, AQP1 does not appear to be a physiologically important mechanism of pleural fluid accumulation or clearance.

A similar conclusion was reached for the role of AQP1 in fluid movement into and out of the peritoneal cavity (37). The peritoneal cavity is lined by a membranous barrier that provides a large surface for fluid movement between peritoneal capillaries and the peritoneal cavity. Ascites can accumulate in conditions associated with decreased serum oncotic pressure, increased portal venous pressure, or peritoneal cavity

inflammation or infection. The large peritoneal surface is exploited in peritoneal dialysis, where water, electrolytes, urea, and uremia-causing toxins are extracted from blood by repeated infusion and removal of dialysate solutions into the peritoneal cavity. AQP1 is expressed in the capillary endothelium and mesangium near the peritoneal luminal surface. Osmotically induced water transport in *AQP1*-null mice was approximately 2.5-fold reduced, compared with wild-type mice, suggesting a role for AQP1 in osmotic water removal during peritoneal dialysis. However, fluid absorption after intraperitoneal saline infusion was not affected by AQP1 deletion, suggesting that AQP1 is not an important determinant of peritoneal fluid movement under physiological conditions.

### AQUAPORIN 1 IN LACTEAL ENDOTHELIUM IN SMALL INTESTINE

AQP1 is expressed at those sites in the proximal gastrointestinal tract that play a role in dietary fat processing, including cholangiocytes in liver (bile production), pancreatic microvascular endothelium (pancreatic fluid production), gallbladder microvascular endothelium (bile storage), and intestinal lacteal endothelium (chylomicron absorption). The hypothesis was tested that AQP1 facilitates dietary fat processing (38). It was found that relatively young *AQP1*-null mice fed a high-fat (50%) diet failed to gain weight and developed steatorrhea and serum hypertriglyceridemia, whereas litter-matched wild-type mice gained weight rapidly. The *AQP1*-null mice thrived when returned to a normal low-fat diet. The *AQP1*-null mice on a high-fat diet had elevated concentrations of pancreatic enzymes in their small intestine and stool, normal pH in duodenal fluid, and normal bile/pancreatic fluid production, suggesting a defect in fat absorption rather than digestion. The mechanisms by which AQP1 acts in lacteal endothelium to facilitate chylomicron absorption remain to be determined.

### AQUAPORIN 1 IN CORNEAL ENDOTHELIAL FUNCTION

AQP1 is expressed in corneal ECs, and AQP5 in corneal epithelial cells. Corneal thickness, water permeability, and response to experimental swelling was compared in wild-type mice and mice lacking AQP1 or AQP5 (39). Corneal thickness was significantly reduced in *AQP1*-null mice (101  $\mu\text{m}$ ) and increased in *AQP5*-null mice (144  $\mu\text{m}$ ) compared with wild-type mice (123  $\mu\text{m}$ ). After exposure of the corneal endothelial surface to hypotonic saline by anterior chamber perfusion, the rate of corneal swelling (7.1  $\mu\text{m}/\text{min}$  in wild-type mice) was greatly reduced by AQP1 deletion (1.6  $\mu\text{m}/\text{min}$ ), indicating that AQP1 provides the principal route for osmotically driven water transport across the corneal endothelium. Although baseline corneal transparency was not impaired by AQP1 deletion, the recovery of corneal transparency and thickness after hypotonic swelling (10 min exposure of corneal surface to dis-

tilled water) was remarkably delayed in *AQP1*-null mice, with approximately 75% recovery at 7 minutes in wild-type mice compared to 5% recovery in *AQP1*-null mice. The impaired recovery of corneal transparency in *AQP1*-null mice provides evidence for the involvement of AQP1 in the active extrusion of fluid from the corneal stroma across the corneal endothelium. Measurements in ECs cultured from the corneas of wild-type and *AQP1*-null mice confirmed the reduced water permeability in AQP1 deficiency and suggested a potential role for AQP1 in corneal EC volume regulation (40).

### NOVEL ROLE OF AQUAPORIN 1 IN ANGIOGENESIS AND CELL MIGRATION

AQP1 is expressed strongly in the ECs of proliferating microvessels in malignant brain tumors, bone marrow microvessels in multiple myeloma, and proliferating microvessels in chick embryo chorioallantoic membrane. We recently found remarkably impaired tumor growth in *AQP1*-null mice after subcutaneous or intracranial tumor cell implantation, with reduced tumor vascularity and extensive necrosis (Figures 78.2A and 78.2B; for color reproduction, see Color Plate 78.2) (32). Reduced microvessel growth also was found in implanted pellets of Matrigel containing endothelial growth factors. A novel mechanism for the impaired angiogenesis was established from cell culture studies. Although adhesion and proliferation were similar in primary cultures of aortic endothelium from wild-type versus *AQP1*-null mice, cell migration was greatly impaired in AQP1-deficient cells (Figure 78.2C), with abnormal vessel formation in vitro. Stable transfection of non-ECs with AQP1, or a structurally different water-selective transporter (AQP4), accelerated cell migration and in vitro wound healing. Interestingly, motile AQP1-expressing cells had prominent membrane ruffles at the leading edge, with polarization of AQP1 protein to lamellipodia, where rapid water fluxes occur. As a possible mechanism for the dependence of cell migration on AQPs, it has been proposed that cell membrane protrusions are formed as a consequence of actin cleavage and ion uptake at the tip of a lamellipodium, creating local osmotic gradients that drive the influx of water through the cell membrane (41,42). Water entry is thought to then increase local hydrostatic pressure to cause cell membrane protrusion. Aquaporins may thus provide an important pathway for water entry into lamellipodia in some cell types.

### CONCLUSION

Phenotype studies in AQP-deficient mice indicate a variety of diverse roles for AQPs in mammalian physiology, ranging from urinary concentrating function and exocrine gland fluid secretion, to water balance in brain, and glycerol/triglyceride regulation in adipocytes. AQP1 is widely expressed in microvascular endothelia outside the brain; however, only in renal

vasa recta, where transendothelial osmotic transport driven by gradients of small solutes occurs, is AQP1 of clear physiological significance. The reasons for the expression of aquaporins in microvascular endothelia without demonstrable functional significance remain unclear. Reduced angiogenesis in AQP1-null mice and the impaired migration of AQP1-deficient ECs

suggests a novel role for AQP1 in rapid vessel proliferation in tumors and after injury. Indeed, AQP-dependent cell migration may be a general phenomenon of relevance to tumor spread, wound healing, and organ regeneration. In nonmicrovascular endothelium, AQP1 in intestinal lacteals may facilitate intestinal absorption, and AQP1 in corneal endothelium

appears to be quite important for corneal fluid balance. The phenotype studies suggest that the pharmacological inhibition of AQP1 may provide new therapies in human diseases, such as in diuretics, regulators of intraocular pressure and swelling in brain and cornea, and inhibitors of tumor angiogenesis.

#### KEY POINTS

- AQP1 provides the major water transport pathway in the endothelium.
- AQP1 is required for normal EC function in renal vasa recta and cornea; AQP1 facilitates tumor vessel angiogenesis by enhancing EC migration.

#### Future Goals

- To develop AQP1 inhibitors as diuretics and antiangiogenesis agents

#### ACKNOWLEDGMENTS

Supported by grants DK35124, HL59198, EY13574, EB00415, and HL73854 from the National Institutes of Health, and grant R613 from the Cystic Fibrosis Foundation.

## Ion Channels in Vascular Endothelium

Xiaoqiang Yao

*Faculty of Medicine, Chinese University of Hong Kong*

Among the innumerable proteins that support life in its many forms, ion channels are some of the most fascinating, partly for what they do, and partly for how they do it. Endothelial cells (ECs) express a great variety of ion channels. The most obvious function of these channels is to sense chemical and mechanical stimuli, by which they are activated, and to transform these stimuli into changes in ion fluxes. Simply put, in response to stimuli, the ion channels undergo an extremely rapid conformational change that converts an impermeable structure into highly permeable holes in the membrane through which ions can pass.

It appears that the main functions of these channels are to control two vital parameters: Calcium ( $\text{Ca}^{2+}$ ) influx and membrane potential (Figure 79.1). ECs generally are regarded as nonexcitable. Little functional role exists for voltage-gated  $\text{Ca}^{2+}$  channels such as the L-type and T-type  $\text{Ca}^{2+}$  channels in ECs; these channels play more important roles in myocytes and neurons. In ECs,  $\text{Ca}^{2+}$  enters the cells via nonselective cation channels.  $\text{Ca}^{2+}$  influx results in a rise in cytosolic  $\text{Ca}^{2+}$  level ( $[\text{Ca}^{2+}]_i$ ), which in turn controls the production and/or release of numerous vasoactive agents from endothelium. These agents include nitric oxide (NO), endothelium-derived hyperpolarizing factor (EDHF), vasodilatory and vasoconstrictive prostaglandins, endothelins, and tissue-type plasminogen activator (t-PA), and they serve to regulate multiple vascular functions, such as vessel tone, vascular permeability, blood coagulation, and EC growth. In addition to controlling the endothelial  $[\text{Ca}^{2+}]_i$ , endothelial ion channels, especially potassium ( $\text{K}^+$ ) and chloride ( $\text{Cl}^-$ ) channels, also act to maintain endothelial membrane potential. Membrane potential, together with the transmembrane concentration gradient for  $\text{Ca}^{2+}$ , provides the electrochemical driving force for transmembrane  $\text{Ca}^{2+}$  influx into ECs. Furthermore, endothelial membrane hyperpolarization may spread to underlying vascular smooth muscle layers through myoendothelial gap junctions and directly hyperpolarize the smooth muscle, causing vascular relaxation (1).

Endothelial ion channels originally were studied by measuring radioisotope (such as  $^{45}\text{Ca}^{2+}$  and  $^{86}\text{Rb}^+$ ) uptake and, more recently, with the patch clamp technique and by measuring changes in the fluorescence of ion-sensitive indicator

dyes. Rapid developments in molecular biology have led to the cloning of a large number of ion channels, many of which are found to be expressed in ECs. However, it still remains difficult to directly correlate a cloned channel with endogenous channel activity recorded from ECs. This is attributable, in part, to a lack of specific compounds with which to block or activate the different ion channels and especially different channel isoforms, as well as the inherent complexity of EC ion channels. Many important ion channels in ECs such as transient receptor potential (TRP) channels and  $\text{K}^+$  channels are composed of several subunits, which can exist as homo- or heteromultimers. Unfortunately, the precise subunit composition and relative stoichiometry of many of these channels are still unclear. As a result, the electrophysiological and pharmacological properties of native channels and their regulation may be very different from those of the cloned channels, which are mostly studied in the form of functional homomultimeric channel complexes.

### EVOLUTIONARY CONSIDERATIONS

Some of the most important channels in ECs are TRP, cyclic nucleotide-gated channels (CNG), inwardly rectifying  $\text{K}^+$  channels ( $\text{K}_{ir}$ ),  $\text{Ca}^{2+}$ -sensitive  $\text{K}^+$  channels ( $\text{K}_{Ca}$ ), adenosine triphosphate (ATP)-sensitive  $\text{K}^+$  channels ( $\text{K}_{ATP}$ ), voltage-gated  $\text{Cl}^-$  channels (ClC), and  $\text{Ca}^{2+}$ -sensitive  $\text{Cl}^-$  channels (CLCA) (Table 79-1). Most TRP channels and  $\text{K}^+$  channels are composed of four principal subunits, each of which contains either six transmembrane segments (6-TMS) (TRP,  $\text{K}_{Ca}$ ) or two transmembrane segments (2-TMS) ( $\text{K}_{ir}$ ,  $\text{K}_{ATP}$ ). The evolutionary precursor of these channels appears to be the basic building block of 2-TMS, which constitutes the entire protein in many prokaryotic channels. An additional 4-TMS is added to 2-TMS in the process of evolution to create 6-TMS channels (2). A likely ancestor for endothelial  $\text{K}^+$  channels and cation channels (TRP, CNG) appears to be those channels akin to bacterial  $\text{K}^+$  channel KcsA (3). Interestingly, the structure of  $\text{Cl}^-$  channels is very different from that of cation channels. ClC channels are found

Figure 79.1. A general scheme showing the role of endothelial ion channels in the control of  $\text{Ca}^{2+}$  influx and membrane potentials. Agonists bind to G-protein-coupled receptors (GPCR) or tyrosine kinase-linked receptors (RTK), causing activation of phospholipase C (PLC), leading to the production of diacylglycerol (DAG) and  $\text{InsP}_3$ . DAG activates some TRP channels.  $\text{InsP}_3$  binds to its receptor ( $\text{InsP}_3\text{R}$ ), resulting in store- $\text{Ca}^{2+}$  release and store-operated  $\text{Ca}^{2+}$  influx via TRP channels.  $\text{K}^+$  channels and  $\text{Cl}^-$  channels control membrane potential, which is the driving force for  $\text{Ca}^{2+}$  influx. Endothelial  $[\text{Ca}^{2+}]_i$  regulates the production and release of vasoactive agents from endothelium, causing subsequent vascular responses.

in bacteria and contain two identical subunits. Each subunit consists of 18 helices, and together they form two topologically related domains, which span the membrane in opposite directions in an arrangement called *antiparallel architectures* (4).

### $\text{Ca}^{2+}$ -PERMEABLE NONSELECTIVE CATION CHANNELS

Early studies showed that binding of agonists such as bradykinin, histamine, ATP, and endothelin-1 to their membrane receptors stimulates the activity of  $\text{Ca}^{2+}$ -permeable nonselective cation channels (5,6) and thus enhances  $\text{Ca}^{2+}$  influx (5) in vascular ECs. The single channel conductance of these channels is between 20 and 30 picosiemen (pS) for monovalent cations and 4 to 12 pS for  $\text{Ca}^{2+}$ . In general, these channels do not discriminate between  $\text{K}^+$  and sodium ( $\text{Na}^+$ ), and the permeability ratio of  $P_{\text{Ca}^{2+}}/P_{\text{K}^+, \text{Na}^+}$  varies from 0.03 to 2 (6).

It is widely accepted that, as in many other cell types, one of the predominant mechanisms for the above-mentioned agonist-induced  $\text{Ca}^{2+}$  influx in ECs is the capacitative  $\text{Ca}^{2+}$  entry (CCE), which was first proposed by Putney (7). According to this model, binding of agonists to their respective membrane receptors activates G-proteins, which in turn stimulate phospholipase C (PLC), leading to the generation of inositol 1,4,5-triphosphate ( $\text{InsP}_3$ ) and diacylglycerol (DAG) (7,8).  $\text{InsP}_3$  binds to its receptor ( $\text{InsP}_3\text{R}$ ), causing  $\text{Ca}^{2+}$  release from

intracellular  $\text{Ca}^{2+}$  stores within endoplasmic reticulum (8). The resultant decrease in  $\text{Ca}^{2+}$  content within endoplasmic reticulum triggers  $\text{Ca}^{2+}$  influx from the extracellular milieu. In addition to CCE, agonists also may stimulate  $\text{Ca}^{2+}$  entry in ECs via noncapacitative mechanisms.

The molecular identity of endothelial CCE is still not well understood. TRP channels, which were first cloned in *Drosophila melanogaster* (9), provide the molecular candidates for CCE. Tremendous advances in recent years have resulted in the isolation of at least 28 unique mammalian TRP homologues from human, mouse, rat, rabbit, and bovine tissues (10). These mammalian TRP homologues have been divided into six subfamilies: canonical (TRPC), vanilloid (TRPV), melastatin (TRPM), mucolipin (TRPML), polycystin (TRPP), and ankyrin transmembrane proteins (TRPA) (10). With the exception of some polycystins, all TRPs possess 6-TMS and a pore region between TMS5 and TMS6. Functional TRP channels are believed to be composed of four subunits (11). The charged residues in the putative TMS4 helix, which usually underlie voltage gating in voltage-gated channels, are not present in TRP. Vascular ECs at a minimum express TRPC, TRPV, TRPP, and TRPM.

### Canonical Transient Receptor Potential

TRPC is the most extensively studied TRP. TRPC contains three highly conserved ankyrin domains at the  $\text{NH}_2$  terminus and a TRP box, which contains a conserved stretch of 25 amino acids at its  $\text{COOH}$  terminal to TMS6. TRPC is activated

Table 79-1: Properties of EC Ion Channels

	Ions	EC Expression	Activation	—/—
<b>Voltage-gated Ca<sup>2+</sup> channels</b>	Ca <sup>2+</sup>	L-type? T-type?	Membrane depolarization	
<b>Nonselective cation channels</b>				
TRPC	Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup>	All 7 isoforms	TRPC1-C7: CCE? TRPC3,C6,C7: DAG	<i>TRCP4<sup>-/-</sup></i> : impaired store-operated currents; impaired EC-dependent vascular smooth muscle cell relaxation; lack of thrombin-induced actin stress fiber formation; reduction in thrombin-induced permeability
TRPV	V1–V4: Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup> V5–V6: Ca <sup>2+</sup>	TRPV1, V2, V4	TRPV1–V4: hot or warm temperature. TRPV1: vanilloids, anandamide, eicosanoid. TRPV4: 5',6'-EET, osmotic swelling, shear stress.	
TRPM (except M4,M5)	Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup> M6,M7: Mg, Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup>	TRPM3, M6–M8	TRPM2: ADP-ribose, NAD, H <sub>2</sub> O <sub>2</sub> TRPM3: decrease in osmolarity. TRPM7: Mg-ATP, phosphorylation, TRPM8: Menthol, icillin, cool temperature	
TRPP CNG	Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup> Ca <sup>2+</sup> , Na <sup>+</sup> , K <sup>+</sup>	TRPP1, P2 CNGA1, A2, A4	Flow shear stress cGMP, cAMP	
<b>Membrane Potential K channels</b>				
K <sub>ir</sub>	K <sup>+</sup>	K <sub>ir2.1, 2.2, 2.4</sub>	K, ATP	
K <sub>ca</sub>	K <sup>+</sup>	BK <sub>ca</sub> , IK <sub>ca</sub> , SK2, SK3	All K <sub>ca</sub> : Ca BK <sub>ca</sub> : membrane depolarization	Conditional transgenic mice: low SK3 expression enhances EC-dependent pressure- and phenylephrine-induced vascular constrictions, elevates blood pressure
K <sub>ATP</sub>	K <sup>+</sup>	K <sub>ir6.1, 6.2</sub>	Reduction in ATP	
<b>Cl channels</b>				
CLCA	Cl <sup>-</sup>	CLCA1,2,5	Ca	
VRAC	Cl <sup>-</sup> , HCO <sub>3</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup>	VRAC	Osmotic swelling, low ionic strength	
CLC	Cl <sup>-</sup>	CLC2–7	All CLC: membrane depolarization CLC2, CLC3: osmotic swelling	

either by binding of agonists to plasma membrane G-protein-coupled receptors, leading to the activation of PLC- $\beta$ , or by binding of growth factors to tyrosine kinase-linked receptors, resulting in the activation of PLC- $\gamma$  (12,13). Activity of either PLC- $\beta$  or PLC- $\gamma$  hydrolyses the lipid precursor phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>) to yield InsP<sub>3</sub> and diacylglycerol (12,13). Although it is well accepted that

stimulation of PLC is essential for TRPC activation, the activation steps following PLC stimulation are diverse and sometimes controversial. The proposed mechanisms of TRPC activation include the capacitative mechanism mediated by InsP<sub>3</sub>-InsP<sub>3</sub>R (12,14) and a noncapacitative mechanism that involves diacylglycerol (15). DAG is a product of PLC activity, and it can activate some TRPC isoforms (TRPC3, -C6, -C7),

but it is unable to activate other isoforms (TRPC4, -C5) (15,16).  $\text{Ca}^{2+}$  may also modulate the activity of TRPC (12,17). A calmodulin (CaM) binding site is found in the COOH terminus of TRPC that overlaps with the  $\text{InsP}_3\text{R}$  binding domain. The activity of TRPC also is regulated by protein phosphorylation. Protein kinase G and protein kinase C can both phosphorylate multiple TRPC isoforms, causing a decrease in channel activity (18,19), thereby providing negative feedback regulation to allow fine control for TRPC-mediated  $\text{Ca}^{2+}$  influx.

ECs have been shown to express seven isoforms of TRPC (as well as TRPV1, -2, and -4; all TRPM except TRPM5; and TRPP1, and -2) (1,6,20). Most of these data concerning the expression of TRP were collected from cultured ECs based on reverse transcription polymerase chain reaction (RT-PCR) assays (1,6,20). A recent study utilizing both in situ hybridization and immunohistochemistry confirmed the expression of all seven TRPC isoforms in ECs of different-sized human arteries (20). Unfortunately, there is still little information about the relative abundance of different TRPC isoforms in ECs in vivo. Moreover, the extent to which expression of the isoforms varies between different vascular beds remains unknown.

Functional studies show that TRPC1 mediates CCE in ECs (17,21). Transfection of an antisense oligonucleotide against TRPC1 effectively reduces *TRPC1* mRNA levels and, at the same time, decreases the CCE induced by the endoplasmic reticulum  $\text{Ca}^{2+}$ -ATPase inhibitor, thapsigargin, and it also reduces store-operated  $\text{Ca}^{2+}$  currents in human pulmonary artery ECs (21). Evidence also shows that TRPC1-mediated  $\text{Ca}^{2+}$  entry may be important for arrangement of the microfilamentous cytoskeleton (17). TRPC4 is another channel that may play a crucial role in vascular function. *TRPC4*-knockout (*TRPC4*<sup>-/-</sup>) mice display impaired CCE and store-operated currents in aortic and lung ECs. Endothelium-dependent smooth muscle relaxation in response to the vasoactive agonists ATP and acetylcholine also is impaired in these mice (22). Furthermore, ECs of *TRPC4*<sup>-/-</sup> mice exhibit lack of actin stress fiber formation and cell retraction in response to thrombin (23), and the knockout mice demonstrate reduced thrombin-mediated lung microvascular permeability (23). TRPC1 also may participate in the control of vascular permeability. Inhibition of TRPC1 activity either by using an anti-TRPC1 antibody or by interfering with the interaction of TRPC1 with  $\text{InsP}_3\text{R}$ , reduces the vascular endothelial growth factor (VEGF)-induced increase in transendothelial permeability (24). Evidence also suggests that TRPC is involved in oxidative stress-induced increases in membrane conductance. The oxidant tert-butylhydroperoxide (tBHP) activates cation conductance in porcine aortic ECs. The tBHP-induced currents resemble TRP-related currents in terms of cation selectivity, sensitivity to  $\text{La}^{3+}$  inhibition, and lack of voltage dependence. Expression of the N-terminal fragment of human TRPC3 (NTRP3), which interferes with the channel assembly, abolishes the oxidant-induced cation currents, thus suggesting that TRPC3 proteins may be the molecular basis of endothe-

lial oxidant-activated cation channels (25). Taken together, these data provide compelling evidence for an important role of TRPC in regulating vascular tone and controlling vascular permeability.

Another important consideration for the physiological function of TRPC is the coassembly mechanism. Although TRPC is predicted to form tetrameric structures (11), the stoichiometry of the functional channels has not been determined. Several studies have established the ability of TRPC to coassemble to form heteromultimers (12,26). Coassembly could occur at least between TRPC1 and C3 (12); TRPC1 and -C4 and -C5 (12); and between the members within the same TRPC subgroups (e.g., TRPC4 and -C5 or TRPC3, -6, and -7) (26). Because multiple TRPC homologues are expressed within a single EC type (17,20), it is likely that ECs contain multiple forms of TRPC heterotetramers, which may confer on the ECs a variety of different  $\text{Ca}^{2+}$ -permeable channels with different properties. At present, however, no structural analysis data are available concerning the oligomeric states of endothelial TRPC channels. Resolving this puzzle is an important priority.

### Vanilloid Transient Receptor Potential

At least three members of TRPV are expressed in vascular ECs: TRPV1, -V2, and -V4 (1). TRPV1 and -V4 are activated by endogenous vanilloids such as anandamide and 2-arachidonoyl-glycerol (2-AG), both of which have vascular effect in their own right (27,28). Functionally, TRPV1 is involved in endothelium-dependent dilation in rat mesenteric arteries (29). Another important property of TRPV4 is its mechanosensitivity. TRPV4 is activated by cell swelling or flow shear stress (30). Cell swelling stimulates the phospholipase A<sub>2</sub> (PLA<sub>2</sub>)-dependent formation of arachidonic acid, which, through its metabolic product 5',6'-EET, activates TRPV4 (30,31).

All three EC TRPV channels are temperature-sensitive. TRPV4 is activated by warm temperature, with its low threshold at around 25°C to 27°C; therefore the channels may be constitutively open in ECs at body temperature, and this may contribute to the elevated intracellular  $\text{Ca}^{2+}$  concentration in native endothelium, causing a steady-state release of NO. TRPV1 and -V2 are activated at  $\geq 43^\circ\text{C}$  and  $\geq 53^\circ\text{C}$ , respectively (32), but these threshold values can be modulated by chemical ligands and the phosphorylation state of the channels. This plasticity potentially may confer a broad range of temperature sensitivity to cells expressing TRPV1 (32). The temperature sensitivity of TRPV channels may contribute to peripheral vasoconstriction at low temperature and vasodilation at high temperature.

### Polycystin Transient Receptor Potential

The best-known TRPP channels are TRPP1 (PKD1) and TRPP2 (PKD2). Mutations in either the TRPP1 or TRPP2 gene, which encodes respectively for polycystin 1 (PC1) and

polycystin-2 (PC2) proteins, result in a common genetic disease known as autosomal dominant polycystic kidney disease. Both PC1 and PC2 are integral membrane proteins. PC1 contains a large extracellular NH<sub>2</sub> terminus, and the proteins act as a G-protein-coupled receptor. PC2 shares sequence similarity with the TRP channel family and functions as a Ca<sup>2+</sup>-permeable cation channel. In renal epithelial cells, PC1 and PC2 physically interact with each other to form a mechanosensor to detect fluid flow (33). Both PC1 and PC2 are required for flow-induced Ca<sup>2+</sup> influx in renal epithelial cells (33).

TRPP1 and TRPP2 are found to be expressed in cultured vascular ECs by immunohistochemical studies (1,34). In cultured human umbilical vein ECs, TRPP1 is localized to the lateral membrane of cells in contact with one another, whereas no expression is found at the apical and basal membrane, suggesting a role of polycystin proteins in cell differentiation and cell-cell interactions. In addition, the fact that TRPP1 acts as the mechanosensor in renal epithelial cells to sense flow shear stress also raises the possibility that TRPP channels may play a similar role in vascular ECs to sense flow shear stress.

### Cyclic Nucleotide-Gated Channels

At least six CNG-related genes have been cloned. CNGA1 through -A3 are referred to as principal subunits, because they can form functional channels on their own. CNGA4, -B1, and -B3 are referred to as modulatory subunits, because unlike the A1 to A3 subunits, they do not form functional channels on their own (35). ECs express at least CNGA1, -A2, and -A4 (36,37). Inhibition of CNGA2 channels reduces the capacitative Ca<sup>2+</sup> entry as well as thapsigargin-induced cation currents in pulmonary artery ECs (36).

## THE ION CHANNELS CONTROLLING MEMBRANE POTENTIAL

The measured resting membrane potential of vascular ECs varies considerably between -10 mV to -80 mV due to differences in seal resistances, culture conditions, and interspecies and arterial-venous variations (6,38). The endothelium of the intact rat aorta has an average membrane potential of -58 mV (6). K<sup>+</sup> and Cl<sup>-</sup> channels are the two most important classes of channels controlling endothelial membrane potential. ECs in culture consist of two population of cells, one with a resting potential between -70 and -60 mV that is mainly determined by inwardly rectifying K<sup>+</sup> channels (K<sup>+</sup>-type ECs) and the other with resting potential between -40 mV to -10 mV that is controlled by Cl<sup>-</sup> conductance (Cl<sup>-</sup>-type ECs) (6).

### Potassium Ion Channels

#### *Inwardly Rectifying Potassium Ion Channels*

K<sub>ir</sub> is considered to be the major determinant for the resting membrane potential of ECs (6). The predominant K<sub>ir</sub>s

expressed in ECs are K<sub>ir2.1</sub>, but K<sub>ir2.2</sub> also may have an important role in resting conditions (39). K<sub>ir</sub> channels conduct large inward currents at potentials more negative than the K<sup>+</sup> equilibrium potentials (E<sub>K</sub>), but permit very small outward currents at potentials slightly more positive than E<sub>K</sub> (6,38). Strong inward rectification of K<sub>ir2.1</sub> reportedly is due to the blockage of outward currents by cytoplasmic Mg<sup>2+</sup> and polyamine, which is known to be determined partly by the negatively charged amino acid residues Asp172, Glu224, and Glu299. K<sub>ir</sub> currents are blocked by external divalent cations with Ba<sup>2+</sup> >> Sr<sup>2+</sup> >> Mg<sup>2+</sup> > Mn<sup>2+</sup> = Ca<sup>2+</sup> (38). K<sub>ir</sub> may also act as a K<sup>+</sup> sensor. A small increase in extracellular K<sup>+</sup>, such as that resulting from the activation of large-conductance K<sub>Ca</sub> channels, may shift the reversal potential of K<sub>ir</sub> toward a more positive value, thereby increasing the conductance of the channels (6).

Functionally, endothelial K<sub>ir</sub> is inhibited by vasoactive agonists such as angiotensin II, vasopressin, vasoactive intestinal polypeptide, and histamine (6,38). K<sub>ir</sub> also seems to be metabolically regulated. ATP and channel phosphorylation appear to be essential for maintaining the activity of channels (6). Reduction of intracellular ATP and induction of hypoxic conditions dramatically downregulate K<sub>ir2.1</sub>. More recently, it has been shown that K<sub>ir2.1</sub> expressed in *Xenopus* oocytes and HEK293 can be activated by flow shear stress via a tyrosine phosphorylation-dependent mechanism, suggesting that K<sub>ir2.1</sub> channels in ECs can act as a mechanotransducer in response to flow shear stress (38).

#### *Calcium Ion-Sensitive Potassium Ion Channels*

The influx of Ca<sup>2+</sup> in stimulated ECs exerts a depolarizing effect that is offset by activation of a variety of K<sub>Ca</sub> channels. K<sub>Ca</sub> channels can be classified into large (BK<sub>Ca</sub>), intermediate (IK<sub>Ca</sub>), and small conductance channels (SK<sub>Ca</sub>) based on their single channel conductance. All K<sub>Ca</sub> channels are comprised of four functional  $\alpha$ -subunits, each of which exhibits six trans-membrane segments and an intracellular COOH and NH<sub>2</sub> terminus. BK<sub>Ca</sub>, IK<sub>Ca</sub>, and at least two SK<sub>Ca</sub> channels (SK2, SK3) are found to be expressed in ECs in vivo (6,40). BK<sub>Ca</sub> has a conductance between 165 and 220 pS, and is activated by the concerted actions of cytosolic Ca<sup>2+</sup> and membrane depolarization. The channel is blocked by tetraethylammonium, charybdotoxin, iberiotoxin, and D-turbocurarine. The benzimidazolone compounds NS004 and NS1619 increase the activity of BK<sub>Ca</sub>. Unlike BK<sub>Ca</sub>, the activity of IK<sub>Ca</sub> and SK<sub>Ca</sub> is not voltage-dependent. Instead, they are activated solely by cytosolic Ca<sup>2+</sup>, with a unit conductance of 2 to 20 and 20 to 85 pS, respectively, and they are more sensitive to Ca<sup>2+</sup> than is BK<sub>Ca</sub>. IK<sub>Ca</sub> is blocked by charybdotoxin, clotrimazole, and tetrabutylammonium, but is not affected by iberiotoxin (41). IK<sub>Ca</sub> is activated by InsP<sub>3</sub>-sensitive Ca<sup>2+</sup> release (6). SK<sub>Ca</sub> is blocked by tetrabutylammonium, apamin, and clotrimazole.

Functionally, it has been shown that SK<sub>Ca</sub> and IK<sub>Ca</sub> in ECs play a pivotal role in the endothelium-dependent

smooth muscle hyperpolarization.  $K^+$  efflux via  $IK_{Ca}$  and  $SK_{Ca}$  may activate  $K^+$ -sensitive  $K_{ir}$  channels in smooth muscle cells and induce hyperpolarization (41). A recent study, using a transgenic mouse in which SK3 expression levels can be manipulated using dietary components, provides compelling evidence that SK3 in ECs exerts a profound and tonic hyperpolarizing influence in resistance arteries (40).

#### ATP-Sensitive $K^+$ Channels

$K_{ATP}$  is believed to exist as an octameric structure composed of four  $\alpha$ -subunits and four  $\beta$ -subunits. The  $\alpha$ -subunits belong to the inward rectifier family ( $K_{ir6.1/6.2}$ ), whereas the  $\beta$ -subunits (SUR1, SUR2A, SUR2B) are the site of sulfonylurea binding. The activity of  $K_{ATP}$  channels increases as the concentration of intracellular ATP or glucose availability decreases (38).  $K_{ATP}$  is blocked by tetraethylammonium, the sulfonylurea drugs glibenclamide and tolbutamide, and an elevation of intracellular pH. Cromakalim, pinacidil, and diazoxide can increase the activity of  $K_{ATP}$ . The role of  $K_{ATP}$  in ECs has attracted significant interest because it has the potential to provide a mechanism for coupling blood flow to the metabolic requirements of the tissue. It is possible that a high metabolic rate decreases intracellular ATP, which in turn activates  $K_{ATP}$ , causing membrane hyperpolarization and smooth muscle relaxation.

#### $Cl^-$ Channels

ECs express volume-sensitive anion channels (VRAC). These channels are mainly permeable to  $Cl^-$  under physiological conditions, but amino acids and organic osmolytes also may permeate through the channels. The single-channel conductance of VRAC is approximately 40 to 50 pS at positive potentials and 10 to 20 pS at negative potentials, indicating that the channels are outward rectifiers. The channels are inhibited by the classical  $Cl^-$  channel blockers DIDS, SITS, 9-AC, and niflumic acid. Cell shrinkage reduces the basal current in ECs below its values in control conditions, indicating that VRAC is partially activated in resting cells and therefore important for the resting membrane potential. On the other hand, cell swelling or low intracellular ionic strength may activate tyrosine kinase, leading to the activation of VRAC (6). The molecular nature of the VRAC channel is still unknown. Several putative extracellular candidates have been proposed, including P-glycoprotein, pIcn, and ClC3, but all these candidates have been questioned (6).

ClC channels are voltage-gated  $Cl^-$  channels and many of them (ClC2 through ClC7) are expressed in ECs (42). CLCA channels are  $Ca^{2+}$ -dependent  $Cl^-$  channels and at least CLCA1, -2, and -5 are expressed in ECs (43). Although all CLCA channels show strong outward rectification, the current-voltage relationship may vary among different channel subtypes. Some ClC channels such as ClC2 and ClC3 are volume-sensitive, and thus may play a role in volume regu-

lation (6). Different  $Cl^-$  channels regulate endothelial anion efflux under different conditions.

## FUNCTIONAL ROLE OF ENDOTHELIAL ION CHANNELS

### Vascular Tone Control

One of the most important functions of endothelial ion channels is to regulate vascular tone. Vascular ECs are exposed to circulating blood that contains numerous  $Ca^{2+}$ -mobilizing agents including metabolites, local paracrine agents, neurotransmitters, growth factors, and cytokines. Some of these factors, such as serotonin, ATP, and adenosine diphosphate (ADP), are released from platelets and erythrocytes into circulating blood. Others are mostly produced in ECs themselves, such as substance P, ATP, vasopressin, angiotensin II, histamine, and endothelin (44). These compounds bind to their respective membrane receptors and elicit a rise of endothelial  $[Ca^{2+}]_i$  via  $InsP_3$ -mediated store- $Ca^{2+}$  release, and via capacitative and noncapacitative  $Ca^{2+}$  influx. Examples of noncapacitative  $Ca^{2+}$  influx include diacylglycerol-mediated activation of TRPC3, -C6, and -C7 (15). The rise in endothelial  $[Ca^{2+}]_i$  also may be elicited by some other physical and chemical stimuli, such as flow shear stress, cell swelling, and oxidative stress.

A rise in  $[Ca^{2+}]_i$  triggers the ECs to produce and release vasorelaxants such as NO, EDHF, and prostacyclin, causing a subsequent reduction in vascular tone. Basal release of NO from ECs appears to be a  $Ca^{2+}$ -independent process, but a rise in  $[Ca^{2+}]_i$  is certainly able to stimulate endothelial NO synthase, thereby increasing the production and release of NO in ECs (45). A rise in  $[Ca^{2+}]_i$  may also stimulate  $PLA_2$ , an enzyme required for prostacyclin production. EDHF is another relaxing factor, the production and release of which is  $Ca^{2+}$ -dependent. The chemical identity of EDHF is not fully resolved. Candidates for EDHF may vary with vascular beds and vessel sizes. The proposed candidates for EDHF include the cytochrome P450 metabolites of arachidonic acid such as 5,6-EET,  $K^+$  ions released from ECs due to activity of  $K_{Ca}$ , and hydrogen peroxide (5,41,44).

TRP and CNG channels play pivotal roles in endothelial  $Ca^{2+}$  signaling, because they allow  $Ca^{2+}$  to enter ECs in response to various stimuli.  $K^+$  and  $Cl^-$  channels are also important, because they maintain endothelial membrane potential, which is one of the driving forces for transmembrane  $Ca^{2+}$  influx. EC hyperpolarization also may spread to underlying vascular smooth muscle layers through gap junctions, directly causing smooth muscle hyperpolarization and subsequent vascular relaxation (6,41). At present, at least two channels, TRPC4 and SK3, have been convincingly demonstrated to play critical roles in the control of vascular tone and blood pressure. Freichel and colleagues showed that knocking out the *TRPC4* gene impairs endothelium-dependent vascular relaxation (22), and Taylor and colleagues demonstrated

that transgenic mice in which SK3 expression is suppressed by dietary doxycycline display an enhanced vascular constriction and a pronounced elevation of blood pressure (40).

### Blood Coagulation

ECs also release factors that influence blood coagulation. NO, prostacyclin, t-PA, and tissue factor pathway inhibitor (TFPI) function as natural anticoagulants, whereas von Willebrand factor (vWF), platelet activating factor (PAF), and plasminogen activator inhibitor (PAI)-1 serve as procoagulants. The release of these factors from ECs is  $\text{Ca}^{2+}$ -dependent. Many of these factors, such as t-PA, TFPI, vWF, are stored in granules and then released by  $\text{Ca}^{2+}$ -dependent exocytosis.

### Control of Vascular Permeability

Inflammatory mediators such as thrombin and histamine induce vascular leakage, which is defined as increased endothelial permeability to plasma proteins and other solutes. These inflammatory mediators induce an  $[\text{Ca}^{2+}]_i$  increase in ECs. The rise in  $[\text{Ca}^{2+}]_i$  activates key signaling pathways, which lead to myosin light chain-dependent EC contraction and disassembly of vascular endothelial (VE)-cadherin at the adherens junctions, causing a subsequent increase in vascular permeability. Evidence shows that TRPC1 and -C4 channels play important roles in the control of vascular permeability (23,24). In *TRPC4*<sup>-/-</sup> mice, thrombin-induced increase in vascular permeability was significantly impaired (23).

### Endothelial Cell Growth and Angiogenesis

Angiogenesis inducers such as VEGF, basic fibroblast growth factor (bFGF), platelet-derived growth factor, and others can stimulate the proliferation and migration of ECs, and regulate the formation of new blood vessels. Evidence shows that VEGF, by binding to its receptors, activates a signaling transduction cascade involving autophosphorylation, activation of PLC- $\gamma$ , and induction of CCE. TRP channels, especially TRPC1, TRPC6, and VRAC, appear to be particularly important for  $\text{Ca}^{2+}$  influx induced by angiogenesis factors (6,24,46). Blockers of VRAC such as tamoxifen, 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS), and flufenamic acid, suppress angiogenesis (6). The mechanism of action for VRAC in angiogenesis is still unknown, but it may be linked to the role of VRAC in volume regulation or in the modulation of endothelial  $\text{Ca}^{2+}$  levels, which is important for cell cycle control.

### Mechanosensing

Blood flow exerts a viscous drag, or shear stress, on the surface of the vascular ECs. Furthermore, pulsatile stretch on the vascular wall stretches the cell membrane of the ECs. In response, ECs undergo diverse biochemical and physiological changes, including the release of vasodilators and alter-

ations of gene expression. Many of these responses depend on mechanosensitive  $\text{Ca}^{2+}$  influx into the ECs. ECs express several flow shear stress-activated channels including TRPV4 (28), the complex of TRPP1 and TRPP2 (1), and  $\text{K}_{ir2.1}$  (6). Several stretch-activated channels also are expressed in ECs. These include TRPC1 and TRPV2, which are directly activated by membrane stretch, and TRPM4 and TRPC6, which are indirectly activated by endogenous ligands produced after membrane stretch. However, note that the mechanosensitivity of these channels has only been demonstrated in other cell types, and that no experimental evidence directly links any of these channels to the global increase of  $[\text{Ca}^{2+}]_i$  in ECs.

### KEY POINTS

- Ion channel controls endothelial  $\text{Ca}^{2+}$  influx, thereby influencing diverse vascular functions such as vascular tone, vascular permeability, secretion, EC proliferation and angiogenesis.
- TRP channels (except TRPM4 and -M5) and CNG channels allow  $\text{Ca}^{2+}$  influx in ECs.
- $\text{K}^+$  channels and  $\text{Cl}^-$  channels control membrane potential, which is one of the driving force for  $\text{Ca}^{2+}$  influx.
- Experiments with transgenic mice provide compelling evidence for crucial roles of several ion channels such as TRPC4 and SK3 in the regulation of vascular permeability and vascular tone.

### Future Goals

- To develop selective drugs targeting different isoforms of TRP channels,  $\text{K}^+$  channels and  $\text{Cl}^-$  channels
- To elucidate the mechanism of regulation for endothelial ion channels
- To resolve the oligomeric states of endothelial TRP channels

## Regulation of Angiogenesis and Vascular Remodeling by Endothelial Akt Signaling

Ichiro Shiojima and Kenneth Walsh

*Whitaker Cardiovascular Institute, Boston University School of Medicine,  
Boston, Massachusetts*

Since the initial identification of several classes of receptor tyrosine kinases and their ligands as crucial mediators of vascular development, considerable progress has been made toward understanding the process of angiogenesis at sites of tissue growth and/or repair (1,2). A number of clinical trials are currently evaluating angiogenic ligands for their ability to induce neovascularization in ischemic tissues (3,4), and the intracellular signaling pathways that mediate the proangiogenic effects of these growth factors are being extensively investigated. Among a number of signaling pathways activated by angiogenic growth factors, the phosphoinositide 3-kinase (PI3K)/Akt pathway is of particular interest because it regulates downstream target molecules that are potentially involved in blood vessel growth and homeostasis, and thus seems to be a major mediator that couples “inputs” with “outputs” in the endothelium.

### PI3K-AKT SIGNALING AXIS: UPSTREAM ACTIVATORS AND DOWNSTREAM TARGETS

Akt originally was identified as a cellular counterpart of the oncogene derived from the murine AKT8 retrovirus; the same gene product was independently isolated as a protein kinase related to protein kinase A and C and was therefore named protein kinase B (PKB) or RAC (related to protein kinase A and C) (5–8). Mammalian genomes contain three *Akt* genes, *Akt1/PKB $\alpha$* , *Akt2/PKB $\beta$* , and *Akt3/PKB $\gamma$* , whereas *Drosophila melanogaster* and *Caenorhabditis elegans* contain one and two *Akt* genes, respectively (9,10). These genes encode proteins containing a pleckstrin homology (PH) domain in the amino terminus, a central kinase domain, and a carboxy terminal regulatory domain. All three mammalian *Akt* genes are widely expressed in various tissues, but Akt1 is most abundant in brain, heart, and lung, while Akt2 is expressed primarily in skeletal muscle and embryonic brown fat, and Akt3 is predominantly expressed in brain, kidney, and embryonic heart

(9,10). In unstimulated cells, Akt protein exists in cytoplasm, and the two regulatory phosphorylation sites (T308 and S473 in the case of Akt1) are in an unphosphorylated state. Upon growth factor stimulation, the PH domain binds to the lipid products of PI3K, and Akt is recruited to the plasma membrane. Akt is then sequentially phosphorylated at T308 and S473 by upstream kinases referred to as 3-phosphoinositide-dependent protein kinase 1 (PDK1) and PDK2, respectively, to yield a fully activated kinase (Figure 80.1) (11). PDK1 has been isolated and characterized, but the identity of PDK2 is still controversial. Several candidate molecules have been suggested to be a potential S473-kinase, including integrin-linked kinase (ILK) and Akt itself (autophosphorylation) (12). Fully activated Akt becomes available to phosphorylate its downstream substrates, and a portion of these molecules detach from the plasma membrane and translocate to various subcellular locations including the nucleus. Akt then is dephosphorylated and inactivated by protein phosphatases such as protein phosphatase 2A (PP2A).

Akt is a critical regulator of PI3K-mediated cell survival (9). A large number of studies have demonstrated in various cell types that constitutive activation of Akt signaling is sufficient to block cell death induced by a variety of apoptotic stimuli, and that transduction of dominant-negative Akt inhibits growth factor-induced cell survival. Several downstream targets of Akt are recognized to be apoptosis-regulatory molecules including Bad, the FOXO family of forkhead transcription factors, IKK $\alpha$ , MDM2, and Yes-associated protein (YAP), and these findings are consistent with the notion that Akt functions as a survival kinase (13). However, other downstream effectors of Akt are involved in different aspects of cellular regulation. For example, Akt (a) mediates the metabolic effects of insulin by inducing membrane translocation of the glucose transporter GLUT4 or through the phosphorylation and inactivation of glycogen synthase kinase (GSK)-3 (14); (b) regulates cell cycle and cellular senescence, at least in part, through modulating the activities of downstream

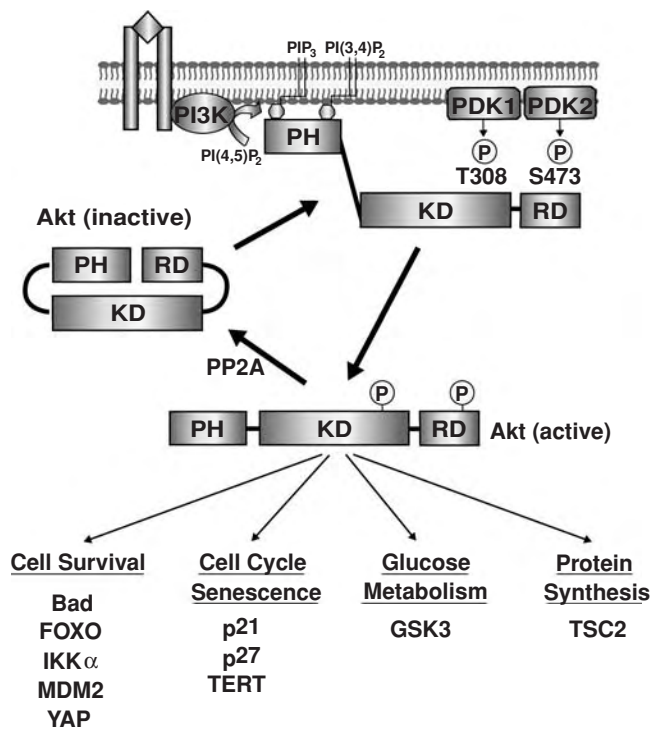

Figure 80.1. Mechanism of Akt activation and partial list of downstream molecules. Akt is activated by growth factors or cytokines in a PI3K-dependent manner, and phosphorylation of two residues by PDK1 (T308) and PDK2 (S473) is required for its full activation. Downstream target molecules are grouped according to their function.

substrates such as p21<sup>cip1/waf1</sup>, p27<sup>kip1</sup>, and human telomerase reverse transcriptase subunit (hTERT) (15,16); and (c) enhances protein synthesis by activating the mammalian target of rapamycin (mTOR) pathway through phosphorylation/inactivation of the tuberous sclerosis complex gene product TSC2 (see Figure 80.1) (17). Taken together, it would be more appropriate to classify Akt as a multifunctional protein kinase rather than a simple regulator of cell survival.

The functions of Akt gene products also have been studied *in vivo* using transgenic or knockout mice (Table 80-1). Overexpression of Akt1 in the heart results in cardiac hypertrophy (18–21), and Akt1 overexpression in pancreatic  $\beta$ -cells leads to both hypertrophy and hyperplasia of  $\beta$ -cells (22,23), consistent with the idea that Akt promotes cell growth and proliferation. Expression of Akt1 in T lymphocytes resulted in the development of lymphomas (24,25), and prostate cancer formation was observed in transgenic mice overexpressing Akt1 in prostate epithelial cells (26). However, Akt1 overexpression in mammary glands failed to induce tumor formation (27–30). Thus, sustained Akt activation is sufficient to induce malignant transformation in some, but not all cell types. Targeted disruption of the *Akt1* gene in mice results in a growth retardation phenotype (31,32). *Akt2*-null mice exhibit insulin resistance and, depending on genetic back-

ground, mild growth retardation (33,34). In contrast, *Akt3*-null mice do not show the general growth retardation phenotype, but brain size and weight are reduced in adult *Akt3*-null mice due to the reduction in both cell size and cell number (35,36). Mutual compensations among three *Akt* gene products also were demonstrated by combined deletion of these genes. *Akt1/Akt2* double mutant mice die shortly after birth due to defects in multiple tissues including skeletal muscle, bone, and skin (37), and *Akt1/Akt3*-double knockout mice die *in utero* (38). Thus, the phenotypes of these compound mutants are more severe than single knockout mice, pointing to the functional redundancies among three *Akt* genes in mammals.

Recently, the role of Akt signaling in the vascular endothelium was examined in transgenic and knockout mice. Endothelial cell (EC)-specific overexpression of an activated form of Akt1 resulted in embryonic lethality, associated with abnormal vascular remodeling and patterning. Transient expression of Akt in ECs also blocked hyperoxia-induced capillary clearing in retina (39). On the other hand, ischemia or vascular endothelial growth factor (VEGF)-induced angiogenesis and mobilization of endothelial progenitor cells (EPCs) were impaired in *Akt1*-null mice (40), and newly formed vessels in *Akt1*-null mice were immature and leaky (41). These data suggest that Akt signaling plays an important role in promoting angiogenesis and maintaining vascular homeostasis, and that fine-tuning of the Akt signal in ECs is required for normal vascular patterning and remodeling.

#### AKT-DEPENDENT SURVIVAL SIGNALS IN ENDOTHELIAL CELLS

Although originally identified as a factor that induces vascular permeability, VEGF exhibits multiple biological activities in ECs, including the enhancement of EC survival. This pro-survival effect of VEGF is mediated by the FLK-1/PI3K/Akt pathway (42–44). Subsequently it also was shown that several other EC stimuli including angiopoietin 1 (Ang1), insulin, insulin-like growth factor (IGF)-I, sphingosine-1-phosphate (S1P), hepatocyte growth factor (HGF), the small proteoglycan decorin, leptin, adiponectin, and fluid shear stress also activate PI3K–Akt signaling and inhibit apoptosis, illustrating the central role of this pathway in controlling EC viability (43,45–47).

Growth factor activation of angiogenesis depends on proper EC–extracellular matrix (ECM) attachment and, in the absence of matrix attachment, cells undergo apoptotic cell death through a process termed *anoikis* (a Greek word for “homelessness”) (48). VEGF activation of Akt in ECs is dependent on matrix attachment, and constitutively active Akt blocks cell detachment–induced apoptosis (42). These findings suggest that matrix attachment is required for growth factors to activate Akt and maintain EC viability. Cell attachment is mediated mainly through the engagement of ECM with integrin molecules. When integrins bind to ECM, they

**Table 80-1: Summary of Genetic Mouse Models**

<i>Gene</i>	<i>TG/KO</i>	<i>Phenotype</i>	<i>References</i>
<i>Akt1</i>	TG (heart)	Cardiac hypertrophy, heart failure	18–21
	TG ( $\beta$ -cells)	Hypertrophy and hyperplasia of beta-cells	22, 23
	TG (T lymphocytes)	T-cell lymphoma	24, 25
	TG (prostate)	Prostate neoplasia	26
	TG (mammary glands)	Delayed involution, fatty milk synthesis	27–30
	TG (ECs)	Abnormal vascular patterning	39
<i>Akt1</i>	KO	Growth retardation, apoptosis in thymus	31, 32
<i>Akt2</i>	KO	Diabetes, mild growth retardation, lipoatrophy	33, 34
<i>Akt3</i>	KO	Reduced brain size	35, 36
<i>Akt1/Akt2</i>	Double KO	Perinatal lethality, severe growth retardation	37
<i>Akt1/Akt3</i>	Double KO	Embryonic lethality, placental defect	38

TG, transgenic; KO, knockout.

become clustered and associate with the actin cytoskeleton through adaptor/signaling molecules. This further promotes integrin clustering and the assembly of actin filaments and leads to the formation of focal adhesion and activation of intracellular signaling (49). The  $\alpha v$  integrin combinations have been most extensively investigated in terms of their roles in angiogenesis (50). ECs stimulated with angiogenic growth factors or those in newly formed vessels express high levels of  $\alpha v \beta 3$  integrin, and antagonists against  $\alpha v \beta 3$  or  $\alpha v \beta 5$  integrin block the growth factor–induced angiogenesis. It also has been shown that  $\alpha v \beta 3$  integrin associates with VEGF and platelet-derived growth factor (PDGF) receptors and potentiates VEGF or PDGF signaling, respectively (50). Because several integrin signaling molecules, including focal adhesion kinase (FAK), ILK, and Shc, have been implicated in Akt activation (48), downregulation of Akt activity induced by cell detachment is likely caused by the decrease in integrin-dependent Akt activation. Caspase-mediated cleavage of Akt also is implicated in the downregulation of Akt protein levels during long-term suspension culture (51). Collectively, these findings suggest that integrin signaling induced by cell attachment (outside-in signal) is an important regulator of growth factor–dependent EC survival and angiogenesis through PI3K/Akt pathways. Furthermore, VEGF induction of inside-out signals has also been shown to activate integrins (52), suggesting that integrin and growth factor signaling are cooperative and synergistic with regard to activation of Akt signaling.

Currently, relatively little is known about the downstream mediators of the Akt-dependent survival pathway in ECs, although several candidate signaling molecules have been identified including survivin (53), death domain (FADD)–like interleukin (IL)-1-converting enzyme–inhibitory protein (FLIP) (54), mitogen-activated protein kinase (MAPK) kinase kinase 3 (MEKK3) (55), FOXO3a (56), GSK-3, and  $\beta$ -catenin (57,58). Thus, possible combinations of these and other unidentified Akt target molecules may control EC survival, depending on the context of pro- and antiapoptotic stimuli encountered in the cellular environment.

### REGULATION OF ENDOTHELIAL NITRIC OXIDE SYNTHASE ACTIVITY BY AKT

In addition to its antiapoptotic effects, VEGF induces nitric oxide (NO) release from ECs. It was shown that this effect of VEGF is mediated by Akt-dependent endothelial NO synthase (eNOS) phosphorylation at Ser 1179 (in bovine eNOS, equivalent to Ser 1177 in human eNOS), which results in an increase in eNOS activity (59). It also was reported that production of NO in response to fluid shear stress in cultured ECs is controlled by Akt-dependent phosphorylation of eNOS (60), although another study has shown that shear stress induces eNOS phosphorylation at Ser 1179 predominantly through a protein kinase A (PKA)–dependent, Akt-independent mechanism (46). Subsequently, it was found that Ser 617 (in bovine eNOS) phosphorylation by Akt in part mediates shear stress–induced activation of eNOS (61). Studies in intact animals have shown that overexpression of constitutively active Akt in the vascular endothelium results in an increase in resting diameter and blood flow that is blocked by an eNOS inhibitor N-nitro-L-arginine methyl ester (L-NAME), and transduction of dominant negative Akt attenuates endothelium-dependent vasodilation induced by acetylcholine (62). These findings demonstrate that Akt functions as a regulator of vasomotor tone in vivo. Furthermore, a possible link between Akt and endothelial dysfunction in hypertension was suggested by a recent study showing that agonist-induced eNOS activation is reduced in spontaneously hypertensive rats (SHR), and this defect is normalized by *Akt* gene transfer into the endothelium (63).

The activity of eNOS also is regulated by subcellular localization and/or protein–protein interactions. Of note, it has been shown that eNOS is localized in a specific domain of the plasma membrane, the caveolae, and interacts with caveolin-1 through the caveolin-1 scaffolding domain, and that the interaction between eNOS and caveolin-1 results in the inhibition of eNOS activity (64,65). Although originally implicated in transmembrane trafficking of macromolecules, the findings that caveolae contain a variety of signaling molecules

Figure 80.2. Schematic illustration of the Akt–eNOS interaction at caveolae. Caveolin-1 is localized to caveolae and associates with a number of regulatory molecules including eNOS. Association of eNOS with caveolin-1 negatively regulates eNOS activity, although targeting of eNOS to caveolae is required for proper eNOS function. Activated Akt and eNOS also associate with Hsp90. Hsp90 is believed to function as a scaffold protein for activation of eNOS by Akt-mediated phosphorylation.

and that caveolin-1 interacts directly with those caveolae-associated proteins has suggested that caveolae and caveolin-1 are involved in the compartmentalization and integration of signal transduction pathways at the cell membrane. Consistent with the inhibitory effect of caveolin-1 on eNOS activity, administration of the caveolin-1 scaffolding domain fused to cellular internalization sequences *in vivo* attenuates eNOS activity (65). Acetylcholine-induced vasorelaxation and NO production are enhanced in caveolin-1-deficient mice (66), and endothelial-specific overexpression of caveolin-1 impairs eNOS activation (67). The targeting of eNOS to caveolae, however, seems to be required for efficient and proper activation of eNOS upon stimulation, because conditions that inhibit the localization of eNOS in caveolae also attenuate eNOS activity (68). It also has been shown that eNOS interacts with heat shock protein 90 (Hsp90) upon stimulation with VEGF or shear stress, and this interaction enhances eNOS activity (59). Interestingly, Akt also interacts with Hsp90 upon stimulation, and this interaction enhances Akt enzymatic activity (69), suggesting that Hsp90 may serve as a scaffold protein for the efficient phosphorylation of eNOS by Akt at caveolae (Figure 80.2).

### REGULATION OF ENDOTHELIAL CELL MIGRATION BY AKT

The ability of ECs to migrate and form capillary-like structures is essential for angiogenesis *in vivo*. VEGF enhances EC migra-

tion and capillary-like structure formation *in vitro*, and these activities of VEGF are PI3K/Akt-dependent (44). S1P also has been shown to enhance EC migration and capillary formation *in vitro* through the activation of the endothelial differentiation gene (EDG) family of G-protein-coupled receptors and PI3K/Akt-dependent pathways (70,71). Conversely, oxidized low-density lipoprotein (LDL) inhibits EC migration toward VEGF by promoting the dephosphorylation of Akt (72).

Studies in other cell types also have implicated PI3K and Akt in the control of directional cell migration and the sensing of chemoattractant gradients by the cell. For example, it has been shown that Akt transiently localizes to the leading edge membrane of migratory cells in a PI3K-dependent manner (73,74), and gene ablation studies in mice have demonstrated that PI3K $\gamma$  is required for chemotaxis and chemoattractant-dependent activation of Akt in macrophages and neutrophils (75). Akt has been shown to be required for chemotaxis in *Dictyostelium* cells as well (73,74).

Cellular movement requires the reorganization of the actin cytoskeleton, and distinct patterns of actin reorganization are required as cells establish a leading edge and then generate contractile force to migrate forward (76). Previous studies have implicated the Rho family of small G-proteins as one of the major regulators of actin reorganization. Among Rho family members, Rho, Rac, and Cdc42 are most widely studied, and each regulates specific aspects of cytoskeletal reorganization. Rho stimulates cytoplasmic stress fiber formation and actomyosin-based contractility, Rac induces membrane ruffling and extension of lamellipodia, and Cdc42 induces the extension of membrane protrusions (filopodia) and is also involved in chemoattractant gradient sensing (77,78). Although it has been shown that VEGF-induced EC migration is dependent on Rho family GTPases, the relationship between Akt and the Rho family of G-proteins is complicated and controversial (43). On one hand, Akt negatively regulates Rac1 activity by phosphorylating Rac1 and inhibiting its GTP-binding activity. On the other hand, Akt phosphorylates S1P receptor EDG-1 and induces Rac activation and cell migration in ECs. Other reports show that Rac and Cdc42 are situated upstream of Akt and that they promote Akt signaling. It is possible that the upstream–downstream relationship between Akt and Rho/Rac/Cdc42 differs depending on cell type and external stimuli.

Another possible downstream effector of Akt that regulates cell motility is p21-activated protein kinase (PAK). PAK was originally identified as a Rac1-binding protein that specifically interacts with the GTP-bound form of Rac (79). Subsequently, it was shown that PAK is activated by Rac or Cdc42 and that it regulates polarized cytoskeletal reorganization (79). It was shown in *Dictyostelium* cells that Akt regulates cell polarity and chemotaxis through the regulatory phosphorylation of PAK (80), suggesting a direct functional link between Akt and PAK in the regulation of cytoskeletal reorganization. In mammalian fibroblasts, it also was shown that Akt stimulates PAK1 activation, and that dominant-negative Akt inhibits Ras-induced activation of PAK1 (81). However, the Akt phosphorylation

site in *Dictyostelium* PAK is not conserved in mammalian PAK1, suggesting an indirect activation of mammalian PAK1 by Akt. Nonetheless, the PAK family of protein kinases are attractive candidates for Akt effectors in the regulation of EC migration, and may be a convergence point of signals from Rac/Cdc42 and Akt.

## STATINS AND AKT SIGNALING

The 3-hydroxyl-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, are widely prescribed for the treatment of hypercholesterolemia, and several clinical trials have demonstrated that statins are effective for both primary and secondary prevention of coronary artery diseases (82). It also has been shown that the cardioprotective effects of statins are partly independent of their serum lipid-lowering effects (82,83). Subsequently, it was found that statins rapidly promote the activation of Akt in ECs, leading to eNOS phosphorylation (at Ser 635 and Ser 1179) and increased NO production (84,85). Statins also protect ECs from serum deprivation-induced apoptosis and promote capillary-like structure formation on Matrigel in an Akt-dependent manner, and statin treatment enhances angiogenesis in hindlimb ischemia of normocholesterolemic animals through an eNOS-dependent mechanism (84,86). In addition to its effect on mature ECs, it was shown that statins enhance the mobilization of EPCs from bone marrow in a PI3K/Akt-dependent manner both in mice and humans (87–89), suggesting another mechanism of Akt-dependent proangiogenic effects in statins. Although numerous lines of evidence suggest that statins promote EC function and angiogenesis, currently no evidence in clinical studies links statin treatment to an increase in cancer risk (90).

Activation of Akt by statins is blocked by treatment with inhibitors of PI3K (wortmannin or LY294002) (84), and statin treatment rapidly induces translocation of Akt to the plasma membrane in a PI3K-dependent manner (91). However, the mechanisms by which statins activate PI3K are unknown at present. In this regard, statins have been shown to decrease caveolin-1–eNOS interaction and enhance the formation of eNOS-Hsp90-Akt complex in ECs (92), although it is not clear whether these effects of statins are secondary to Akt activation. Another recent report has shown that statins have biphasic effects on angiogenesis and that low doses of statins (relevant to the serum concentrations observed in patients treated with statins) enhance, whereas high doses inhibit, angiogenesis (93). This may explain the antiangiogenic effects of statins observed in studies using higher concentrations of statin treatment (94).

In addition to their proangiogenic effects, statins also have been shown to exhibit antithrombotic actions in humans, which appear to be independent of their serum cholesterol-lowering effects (95). Recent studies have shown that the PI3K/Akt pathway inhibits the expression of tissue factor (96,97), which is the primary cellular initiator of blood

coagulation and whose expression is induced in ECs and macrophages by a number of stimuli, including IL-1 $\beta$  and tumor necrosis factor (TNF)- $\alpha$  (98). Although VEGF activates both tissue factor expression and PI3K/Akt signaling, administration of inhibitors of PI3K/Akt signaling further enhances VEGF-induced tissue factor expression (96,97). Taken together, these data suggest that statins may inhibit blood coagulation, at least in part, through a selective activation of PI3K/Akt signaling in ECs, leading to an inhibition of tissue factor expression.

## CONCLUSION

The PI3K/Akt signaling axis is activated by a variety of stimuli in ECs, and it regulates multiple critical steps in angiogenesis, including EC survival, migration, and capillary-like structure formation. Furthermore, this signaling pathway also regulates cardiovascular homeostasis and vessel integrity at least, in part, by controlling NO synthesis. Angiogenesis has been implicated in the pathophysiology of a number of diseases, and regulation of angiogenesis, both its increase and decrease, could be an important therapeutic strategy for those disease states. Thus, further dissection of the PI3K/Akt pathway and elucidation of downstream effector molecules will lead to a better understanding of blood vessel growth and may provide avenues for the development of novel therapeutic interventions.

### KEY POINTS

- Akt signaling in ECs regulates angiogenesis and vascular remodeling.
- Akt mediates EC survival and migration.
- Akt mediates eNOS activity and vascular tone.
- Statins activate Akt in ECs and promotes angiogenesis.

### Future Goals

- To determine the role of Akt signaling in physiological and pathological angiogenesis
- To determine the downstream Akt substrates in ECs that promotes survival, migration, and angiogenesis
- To develop small-molecule Akt activators or inhibitors for therapeutic angiogenesis or antiangiogenesis therapies

## Mitogen-Activated Protein Kinases

Natalia V. Bogatcheva and Alexander D. Verin

*University of Chicago, Illinois*

The family of mitogen-activated protein kinases (MAPKs) comprises several protein kinases, united by their ability to phosphorylate serine or threonine residues followed by proline; therefore, these often are termed *proline-directed protein kinases*. Another characteristic feature of the MAPKs is the presence of specific phosphoacceptor site(s) in the regulatory loop of the enzyme catalytic core.

### HISTORY AND EVOLUTION

MAPKs were originally named after the protein they were discovered to phosphorylate in insulin- or growth factor-treated mammalian cells, namely microtubule-associated protein 2 (MAP-2). Later, with the realization that virtually all mitogens lead to the rapid activation of these protein kinases, the enzymes were renamed *mitogen-activated protein kinases*. Now, it is clear that MAPK function is not limited to the initially described induction of cell division, but also extends to control over cell differentiation, survival, motility, and gene expression. Because MAPKs orchestrate the physiological processes fundamental for both single- and multicellular organisms, it is not surprising that homologous enzymes are found in eukaryotes from budding yeast to mammals (1). The deletion of certain MAPK genes in mammals leads to early embryonic lethality, proving the essential role of MAPK signaling in the developmental processes (Table 81-1).

### MITOGEN-ACTIVATED PROTEIN KINASE STRUCTURE AND FUNCTION

To date, five different groups of MAPKs are known in mammals. Enzymes within groups are generated from a number of gene products; additional isoforms were shown to derive from the alternative splicing of pre-mRNAs (12). Mammalian MAPKs include extracellular-signal-regulated protein kinase (ERK)1/2; p38 MAPKs ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ); c-jun N-terminal kinases (JNK1, JNK2, JNK3); ERK5, also known as BMK1 (13); and the recently identified ERK3 subfamily, comprising the

products of two genes, *MAPK4* and *MAPK6* (14). All kinases of the MAPK family display approximately a 40% to 50% amino acid sequence identity within their catalytic domains (13–15). ERK5 and ERK3 carry certain structural differences from the conventional MAPKs ERK1/2, p38, and JNK (13,14).

The three-dimensional (3D) structure of the earliest described MAPK representative, ERK2, reveals that this enzyme consists of two domains, connected by a linker region. Interface between the two domains forms an ATP-binding site, buried deep inside the enzyme; the protein substrate-binding site, on the contrary, is located on the surface. Because the two domains of ERK2 are rotated apart in the inactive state, activation requires the closure of the 3D structure to form an active substrate-binding site (Figure 81.1). Thus, unlike kinases activated by the displacement of the autoinhibitory domain (e.g., protein kinase C [PKC], protein kinase A [PKA], myosin light-chain kinase [MLCK]), MAPKs acquire activity after conformational changes within the region positioned within the catalytic core of the enzyme (16). These conformational changes are induced by the phosphorylation of the specific regulatory motif that is conserved between different members of the MAPK family. ERK1/2, p38 MAPK, JNK, and ERK5/BMK1 possess the double phosphoacceptor site TXY in the activation loop, whereas ERK3 is regulated by the phosphorylation of a single site in the SEG motif (14). Another unique feature of ERK3 is its regulation by protein turnover (17), in contrast to the other relatively stable members of the MAPK family.

Early study of the ERK1/2 activation mechanism revealed that these enzymes require both tyrosine and threonine phosphorylation of the phosphoacceptor site to display activity. Initially, the integration of two signaling pathways controlling dual MAPK phosphorylation was considered. However, MAPK “activating factor” isolated from cells behaved rather as a single component, capable of phosphorylating both tyrosine and threonine residues in the structure of MAPKs. To be active, this factor itself required serine/threonine phosphorylation. Thus, activation of MAPK “activating factor” (named MAPK kinase [MAPKK]) by receptor tyrosine kinases implied the presence of at least one more upstream protein kinase,

**Table 81-1: MAPK-Knockout Phenotypes**

<i>Genes</i>	<i>Phenotypes (Refs.)</i>
<i>ERK1</i>	Decreased T-cell responses Skin lesions and hyperkeratosis, inhibition of keratinocytes apoptosis and proliferation (3) Enhanced cocaine-evoked behavioral plasticity (4)
<i>ERK2</i>	Lack of mesoderm differentiation, defects in placenta, embryonic death
<i>p38<math>\alpha</math></i>	Defects in placental angiogenesis, embryonic death Survivors exhibit defects in erythropoiesis Increased adipogenesis (5) Cardiac-specific knockouts exhibit dedifferentiation and proliferation of neonatal cardiomyocytes (6)
<i>p38<math>\beta</math></i>	No obvious phenotype (7)
<i>p38<math>\gamma</math></i>	No obvious phenotype
<i>JNK1</i>	Defects in T-cell differentiation, proliferation, and apoptosis Low susceptibility to insulin resistance in diabetes models Marked deterioration in cardiac function following transverse aortic constriction (8) Reduced development of steatohepatitis in mice fed with methionine- and choline-deficient diet (9) Reduced inhibition of neovascularization by thrombospondin (10)
<i>JNK2</i>	Defects in T-cell differentiation, proliferation, and apoptosis
<i>JNK1+JNK2</i>	Defects in neural tube closure, embryonic death Increased proliferation and IL-2 production in T cells Resistance to UV-induced apoptosis in embryonic fibroblasts
<i>JNK3</i>	Resistance to kainate-induced neural damage
<i>ERK5</i>	Defects in angiogenesis and cardiovascular development, embryonic death
<i>ERK3</i>	Mice phenotype not yet described Reduced activity of MAPKAP5 (MK5) in $-/-$ embryo fibroblasts (11)

As reviewed in Kuida K, Boucher DM. Function of MAP kinases: insights from gene-targeting studies. *J Biochem.* 2004;135:653–656, with recent data addition.

specific for serine/threonine residues. The proto-oncogene, Raf-1, has been proposed to function as MAPK kinase (MAPKKK). All three enzymes were combined in the so-called *MAPK cascade*, which also was characterized in yeast and frogs, and later discovered in fruit flies, nematodes, slime mold, and plants (1). Thus, functionally, the MAPK cascade appears to be evolutionarily conserved, although the identity of cascade members in the sequence may vary significantly.

Generally, each group of MAPKs possesses specific MAPKK, which, in turn, are activated by their MAPKKK, although some MAPKKKs do not show strict selectivity. Coupling within the cascade is ensured by special docking motifs, present in the cascade enzymes as well as in their substrates. In addition, the recognition and in some cases nonenzymatic activation of cascade members may be provided by certain scaffolding proteins (18).

Upstream of the three-tiered cascade lies a plethora of signals, converging to the activation of MAPKKK. The mechanism of regulation of the most studied MAPKKK, Raf, is known to require binding of the small G-protein Ras (19). “Classical” MAPKKK activation via receptor tyrosine kinases (RTK) is achieved via a sequence of events, including membrane recruitment of the Ras guanine nucleotide exchange factor Sos, with participation of the adapter protein Grb2 (Figure 81.2). Activation of MAPKKK via G-protein-coupled receptors (GPCRs) involves Pyk2/Src-, phosphoinositide 3-kinase (PI3K)-, and PKC-dependent mechanisms (see Figure 81.2), but also may occur via the  $\beta$ -arrestin-dependent pathway. Among other external stimuli leading to MAPK cascade activation are reactive oxygen species (ROS), phorbol esters, proinflammatory cytokines, and shear stress (Figure 81.2). It is generally believed that growth factors and phorbol esters mostly promote ERK1/2 activation, whereas cytokines and stress stimuli induce the activation of p38 MAPK and JNK. However, it would be more correct to say that many of the factors mentioned activate all three types of conventional MAPKs, although the relevance of such activation to the cell physiological response may vary.

Less is known about stimuli regulating unconventional MAPKs. ERK5 was shown to be activated by both mitogens and stress stimuli (13), whereas increased ERK3 activity was noted in response to certain growth factors (11). Inactivation of conventional MAP kinases and ERK5 is achieved mostly with the help of dual specificity phosphatases (DSP), which, in turn, are upregulated by many mitogens and stress treatments. Certain members of the DSP family display specificity to different MAPKs, thereby providing an additional level of control over cascade regulation (20).

The physiological effects of MAPK activation are elicited via the phosphorylation of numerous protein substrates (Figure 81.3). Substrates may be phosphorylated either in the cytoplasm or the nucleus, where MAPKs translocate upon activation. The exception is ERK5, which is constantly localized within the nucleus (21). Which targets are preferentially phosphorylated depends on the intensity and duration of activation and the localization of activated MAPK, determined in turn by the nature of the extracellular signal. MAPKs directly phosphorylate cytoskeletal proteins, signaling enzymes (phospholipases and MAPK-activated protein kinases), proteins involved in control of apoptosis, and transcriptional regulators. Downstream MAPK-activated kinases compose a family of kinases with various degree of structural relativity. They include RSK (MAKAPK1A-D); MSK1 and -2; MNK1 and -2; and MAPKAP2, -3, and -5 (22). Those kinases,

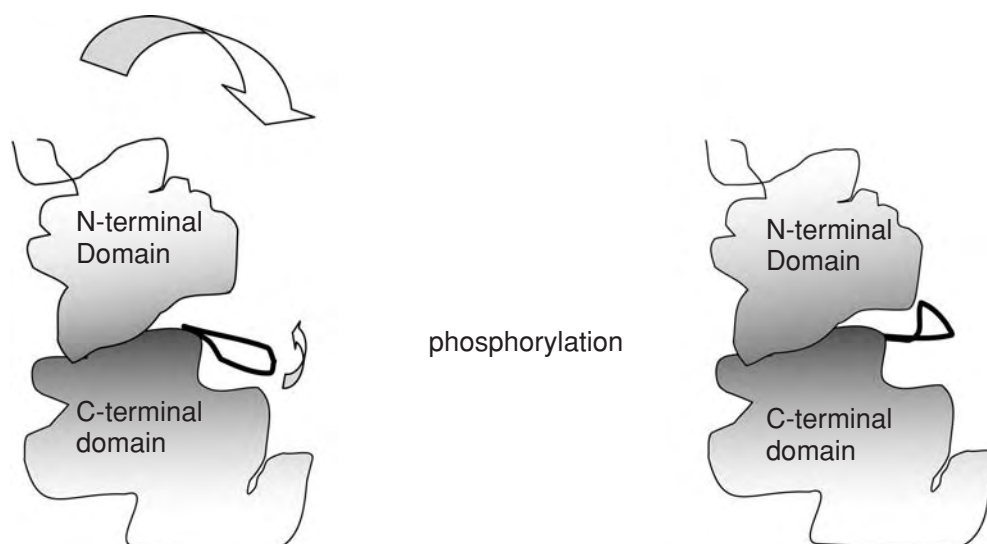

Figure 81.1. Schematic of conformational changes in ERK2 after phosphorylation. The enzyme consists of smaller N-terminal (residues 1–109 and 320–358) and larger C-terminal (residues 110–319) domains. The phosphorylated region, located within the C-terminal domain of ERK2, changes its position to promote domain closure and formation of proline-directed substrate-binding site. (Reproduced with permission from Cangarajah BJ, Khokhlatchev A, Cobb MH, Goldsmith EJ. Activation mechanism of the MAP kinase ERK2 by dual phosphorylation. *Cell*. 1997;90:859–869.)

activated by certain members of the MAPK family, phosphorylate proteins associated with cytoskeleton, ribosomal proteins, signaling or metabolic enzymes such as Akt, glycogen synthase 3 $\beta$ , 5-lipoxygenase, the Na/H exchanger NHE-1, and transcriptional regulators (19). The diversity of MAPKs and downstream kinases substrates allows the MAPK pathway to modulate various functions, such as cell contractility, cell metabolism, and cell fate. It is conceivable that MAPK-induced alteration of cytoskeleton and homeostatic/signaling enzymatic activity by phosphorylation may provide immediate cell response, whereas changes in gene expression would be relatively belated.

Alteration of cell contractility, often seen within minutes of agonist treatment, is achieved via phosphorylation of several actin-binding proteins (see Figure 81.2). Among direct MAPK and MAPK-activated protein kinase substrates are the regulatory actin-binding protein caldesmon, actin-stabilizing chaperone Hsp27, membrane-associated actin-binding proteins filamin and cortactin, and proteins mediating cell adhesion. Control over these protein functions allows MAPK to adjust actomyosin contractility and F-actin stability, remodel membrane structures, and regulate cell contact formation. Among noncytoskeletal MAPK targets not directly involved in the regulation of gene expression are enzymes like phospholipases and nitric oxide synthases (NOS), which allow MAPK to modulate the release of bioactive substances and thereby to coordinate the response of whole tissues or organs (19,23).

Targets of MAPK pathways affecting gene expression include numerous transcription factors and transcriptional regulators. To manipulate the cell transcription machinery, MAPK utilize several pathways. Phosphorylation by MAPK or MAPK-activated protein kinases can stimulate the translocat-

tion of transcriptional regulators to the nucleus or, conversely, from the nucleus, rendering factor activation or inactivation, respectively. Similarly, phosphorylation might alter the ability of some transcription factors to bind DNA. In addition, MAPK pathways control the level of expression of certain transcription factors, modulating their synthesis and stability. Last transcriptional regulation is achieved through the control of nucleosomal structure (12).

Transcriptional regulation often is linked to the alteration of synthesis of several bioactive substances by the cell, but it also determines cell fate, targeting the cell toward proliferation, differentiation, or apoptosis. Cell proliferation is thought to be regulated by MAPK pathways via activation of Elk-1, c-Myc, c-Fos, Ets-1, serum response factor (SRF), and other transcription factors. Cell survival signals may be conveyed by MAPK via cross-talk with the PI3K/Akt and nuclear factor (NF)- $\kappa$ B pathway, and the regulation of nitric oxide (NO) release. Apoptosis is likely controlled by the phosphorylation and downregulation of antiapoptotic proteins such as Bcl-2 and upregulation of caspase activity (19,23,24). In summary, the consequences of MAPK activation on a cellular level depend on the balance between different MAPK activities and the activities of other signaling pathways, which, in turn, will vary from cell to cell and from stimulus to stimulus.

#### MITOGEN-ACTIVATED PROTEIN KINASE CASCADE IN THE ENDOTHELIUM

The importance of MAPK for vascular functions was demonstrated in experiments using knockout animals in which *ERK2*-, *p38 $\alpha$* -, and *ERK5*-null animals displayed impaired

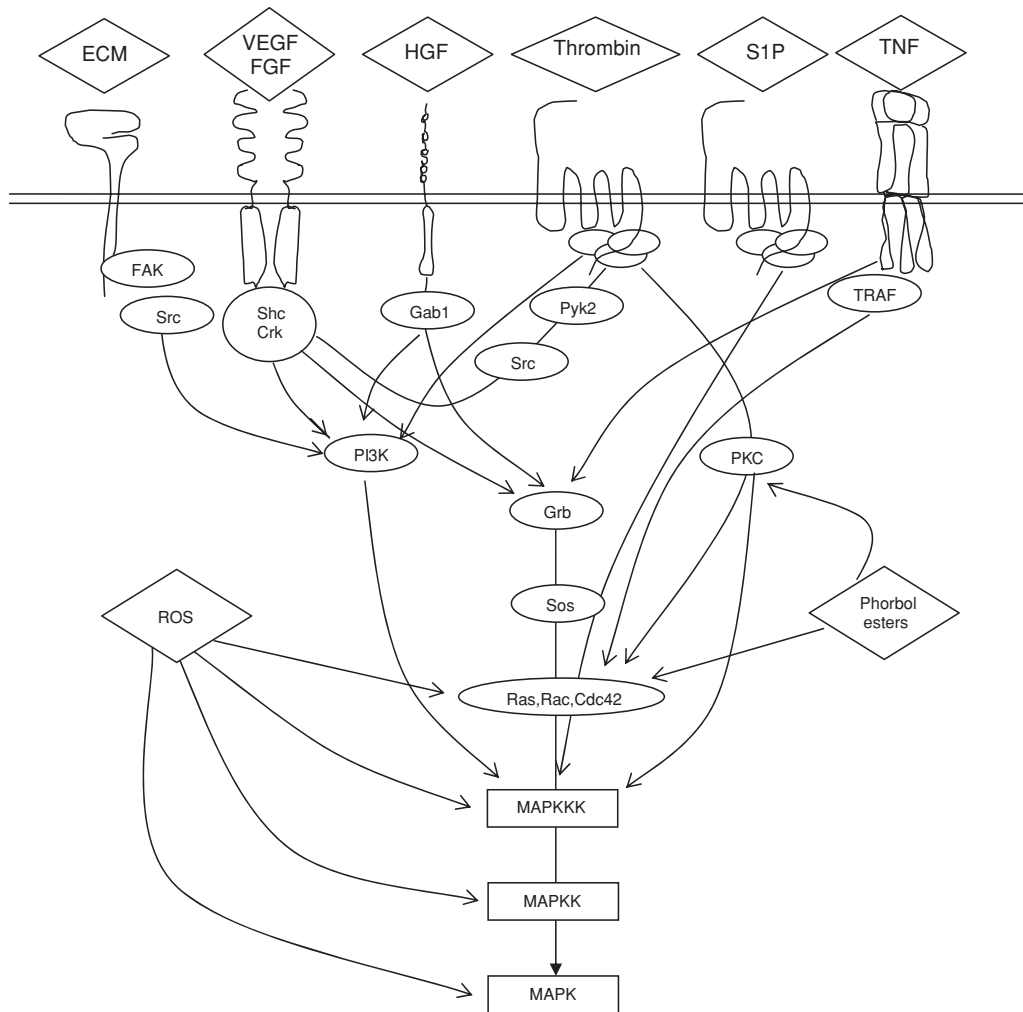

Figure 81.2. Main signaling pathways, leading to the activation of MAPK cascade in ECs cells. Numerous signals, originating from membrane receptors, utilize several mechanisms to achieve MAPK activation. One of the mechanisms involves the activation of various adapter proteins, such as Shc, Crk, Gab1, and Grb2. Other mechanisms depend on the activation of PKC or PI3K. All of them converge at the activation of small G-proteins (Ras, Rac, and Cdc42) or downstream MAPKK. Membrane-penetrating substances, such as reactive oxygen species (ROS) or phorbol esters, act through the PKC or small G-protein activation, but also suppress tyrosine dephosphorylation and deactivation of the MAPK module members. ECM, extracellular matrix proteins; FAK, focal adhesion kinase; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; TNF, tumor necrosis factor; TRAF, TNF receptor associated factor; VEGF, vascular endothelial growth factor.

placental or embryonic angiogenesis (see Table 81-1). Although deficits of ERK1, JNK1, JNK2, JNK3, p38 $\beta$ , or p38 $\gamma$  were not shown to lead to abrupt vascular aberration (2), these data do not preclude the participation of the aforementioned MAPKs in prenatal angiogenesis, because a certain functional redundancy exists between isoforms, and double or triple knockouts may be necessary to exhibit the mutant phenotype.

### Migration

On the cellular level, the process of vascularization is driven by endothelial cell (EC) migration and differentiation, which allows capillary tube formation and is, by the timely shift

between proliferative and antiproliferative signals, necessary for the formation of a functional vasculature. EC migration, induced by growth factors or sphingosine-1 phosphate (S1P), critically depends on ERK1/2, p38 MAPK, and/or JNK activation (23,25). Because motile activity requires the cell to contract and establish contacts with the surrounding environment (24), it is hardly surprising that migrating cells display increased stress fiber formation and vinculin-mediated membrane anchoring, evidence of integrin-mediated contacts with extracellular matrices (26). The potential targets of MAPK, leading to actin network remodeling, are likely to be caldesmon and Hsp27 (Figure 81.3). Caldesmon is a known substrate for ERK1/2 and p38 MAPK, whereas Hsp27 is

Figure 81.3. MAPK involvement in proinflammatory and proangiogenic endothelial responses. In endothelium, MAPK activation often is followed by the loss of EC monolayer integrity, increased leukocyte adhesion, and transmigration and release of bioactive mediators. These responses are a result of numerous phosphorylation events, leading to the alteration of cytoskeletal arrangement, enzymatic activity, or the expression level of several important gene products. Direct protein phosphorylation by MAPK or MAPKAP is depicted here as grey circles. Synthesis regulation by MAPK cascade is shown with arrows. PAF, platelet-activating factor; AA, arachidonic acid; IL, interleukin; MMP, matrix metalloproteinase; HSP, heat shock protein; ECM, extracellular matrix.

phosphorylated via a p38 MAPK/MAPKAP-2–dependent mechanism (23). Both caldesmon and Hsp27 affect the stability of actin filaments under certain conditions. Moreover, caldesmon inhibits actomyosin interaction in quiescent cells and requires phosphorylation or interaction with  $\text{Ca}^{2+}$ -dependent protein to allow contraction. Indeed, involvement of caldesmon in EC migration was recently proved (27), although the question of whether MAPK-induced alteration of caldesmon properties is critical for the migration remains open. Similarly, the role of Hsp27 phosphorylation seems somewhat controversial, because both proangiogenic and antiangiogenic factors were shown to induce Hsp27 phosphorylation (28).

Migrating cell attachment to the substrate is likely to be regulated via a protein synthesis–dependent mechanism. Expression of one of the membrane anchors, integrin  $\beta 3$ , was shown to be controlled by the transcription factor Ets-1 in ECs (26,29). The level of *Ets* mRNA is known to be upregulated by activated ERK1/2 (26). Among Ets-1–controlled proteins are also matrix metalloproteinases (MMP), extracellular matrix (ECM)-degrading enzymes that are necessary for cell migration (29) (see Figure 81.3). The induction of matrix degradation activity depends on the activation of the urokinase-type plasminogen activator (u-PA) pathway. Both ERK1/2 and p38 MAPK were shown to regulate u-PA expression in ECs (30,31), implicating those kinases in control over ECM stability. The targets of the JNK pathway, which mediates migration, have been less thoroughly characterized to date. So far, JNK has been shown to regulate the level of MMP2 and MMP14 expression (32). In summary, ERK1/2, p38 MAPK, and JNK

actively control EC migration, altering both the cellular organization of contractile and membrane proteins and the ECM degradation rate.

### Tubular Morphogenesis, Endothelial Cell Proliferation and Survival

The formation of tubular structures is an intrinsic feature of ECs that allows them to create new capillaries. Grown in 3D matrices, ECs elongate and coalesce; the latter process is followed by the appearance of lumens within tubules. The signaling mechanisms controlling tubular morphogenesis *in vitro* have been studied only sporadically. Endothelial tube formation was found to depend on ERK1/2 or JNK activation (23,26). The role of p38 MAPK in tubular morphogenesis appears more contradictory. Although the inhibition of p38 MAPK in spleen ECs repressed tube formation (26), in other ECs, the ablation of p38 MAPK activity has an opposite effect. The latter event was noted to be associated with the increased expression of Jagged1, a ligand activating the Notch pathway (33). This pathway was earlier implicated in the regulation of EC differentiation and vascular remodeling.

MAPKs are known to regulate the proliferation and survival of many cell types. The general paradigm holds that activated ERK1/2 upregulate cell growth, whereas p38 MAPK and JNK inhibit proliferation and/or induce apoptosis. However, experiments using cultured ECs do not necessarily support that paradigm. The induction of cell growth in ECs treated with vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), hepatocyte growth factor

(HGF), or S1P is indeed dependent on ERK1/2 (23,24,26). However, shear stress-exposed ECs, despite elevated ERK1/2 activity, display an inhibition of proliferation (23). Similarly, although p38 MAPK and JNK mediate EC antiproliferative or proapoptotic responses to high glucose and tumor necrosis factor (TNF)- $\alpha$ , in other studies the inhibition of p38 MAPK or JNK led to the downregulation of EC proliferation rates (23,26). Of note, p38 MAPK and JNK were shown to initiate both pro- and antiapoptotic signaling cascades, depending on cell and signal context. For instance, p38 MAPK induces cell death via downregulation of Bcl and activation of caspases (34), whereas the antiapoptotic mechanism of p38 MAPK action is linked to the NF $\kappa$ B pathway (35) or involves Hsp27 phosphorylation (36).

So far, little is known about the role of ERK5/BMK1 in endothelial functions. Experiments using ectopic expression of constitutively active MAPKK for ERK5 have demonstrated that ERK5 activation protects ECs from apoptosis in a growth factor-deprivation model (37). Targeted deletion of ERK5 in mice leads to the abnormal vascular leakage observed in several organs, mainly due to EC morphological alteration, and their eventual death (13). Future experiments are needed to assess the role of this member of the MAPK family in other endothelial responses.

### Angiogenesis

As discussed earlier, *in vitro* experiments suggest that all processes critical for angiogenesis are tightly regulated by MAPK. Consistent with these results, ERK1/2 inhibition was shown to suppress retinal neovascularization in the rat retinopathy model (38), VEGF-induced angiogenesis in fetal rat cortical explants (39), and thrombin-induced angiogenesis in the chick chorioallantoic membrane (CAM) assay (40). The *in vivo* data regarding p38 MAPK inhibition, however, are conflicting and indicate, along with the *in vitro* data, that primary mechanisms, regulated by p38 MAPK in different models of angiogenesis, may vary. For example, p38 MAPK inhibition decreased vascularization in an air pouch granuloma model (41); this effect was attributed to the suppressed synthesis of proangiogenic inflammatory cytokines. By contrast, in another study, p38 MAPK inhibition abrogated the effect of antiangiogenic factor thrombospondin on mouse cornea vessel formation, suggesting a negative role of p38 MAPK in the regulation of angiogenesis. Indeed, thrombospondin was shown to induce EC apoptosis in a p38 MAPK-dependent manner (42). Along with those data, VEGF- or bFGF-induced CAM neoangiogenesis was significantly potentiated by p38 MAPK inhibitors (33,43). The most intriguing finding was that vessels formed in the presence of p38 MAPK inhibitor were characterized by EC hyperplasia and abnormal vascular structure (33). Thus, p38 MAPK activation serves to balance the processes of EC proliferation, differentiation, and apoptosis necessary for the formation of functional vessels. Data on the involvement of JNK in the process of vascularization are only now beginning to emerge. Experiments with

*JNK-1*-null animals show that, along with p38 MAPK, JNK-1 plays an important role in the abrogation of angiogenesis by thrombospondin-1 (10). Future research is needed to clarify the role of other JNK enzymes in vascularization.

### Endothelial Barrier

Once a functional vessel is created, it starts to act as a selective barrier to control the access of cells and fluids to the underlying tissues. The regulation of endothelial barrier properties is critical for the proper inflammatory response, because increased transendothelial permeability is required to allow mobile luminal cell migration toward the source of the tissue disturbance. Various edemagenic substances, such as H<sub>2</sub>O<sub>2</sub>, phorbol ester, thrombin, VEGF, and TNF- $\alpha$  were noted to evoke barrier dysfunction in cultured ECs in a MAPK-dependent manner (23). Because two events are of major importance for the disruption of the EC barrier – namely a decrease in cell-cell attachment and an increase in actomyosin contractility (23) – proteins associated with cellular junctions or contractile filaments are likely to be the targets of MAPK phosphorylation in activated ECs (see Figure 81.3). Indeed, endothelial junctions lose VE-cadherin, occludin, and ZO-1 as a result of ERK1/2, p38 MAPK, or JNK activation (23). These proteins do not seem to be phosphorylated by MAPKs directly, but rather by intermediate protein kinases whose identity remains unknown. One of the mechanisms, however, may involve MMP-dependent degradation of tight junctional proteins (Figure 81.3), because ERK1/2 inhibitors were shown to suppress ZO-1 proteolysis concomitant with barrier protection (44). On the other hand, MAPK and MAPKAP are thought to induce contractile response via direct phosphorylation of the actin-binding proteins Hsp27 and caldesmon (Figure 81.3). Both proteins display an increased level of phosphate incorporation coincidental with the loss of EC monolayer integrity (23). However, the functional importance of these events for endothelial barrier dysfunction remains to be confirmed. Another possible mechanism of MAPK-dependent barrier compromise involves destabilization of microtubules. The inhibition of p38 MAPK was shown to attenuate a TNF- $\alpha$ -induced decrease in stable tubulin content and to ameliorate endothelial barrier dysfunction (45). Last, some edemagenic agents may employ MAPK-dependent regulation of protein synthesis to increase paracellular permeability. As has been shown recently, the increase in myosin light-chain (MLC) phosphorylation in TGF- $\beta$ -treated ECs occurs in a cycloheximide-dependent manner (46). p38 MAPK seems to be the kinase responsible for this event, because both TGF- $\beta$ -induced EC barrier dysfunction and MLC phosphorylation are blocked by inhibition of p38 MAPK. The protein synthesis-dependent mechanism appears to be unique for TGF- $\beta$  producing delayed contractile response; it is not shared by agents that induce immediate contraction, such as thrombin (46).

Interestingly, augmentation of monolayer integrity in cultured ECs may also be MAPK-dependent (23). For example, the restoration of barrier function after ischemia-reperfusion

requires ERK1/2 activity. One might expect that an increase in transendothelial resistance must be associated either with the tightening of cell–cell junctions or thickening of cortical actin rings. Indeed, the tight junction protein claudin-1 was shown to require ERK1/2–dependent phosphorylation to enhance EC barrier function (47). Barrier augmentation in HGF-treated cells was attributed to regulation of the level of the peripheral actin-binding protein,  $\beta$ -catenin.  $\beta$ -Catenin degradation depends on its phosphorylation by GSK3- $\beta$ , which activity, in turn, is regulated by MAPK pathways (23). What exactly switches the MAPK cascade from barrier-disruptive to barrier-protective functions is a question for future research. The fact that MAPK activation may lead to both augmentation and deterioration of endothelial barrier function indicates that an understanding of specifics of cascade activation is required to manipulate EC barrier properties.

### Inflammation

The role of MAPKs in inflammation is not limited to the regulation of EC monolayer integrity. Because leukocyte adhesion to ECs is a prerequisite for their later transmigration, the presence of specific adhesion proteins on the EC surface determines the rate of inflammatory cell infiltration to surrounding tissues. Leukocyte adhesion to ECs is regulated via a p38 MAPK- and/or JNK-dependent increase in the expression of the surface adhesion molecules such as intercellular adhesion molecule (ICAM)-1 and vascular adhesion molecule (VCAM)-1 (48), achieved via transactivation of the NF- $\kappa$ B pathway. Moreover, MAPKs control the subsequent process of leukocyte transmigration. ICAM-1 ligation-induced changes in the EC cytoskeleton were shown to be p38 MAPK-dependent (49). In addition, neutrophil extravasation also depends on ERK1/2 activation in ECs. Soluble neutrophil factor, inducing ERK1/2 activation in endothelium, was recently characterized as a 30-kDa protein (50). Thus, MAPKs control leukocyte transendothelial migration by altering barrier function, modulating EC expression of cell adhesion molecules, and reorganizing the EC cytoskeleton.

### Release of Soluble Mediators

MAPKs modulate the release of several bioactive substances by ECs, including factors controlling inflammatory response, angiogenesis, blood coagulation, and vascular tone (see Figure 81.3). The enzymes producing proinflammatory lipid mediators, namely platelet-activating factor (PAF), arachidonic acid (AA), and its metabolites, are controlled by MAPK pathways at both the transcriptional and post-translational level. Both p38 MAPK and ERK1/2 contribute to the activation of phospholipase A2 (cPLA2) and arachidonic acid and PAF release by ECs (23). EC prostaglandin synthesis is regulated via p38 MAPK or ERK1/2–dependent control over cyclooxygenase (COX)-2 expression. p38 MAPK and JNK govern the induction of interleukin (IL)-8, coagulation factor III, and angiogenic mediator ephrinA1 (23,48). Finally, NO synthesis is controlled by both

ERK1/2 and p38 MAPK via the phosphorylation and/or transcriptional regulation of inducible NOS (iNOS) and eNOS (51–53). Such control over the release of bioactive substances allows MAPKs to adjust the response of several cell types present at the site of disturbance.

### IN VIVO APPLICATIONS

These data suggest that factors inducing MAPK activation affect vascular function via several mechanisms. They alter endothelial permeability or EC ability to recognize leukocytes and change the level of bioactive mediators released into the vascular lumen. Therefore, the response of blood vessels as a whole depends on the type of EC and nature of the initial signal, as well as on the pattern of secondary signals originating from mobile luminal elements and resident cells. Thus, distinct signaling pathways may dominate in specific models of inflammation, suggesting the necessity for different pharmacological inhibitors to suppress edema and neutrophil infiltration and, correspondingly, the duration and severity of inflammation on the tissue level.

For example, the MEK/ERK inhibitor U0126 was shown to reduce phorbol-ester–induced ear edema and trauma-induced brain edema (44,54). p38 MAPK inhibitors FR167653 and SB203508 suppressed carrageenan-induced paw edema, LPS-induced subcutaneous vascular leakage, or lung edema (55–57). In certain models, p38 MAPK inhibitors were shown to decrease the level of TNF- $\alpha$ , prostanoids (55), or IL-1 $\beta$ , whereas in other experiments no significant changes in the level of proinflammatory mediators were found. Surprisingly, in several studies, p38 MAPK inhibition aggravated lung edema (58) and cerebral vascular permeability (59), suggesting that the use of p38 MAPK inhibitors as anti-edemagenic agents might be limited to certain types of inflammation.

### CONCLUSION

MAPKs represent the essential components of those signal transduction pathways implicated in vascular development, vascular remodeling, or inflammatory responses. Given the multiple physiological or pathological processes induced by MAPK activation, it is hardly surprising that significant organ dysfunction may result from the derangement of these processes. As MAPK-mediated pathways are further uncovered, our potential to develop methods to prevent the morbidity associated with vascular leakage–dependent organ failure or vascularization–dependent tumor development may be greatly improved. However, we must keep in mind that the pharmacological inhibition of MAPK would probably affect numerous physiological functions as well. Local intervention at the site of disturbance or specific targeting of certain downstream proteins may be needed to suppress the pathological rather than physiological responses to MAPK activation.

## KEY POINTS

- MAPKs are critically involved in the regulation of vascular endothelial functions.
- The physiological effects of MAPK activation are elicited via the phosphorylation of numerous specific protein substrates.
- The final consequences of MAPK activation on a cellular level depend on the balance between different MAPK activities and the activities of other signaling pathways, which, in turn, vary from cell to cell and from stimulus to stimulus.
- The manipulation of specific MAPK activities may represent a powerful tool in the treatment of vascular diseases.

## Protein Kinase C

---

Alex Toker

*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts*

The discovery of protein kinase C (PKC) by Y. Nishizuka and colleagues in the late 1970s was a landmark event in biology and reinforced the emerging concept at the time that extracellular agonists that stimulate receptor-mediated phospholipid hydrolysis transduce signals through the activation of a variety of serine/threonine protein kinases (1). In this context, the discovery of PKC was particularly illuminating because it also became evident that this kinase serves as the receptor for potent tumor-promoting phorbol esters, which mimic the natural allosteric activator of PKC, diacylglycerol (DAG) (2). These findings propelled the nascent PKC field into one of the most widely studied lipid second-messenger signaling pathways, which has occupied researchers in the last two decades (3). Studies to date have painted a detailed molecular picture of the mechanisms that control PKC activation, localization, and function. Thus, at the dawn of the new millennium, the spatial and temporal controls of PKC regulation by lipid activators and by phosphorylation are now well understood. Although this knowledge has allowed researchers to foray into more complex questions about how PKC transduces signals to modulate cellular responses, this area of investigation lags significantly behind.

This chapter reviews the mechanisms by which PKC functions as a signal-relay enzyme in the endothelium. Although our understanding of the role of PKC in vascular biology and pathology is still in its infancy, studies have clearly identified this kinase as a key regulator of signal coupling in endothelial cells (ECs) and have thus provided exciting prospects for translating this information into therapeutic value. The knowledge that phorbol esters such as phorbol myristate acetate (PMA) are potent activators of PKC in cells has proven to be a powerful tool for studying the role of this kinase in EC function. However, it recently has become clear that there exist numerous cellular targets of PMA and its cellular counterpart DAG other than PKCs, so it is therefore likely that EC responses originally attributed to PKCs may actually be regulated by other PMA/DAG effectors. These include chimaerins, Ras guanine nucleotide releasing proteins (GRPs), protein kinase D (PKD), Munc13 proteins, and DAG-kinases (4). Therefore, attribut-

ing the effects of PMA on cellular responses to PKC alone can be misleading. This is further complicated by the fact that up to 10 distinct isoforms of PKC, which share similar regulatory mechanisms and functional output, can exist in any one cell or tissue. Clearly, more sophisticated methods are required to accurately probe specific functions of this key signaling enzyme. The development of PKC knockouts, transgenes, and RNA interference has begun to shed some light on the role of PKC in EC biology.

### THE PROTEIN KINASE C FAMILY

Although originally discovered as a single enzymatic entity, purification and cloning efforts during the 1980s resulted in the identification of 10 distinct PKC gene products in mammalian cells (5). These are subdivided into conventional PKCs (cPKC: PKC- $\alpha$ , PKC- $\beta$ I, PKC- $\beta$ II, and PKC- $\gamma$ ), novel PKCs (nPKC: PKC- $\delta$ , PKC- $\epsilon$ , PKC- $\eta$ , and PKC- $\theta$ ), and atypical PKCs (aPKC: PKC- $\zeta$  and PKC- $\iota/\lambda$ ). Although originally characterized as a PKC, PKC- $\mu$  has been reclassified into its own family of kinases, the PKDs, which although distantly related, do share some similarities in regulation and function with their cousins, the PKCs. In the human Kinome, PKCs are founding members of the AGC superfamily (protein kinases A, G, and C). The classification of PKCs is shown in Table 82-1, and is largely based on their domain structure, which in turn defines their individual modes of regulation by either calcium, DAG, and/or the anionic phospholipid phosphatidylserine. Conventional and novel PKCs contain two copies of the C1 domain at the DAG/PMA binding site (Figure 82.1). In atypical PKCs, only one C1 domain is present, and so these PKCs are unresponsive to PMA and DAG. The function of the single C1 domain in these PKCs is not known. The C2 domain houses the calcium-binding site in cPKCs, and calcium binding to these enzymes promotes interaction with anionic phospholipids. An atypical C2 domain is found in nPKCs, and the lack of critical residues necessary to promote interaction with calcium renders these PKCs unresponsive

**Table 82-1: Summary of PKC Classes**

PKC Isoform	DAG Binding	Calcium Responsive	Activation Mechanism	Vascular Phenotypes in Knockout Mice
Conventional PKCs: $\alpha$ , $\beta$ I, $\beta$ II, $\gamma$	Yes	Yes	DAG binding	<i>PKC<math>\beta</math>II</i> <sup>-/-</sup> : reduced retinal neovascularization
Novel PKCs: $\delta$ , $\epsilon$ , $\eta$ , $\theta$	Yes	No	DAG binding	No data
Atypical PKCs: $\iota/\lambda$ , $\zeta$	No	No	Phosphorylation	No data

to calcium. nPKCs also are unresponsive to calcium, because they lack a C2 domain. All PKCs also are regulated by interaction with phosphatidylserine on membranes.

The catalytic domain of PKCs is highly conserved, and the secondary and tertiary structure reveals a similar mode of regulation for all enzymes. Although it was appreciated for almost a decade that PKC is itself phosphorylated in cells, it was not until the discovery of phosphoinositide-dependent kinase (PDK)-1 as the upstream kinase for PKCs' close cousin Akt/protein kinase B (PKB) that it became apparent that PDK-1 also phosphorylates PKCs at a crucial residue in a conserved region in the catalytic cleft, the activation loop (6). In fact, it is now known that before PKC is able to bind to DAG, it must first be phosphorylated at the activation loop and two other conserved residues in the carboxyl-terminus. This suggests that phosphorylation of PKC is the rate-limiting step in its activation cycle, such that phosphorylation locks the enzyme in a conformation that is able to bind to DAG and calcium. PDK-1, which is regulated by the phosphoinositide 3-kinase (PI3K) pathway, is the master regulator of PKCs and indeed many other AGC kinases. In the case of cPKCs, phosphorylation by PDK-1 is a processive event that occurs in the absence of extracellular stimuli and serves to maintain the enzyme in a conformation capable of DAG binding. In the case

of nPKCs, although some evidence suggests that phosphorylation by PDK-1 serves to activate the kinase in response to ligand stimulation, the main activating mechanism is DAG binding. Once PKCs are phosphorylated at the activation loop, the two carboxyl-terminal sites, termed the *turn-motif* and the *hydrophobic site*, are phosphorylated (see Figure 82.1). In the case of cPKCs, this occurs through autophosphorylation. Although this also is true for novel and atypical PKCs, evidence suggests that a heterologous upstream kinase for the hydrophobic motif exists.

The mechanisms leading to activation of PKC that are ultimately responsible for positioning the enzyme next to its effector substrates have been elucidated in exquisite detail. Numerous excellent reviews discuss these models, and the reader is referred to these articles for more in-depth discussions (6–8). Briefly, newly synthesized PKC is phosphorylated by PDK-1, which stimulates autophosphorylation in the carboxyl-terminus as part of the maturation of the enzyme. A pseudosubstrate sequence in the PKC amino terminus plugs into the catalytic cleft, effectively preventing access to substrates. Extracellular signals promote the hydrolysis of phospholipids such as phosphatidylinositol 4,5-bisphosphate thus producing DAG and inositol 1,4,5-triphosphate (IP<sub>3</sub>), and the latter induces release of calcium from intracellular stores. Newly

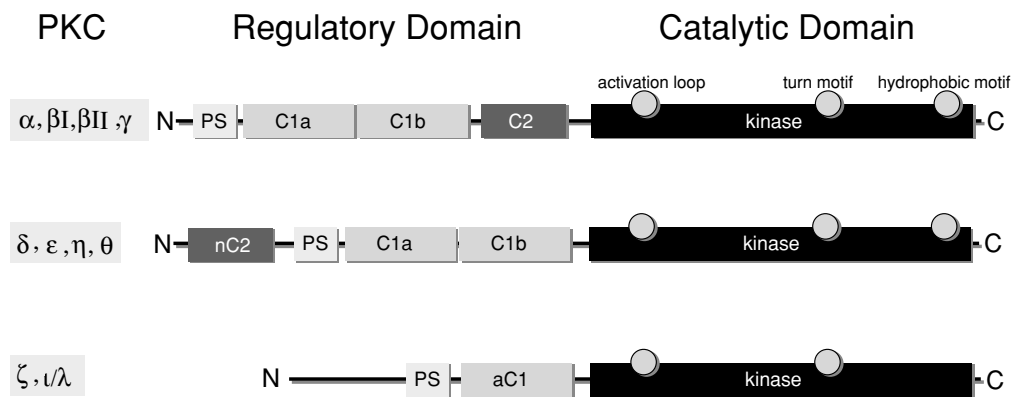

Figure 82.1. The PKC family. Schematic showing the domain structure of conventional (PKC- $\alpha$ , PKC- $\beta$ I, PKC- $\beta$ II, PKC- $\gamma$ ), novel (PKC- $\delta$ , PKC- $\epsilon$ , PKC- $\eta$ , PKC- $\theta$ ), and atypical (PKC- $\zeta$ , PKC- $\iota/\lambda$ ) PKCs. Indicated are the pseudosubstrate (PS), C1a and C1b, C2, and kinase domains. Note that novel PKCs have a novel C2 (nC2) domain that does not bind calcium, and atypical PKCs have one copy of an atypical C1 (aC1) domain that does not bind DAG/PMA. The phosphorylation sites at the activation loop, turn motif, and hydrophobic site in the catalytic domain are also depicted.

synthesized DAG serves to recruit cPKCs and nPKCs to membranes, along with scaffolding proteins that position the enzyme at discrete cellular locations. Binding of calcium (in the case of cPKC) and phosphatidylserine locks the enzyme on membranes and promotes release of the pseudosubstrate domain. In the presence of nucleotide (adenosine triphosphate [ATP]), substrates are now phosphorylated by PKC, and the signal is transduced. In this model, PMA can substitute for DAG, although it is important to note that phorbol esters bind to C1 domains with an affinity of at least two orders higher than does DAG. Thus PMA does not accurately reproduce the kinetics of agonist-stimulated PKC activation. The life cycle of all PKC isoforms is terminated when the enzyme is dephosphorylated by protein phosphatases. Dephosphorylation of PKC is the signal for its degradation, and there is evidence that the ubiquitin/proteasome pathway is responsible.

It is important to note that variations on this model do exist. For example, although phosphorylation of conventional PKCs is part of the maturation process, for atypical and even novel PKCs, evidence suggests that some agonists actually stimulate phosphorylation of PKC at the activation loop, an event that may therefore be coupled to receptor-initiated signaling (7). In the case of aPKCs that are not PMA/DAG responsive, activation is best understood in the context of phosphorylation, which is mediated by PI3K and PDK-1 and which occurs in response to the stimulation of cells with many agonists, including vascular endothelial growth factor (VEGF). This locks the kinase in the active conformation in the absence of interaction with any lipids, although some evidence suggests that phosphatidylserine still is required for maximal aPKC activity. Similarly, other phospholipids, such as the PI3K product PtdIns-3,4,5-P<sub>3</sub> also may moderately affect aPKC activation through allosteric mechanisms. These differences are important in the context of understanding the function of PKC in EC responses.

## PROTEIN KINASE C IN THE ENDOTHELIUM

### General Considerations

Expression patterns of signaling enzymes in adult tissues can provide useful information concerning their potential functions, especially in the case of multigene families such as the PKCs. Although PKCs are essentially ubiquitous in adult mammalian tissues, some isozymes reveal restricted expression profiles. For example, PKC- $\theta$  is restricted to immune cells and skeletal muscle, whereas PKC- $\gamma$  is exclusively expressed in the central nervous system. Interestingly, PKC- $\beta$  shows highest expression in most vascular tissues including retina, heart, and kidney (9). Atypical PKCs are ubiquitous and are expressed in all tissues studied.

When considering a function for PKCs in EC responses, at least two requirements must be fulfilled if PKC is to play a physiologically relevant function: (a) agonist-stimulated DAG synthesis (in the case of cPKCs and nPKCs) and calcium flux

(in the case of cPKCs) must occur subsequent to receptor-initiated signaling and, (b) processive (cPKC) or stimulated (nPKC and aPKC) phosphorylation of PKC by PDK-1 also must occur (Figure 82.2). In the case of VEGF, these requirements appear to be met. Stimulation of cultured ECs with VEGF leads to activation of the receptor VEGFR2 (FLK-1/KDR), leading to tyrosine phosphorylation of phospholipase C (PLC)- $\gamma$ , DAG synthesis, and calcium release, as well as activation of the PI3K/PDK-1 signaling axis (10). Interestingly, this is not observed with placental growth factor (PlGF), which signals through VEGFR1 (FLT-1), suggesting that EC signaling through PKC may be restricted to VEGF-derived inputs. The activation of several PKCs in ECs stimulated with VEGF has been reported. In bovine aortic ECs, VEGF stimulates the activation of PKC- $\alpha$  and PKC- $\beta$ II (11). In human umbilical vein ECs (HUVECs), VEGF stimulates PKC- $\alpha$ , PKC- $\epsilon$ , and PKC- $\zeta$  activation (12–14). PKC- $\delta$  activation by VEGF also has been shown in VEGF-stimulated HUVECs (15). Given that PI3K is potently activated by VEGF, it is not surprising that atypical PKC- $\zeta$  activation by VEGFR2 has been extensively documented (12,16). It should be noted, however, that the complexity of the PKC gene family has necessitated the use of chemical inhibitors to identify the activation profiles of distinct isozymes in cells and, unfortunately, these inhibitors are not sufficiently specific to accurately probe the activation or function of a given PKC. Regardless, clear evidence shows that multiple PKCs are activated by VEGF in ECs in culture.

Other agonists that stimulate PKC activation in ECs include thrombin, which promotes EC leakiness. Thrombin, which stimulates PLC- $\beta$ -induced DAG synthesis, has been shown to promote PKC- $\alpha$ , PKC- $\delta$ , and PKC- $\zeta$  activation in a variety of EC types (17). Exposure of ECs to H<sub>2</sub>O<sub>2</sub> stimulates phosphorylation of VEGFR, and this has been shown to be modulated by PKC- $\delta$  (18). Finally, ECs are continuously subjected to hemodynamic forces, and studies on ECs under mechanical strain have revealed activation of PKC- $\alpha$  and PKC- $\epsilon$  (19). Thus, the overwhelming evidence points to a role for EC stimuli in the activation of various PKCs.

Unfortunately, evidence for the activation of PKCs in the endothelium of whole tissues or organisms is lacking. This is due to technical limitations in our ability to visualize PKC activity in intact cells. For example, phosphorylation state-specific antibodies to monitor PKC activity cannot be used because phosphorylation of PKC is not an accurate measure of activation. More recent advances in imaging technology have permitted the visualization of PKC activity in real-time in transfected cells (20) and, when these techniques are refined to permit imaging in whole organisms, a wealth of important new information is likely to emerge. Until then, we are confined to *in vitro* studies. Similar hurdles are encountered when considering PKC knockouts in mice. All nine PKC genes have been targeted by homologous recombination, and all but eight are viable and show no obvious developmental phenotypes. The only embryonically lethal mouse knockout is PKC- $t/\lambda$ . As discussed later, some of the PKC knockouts have revealed some vascular phenotypes, such as loss of retinal vascularization.

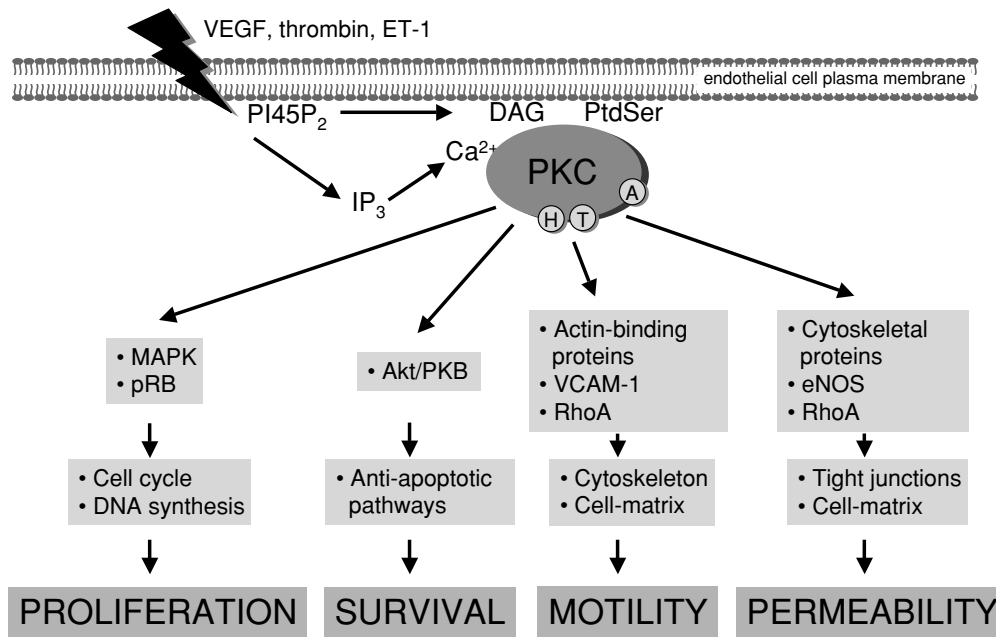

Figure 82.2. EC responses modulated by PKC. Diagrammatic representation of activation of PKC by stimuli that activate ECs, including VEGF, thrombin, and endothelin (ET)-1. All these agonists stimulate phospholipid (PI4,5P<sub>2</sub>) hydrolysis, leading to synthesis of DAG and release of calcium (Ca<sup>2+</sup>). Phosphatidylserine (PtdSer) also is required as a cofactor for PKC activation. Phosphorylation of PKC at the activation loop (A), turn motif (T), and hydrophobic site (H) is rate-limiting for PKC activation. Once activated, PKC transduces the signal in ECs by coupling to secondary signaling cascades including MAPK, phosphorylation of retinoblastoma (pRB), synergy with Akt/PKB, and phosphorylation of actin-regulatory proteins as well as eNOS. This in turn modulates endothelial phenotypes that manifest in altered proliferation, survival, motility, or permeability.

However, given the functional redundancy of the PKC family, double and triple knockouts may be required to reveal more essential roles for PKCs in other aspects of EC function. Although PKC transgenes have been developed, none to date have interrogated a specific function for PKCs in the vasculature. Based on these considerations, it is therefore not surprising that our knowledge on the role of PKCs in EC biology has been limited to cell culture experiments. Despite the simplistic approach, some important advances have been made.

### Endothelial Cell Growth and Survival

Although VEGF originally was discovered as a permeability factor, it also functions as a bona fide mitogen by promoting cell-cycle progression and DNA synthesis. The use of various chemical inhibitors or dominant negative mutants of various isozymes has suggested a role for PKCs in EC proliferation and growth. For example, inhibition of PKC- $\theta$ , PKC- $\alpha$ , PKC- $\zeta$ , PKC- $\varepsilon$ , and PKC- $\eta$  results in inhibition of DNA synthesis and EC proliferation in response to VEGF in vitro (12,13). Can it be that simultaneous signaling through all these PKCs is required for EC growth? This seems unlikely, and until these observations are confirmed using more specific tools such as small interfering RNA (siRNA) or knockouts, the role of a given PKC in vascular proliferation will remain unclear.

However, a critical role for PKC- $\beta$  in EC proliferation has been demonstrated convincingly. Studies have shown that the specific PKC- $\beta$  inhibitor LY333531, currently in clinical trials for the treatment of diabetes and cardiac ventricular hypertrophy, attenuates VEGF-stimulated mitogenesis (11). Even more compelling are the findings that transgenic mice overexpressing PKC- $\beta$ II in vascular tissues show a dramatic increase in the angiogenic response to oxygen-induced retinal ischemia, whereas PKC- $\beta$ II-null mice show a decrease in retinal neovascularization (21). Similarly, mitogenesis induced by VEGF is increased in ECs expressing PKC- $\beta$ I/II, and it is attenuated in cells expressing dominant negative PKC- $\beta$  mutants (21). A role for retinoblastoma phosphorylation, which is essential for cell-cycle progression and entry into S phase, was also suggested in PKC- $\beta$ -expressing cells (21). Finally, myristoylated peptides that specifically blunt PKC- $\beta$  activity also block VEGF-induced EC proliferation in vitro and angiogenesis in vivo (22). These data make a strong case for an important role for PKC- $\beta$  in modulating EC growth and angiogenesis, although the specific substrates and transcriptional events induced by PKC- $\beta$  signaling to promote these responses have yet to be defined.

By analogy with other receptor tyrosine kinases that stimulate cell growth as well as cellular survival, an important function of VEGF is its prosurvival activity in ECs. Although

the PI3K/Akt/PKB signaling pathway plays a major role in promoting survival, some studies have suggested a role for PKCs in modulating this response in ECs. As discussed earlier, the exposure of ECs to oxidative stress stimulates VEGFR phosphorylation and activation, leading to enhanced survival (18). Blocking PKC- $\delta$  signaling attenuates this response. A role for PKC- $\delta$  in modulating the survival capacity of Akt/PKB also has been proposed (15). To date, no data address an *in vivo* role for PKCs in EC survival, either in tumor angiogenesis or developmental angiogenesis.

### Endothelial Cell Adhesion and Motility

Subsequent to local ischemia, wounding, or inflammation, new blood vessels develop, and the normally quiescent ECs become activated and motile as part of the angiogenic response. Studies have implicated PKC in controlling those EC cytoskeletal rearrangements leading to increased adhesion and migration. Inhibition of PKC- $\alpha$  using either chemical inhibitors or antisense oligonucleotides blocks VEGF-stimulated EC migration and capillary tube formation *in vitro* (23). Conversely, overexpression of PKC- $\alpha$  increases EC motility. Similar approaches also have implicated PKC- $\theta$  in EC tube formation (24). Although the mechanisms by which PKCs modulate the motile apparatus of ECs remain obscure, studies have addressed the role of adhesion molecules in this pathway. Vascular adhesion molecule (VCAM)-1 is an adhesion molecule expressed in activated ECs, and PKC signaling controls its expression in cells stimulated with thrombin. In this pathway, the induction of VCAM-1 expression occurs through two transcriptional events modulated by p65 nuclear factor (NF)- $\kappa$ B and GATA. Studies have shown that PKC- $\delta$  signaling controls NF- $\kappa$ B induction, whereas PKC- $\zeta$  controls GATA, and both transcription factors synergize to induce VCAM-1 expression in ECs (17). Moreover, high glucose also stimulates VCAM-1 expression in ECs, and selective inhibition of PKC- $\beta$ II blocks this response (25). The relevance of these studies is that enhanced expression of adhesion molecules such as VCAM-1 in the endothelium may account for vascular damage *in vivo*, especially during stress hyperglycemia. Therefore PKC-selective inhibitors such as LY333531 may hold promise for the treatment of endothelial dysfunction during hyperglycemia and diabetes.

### Vascular Permeability

Arguably the most widely studied role for PKCs in modulating EC function is the regulation of vascular permeability. As with other EC responses, a major role has emerged for conventional PKC- $\beta$  and possibly for PKC- $\alpha$ . Both clinical and experimental evidence has implicated PKC signaling in events leading to microvascular barrier dysfunction, which has obvious implications for the inception and progression of human vascular disorders including diabetes, atherosclerosis, and ischemia-reperfusion injury. Studies *in vitro* have identified a role for PKC- $\alpha$ , PKC- $\beta$ I/II, PKC- $\delta$ , and PKC- $\zeta$

in promoting VEGF- or thrombin-induced EC permeability. For example, the inhibition of PKC- $\alpha$  leads to attenuated thrombin-stimulated transendothelial electrical resistance, a measure of increased endothelial permeability, and the effects of PKC- $\alpha$  have been shown to be modulated, at least in part, through the small GTPase Rho (26). Inhibitors of PKC- $\beta$  also blunt VEGF-stimulated transendothelial albumin flux (27), and similar results have been reported for PKC- $\delta$ , albeit in response to PMA stimulation of pulmonary microvascular ECs (28). In this context, studies also have shown that phorbol esters stimulate the permeability of cultured ECs to albumin, an effect that can be reversed in the presence of PKC inhibitors (29). Gain-of-function studies, using overexpression of PKC- $\beta$ I in human dermal ECs, for example, augment the PMA response (30). Interestingly, angiopoietin 1, which opposes the effects of VEGF on permeability, also blocks the activation of PKC- $\beta$  induced by VEGF, further supporting that signaling through PKC- $\beta$  is crucial for EC permeability (31). Although PKC- $\zeta$  is not PMA-responsive, its overexpression does result in increased thrombin-stimulated HUVEC permeability, whereas a dominant negative PKC- $\zeta$  mutant blunts the thrombin effect (32). Therefore, multiple PKC isoforms appear to positively regulate EC permeability, at least *in vitro*. It is worth noting that at least one study has suggested the opposite, in which the inhibition of PKC- $\alpha$  and PKC- $\beta$  using cell-permeant inhibitory peptides actually increased vascular permeability *in vivo* (22). It is rather difficult to rationalize a dual role for PKCs in both promoting and blocking vascular permeability, so clearly additional data with more selective approaches to target individual PKCs are required to establish a clear-cut role for distinct isozymes in permeability.

*In vivo* studies also have provided compelling evidence for a role for PKC (particular PKC- $\beta$ ) in regulating vascular permeability. The oral administration of LY333531 or LY290181, both reportedly PKC- $\beta$ -specific inhibitors, blocked endothelial abnormality and microvascular leakage in the retina and kidney of diabetic mice (33,34). This is consistent with detectable increases in PKC- $\beta$  expression in the heart and aorta of diabetic animals, concomitant with increased basal permeability of coronary venules. Again, this could be reversed with PKC- $\beta$ -selective, but not PKC- $\alpha$ -selective, inhibitors (35).

An obvious question that arises is: How do PKCs such as PKC- $\beta$  alter endothelial permeability? The cellular structures that define permeability in ECs include the actin cytoskeleton, cell-adherens junctions, and cell-matrix interactions. Signaling through PKC has been shown to modulate all these structures, although the precise mechanisms have yet to be elucidated. PKCs phosphorylate several cytoskeletal proteins, including myosin light chains (MLC), the myristoylated alanine-rich C kinase substrate (MARCKS) protein, actin-binding proteins, as well as intermediate filaments. As discussed earlier, PKC-dependent activation of Rho in ECs has been shown to be required for altered permeability. Disassembly of cadherin junctions also has been shown to occur in a PKC-dependent manner (31). Finally, enhanced nitric oxide (NO) signaling and induction of endothelial NO synthase

(eNOS) also play a crucial role in vascular permeability, and there is evidence that PKCs interface with NO. Exposure of ECs to phorbol esters leads to increased eNOS phosphorylation and NO production. Consistent with this, pharmacological inhibition of eNOS blocks the permeability effects stimulated by PKC activators, suggesting an intimate relationship between PKC and NO production in the regulation of vascular permeability (36).

### THERAPEUTIC INTERVENTION

The only current targeted therapy aimed at ameliorating vascular complications caused by EC dysfunction specifically due to alterations in PKC signaling is the LY333531 inhibitor from Eli Lilly & Co. The *in vitro* and *in vivo* studies that have made use of this compound to specifically block PKC- $\beta$  signaling have been convincing and suggest that it may be viable to target PKCs in human dysfunctions such as retinopathy and other vascular complications. Recent studies in patients with type 1 or 2 diabetes with minimal retinopathy assessed the safety and vascular effects of the drug in the retina. The results were encouraging, revealing statistically significant improvements in retinal blood flow, along with good tolerance for 30 days and no measurable adverse effects (9). Phase III trials are currently under way. Studies such as these rest on the specificity of inhibitors such as LY333531, and clearly this is the rate-limiting feature of all inhibitors aimed at blocking protein kinases. In this context, recent studies have actually demonstrated that LY333531 is not as uniquely selective as previously thought, because it can inhibit other protein kinases such as PKA and PDK-1, albeit at slightly higher doses than the  $IC_{50}$  for PKC- $\beta$ . Clearly needed at this stage is a more rigorous exploration of the specific roles of distinct PKC isozymes in modulating EC function. Once this is achieved, it may be possible to design more specific and potent inhibitors of a given PKC with the goal of targeting specific vascular abnormalities.

### CONCLUSION

Despite the relative infancy of the PKC field in EC biology, it is readily apparent that PKC signaling regulates multiple vascular phenotypes, ranging from cell growth and survival, to microvascular permeability. The *in vitro* studies discussed here should serve as an ideal springboard for more accurately dissecting the role of individual PKC isozymes in ECs *in vivo*. It is clear thus far that conventional PKC- $\beta$  is an important signal transduction enzyme that is activated by most stimuli that control EC responses. This does not rule out equally important roles for other PKCs in controlling one or more aspects of EC responses, but clearly more work is required to confirm the function of novel and atypical PKCs in the vasculature. Now that more specific tools are available to investigate these questions, including transgenes and RNA interference, there is reason to be excited about future progress in this field.

### KEY POINTS

- PKC- $\beta$  is activated by most stimuli that promote EC responses, leading to alterations in growth, survival, motility, and permeability.
- Other PKCs such as PKC- $\delta$  and PKC- $\zeta$  also appear to play important roles in specific EC functions, and may thus prove to be useful molecular targets for therapeutic intervention in vascular diseases.

### Future Goals

- Future exploration of the role of specific PKC isozymes in EC function should make use of RNA interference as a loss-of-function approach, and activated alleles as a gain-of-function approach. Both approaches are amenable to *in vitro* and *in vivo* manipulation.
- Double and triple knockouts of PKCs may reveal important developmental phenotypes in the vasculature and reaffirm the notion that PKCs are important for angiogenesis.

### ACKNOWLEDGMENTS

I would like to thank members of my laboratory for their critical evaluation of this chapter. Work in the laboratory is supported by National Institutes of Health grants CA075134 and CA096710.

## Rho GTP-Binding Proteins

Allan Murray

*University of Alberta, Edmonton, Canada*

Remodeling of the endothelial cell (EC) cytoskeleton is central to many functions of the endothelium. The Rho family of small GTP-binding proteins have been identified as key regulators of F-actin cytoskeletal dynamics in a variety of cell types. They integrate signals from soluble mediators interacting with cytokine, growth factor tyrosine kinase, and G-protein-coupled receptors (GPCRs); as well as signals from cell–cell, and cell–matrix protein adhesion molecules. Recently, it has become appreciated that effector molecules downstream of Rho GTP-binding proteins also modulate several other well-described cell signaling pathways. We review the role these molecules play in the cell, with a particular focus on the EC.

### HISTORY

The Rho family of small GTP-binding proteins, which consists of 22 members, is part of the larger Ras GTP-binding protein superfamily. These approximately 21-kDa proteins cycle between inactive GDP- and active GTP-bound forms to act as a molecular switch in signal transduction pathways. The members of this family are grouped by virtue of a shared structural motif, the Rho insert loop, that is present in the GTPase domain and contributes to the binding specificity for downstream effector molecules (1,2). In addition to this shared structural feature, most Rho family members undergo post-translational modification to link farnesyl or geranylgeranyl groups to the cysteine in a CAAX motif at the C-terminus of the molecule. Subcellular localization of the molecule is directed by the lipid moiety and, in some family members, is also influenced by additional domains in the C-terminus.

The first members of the Rho family of small GTP-binding proteins were discovered in the late 1980s by their similarity to Ras, and today the original family members RhoA, Rac1, and Cdc42 remain the best characterized functionally (3–5). These molecules are the first representatives of three of the six subfamilies of Rho GTP-binding proteins now identified.

Pivotal work done during the early 1990s identified characteristic cellular responses to Rho GTP-binding protein activation. Activation of RhoA, either by the administration of

the bacterial toxin cytotoxic necrotizing factor-1 or overexpression of dominant active mutants in Swiss 3T3 fibroblasts resulted in prominent F-actin stress fiber formation in serum-starved cells (Figure 83.1) (6,7). In contrast, the expression of active Rac1 stimulated the extension of lamellae, and active Cdc42 expression induced the formation of filopodia (6,7). Common to each of these changes in cell morphology is reorganization of the cell F-actin cytoskeleton.

The importance of Rho-dependent signaling in development is highlighted by observations of Rho-deficient mice (Table 83-1). Mouse embryos deficient in Rac1 fail to progress to gastrulation, apparently because of a failure of cell migration, and hence die in utero (8). Similarly, the conditional deletion mutation of Rac1 in myeloid lineage cells demonstrates defects in cell polarization and cell movement in vitro, consistent with failure to extend lamellae at the advancing edge of the cell (9,10). Deletion of Cdc42 expression in mice also results in an embryonically lethal phenotype at a slightly earlier point in gestation, prior to gastrulation, with small embryos lacking primary embryonic ectoderm (11). RhoA deletion mutations have not been reported, but expression of a RhoA-selective bacterial toxin that inactivates Rho function in the thymus induces a dramatic decrease in cellularity, indicating profound effects on cell division and apoptosis (12). Taken together, these observations identify a critical nonredundant role for each of these molecules in the regulation of cell positioning in the embryo. Later developmental abnormalities are evident in mice lacking key proteins that terminate RhoA signals. For example, *RhoGAP*<sup>-/-</sup> mice manifest abnormal neural development, whereas *RhoGAP-B*<sup>-/-</sup> mice have less severe abnormalities in neuron patterning, but are remarkably small with reduced cell volumes (13). Neither loss-of-function mutation is compatible with survival.

### MEMBERS OF THE Rho FAMILY

The Rho subfamily consists of three isoforms, RhoA, -B, and -C. Most experimental evidence is available for the effects of RhoA, however, the RhoB isoform also is expressed in vascular

Figure 83.1. Active RhoA induces actin filament stress fibers in serum-starved Swiss 3T3 cells. The cells were fixed without (A) or after injection with  $V^{14}$ RhoA (B) then stained with FITC-conjugated phalloidin to visualize F-actin structures. The small GTP-binding protein RhoA regulates the assembly of focal adhesions (i.e., the plaques of matrix receptors and associated molecules assembled at the base of the cell) and actin stress fibers (i.e., the cables of filamentous actin [F-actin] traversing the cell body) in response to growth factors. (Reproduced with permission from Ridley AJ, Hall J. The small GTP-binding protein rho regulates the assembly of focal adhesions and actin stress fibers in response to growth factors. *Cell*. 1992;70:389–399.)

cells (14). Unlike RhoA, RhoB is a short-lived protein that is highly regulated at the transcriptional level. Most of the primary amino acid residue differences between the subfamily members occur in the C-terminus, and this likely accounts for differences in intracellular localization of the isoforms. When overexpressed in cells, RhoA is largely cytosolic, whereas RhoB is enriched at the plasma membrane. The Rac subfamily includes four members, of which functional information for Rac1 and Rac2 is most developed. Rac2 is expressed in bone-marrow-derived cells, whereas Rac1 is ubiquitous in distribution. Of the five Cdc42-related subfamily members, the function of Cdc42 has been investigated most thoroughly. Cdc42 is expressed in endothelium. Rho-dependent pathway activation can be regulated by tissue or cell type-specific expression of a specific member within a Rho subfamily, but each tissue requires Rho GTP-binding protein expression.

### REGULATION OF Rho ACTIVITY

Rho-dependent pathway activation is controlled by GTP binding, which in turn is closely regulated by the association of GDP dissociation inhibitors (RhoGDI), GTPase activating proteins (RhoGAP), and GDP/GTP exchange factors (RhoGEFs) with the target Rho protein (Figure 83.2). RhoGDI binds to Rho proteins to inhibit GDP dissociation and membrane localization, and therefore pathway activation. RhoGAPs accelerate the intrinsic GTPase activity of the Rho proteins, and therefore limit interaction of the activated form with downstream effector molecules. RhoGEFs act to release GDP and facili-

tate Rho protein binding with GTP present in the cytosol. On the basis of sequence data, there are estimated to be a total of three RhoGDIs, 80 RhoGAPs, and 80 RhoGEFs, but most candidates have not been characterized functionally.

### GDP/GTP Exchange Factors

Much interest has focused on pathway regulation through the RhoGEFs, but examples of pathway regulation achieved by influencing RhoGDI and RhoGAP activity also are known. RhoGEFs contain a characteristic tandem arrangement of a diffuse B cell lymphoma (Dbl) oncogene, and a plekstrin homology (PH) domain. Activation of Rho family members is achieved by the exchange of GTP for GDP in the nucleotide binding pocket. The Dbl domain of the RhoGEF interacts with the “switch” regions of the Rho protein and so repositions the switch to cause intramolecular restructuring and disruption of the GDP and  $Mg^{2+}$  interactions within the binding pocket (15). Because GTP is in excess in the cell, the GDP is then replaced by GTP. The PH domain may function to localize the RhoGEF to phospholipid-rich membrane locations where the Rho molecule is positioned through its prenyl moiety, or to orient the GEF at such sites to facilitate efficient GDP/GTP exchange activity (16). However, RhoGEF PH domains also appear to mediate protein–protein interactions, notably with actin-binding proteins (17,18). RhoGEF specificity for one or more target Rho proteins may be achieved by spatial localization within the cell and conformational constraints determined by the characteristics of the binding interface between the RhoGEF and Rho target protein. However, it appears that

**Table 83-1: Rho GTP-Binding Proteins and Knockout Phenotypes**

<i>Gene</i>	<i>Phenotype</i>
<i>Rac1</i>	Early embryonic lethal at E8.5
<i>Rac2</i>	Defect in leukocyte function
<i>Cdc42</i>	Early embryonic lethal at E6.5
<i>RhoGAP</i>	Early postnatal death, defect in neural development

many RhoGEFs are promiscuous in their ability to exchange GTP on several Rho subfamilies.

RhoGEFs act to couple the Rho GTP-binding protein pathways to upstream receptors. Many signals originate at the cell surface from heterotrimeric GPCRs. Well characterized Rho-dependent signal transduction pathways coupled to heterotrimeric  $G_{\alpha 12/13}$  via RhoGEFs are described. For example, p115-RhoGEF, PDZ-RhoGEF, and LARG each promote GTP exchange on RhoA via a Dbl domain, but also exhibit GAP activity for  $G_{\alpha 12/13}$  via a tandem RGS domain. In this way, the downstream activation of Rho signaling is coupled to the means to extinguish the heterotrimeric G-protein signal (19,20). Recently, a redundant mechanism to activate Rho GTP-binding proteins via  $G_{\alpha q}$ -linked GPCRs has been described (21). Rho signaling also can be initiated by protein tyrosine kinase activity. For example, tyrosine phosphorylation of Vsm-RhoGEF serves to increase RhoA activity, likely by release of N-terminal autoinhibition of the Dbl domain by an intramolecular conformation change (22). In other cases, such as Vav1–3, promiscuous exchange factors for Rho, Rac, and Cdc42, the GEF may be localized by interaction between the Vav SH2 domain and phosphotyrosine residues (23). The large number of possible combinations between 22 Rho proteins and approximately 70 Dbl domain-containing or approximately 10 DOCK-family RhoGEFs represents a significant challenge to fully characterize biologically functional interactions, and the complexity is compounded by heterogeneity in the use of targeting domains among different cell types.

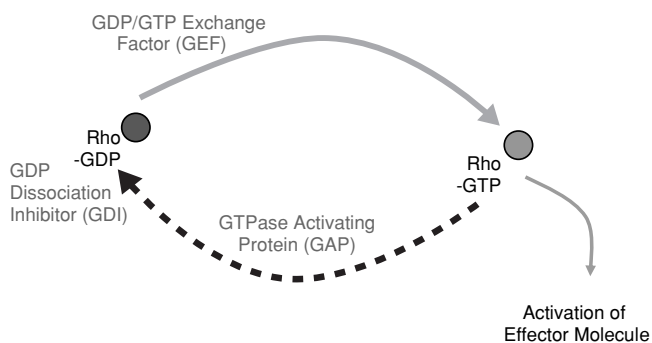

Figure 83.2. The Rho GTP-binding protein switch.

### GTPase Activating Proteins

Although up to 80 RhoGAP proteins are predicted in the human genome, most candidates have yet to be characterized functionally. Structural analysis of p50RhoGAP indicates that a conserved arginine is inserted into the Rho protein GTP-binding pocket to promote GTP hydrolysis (24). Specificity of RhoGAP activities is achieved by selective expression among cell types as well as the characteristics of the complementary interacting surfaces of the GAP with the target Rho protein. Regulation of RhoGAP activity is best illustrated by the ubiquitously expressed p190RhoGAP. GAP activity is enhanced by tyrosine phosphorylation under the influence of Src family kinases, and inhibited by protein phosphatase activity (25,26).

### DOWNSTREAM EFFECTOR MOLECULES

The control of downstream effector molecules is mediated by interaction of the binding surface of the Rho protein with characteristic binding motifs in the effector molecule, the Rho binding domains (RBD), or Cdc42/Rac-interactive binding (CRIB) domains. Rho pathway signaling depends on the specific activation conferred by the presence of GTP in the nucleotide binding pocket of the Rho molecule. Recent work has confirmed that interaction between the Rho effector molecule and the switch region of the Rho protein is conserved among several Rho/effector pairs studied (27). This is consistent with the observations that the switch region undergoes pronounced conformational change upon GTP loading of the Rho protein. However, additional sites of interaction also have been demonstrated to participate in the binding of various Rho effector molecules. For example, the insert loop, characteristic of the Rho GTP-binding protein family, is involved in Rho binding of Rho-dependent kinase (ROCK) and Rac binding of p67<sup>Phox</sup>, hence the insert loop may be a structural feature common to the family-specific binding or activation of additional effector proteins (28,29).

### Rho-MEDIATED REGULATION OF THE CELL CYTOSKELETON

Modification of the cell cytoskeleton is achieved by the coordinated activity of particular Rho effector molecules. The activation of RhoA activity, for example, leads to prominent stress fiber formation in fibroblasts and ECs in culture. Stress fibers (see Figure 83.1) in turn enable cells to contract. The formation of stress fibers depends on the levels of myosin phosphorylation, which are governed by the relative activity of myosin light-chain (MLC) kinase and MLC phosphatase. RhoA activates the downstream effector molecule, ROCK, which then promotes serine phosphorylation and downregulation of MLC phosphatase activity, leading to increased myosin phosphorylation and stress fiber formation (30). ROCK also activates LIM kinase, which phosphorylates and inactivates the

F-actin–severing activity of cofilin (31–33). Similarly, a third kinase regulated by Rho GTP binding proteins through Rho kinase, phosphoinositide 5-kinase (PI5K), participates in actin assembly by generating phosphatidylinositol 4,5-bisphosphate (PIP<sub>2</sub>) that promotes the dissociation of actin capping protein from the barbed end of F-actin to facilitate further actin polymerization (34). In this way, both net actin polymerization and F-actin bundling are enhanced, because F-actin depolymerization is inhibited by the cooperative activity of several downstream effectors of Rho GTP-binding proteins.

In addition to signaling through kinase activation to regulate cytoskeletal dynamics, Rho GTP-binding proteins also stimulate de novo actin nucleation and the polymerization of F-actin filaments. The most intensively studied pathway involves a Cdc42-binding–dependent conformation change in the actin-binding Wiscott-Aldrich syndrome protein (WASP) and subsequent downstream activation of actin polymerization through recruitment of the arp2/3 complex (35). A similar interaction between Rac and WASP family verprolin-homologous protein (WAVE), a WASP-related protein, has been identified (36). Rho proteins also interact with diaphanous-related formins (DRF). Mammalian diaphanous

(mDia) has a Rho interacting motif that, on binding the cognate RhoA or Cdc42, releases autoinhibition of the DRF activity (37,38). Formins directly bind to F-actin and enhance actin polymerization; of note, they act independently of the arp2/3 complex. Furthermore, formins may be important to establish cell polarization by coordinating both F-actin and microtubule orientation (39).

#### Rho-MEDIATED REGULATION OF CELL MIGRATION

In motile cells such as Dictyostelium or motile mammalian leukocytes, Rho and Rac have been found localized to distinct regions of the cell membrane. At the leading edge, Rac-GTP is enriched in lamellipodia (Figure 83.3) in association with phosphoinositide 3-kinase (PI3K) and PIP<sub>3</sub> at the plasma membrane, whereas phosphatase and tensin homologue deleted on chromosome 10 (PTEN) is excluded from this region (40). The mechanism of this localized activity is thought to be by direct interaction of the RacGEF PH domain with the PIP<sub>3</sub>-rich membrane. Recent work in neutrophils has established

Figure 83.3. Rac1 regulates integrin activation in ECs. Bovine aortic ECs were injected with cDNA coding for dominant active L61Rac1 (*upper panels*) or dominant negative N17Rac1 (*lower panels*). The cells were fixed and stained for active (WOW-1) or total  $\beta$ 3 integrin distribution. The ratio of active to total  $\beta$ 3 integrin is shown in the right panels. (Reproduced with permission from Kiosses WB, et al. Rac recruits high-affinity integrin  $\alpha$ v $\beta$ 3 to lamellipodia in EC migration. *Nature Cell Biol.* 2001;3:316–320.)

that Rac1 and Rac2 have distinct functions in polymorphonuclear leukocyte (PMN) migration to chemoattractant. Rac1 and PI3K are necessary for chemoattractant gradient sensing, whereas Rac2 acting upstream of Cdc42 functions to mediate actin polymerization (9). Another group has proposed a similar function for Cdc42 and the Cdc42GEF PIX $\alpha$ , acting distinctly from Rac activity (40). Cdc42 and Rac also are implicated in control of the direction of movement in monocytes and nerve cells in *Drosophila* (41,42). These observations illustrate exquisite functional specificity even among Rho subfamily members and the degree of conservation across species.

RhoA activity in the migrating cell is localized to the rear, where myosin-based contractility is required. The inhibition of RhoA or ROCK blocks retraction of the trailing uropod, increases integrin-mediated adhesiveness for matrix, and ultimately decreases leukocyte migration (43,44). Moreover, inhibition of Rho or ROCK activity results in a loss of cell polarity, such that lamellipodia form at numerous points around the cell periphery (45). The same authors identify distinct Rho GTP-binding protein coupling to heterotrimeric G-protein-coupled chemoattractant receptor: G $\alpha_i$  governs leading edge Rac activity and G $\alpha_{13}$  regulates Rho. Further work is needed to identify the mechanisms of subcellular compartmentalization in Rho family members and the exchange factors used among different cell types and growth factor receptors to govern localized Rho family activation.

#### Rho-MEDIATED REGULATION OF GENE EXPRESSION

Rho GTP-binding proteins are involved in the regulation of gene expression. Early work identified the modulation of genes using the serum response element by Rho protein activities (46). However, this appears to be regulated indirectly by levels of G-actin in the cell, sensed by G-actin-dependent translocation of a coactivator for the serum response factor (SRF), megakaryocytic acute leukemia (MAL) (47). Several studies have demonstrated stress-activated protein kinase (SAPK), p38 MAPK, and c-jun N-terminal kinase (JNK) activation by expression of dominant-active Rac and Cdc42 (48–51). Conversely, JNK activity and mast cell protease 7 expression is impaired in *Rac2*-knockout mast cells stimulated with stem cell factor, and reconstituted by Rac2 re-expression (52). Other reports implicate the nuclear factor (NF)- $\kappa$ B (49,53), and Jak/STAT pathway activation (54,55) downstream of dominant active Rho family member expression.

#### Rho-MEDIATED REGULATION OF REDOX POTENTIAL

A third general effect of Rho GTP-binding protein activation is the generation of reactive oxygen species (ROS) under the control of Rac. Neutrophil activation, an intensively studied model for the generation of superoxide, promotes the assembly

of a multimeric nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex on cell membranes. Myeloid cells deficient in Rac2 lack the ability to assemble the NADPH oxidase (NOX) complex and fail to generate a respiratory burst (56). One subunit, p67<sup>phox</sup>/NOXA1, interacts directly with the switch region, and a second subunit, gp91<sup>phox</sup>/NOX2, interacts with the Rho insert loop of GTP-bound Rac2. Remarkably, Rac1 is unable to complement a deficiency in Rac2 to facilitate the generation of ROS, and indeed, it appears Cdc42 may act as a competitive antagonist to Rac2 binding to p67<sup>phox</sup> (56). Differences in subcellular localization conferred by the polybasic residues in the C terminus of Rac1, which direct Rac1 to the plasma membrane rather than granule or lysosomal membranes, probably account in part for this difference in Rac isoform function. In other nonmyeloid cell types, NADPH oxidase-generated ROS acts in signal transduction pathways to inactivate tyrosine phosphatases. For example, angiotensin II stimulation of vascular smooth muscle cells (VSMCs) is associated with biphasic generation of free oxygen radicals, dependent in the first phase on protein kinase C (PKC) and in the second phase on Rac and tyrosine kinase activity. The NOX family members involved in nonmyeloid cell ROS generation remain to be clarified in most cases.

### THE ROLE OF RHO GTP-BINDING PROTEINS IN THE ENDOTHELIUM

#### Vasculogenesis and Angiogenesis

Because mice null for Rho family members die in utero before their vasculature develops, it is difficult to directly examine the function of these molecules in endothelial lineage development or vasculogenesis in vivo. At present, hints to the critical role the Rho family is likely to play can be taken from the observation that knockout mice lacking the G $\alpha_{13}$  heterotrimeric G-protein that couples these receptors to Rho family members die at about day E10 with marked abnormalities in vascular patterning by primitive ECs (57). On the other hand, angiogenesis is a feature of both wound repair and tumor development in the adult, and is more amenable to study. Expression of a dominant negative RhoA mutant in invading ECs using retroviral transduction markedly reduced tumor neovascularization in vivo, confirming that RhoA activity is involved in microvessel formation (58). Growth factors that play a critical role in angiogenesis signal through vascular endothelial growth factor (VEGF) receptor (VEGFR2/KDR), Tie2, transforming growth factor (TGF)- $\beta$ , and Eph receptors. Rho signaling has been implicated downstream of each of these receptors.

Angiogenesis involves both cell migration and changes in cell shape to form tubes. These events have been studied individually using in vitro cell culture models. EC migration into a denuded area in vitro is characterized by cell polarization and lamellipodia formation. Early investigations documented that Rho GTP-binding protein activity was required to migrate and fill the defect in a wounded EC monolayer (59,60). Further work identified a role for EC Rac and Cdc42

acting downstream of VEGF-stimulated cell migration (61). Cell movement requires the coordinated remodeling of matrix adhesion structures, apparent as focal adhesion complexes in ECs cultured *in vitro*. The adaptor proteins, Crk and Nck, are complexed to VEGFR2/KDR after VEGF stimulation and participate in the activation of Rac and the Rac effector kinase, PAK, to remodel EC focal adhesions (62). However, PAK activation may occur independently of Rac- or Cdc42-GTP binding.

RhoA activity also is increased after VEGFR2/KDR stimulation, but interestingly appears to be dependent on the transactivation of a  $G_{\alpha q}$  heterotrimeric GPCR (63). Similarly, stimulation of EC *in vitro* with angiopoetin 1 (Ang1) elicits cell migration, and like VEGF, stimulates both RhoA and Rac activity. Further, following Ang1 stimulation, Nck is found complexed with PAK and is associated with increased PAK activity in a signal transduction pathway analogous to VEGFR2/KDR stimulation (64,65).

The role played by Rho proteins also has been analyzed in capillary tube formation. *In vitro*, ECs cultured on Matrigel spontaneously reorganize their shape to form an elongated spindle morphology, assemble to form short multicellular capillary-like segments, then develop more complicated branching networks. Rac and PAK, but not Rho, activity is implicated in capillary tube formation (66,67). The assembly of capillary-like segments involves the establishment of interendothelial cell contacts and the assembly of vascular endothelial (VE)-cadherin-based adherens junctions between the cells. Rac recruits high-affinity integrin to the lamellipodia extensions formed during the change to the spindle shape (68). Dominant negative Rac1 expression in ECs further inhibits the development of VE-cadherin interendothelial cell junction structures *in vitro* (67), and inactivation of Rac disorders the established VE-cadherin junctions (69,70). In part, this is related to remodeling of the association of VE-cadherin to the cortical F-actin cytoskeleton (71). Thus, Rac participates in the events leading to the formation of primitive microvessels and maintenance of microvessel integrity.

Coordination between Rho subfamilies is nevertheless important for capillary network maturation. Cdc42 regulation of WASP activity is needed for lumen development of primitive capillary tubes *in vitro* (72). Inhibition of Rho activity appears to be involved in maintaining capillary lumen patency (73). However, inhibition of Rho or ROCK activity markedly decreases branching cord formation *in vitro* and *in vivo*, indicating that Rho activity is involved in the development of complex microvessel networks, but not the development of a patent lumen (58,66). Together, these observations illustrate that Rac, Cdc42, and Rho each participate in the formation of microvessel networks, but differential regulation of distinct aspects of microvessel assembly and maturation is evident in the *in vitro* experiments.

### Endothelial Response to Shear Stress

ECs at different sites in the vasculature are specialized for functions at each location. In the arterial circulation, the EC is

subjected to mechanical stresses during each cardiac cycle that contribute to a characteristic phenotype of arterial endothelium aligned in the direction of blood flow. Fluid shear stress sensed at the luminal surface by structural deformations in the plasma membrane or underlying cytoskeleton, at the interendothelial cell junctions, or at the matrix adhesion sites is translated into chemical signals that affect cytoskeletal organization and gene transcription.

*In vitro*, randomly oriented ECs subjected to shear stress realign in the direction of flow in a process requiring cytoskeletal remodeling, suggesting that Rho GTP-binding proteins may be under the influence of shear stress receptors. The initial application of shear induces a rapid increase in Rho-GTP, followed by suppression from basal values, then a late increase several hours later. Rac and Cdc42 activity, in contrast, are increased in a reciprocal pattern to Rho-GTP (74). The suppression of Rho-GTP is necessary for remodeling of cell shape, and is preceded by changes in cell matrix adhesion structure morphology and integrin affinity (75).

The mechanotransduction of shear stress to the matrix adhesion sites may directly regulate integrin affinity, which in turn appears to signal suppression of Rho through outside-inside signaling. In addition, reorientation of the EC requires the re-establishment of cell polarity. Rac activity regulates directional lamellipodia extension along the axis of flow (74). Cdc42 participates in EC polarization by governing the characteristic positioning of the microtubule organizing center upstream of the nucleus (76). Shear stress activation of Rho also is linked to the transcription of genes (such as the low-density lipoprotein [LDL] receptor) through effects on sterol regulatory element-binding proteins (77).

### Reactive Oxygen Species Production by the Endothelium

Vascular ECs express p47<sup>phox</sup> and p67<sup>phox</sup> in addition to both NOX1 and NOX4 (which are homologues of leukocyte gp91<sup>phox</sup>/NOX2). Hence, vascular ECs are competent to generate superoxide from this enzyme system. However, NOX4 is reported to be the principal component to generate superoxide in ECs (78). Indeed quiescent ECs in culture appear to maintain assembled NADPH oxidase complexes and constitutively produce oxygen-free radicals at low levels (79). NADPH oxidase activity in ECs can be upregulated by heterotrimeric G-protein receptor activation (80,81). For example, angiotensin II stimulation of the AT-1 receptor rapidly induces EC NADPH oxidase activity (80,82) and also can induce NOX expression in vascular ECs (83). In VSMCs, it has been demonstrated that similar activity is dependent on Rac GTP. Superoxide also is generated in response to receptor tyrosine kinase stimulation in ECs. The best characterized pathway is downstream of the VEGF receptor VEGFR2/KDR (84,85). VEGF-stimulation of coronary or venous ECs elicits a transient pulse of ROS regulated by RacGEF activity that can be inhibited by dominant negative Rac1 expression. This signal appears to promote Mn-dependent superoxidase transcription in a complicated

adaptive response. Interestingly VEGF-stimulated membrane translocation of the endothelial WASP homologue WAVE1 also has been demonstrated to depend on the Rac activation of PAK1-mediated phosphorylation of p47<sup>phox</sup>, an adaptor component of the NADPH oxidase complex (86). Thus, Rac activity links VEGFR2/KDR stimulation of EC to effects such as changes in the cytoskeleton, EC motility, and gene transcription.

The activation of the NADPH oxidase system is proposed to be a critical event in repair phenomenon such as endothelial migration and angiogenesis (85). However, NADPH oxidase-dependent oxidative stress of the endothelium is also linked to endothelial dysfunction and later arteriosclerosis (87). Diverse clinically relevant noxious stimuli including hyperglycemia, stimulation by advanced glycosylation end products, or oxidized LDL have been demonstrated to activate Rac GTP and generate ROS in cultured cells (88–90). Indeed, evidence has accumulated that the inhibition of endothelial Rac prenylation may be an important mechanism of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG CoA) reductase inhibitor-mediated vascular protection (90,91).

### Endothelial Barrier Function and Inflammation

The endothelium plays an active role in inflammation by changing capillary permeability and facilitating the tethering and transendothelial migration of leukocytes to the inflamed vessel surface. The development of small pores in confluent ECs and increased permeability of an endothelial monolayer in vitro can be elicited by GPCR agonists such as thrombin or histamine. The thrombin receptor is known to couple to G $_{\alpha 12/13}$  heterotrimeric G-proteins and, through p115RhoGEF, to the Rho GTP-binding proteins (92). Stimulation of EC monolayers with thrombin increases Rho GTP and myosin phosphorylation, consistent with increased cell contractility. Inhibition of RhoA blocks this response and the loss of the barrier function, demonstrating a critical role for Rho activation to elicit a cardinal feature of inflammation – vascular permeability (69,93). A similar signaling pathway is activated by tumor necrosis factor (TNF)-induced monolayer permeability in vitro (94).

Proinflammatory signals that decrease EC monolayer barrier function are accompanied by a decrease in Rac activity and redistribution of adherens junction proteins such as VE-cadherin (95). However, other signals generated during an inflammatory response act to counter the vascular leak and modulate Rho GTP-binding protein signaling. For example, sphingosine-1-phosphate (S1P), a mediator derived from platelet activation that decreases capillary permeability, acts to counter the thrombin-induced increase vascular permeability (96,97). Mechanistic investigations into the signal transduction pathways recruited by EC S1P signaling have demonstrated that Rac activation downstream of the S1P1 receptor mediates the effect (96,98). Moreover other mechanisms that attenuate the effect of proinflammatory agents on Rho-dependent signal pathways and vascular permeabil-

ity have been identified. Protein kinase A (PKA)-dependent increases in endothelial monolayer barrier characteristics are mediated by RhoGDI inhibition of RhoGTP relocation to the membrane (99). In contrast, Cdc42 activity is linked to restoration of monolayer barrier function after edemagenic stimulus (100).

Endothelial display of adhesion molecules provides a critical cue for the recruitment of leukocytes to sites of inflammation. Mobilization of stored P-selectin – a key adhesion molecule involved in the rapid recruitment of neutrophils – from endothelial Weibel-Palade bodies after thrombin receptor stimulation is inhibited by dominant negative Cdc42 expression (101). Further, Rac and Cdc42 modulate TNF-stimulated transcription of *E-selectin*, an adhesion molecule that participates in the later recruitment of neutrophils (102). Therapeutic intervention using HMG-CoA reductase inhibitors to block prenylation of Rho molecules inhibits TNF-induced E-selectin expression and may represent a clinically relevant effect of this class of drugs (103).

Endothelial cytoskeletal reorganization to form a “docking structure” has been identified at the sites of tight adhesion of the leukocyte to inflamed EC and correlates with the efficiency of subsequent transendothelial migration (104,105). These structures involve clustering of endothelial adhesion molecules intracellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 in association with the extension of F-actin rich fingers or ridges around the adherent leukocyte (105). In vitro clustering of ICAM-1 has been found to upregulate endothelial Rho GTP, and is critical for lymphocyte migration across a brain EC monolayer in vitro (106,107). However, it is not clear that ICAM-1-stimulated Rho-GTP initiates docking structure formation or if this is the Rho-dependent event that limits leukocyte transendothelial migration in vitro or extravasation in vivo.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Therapeutic targeting of Rho GTP-binding protein activity may be a useful approach in several clinical settings. In the management of cancer, for example, the inhibition of Rho activity in the transformed cell might impair tumor growth or metastasis. Moreover, neovascularization of the tumor may be impaired by Rho inhibition (108). Rho inhibition may be useful in the management of cardiovascular diseases such as hypertension (109) or angina related to coronary artery vasospasm (110). Indeed some of the beneficial therapeutic effects attributed to HMG CoA reductase inhibitors used in the management of dyslipidemia may be related to the effects of these drugs on small GTP-binding proteins, including Rho family members. In addition to desirable effects on cholesterol biosynthesis, these agents inhibit the production of farnesyl and geranylgeranyl pyrophosphates used to isoprenylate Ras and Rho GTP-binding proteins, which facilitate membrane localization of the small GTP-binding proteins (111).

Pharmacologic agents that specifically inhibit geranylgeranyl transferase activity are currently under investigation by the pharmaceutical industry.

### KEY POINTS

- Rho GTP-binding proteins are critical checkpoints that regulate key functions of the EC including angiogenesis, endothelial dysfunction, and inflammation.
- Identification of endothelial RhoGEFs and functional characterization of the participation of these molecules under particular pathological conditions is needed.
- Inhibition of these cell signaling systems may provide novel opportunities for therapeutic intervention.

# Protein Tyrosine Phosphatases

Arne Östman and Kai Kappert

*Cancer Center Karolinska, Karolinska Institute, Stockholm, Sweden*

Tyrosine phosphorylation is a fundamental regulatory mechanism, occurring exclusively in multicellular eukaryotes. This signaling mechanism is regulated by the balanced action of tyrosine kinases and protein tyrosine phosphatases (PTPs). The first PTP was purified in 1988 (1), approximately 10 years after the discovery of tyrosine kinases. The following years witnessed a rapid development that established PTPs as a family of highly specific and tightly regulated signaling proteins. It is now well established that PTPs equal tyrosine kinases in importance for the regulation of tyrosine phosphorylation (2–5). It is also predicted that, like tyrosine kinases, PTPs may emerge as drug targets for many major diseases, including conditions associated with endothelial pathology (6).

## THE FAMILY OF PROTEIN TYROSINE PHOSPHATASES

### Protein Tyrosine Phosphatase Subfamilies

A recent survey identified a total of 107 genes encoding PTPs in the human genome, of which 105 have mouse orthologues (3). Of these 107 genes, 38 belong to the subtype of classical PTPs, which display a specificity for dephosphorylation of tyrosine residues. Other major subgroups include the dual-specificity phosphatases (61 genes), the myotubularins (16 genes), and the non-cysteine-based Eya family of phosphatases (4 genes). This chapter is restricted to discussing the classical PTPs, hereafter only referred to as PTPs (Figure 84.1).

### Structure of the Protein Tyrosine Phosphatase Domain and Catalytic Mechanism

The conserved catalytic domain of PTPs consists of approximately 280 amino acid residues, of which 22 are perfectly conserved among the 38 human PTPs (7). Six of the conserved residues are part of the active-site sequence V/I H C S X G X G R. In addition to this PTP signature motif, three conserved regions contribute to the formation of the catalytic site. The

WPD loop closes in over the active site after substrate binding and provides an aspartic acid necessary for catalysis. The phospho-tyrosine (pTyr) recognition loop contains a tyrosine residue that defines the depth of the active site and thereby gives PTPs their specificity for phospho-tyrosine. Finally, the Q-loop contributes with a glutamine residue, which is also necessary for the activity. The PTP domains also share a common overall fold composed of a mixed  $\beta$ -sheet flanked by  $\alpha$ -helices.

Catalysis proceeds in a two-step manner (detailed in Ref. 8). In the first step, a covalent PTP-phosphate intermediate is formed in which the phosphate group is covalently linked to the active site cysteine. In the second step of catalysis, this cysteine-phosphate is hydrolyzed. The detailed understanding of the catalytic mechanism and its structural basis has already been exploited for the structure-based design of PTP inhibitors (6,9–11). It also has provided the rationale for the design of “substrate-trapping” mutants used to identify the substrates of individual PTPs (12).

### Domain Organization

PTPs are broadly categorized into receptor-like PTPs (RPTPs) and nonreceptor cytosolic variants (NRPTPs). In addition to the conserved PTP domain, PTPs display a striking variation with regard to associated domains (see Figure 84.1) (3).

The RPTPs all share the features of an extracellular domain, a single transmembrane segment, and an intracellular part composed of one or two PTP domains. In many cases, the extracellular parts are composed of multiple fibronectin type III or Ig-like domains, and thus share structural features with cell adhesion molecules. Based on these characteristics, RPTPs have been grouped into eight subtypes (3). Features distinguishing these subtypes include the presence of one (subtypes VI–VIII) or two (subtypes I–V) intracellular PTP domains, and the composition of extracellular domains, which are composed (for example) of fibronectin type III domains only in subgroup VI, whereas members of subgroup III have an

Figure 84.1. Schematic of domain structure of classical PTPs. Black box indicates transmembrane part of receptor-like PTPs. RPTP, receptor-like PTPs; NRPTP non-receptor-like PTP; D1, domain 1; D2, domain 2; FN, fibronectin-like; Ig, immunoglobulin-like; KIM, kinase interaction motif; PDZ, postsynaptic density-95/discs large/Z01 homology; SH2, src homology 2; BRO, baculovirus BRO homology; Pro-rich, proline-rich; FERM, band 4.1/ezrin/radixin/moesin homology; KIND, kinase N lobe-like domain; Sec14p, Sec14p homology (or CRAL/TRIO). (Modified with permission from Alonso A, Sasin J, Bottini N, et al. Protein tyrosine phosphatases in the human genome. *Cell* 2004;117:699–711.)

extracellular domain composed of both Ig-like and fibronectin type III domains. The significance of two tandem PTP domains in most RPTPs is still incompletely understood. However, recent evidence suggests that the second PTP domain, which in most cases has low or no catalytic activity, predominantly exerts a regulatory function.

Among the cytosolic PTPs, a common feature is additional domains involved in directing the proteins to specific subcellular locations or in mediating specific protein–protein interactions (see Figure 84.1). Such domains include the carboxy-terminal endoplasmic reticulum-targeting sequence of

PTP-1B, the FERM domains of PTP-HI, which is involved in mediating interactions with the cytoskeleton, and the SH2 domains of SHP-1 and SHP-2 that mediate interactions with tyrosine-phosphorylated proteins.

### Regulation of Protein Tyrosine Phosphatase Activity

PTPs are subject to multiple mechanisms that control their specific activity. Phosphorylation of PTPs on tyrosine, serine, or threonine residues has been shown to either increase or decrease their activity (13–16). More recently, an additional

reversible modification, namely inhibitory oxidation of the active site cysteine residue, has emerged as a potentially general mechanism for controlling PTP activity (17,18). This phenomenon has been described both after treatment with pathological oxidizing stimuli such as hydrogen peroxide ( $H_2O_2$ ) or ultraviolet (UV) irradiation, and also after treatment with physiological inducers of reactive oxygen species (ROS), like tyrosine kinase receptors (19–22). These findings provide intriguing indications of PTPs as mediators of cross-talk between redox signaling and tyrosine phosphorylation.

Although a series of reports has identified various putative ligands of RPTPs, there is still very limited information available concerning regulatory PTP ligands. The few examples include reports of pleiotrophin as an inhibitory ligand of PTP- $\gamma$  and the demonstration of a yet unidentified agonistic density-enhanced phosphatase (DEP)-1 ligand present in a crude extracellular matrix preparation (23,24). In addition to ligand binding, regulated dimerization also has been implicated as a mechanism for negative regulation of RPTP activity. This was first suggested based on the structure of the catalytic domain of RPTP- $\alpha$ . This domain occurred as a symmetric dimer, in which the active sites were blocked by the insertion of a “wedge-like” segment of the other subunit (25). Although subsequent functional studies have provided some support for the structural findings, recent studies also indicate that this mode of regulation might not apply to all RPTPs (26).

A final mode of regulation, which has been observed both for NRPTPs and RPTPs, is stimulus-triggered proteolytic cleavage. This has been shown, for example, with the demonstration of a calpain-mediated release of PTP-1B from the endoplasmic reticulum, and the calcium-dependent shedding of the extracellular domain of LAR and PTP- $\sigma$  (27,28). The latter was also associated with a translocation of the cleaved forms to intracellular compartments. Finally, proteolytic cleavage and degradation of PTP-1B, SHP-1, and LAR also recently was shown to occur after UV irradiation of cells (29).

### Substrate Specificity of Protein Tyrosine Phosphatases

Early biochemical studies indicated a more than 1,000-fold difference in the  $K_m$  when different tyrosine phosphorylated peptides as PTP substrates were compared (30). These indications of stringent substrate specificity were confirmed by the use of substrate-trapping mutants of various PTPs, which showed capture of specific substrates by different PTPs (12). It also recently was demonstrated that within proteins with multiple sites of tyrosine phosphorylation, individual PTPs preferentially dephosphorylate certain subsets of these sites (31,32).

The observed selectivity has at least two determinants. First, as revealed by cocrystallization of peptide substrates and PTPs, significant interactions occur between side chains of residues near the phospho-tyrosine residues of substrates and residues flanking the active site of PTPs between substrate and enzyme (33). Second, subcellular compartmentalization restricts access to substrates and thereby also contributes to substrate specificity (34).

## PROTEIN TYROSINE PHOSPHATASES AND REGULATION OF ENDOTHELIAL CELL FUNCTION

### Endothelial Protein Tyrosine Phosphatases and Pathways Affected by Them

It is noteworthy that only a subset of PTPs has been described to be expressed in endothelial cells (ECs). A recent review summarizing available data tabulated 10 RPPTs and eight NRPTPs that have been demonstrated to be expressed in ECs, using different methods to detect either mRNA or proteins (35) (Table 84-1). As indicated in more detail later, some of these enzymes have been implicated as important modulators of tyrosine kinase receptor signaling, adhesion-modulated signaling, and nitric oxide (NO) signaling. In addition, PTPs are also candidate mediators of signaling triggered by shear stress and hypoxia.

### Protein Tyrosine Phosphatases and Vascular Endothelial Growth Factor Receptor 2 or Tie2 Signaling

The major receptor tyrosine kinases controlling ECs are vascular endothelial growth factor (VEGF) receptor 2 (VEGFR2) and Tie2. Whereas VEGF receptors are strongly linked to EC proliferation and migration, Tie2 appears to be more important for functional maturation of ECs.

Two PTPs that have been identified as negative regulators of VEGFR2 signaling are DEP-1 and SHP-1. siRNA-mediated downregulation of DEP-1, or overexpression of a dominant-negative form of DEP-1, led to enhanced VEGFR2 phosphorylation and activation of downstream signaling (36). Interestingly, this effect was most prominent under conditions of high cell density. Association between DEP-1 and vascular endothelial (VE)-cadherin was shown to be necessary for this effect, emphasizing the importance of a localized recruitment of PTPs to their substrates. SHP-1 has been linked to VEGFR2 signaling based on evidence of direct physical associations between SHP-1 and VEGFR2, and the finding that tumor necrosis factor (TNF)- $\alpha$ -mediated downregulation of VEGFR2 phosphorylation requires SHP-1 expression (37,38). Also, enhanced SHP-1 association with VEGFR2 appears to be one component of tissue inhibitor of metalloproteinase (TIMP)-2-mediated inhibition of angiogenesis (39).

Concerning Tie2, special interest has been paid to the receptor-like protein PTP- $\beta$ , also designated vascular endothelial (VE)-PTP (40). PTP- $\beta$  was implicated as a Tie2-relevant PTP based on interaction in a yeast two-hybrid screen. Subsequently, a substrate-trapping mutant of PTP- $\beta$  was found to interact with Tie2, but not with VEGFR2. Interestingly, like DEP-1, PTP- $\beta$  has been shown to interact also with VE-cadherin (41).

Preliminary animal studies with PTP inhibitors also support the notion that PTPs negatively control VEGFR2 signaling. For example, enhanced vascularization has been observed in various models after treatment with PTP inhibitors (42–44).

**Table 84-1: Overview of Functions of Certain PTPs Expressed in ECs and Their Knockout Phenotype**

	<i>Function in ECs</i>	<i>-/- Phenotype</i>	<i>References</i>
<b>RPTPs</b>			
DEP-1/CD148	Inhibits VEGF function; associates with VE-cadherin	Die at midgestation; enlarged vessels with highly proliferative ECs	57
RPTP- $\alpha$	Not described	Viable, fertile, no gross abnormalities	59
PTP- $\beta$ /VE-PTP	Interacts with Tie2 (not VEGFR2); associates with VE-cadherin, promotes barrier function	Embryonic lethality, vascular malformations, enlarged cavities in vessels of yolk sac	60
PTP- $\delta$	Not described	Insufficient food intake (consecutive semilethal), impaired learning	61
PTP- $\epsilon$	Enhances EC migration and survival	Myelination defects	62
PTP- $\mu$	Binds to VE-cadherin, regulates barrier integrity	Viable, fertile, no aberrant phenotype	47, 63
PTP- $\sigma$	Not described	Increased neonatal mortality, retarded growth, altered nerve regeneration, pituitary, pancreatic and gut neuroendocrine defects	64–66
LAR	Not described	Normal growth, no histological abnormalities, increased neonatal death rate for mice from $^{-/-}$ females, altered mammary gland development and function	67
<b>Cytosolic PTPs</b>			
PTP-1B	Alters VEGF-induced proliferation/migration, regulates neovascularization	Enhanced insulin sensitivity and resistance to weight gain, increased basal metabolic rate	42, 68, 69
SHP-1	Inhibits VEGF function; dephosphorylates PECAM-1	Shortened lifespan, immune deficiency*	70, 71
SHP-2	Dephosphorylates PECAM-1; associates with and mediates downstream signaling of E-selectin	Embryonic lethality	72
TC-PTP	Not described	Splenomegaly, lymphadenopathy, premature death	73

In addition to these 12 PTPs, expression in ECs also has been described for PTP- $\gamma$ , PTP- $\kappa$ , FAP-1, PTP-D1, PTP-D2, and PTP-PEST (see Ref. 35).

\*Mice exist in the form of two natural mutations. Homozygous mutations in the SHP-1 gene cause motheaten (*me/me*) and motheaten viable (*me<sup>v</sup>/me<sup>v</sup>*) mice, which differ in phenotype severity (see Ref. 70).

Although most available information thus emphasizes the role of PTPs as negative regulators of RTK signaling in ECs, it should be cautioned that this view might be simplified. It is well established from other RTK pathways that some PTPs, particularly SHP-2, actually act as positive mediators of signaling (45). In the context of EC signaling, this also has been demonstrated by enhanced migration and survival after overexpression of the receptor-like variant of PTP- $\epsilon$ , presumably caused by dephosphorylation of the negative regulatory element pY527 of c-Src (46).

### Endothelial Cell Adhesion and Permeability

ECs adhere to each other as well as to the extracellular matrix of the vessel wall. These aspects of endothelial biology are directly linked to vascular permeability. In addition, ECs express surface molecules, such as selectins, to which circulating cells adhere. These adhesive processes all involve reversible tyrosine phosphorylation and, as indicated by a few examples given here, PTPs are actively involved in the regulation of these processes.

As mentioned earlier, both PTP- $\beta$  and DEP-1 have been shown to associate with VE-cadherin. In the case of PTP- $\beta$ , it was shown that this interaction, analyzed in transfected cells, promoted the barrier function of VE-cadherin (41). Similar functions of PTP- $\mu$  have been demonstrated (47). An involvement of PTPs in the maintenance of barrier function also is supported by the observation that treatment of cells with a general PTP inhibitor increased serum albumin flux across cultured monolayers of ECs (48). Furthermore, evidence for PTP-mediated control of VE-cadherin phosphorylation and function in vivo was shown by increased phosphorylation of VE-cadherin after systemic treatment with peroxovanadate (49).

The receptor platelet-endothelial cell adhesion molecule (PECAM)-1 is mainly expressed at endothelial intercellular sites. PECAM-1 activity is subjected to control by integrins in a manner that involves PECAM-1 dephosphorylation (50). One aspect of this cross-talk appears to be the recruitment and dephosphorylation of PECAM-1 by SHP-1 and SHP-2 (51). More recently, ROS have been implicated in these processes, both as regulators of PECAM-1 phosphorylation and of SHP-2 catalytic activity (52).

E-selectin is an inducible adhesion molecule that is expressed at relatively high density on the surface of cultured ECs that have been activated by proinflammatory cytokines, such as interleukin (IL)-1 $\beta$ , TNF- $\alpha$ , or bacterial endotoxin. It is also detectable in vivo at sites of inflammation. In addition to supporting the rolling and stable arrest of leukocytes on activated endothelium, there is increasing evidence that E-selectin can transduce outside-in signals. Hu and colleagues (53) demonstrated that SHP-2 associates with E-selectin and subsequently acts as a positive mediator for downstream signaling in ECs. This interaction might have functional implications for the pathology of inflammation.

### Protein Tyrosine Phosphatase Inhibition in Association with Shear Stress and Hypoxia in Endothelial Cells

Hypoxia-reoxygenation and shear stress are known stimuli for the production of ROS in the vessel wall. As discussed earlier, PTPs recently have been implicated as major targets for ROS signaling and are thereby candidate mediators of hypoxia and shear stress signaling in ECs. Although still sparse, some experimental support for this notion has been gathered.

ECs are constantly exposed to blood flow. A well-balanced laminar flow is considered atheroprotective, whereas a turbulent flow pattern might lead to endothelial dysfunction and preatherosclerotic conditions. That flow conditions can influence signaling is indicated by the rapid phosphorylation of PECAM-1 after shear stress exposure (54). A possible role of reversible oxidation of PTPs in this response is suggested by the observed reduction of SHP-2 activity following shear stress (55).

Hypoxia-reoxygenation affects EC signaling, and increased ROS production is one intracellular mediator of this process. Although direct demonstration of PTP inhibition

under these conditions is still lacking, some indirect observations support this possibility. Waltenberger and colleagues (56) showed that VEGFR2 was upregulated in human umbilical ECs after hypoxia. Moreover, an increase of VEGF-induced receptor phosphorylation due to hypoxia was observed, and VEGF-dependent mitogenesis was increased. The possibility that PTP inhibition contributes to the increased RTK signaling in ECs under hypoxia deserves further investigations. An interesting therapeutic implication of this scenario is treatment with antioxidants for prevention of pathological angiogenesis.

### Protein Tyrosine Phosphatases in the Context of Endothelial Cell Biology

As is clear from this review of PTP involvement in EC signaling, PTPs have an impact on a broad range of pathways that affect fundamental aspects of EC biology. Some of the findings discussed earlier are summarized in a cellular context in Figure 84.2 and Table 84-1.

As negative regulators of VEGFR2 and Tie2 signaling, the PTPs DEP-1, PTP- $\beta$ /VE-PTP, and SHP-1 are central negative regulators of endothelial proliferation, migration, and maturation (36–38,40,41). Also, it is anticipated that hypoxia-induced endothelial proliferation involves ROS-mediated attenuation of PTPs. Concerning cell-cell interactions between ECs, the observed functional cooperation between VE-cadherin and PTP- $\beta$ /VE-PTP points to the role of this PTP, and possibly others, in maintaining the barrier integrity of the endothelial layer (41). Also, SHP-2 negatively regulates the adhesive and antimigratory effects of PECAM-1 by dephosphorylation of PECAM-1 (50,51). Finally, the requirement of SHP-2 for E-selectin-mediated signaling points to a role for this PTP in the signaling events triggered by neutrophil-endothelial interactions (53).

Analyses of vascular phenotypes in PTP knockouts represent an alternative strategy for investigating the role of PTPs in EC biology. In this context, the phenotype of DEP-1 depletion provides the strongest evidence for PTP involvement in vascular biology (57). *DEP-1*<sup>-/-</sup> embryos die at midgestation (see Table 84-1). They display enlarged vessels with highly proliferative ECs expressing markers of low differentiation. Vessels also are characterized by reduced pericyte coverage. Although the biochemical basis for this phenotype has not been characterized extensively, it is likely that they at least partially are caused by hyperactive VEGFR2 signaling.

### THERAPEUTIC OPPORTUNITIES

ECs are obvious targets for pro- and antiangiogenic strategies. As important enzymatic regulators of endothelial biology, PTPs are emerging as interesting drug targets. The development of PTP antagonists is envisioned to be a more realistic venture than the development of specific activators. However, reactivation of oxidized PTPs by antioxidants might be an

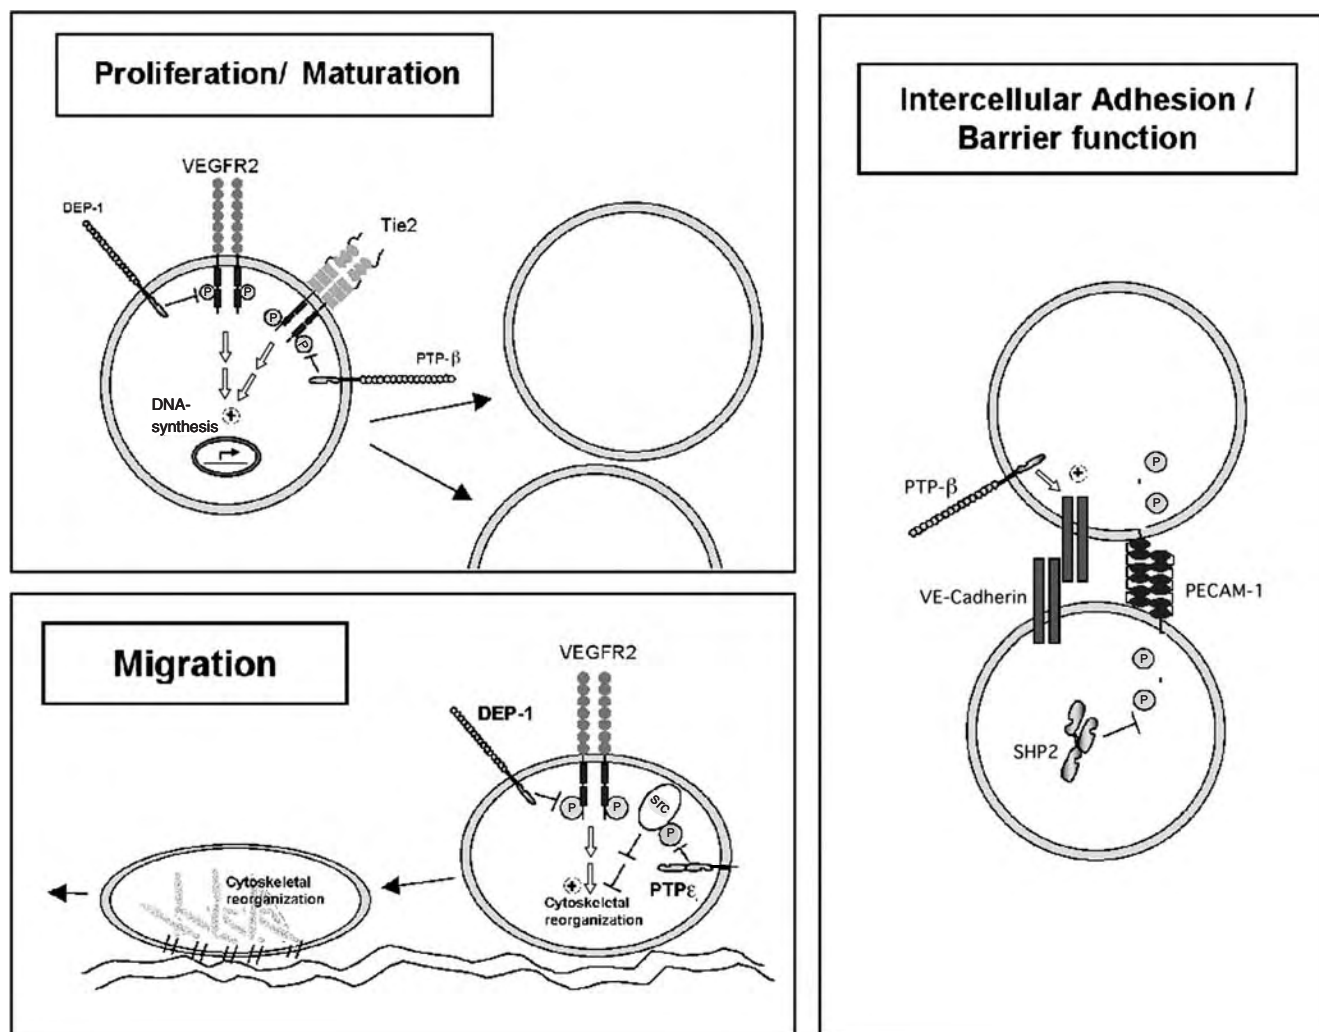

Figure 84.2. Schematic illustration of PTP involvement in EC biology. Some cellular processes that involve PTPs as signaling molecules are illustrated. The figure highlights the roles of some individual PTPs as presently understood. It is likely that the true situation involves multiple members of the PTP family.

option in situations where high specificity is not crucial. In general terms, the inhibition of PTPs that antagonize VEGFR2 and Tie2, such as DEP-1 and PTP- $\beta$ , holds promise for proangiogenic approaches, whereas the inhibition of PTPs acting as positive regulators of VEGFR2 signaling, such as SHP-2, can be hypothesized to have antiangiogenic effects.

Given the structural similarity of the active site of different PTPs, the issue of inhibitor specificity has been a concern. However, a series of recent studies have indicated the possibility of generating inhibitors with submicromolar potency that display significant specificity. In the context of endothelial biology, recent PTP- $\beta$  inhibitors developed at Novo Nordisk are of special importance (58). These compounds, generated by structure-based drug design, show a more than 100-fold selectivity for PTP- $\beta$  when compared with (for example) PTP-1B and RPTP- $\alpha$ . In addition to the issue of specificity, poor bioavailability has been a concern in the development of PTP inhibitors. This mainly derives from the fact that most PTP

inhibitors, developed as phospho-tyrosine mimics, display a high polarity. Prodrug strategies are therefore being tested to overcome this problem.

### CONCLUSION

During the last decade, improved understanding of the general aspects of PTP biology is being integrated in more detailed studies on the roles of PTPs in EC biology. Although clear progress has been made, it is also obvious that the present knowledge is still scarce and incomplete. It is envisioned that applications of modern methods, leading to endothelial-specific depletion of individual PTPs, will reveal yet unrecognized roles for PTPs in the context of vascular biology. Furthermore, specific PTP-inhibitors, useful for *in vivo* applications, will ultimately be required to evaluate the therapeutic potential of PTPs.

## NOTE ADDED IN PROOF

Concerning the regulation of PTPs, it has been shown that PTP-1B and possibly other PTPs are also regulated by sumo-lation (74). Inactivation of VE-PTP has confirmed important functions of this enzyme in ECs (60). Also, a DEP-1 monoclonal antibody has been described that also indicates a regulatory role of DEP-1 in EC biology (75). Finally, a second *DEP-1*-knockout mouse lacking an obvious vascular phenotype has been described (76).

## KEY POINTS

- PTPs constitute a structurally diverse, tightly regulated enzyme family with important regulatory roles in the control of vessel biology, particularly EC proliferation, migration, and adhesion, and capillary permeability.
- DEP-1 and SHP-1 act as negative regulators of VEGFR2 receptor-induced EC proliferation.
- PTP- $\beta$  and PTP- $\mu$  promote the VE-cadherin-mediated barrier function of ECs.

## Future Goals

- To continue a systematic determination of the expression and activity of different PTPs in ECs under various physiological and pathological conditions
- To continue analyses of the involvement of ROS-mediated PTP inhibition in EC signaling, with emphasis on signaling triggered by shear stress or hypoxia
- To explore the potential of PTP inhibition, and reactivation of oxidized PTPs, for pro- and antiangiogenic purposes

## Role of $\beta$ -Catenin in Endothelial Cell Function

Anna Cattelino\* and Stefan Liebner†

\*IFOM-Fondazione Istituto FIRC di Oncologia Molecolare, Milan, Italy;

†Institute of Neurology, University of Frankfurt, Germany

Originally, a homologue of the vertebrate  $\beta$ -catenin was identified as a segment polarity gene involved in the wingless pathway in *Drosophila melanogaster*. Because of the structural organization of the gene, it was named *armadillo* (ARM), showing several repeats of a 42-amino acid motif in its central region (ARM-repeats) flanked by N-terminal and C-terminal regulatory domains. Its vertebrate homologues,  $\beta$ -catenin and  $\gamma$ -catenin (also named *plakoglobin*), were first characterized as structural proteins involved in cell adhesion, linking the cytoplasmic tail of type 1 cadherins (E, N-, P-, VE-cadherin) via  $\alpha$ -catenin to the actin cytoskeleton. Although  $\beta$ -catenin is specific for classical cadherins of the adherens junction (AJ) complex,  $\gamma$ -catenin also associates with the desmosomal cadherins, desmocollin, and desmoglein, linking them via desmoplakin to the vimentin intermediate filament system. Due to its high sequence similarity to armadillo, a signaling function was also suggested for  $\beta$ -catenin and  $\gamma$ -catenin and was subsequently demonstrated by loss- and gain-of-function experiments in *Xenopus laevis*, leading to ventralized embryos and axis duplication, respectively (1). Furthermore, similar to the *wingless* growth factor in *Drosophila*, vertebrate Wnts, on binding to frizzled (Fz) receptors, stabilize cytoplasmic  $\beta$ -catenin or  $\gamma$ -catenin, leading to their activation in nuclear signaling. To accomplish this function,  $\beta$ -catenin interacts with HMG-box transcription factors of the lymphoid enhancer binding factor/ T-cell factor (Lef/TCF) family, which mediate DNA binding and thus enable the transactivating function of  $\beta$ -catenin.

The Wnt signaling pathway was initially characterized in development, where it was shown to be involved in processes as diverse as somitogenesis, and brain, limb, and vascular differentiation. In the adult, the Wnt-pathway seemed to be less important until it was shown that adenomatous polyposis coli (APC), a tumor suppressor gene, serves as a negative regulator of  $\beta$ -catenin stability and that a lack-of-function mutation of APC is responsible for familial adenomatous polyposis (FAP) (2). Affected patients show a predisposition for colon cancer due to increased  $\beta$ -catenin signaling. So far, increased  $\beta$ -catenin signaling has been demonstrated in various kinds

of tumors, such as mammary carcinoma, hair follicle tumors, gallbladder carcinoma, and neuroblastoma.

In addition to  $\beta$ - and  $\gamma$ -catenin, other armadillo family members have been identified in vertebrates, such as p120<sup>ctn</sup>, plakophilins, neural plakophilin-related armadillo protein (NPRAP/ $\delta$ -catenin), APC, SRP1, p0071, and smgGDS. The common ARM-repeat is believed to mediate protein-protein interaction similar to those of SH2- or ankyrin-domains in other proteins. Although all these proteins share the ARM-repeat as a structural motif in their core region, functionally, several subfamilies can be defined, underlining the involvement of ARM family proteins in diverse cellular processes.

### FROM ASCIDIANS TO HUMANS

The ability of unicellular organisms to communicate and share nutrients and information is considered the key molecular event for the evolution of multicellular organisms. Therefore, cell-to-cell adhesion structures such as AJs and  $\beta$ -catenin must have been evolved very early. In fact,  $\beta$ -catenin, and ARM family proteins in general, are highly conserved, and have been found in phylogenetically very distant species, from ascidians to humans.

The importance of Wnt signaling is underlined by the fact that mutations of this pathway have been shown to cause severe defects in numerous cell specification events during development, including formation of endomesoderm in *Caenorhabditis elegans*, sea urchins, and ascidians; segmentation in *Drosophila*; and dorsal-ventral axis formation in vertebrates. In a strict sense, Wnt signaling is limited to metazoan animals. It has been postulated that a single  $\beta$ -catenin gene fulfilled both adhesion and signaling functions in the last common ancestor of metazoans some 700 million years ago. The diploblastic Cnidaria (e.g., *Hydra*) possess genes encoding most of the Wnt pathway, including a Wnt growth factor, a Fz receptor,  $\beta$ -catenin, and Lef/TCF. The Wnt and Lef/TCF genes show interesting expression patterns during head formation in *Hydra*. In the sea cnidarian *Nematostella vectensis*,

$\beta$ -catenin is needed to specify the endoderm, indicating an evolutionarily ancient role for this protein in early pattern formation (3). Both a Wnt family member and a bona fide member of the Fz family have been identified in *Platyhelminthes* in *Desmosponges*, respectively. Proteins with the ARM repeats are also widespread and present in plants and yeast. However, no evidence for a Wnt growth factor has been obtained in any of these latter organisms.

The most divergent parts of the metazoan  $\beta$ -catenin proteins and other ARM family members are the terminal domains. Strikingly, each ARM repeat from cnidarian  $\beta$ -catenin aligns with its respective ARM repeat from mouse, suggesting a strong, phylogenetic conservation of each of these motifs.

Whereas  $\beta$ -catenin is represented by a single gene in most species, in the *C. elegans* genome three  $\beta$ -catenin genes – *hmp-2*, *bar-1*, and *wrm-1* – have been detected. Interestingly, one of their gene products (HMP-2) is dedicated to adhesion only, whereas BAR-1 and WRM-1 act in Wnt signaling. The biochemical and genetic functions of  $\beta$ -catenin have been most extensively studied in vertebrates (human, mouse, frog, zebrafish) and *Drosophila*.

Vertebrates have two Armadillo/ $\beta$ -catenin homologues,  $\beta$ -catenin and  $\gamma$ -catenin. Although the former remained remarkably conserved over most of metazoan evolution, the latter probably developed through a gene duplication of the bifunctional  $\beta$ -catenin, yielding the ancestor of  $\gamma$ -catenin. This duplication is probably attributable to one of the two genome duplications that occurred in the vertebrate branch 600 to 490 million years ago.  $\gamma$ -Catenin evolved relatively rapidly from the ancestral protein, giving rise to novel functions. Differences in  $\gamma$ -catenin's cellular sequestration, its accessibility for the protein degradation machinery, its affinity to Lef/TCF, and its level of transactivating ability, suggest that  $\gamma$ -catenin is unlikely to play a  $\beta$ -catenin-like role in the canonical Wnt signaling pathway. However,  $\gamma$ -catenin may indirectly modify or attenuate  $\beta$ -catenin-mediated Wnt signal-

ing. Interestingly, it has recently been reported that  $\beta$ -catenin and  $\gamma$ -catenin associate with distinct TCF-4 subdomains, causing opposite effects on TCF-4 DNA binding: Whereas  $\beta$ -catenin does not affect this binding,  $\gamma$ -catenin prevents it (4). Although its presumed ancestral role in Wnt signaling has been reduced or modified,  $\gamma$ -catenin has acquired a novel role in desmosomal adhesion.

### THE ROLE OF $\beta$ -CATENIN IN ADHERENS JUNCTIONS ORGANIZATION

$\beta$ -Catenin is a multifunctional protein known to interact with more than 20 different molecules (Figure 85.1). Similar to epithelial cells, endothelial cells (ECs) have specialized junctional regions that are functionally defined into AJs and tight junctions (TJs). However, in contrast to epithelial cells, endothelial junctions are less rigidly organized. Whereas in most epithelia TJs are located at the most apical side of the lateral plasma membrane, in the endothelium they are regularly intermingled with AJs along the lateral membrane.

As in epithelia, in endothelial AJs  $\beta$ -catenin acts as a bridge connecting cadherin C-termini to cytoplasmic proteins such as  $\alpha$ -catenin, which in turn couples the cadherin–catenin complex to the actin cytoskeleton (Figure 85.2, upper panel). The main endothelial cadherins are vascular endothelial (VE)-cadherin and neuronal (N)-cadherin. Only VE-cadherin is organized in AJs, whereas the role of N-cadherin remains elusive and is probably related to the interaction between the endothelium and perivascular pericytes. Like other cadherins, VE-cadherin mediates calcium ( $\text{Ca}^{2+}$ )-dependent, homophilic adhesion. Structural studies of  $\beta$ -catenin revealed that the ARM repeats are tightly packed and form a superhelix of helices, resulting in a compact structure that forms a binding interface for several interacting partners, including cadherins (5). Both  $\beta$ -catenin and its cognate  $\gamma$ -catenin bind to the distal region of the cadherin cytoplasmic tail in a highly conserved

Figure 85.1.  $\beta$ -Catenin structure and its main molecular interactors. Schematic drawing of  $\beta$ -catenin from its N- to C-terminus. The central region containing the ARM repeats is indicated together with the main Ser/Thr and Tyr phosphorylation sites. The diagram displays some interactions between  $\beta$ -catenin and proteins of the Wnt-pathway, showing also their appropriate binding sites.

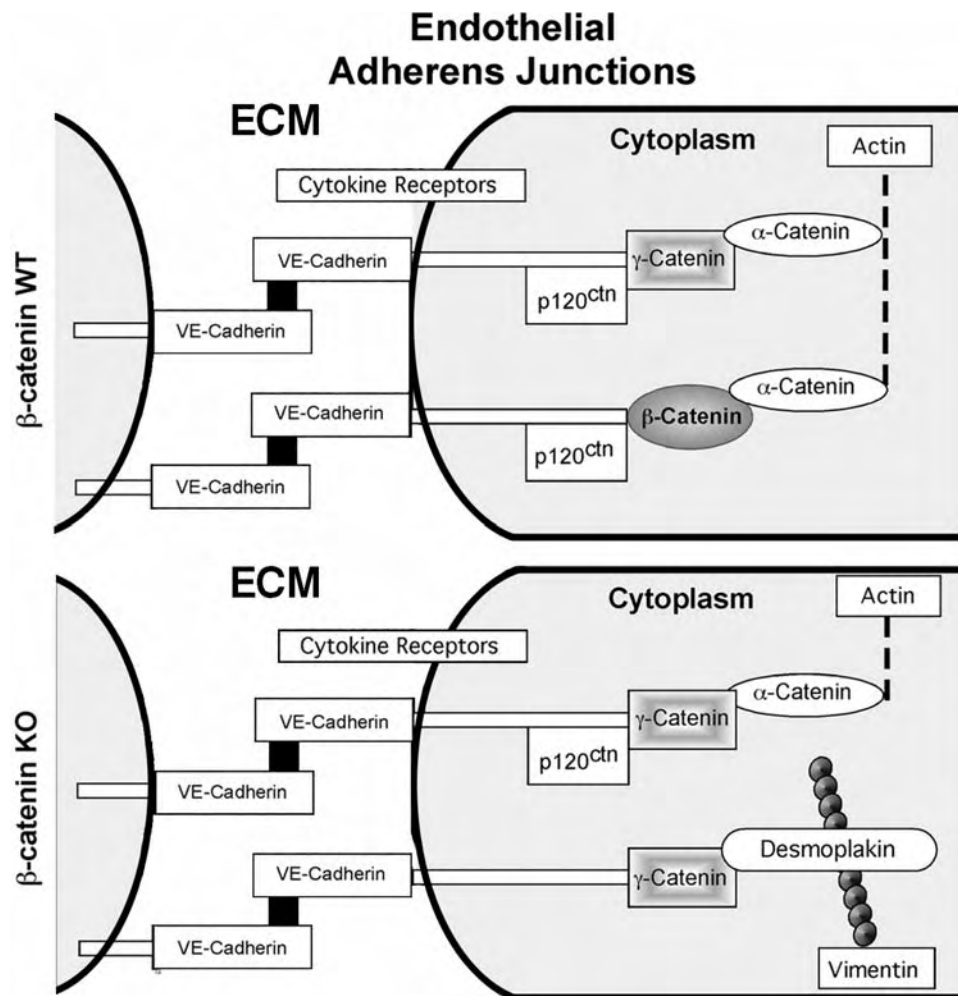

Figure 85.2. Schematic model of endothelial AJs and their modification in the absence of  $\beta$ -catenin. *Upper panel:* In the presence of  $\beta$ -catenin (WT),  $\alpha$ -catenin is normally expressed at cell–cell junctions and connects VE-cadherin/ $\beta$ -catenin or VE-cadherin/ $\gamma$ -catenin to the actin cytoskeleton. *Lower panel:* In the absence of  $\beta$ -catenin (KO), the decrease in  $\alpha$ -catenin is accompanied by an increase in desmoplakin, leading to a shift from  $\alpha$ -catenin and actin based AJs to desmoplakin- and vimentin-based *complexus adherens*.

region termed the “catenin binding domain.” Analysis of the cadherin– $\beta$ -catenin complex revealed that the cadherin cytoplasmic tail is unstructured in the absence of  $\beta$ -catenin and is sensitive to proteolytic degradation (6). Whereas the central arm region of  $\beta$ -catenin is involved in cadherin binding, the amino-terminal region is involved in  $\alpha$ -catenin interaction (see Figure 85.1).

By modulating the interaction of cadherins and the actin cytoskeleton, catenins – and in particular  $\beta$ -catenin – have a well-established role in the regulation of cadherin-mediated adhesion. In fact, in a variety of cellular contexts, cadherin mutants, lacking the ability to bind catenins, exhibit a compromised ability to mediate tight cell–cell adhesion. In line with this observation is that phosphorylation of the cadherin–catenin complex at tyrosine residues increases vascular permeability. Histamine and vascular endothelial growth factor (VEGF), which are potent inducers of vascular permeability, led to tyrosine phosphorylation of both cadherins and

catenins in long-term confluent EC cultures, causing loosening of cell-to-cell contacts and dissociation of VE-cadherin from the actin cytoskeleton (7). It has been suggested that platelet-endothelial cell adhesion molecule (PECAM)-1 can interact with  $\beta$ -catenin and may function as a reservoir for, and modulator of, tyrosine phosphorylated  $\beta$ -catenin under conditions in which junctions are destabilized (8,9).

At the membrane,  $\beta$ -catenin may participate also in other signaling pathways. For example, it has been demonstrated that  $\beta$ -catenin is required for VE-cadherin–mediated attenuation of VEGF-induced phosphorylation of the VEGF receptor 2 (VEGFR2), thus participating in contact inhibition of ECs (7).

In epithelial cells, E-cadherin associates with actin and assembles into AJs, whereas the desmosomal cadherins desmocollin and desmoglein interact with intermediate filament-binding proteins and are organized into desmosomes. As opposed to most epithelial cells, ECs lack classical

desmosomes. Nevertheless some types of ECs have *complexus adherens* formed by VE-cadherin linked to plakoglobin or p0071, which mediate the anchorage to vimentin intermediate filaments through desmoplakin (Figure 85.2, lower panel).

As described later in detail, the stabilized cytoplasmic pool of  $\beta$ -catenin can enter the nucleus and activate transcription of various target genes. This raises the important question of whether  $\beta$ -catenin interaction with cadherins at the cell membrane may limit its nuclear translocation. Because in the nucleus  $\beta$ -catenin upregulates the transcription of important cell cycle regulators, such as cyclin D1 and c-myc, this model would account, at least in part, for contact inhibition of cell growth mediated by cadherin–catenin clustering in confluent cells. However, this model might not explain all observations. For example, in sparse cells,  $\beta$ -catenin remains associated with cadherins, but cells are not inhibited in growth. This could be explained by the fact that even small, and in some cases undetectable, levels of  $\beta$ -catenin may be sufficient to achieve transcriptional activation. Alternatively, there is evidence for the presence of functionally distinct and conformationally different pools of  $\beta$ -catenin that are involved in adhesion and signaling respectively, and which might be regulated independently (10).

### $\beta$ -CATENIN IN WNT SIGNALING

Our current knowledge of Wnt signaling refers mostly to the so-called *canonical* pathway, depending on  $\beta$ -catenin as a bipartite nuclear transcription factor with Lef/TCF. However, so far two other, less well characterized (*noncanonical*) signaling events downstream of Fz receptors involving disheveled (Dvl) but not  $\beta$ -catenin have been demonstrated: (a) the planar cell polarity pathway (PCP), which is important for the planar organization of epithelial cells; and (b) a  $\text{Ca}^{2+}$ -dependent pathway controlling dorso-ventral axis formation in vertebrates (11).

In ECs, Wnt signaling has not yet been systematically characterized. However, some evidence points to a role for the canonical as well as the noncanonical pathway in vascular development, regression, and pathology. Here we give a general state-of-the-art description of the current understanding of Wnt signaling from the outside-in, starting with the Wnt growth factors. If available, the known situation in ECs is indicated specifically.

Wnt growth factors/morphogens are secreted, strongly glycosylated, and palmitoylated proteins. Currently 19 different vertebrate Wnt genes have been identified and their signaling roles have been characterized only in few cases. Wnt-1 is the best characterized family member, known to induce the canonical pathway via  $\beta$ -catenin, but induction of canonical signaling also has been demonstrated by Wnt-2, Wnt-3, Wnt-3a, Wnt-7a, Wnt-7b, and Wnt-8a. In contrast, Wnt-4, Wnt-5a, and Wnt-11 failed to induce or poorly induced  $\beta$ -catenin-dependent target gene expression, but inhibited canonical signaling via a  $\text{Ca}^{2+}$ -dependent pathway.

Fetal vessels of the murine placenta were shown to express Wnt-2, and vessels of the mouse embryonic yolk sac were tested positive for Wnt-5a and Wnt-10b (12). In vitro, expression of Wnt-7a and -10b could be demonstrated in mouse brain microvascular ECs (MBMECs) and Wnt-5a in human umbilical vein ECs (HUVECs) (13). Furthermore, overexpression of Wnt-4 in a mouse model for the human chromosomal duplication of Wnt-4 leads to lower and altered testicular vascularization (14).

The members of the Fz family of serpentine receptors are seven-transmembrane spanning proteins with a cysteine-rich domain (CRD) in their extracellular N-terminus. The CRD domain serves to bind the Wnt growth factors and is therefore essential for mediating Wnt signaling. Fz-receptors alone are not sufficient to activate the canonical signaling pathway. This can be achieved only by a complex of Fz with the coreceptors LRP-5/-6/*arrow*. Indeed, inherited diseases in humans and gene deletion of LRP-5 in mice demonstrate that LRP-5 is involved and necessary for canonical Wnt signaling. The receptor complex activates, through a yet unknown mechanism, the intracellular phosphoprotein disheveled (Dvl) and further downstream signaling events (Figure 85.3).

Several inhibitors/modulators of the Wnt signaling pathway exist; these act at the extracellular and membrane level of the signaling cascade. Probably the best described are the gene products of the soluble Fz-related proteins (sFRP). Although their name refers to their structural and functional relation to Fz-receptors, they are lacking the transmembrane domain of the latter and, except for the CRD domain, they share no structural homology with the FZ receptors. As a consequence, sFRP are released in the extracellular space, sequestering Wnt growth factors and thereby inhibiting or modulating their availability for signaling. In ECs, first evidence points to a major inhibiting role of FrzA in angiogenesis during vascular development and neovascularization (15).

In addition to the sequestration of Wnts, the receptor complex of Fz and LRPs can be functionally inactivated by the extracellular, cysteine-rich, protein Dickkopf (Dkk), which directly binds to LRP. In addition to this, Dkk interacts with the membrane receptor Kremen, resulting in the reduction of LRP at the membrane.

Although endothelial expression of Fz receptors has not been explored in detail, expression of Fz-1, Fz-2, Fz-3, and Fz-5 has been reported (13). As various sites of the vascular tree have been investigated and different species have been used, the present results may support a site-specific expression of Fz receptors in the vascular tree. This would also help to explain why the knockout for Fz-5 shows vascular defects only in the yolk sac and in the placenta, whereas other sites of vascular development in the embryo proper seem to be unaffected. In the absence of Wnts, free cytoplasmic  $\beta$ -catenin is readily degraded in the 26S proteasome system, involving axin (Axn), APC, glycogen synthase kinase 3 $\beta$  (GSK3 $\beta$ ), and casein kinase 1 (CK1), which form a functional complex to target  $\beta$ -catenin for ubiquitination and subsequent degradation (Figure 85.3). Axn has mostly been considered to be a

Figure 85.3. Schematic representation of the canonical Wnt-pathway. (A) Inactive state. In the absence of a Wnt signal, or when Wnt is sequestered by a soluble inhibitor such as sFRP from binding to the Fz receptor, LRP, and Norrin (Nor), the free pool of  $\beta$ -catenin (which is not bound to VE-cadherin) is phosphorylated by the APC/GSK3 $\beta$ /Axn/CK1 destruction complex. The Ser/Thr phosphorylated  $\beta$ -catenin is recognized by  $\beta$ -TrCP, ubiquitinated (Ub) and rapidly degraded in the proteasomal degradation complex. Consequently, Lef/TCF acts in concert with Groucho and HDAC as a transcriptional inhibitor. (B) Active state. When Wnt binds to Fz and LRP, Dvl becomes phosphorylated, recruiting and inactivating GSK3 $\beta$  in a complex with PAR-1, GBP, and CK1, and thereby inhibiting  $\beta$ -catenin phosphorylation and degradation. Active  $\beta$ -catenin then enters the nucleus, binds to Lef/TCF, CBP, Lgs/Bcl9, and Pygo, and leads to target gene transcription. GBP, GSK3 $\beta$ -binding protein; CBP, CREB binding protein. In an alternative, or parallel activation pathway, GSK3 $\beta$  is inhibited through the PI3K/AKT pathway following Tyr growth factor receptor stimulation.

scaffolding protein, providing the basis for complex formation of  $\beta$ -catenin with APC, CK1, and GSK3 $\beta$ . In a first step,  $\beta$ -catenin receives an N-terminal priming phosphorylation by CK1 in residue Ser45; subsequently GSK3 $\beta$  becomes phosphorylated by CK1 and in turn phosphorylates  $\beta$ -catenin in residues Thr41, Ser37, and Ser33. The N-terminal phosphorylated  $\beta$ -catenin can now be recognized by the E3 ubiquitin ligase  $\beta$ -transducin repeat-containing protein ( $\beta$ TrCP), and the ubiquitinated protein is degraded.

The initial steps in the Wnt signaling cascade are the least understood. After binding of the Wnt growth factor to the Fz-LRP-receptor complex, the intracellular phospho-protein Dvl is activated at the Fz-C-terminus by a yet-unknown mechanism. Dvl in turn inactivates the  $\beta$ -catenin destruction pathway, which is probably achieved through the destabilization of the destruction complex. Evidence points to a fundamen-

tal role of Axn in this scenario, in which, upon stimulation of the Wnt-pathway, Axn is relocated to the plasma membrane by active Dvl, leading to its dephosphorylation and inactivation. As a consequence, the  $\beta$ -catenin degradation complex cannot form, thus shifting the equilibrium toward the free  $\beta$ -catenin pool. In addition to the previously mentioned proteins involved in the Wnt pathway, many others have been identified as modulators and regulators of the Wnt-cascade; these are described in more complete detail at <http://www.stanford.edu/~rnusse/wntwindow.html> (see Figure 85.3).

To accomplish its transactivating function,  $\beta$ -catenin must enter the nucleus and interact with members of the Lef/TCF transcription factors in order to bind to DNA. The  $\beta$ -catenin protein itself contains no nuclear localization signal (NLS) and is dependent neither on the nuclear transport proteins

importin- $\beta$ / $\beta$ -karyopherin, nor on Lef/TCF, which contains an NLS. Instead  $\beta$ -catenin can bind directly to the nuclear pore and becomes, by a yet-unknown mechanism, translocated to the nucleus, a process proven to require GTP. Recently, the two  $\beta$ -catenin binding proteins legless (Lgs/Bcl9) and pygopus (Pygo) have been implicated in the shuttling of  $\beta$ -catenin to the nucleus (16). In particular, Lgs/Bcl9, which serves as a linker between Pygo and  $\beta$ -catenin, is essential for the translocation process. However, the point at which GTP is needed and the manner by which the protein complex accomplishes the translocation remains to be elucidated. In the nucleus,  $\beta$ -catenin forms a complex with the HMG-box transcription factors Lef/TCF and, in vertebrates, with other coactivators (such as p300/CBP) to initiate target gene transcription (see Figure 85.3). More than 200 genes have been described as targets for Wnt/ $\beta$ -catenin signaling so far (for a complete list see <http://www.stanford.edu/~rnusse/wntwindow.html>). The most relevant for the vascular system are summarized in Table 85-1. These include regulators of proliferation, such as cyclin D1 and c-myc, extracellular matrix (ECM) components and remodeling factors, and proangiogenic cytokines such as VEGF. Wnt signaling ceases if the transcription factor complex disaggregates and  $\beta$ -catenin is guided out of the nucleus by Axn and APC, which both contain nuclear export sequences (NES); this leads to cytoplasmic destruction of  $\beta$ -catenin.

Not all cells undergo canonical Wnt signaling even in the presence of Wnt growth factors. As known so far, ECs show a strictly time- and site-restricted pattern of Wnt signaling, as revealed by BAT-gal reporter mice for the canonical pathway. These mice show activation of the Wnt pathway exclusively in vessels growing into the brain during embryonic and early postnatal development (17). This might reflect the missing expression of specific Fz-receptors on some ECs, but also the nuclear disposition to respond to pathway activation. When

Wnt signaling is inactive, Lef/TCF still can bind to the specific DNA sites, but acts under these circumstances as an inhibitory transcription factor together with the transcriptional repressor groucho, which specifically activates histone deacetylase (HDAC). Moreover, several lines of evidence point to the existence of different molecules (e.g.,  $\beta$ -catenin interacting protein, ICAT) binding  $\beta$ -catenin and preventing its interaction with Lef/TCF. Also, other nuclear proteins such as Reptin52 (repressor of Pontin52) inhibit  $\beta$ -catenin-dependent transactivation. Most of our understanding of  $\beta$ -catenin-dependent transcriptional regulation has been acquired in vitro, making it difficult to predict the specific situation in vivo. Furthermore, it is impossible to extrapolate from the current state of knowledge on ECs, owing to a lack of data on the expression of core pathway genes in the endothelium.

### NONCANONICAL WNT SIGNALING

Besides the canonical signaling pathway involving  $\beta$ -catenin, certain Wnt growth factors and Fz receptors elicit a downstream signaling through Fz and Dvl on Rho, Rac, c-Jun N-terminal kinase (JNK), and  $Ca^{2+}$ . This type of Wnt signaling was first identified in *Drosophila* as PCP, shown to be crucial for the polarization of some epithelia within a plane perpendicular to the apical-basal axis of the cell (11). The core genes involved in PCP are Fz and Dsh, which overlap with the canonical Wnt signaling pathway; in addition to these common genes, PCP requires also the atypical cadherin Flamingo/Starry night (Fmi) and the putative transmembrane protein Strabismus/Van Gogh (Stbm), as well as the negative regulator Prickl (Pk). In mammals, the best understood process in which PCP is known to be involved is the organization of the hair cells in the inner ear.

In vertebrates, in addition to the PCP pathway a second, noncanonical pathway has been identified, and is shown to signal through protein kinase C (PKC). Also, this pathway is dependent on Fz and Dvl, but acts through PKC and an upregulation of the intracellular  $Ca^{2+}$ -level, leading to stimulated cell migration.

Although striking functional similarity exists, it is not yet clear if the PCP and the PKC pathways are homologous. In vivo and in vitro, it has been demonstrated that at least Wnt-5a predominantly signals through the PKC pathway. This is of particular interest, since mice deficient for Fz-5, which is a designated Wnt-5a receptor, show major defects in vascularization and blood vessel remodeling in the yolk sac (18). This result is in line with the observation that in a reporter mouse for canonical Wnt signaling, no signaling events could be found in yolk-sac blood vessels (17; A. Cattelino, unpublished observations). Instead, the alterations of blood vessels found in mouse embryos bearing an endothelial conditional deletion of  $\beta$ -catenin might be due to the lack of the protein at the plasma membrane (19). As for canonical Wnt signaling, the exact function of the noncanonical pathway in ECs is still to be determined.

## CROSS-TALK WITH OTHER SIGNALING PATHWAYS

As mentioned earlier, Wnt signaling is known to play a crucial role during invertebrate and vertebrate embryogenesis. Obviously, aside from this pathway, many other pathways such as transforming growth factor (TGF)- $\beta$ , hedgehog, nuclear factor (NF)- $\kappa$ B, Notch, and others are necessary for proper embryonic development. During the last several years, an increasing amount of information has become available on the cross-talk of pathways previously thought to be distinct. In particular, the Wnt pathway was shown to be tightly connected with the TGF- $\beta$  pathway, sharing also common target genes, which are cooperatively regulated (20,21). The interaction of the two pathways has been demonstrated at the membrane, cytoplasmic, and nuclear level. Although bound to E-cadherin at the plasma membrane,  $\beta$ -catenin can interact with the TGF- $\beta$  receptor II and, upon TGF- $\beta$  stimulation, elicit downstream signaling interacting with the transcription factors smad3 and smad4 (22). Although in ECs no direct interaction of Wnt- and TGF- $\beta$  signaling has been demonstrated yet, evidence for cooperation between the two pathways during endothelial-mesenchymal transformation (EMT) derives from the endothelial-specific knockout for  $\beta$ -catenin (23).

The hedgehog growth factors, Sonic hedgehog (Shh), Indian hedgehog (Ihh), and Desert hedgehog (Dhh) activate downstream signaling through the receptors patched (Ptc) and smoothened (Smo) and activate the Gli transcription factors through protein kinase A (PKA), CK1, and GSK3 $\beta$  (24). The hedgehog pathway shares the proteins CK1, GSK3 $\beta$ , and  $\beta$ -TrCP with the Wnt pathway. Considerable cross-talk between these pathways has been demonstrated in the differentiation of the sebaceous lineage in the mammalian epidermis, in the differentiation of neuronal progenitor cells in the subventricular zone, in the response of diencephalic cells to dorsal Wnt-stimuli, and in somitogenesis. In the endothelium, Hedgehog signaling was shown to be involved in yolk-sac angiogenesis and arterial endothelial differentiation (25,26). Interestingly, VEGF was demonstrated to be a direct target of the Shh/Gli/pathway, suggesting a possible cooperative regulation of VEGF by Wnt and Shh signaling, although direct evidence for this is still lacking.

Furthermore, in somitogenesis, Wnt signaling induced by Wnt-3a acts upstream of the Notch pathway. Notch1 is an integral membrane receptor, which binds to the transmembrane ligands Delta and Jagged. The Notch/Delta pathway is mainly involved in cell fate decisions during development. Notch and Wnt signaling have been shown to interact at several levels: at the plasma membrane through the binding of Wnts to Notch, at the cytoplasmic level through an interaction of Dvl with the intracellular domain of Notch, and in the cytoplasm through an interaction between presenilin-1 with  $\beta$ -catenin (27). Although considerable evidence indicates that Notch and Wnt signaling play an important role in vascular development and differentiation of ECs, notably in EMT dur-

ing heart valve development (23,28), it still remains to be elucidated whether and to what extent the two pathways interact in the endothelium.

It should be mentioned that the Wnt/ $\beta$ -catenin pathway also interacts with the NF- $\kappa$ B pathway of inflammatory cytokines. The first evidence for cross-talk between the two pathways came from the observation that the phosphorylation motif on  $\beta$ -catenin, which is recognized by GSK3 $\beta$ , is identical to a motif in the inhibitor of NF- $\kappa$ B (I $\kappa$ B). Recently, it was shown that the phosphoinositide 3-kinase (PI3K)/AKT/I $\kappa$ B pathway can simultaneously activate NF- $\kappa$ B and  $\beta$ -catenin/Lef/TCF signaling in colon carcinoma cell lines, leading to the cooperative upregulation of angiogenic genes like VEGF-A, -B, and -C and urokinase-type plasminogen activator (u-PA), therefore facilitating tumor angiogenesis and growth (29). Because it is known that AKT inactivates GSK3 $\beta$ , it might be possible that every signaling pathway involving an activation of PI3K/AKT could participate in the activation of  $\beta$ -catenin signaling (see Figure 85.3).

Finally, tyrosine phosphorylated  $\beta$ -catenin also associates with the receptor tyrosine kinase ErbB2 and with the receptor tyrosine phosphatase LAR in human melanoma cell lines. If ErbB2 is blocked pharmacologically,  $\beta$ -catenin-dependent signaling in the nucleus is decreased, leading to reduced cell motility (30,31).

(A complete and interactive overview of the connection map of Wnt/ $\beta$ -catenin signaling is available at *Science* magazine's website, Signal Transduction Knowledge Environment: [http://stke.sciencemag.org/cgi/cm/stkecm;CMP\\_5533](http://stke.sciencemag.org/cgi/cm/stkecm;CMP_5533).)

## EFFECT ON ENDOTHELIAL CELL PHENOTYPE

In some cell types, Wnt signaling has been associated with an inhibition of apoptosis, an increase in proliferation, and cell cycle progression. Nevertheless, its role in ECs is still poorly understood.

Induction of canonical Wnt signal through stimulation with Wnt-1 leads to proliferation of HUVECs (32). In the same cellular model, it has recently been reported that the stabilization of  $\beta$ -catenin is related to an induction of angiogenesis in Matrigel, both in vitro and in vivo, and this effect is mediated by the transcriptional activation of VEGF by  $\beta$ -catenin in ECs (33). Another study demonstrated an accumulation of cytosolic  $\beta$ -catenin in ECs during neovascularization after myocardial infarction (34). Also the overexpression of a non-degradable form of  $\beta$ -catenin caused enhanced cell growth, suggesting a role for the canonical Wnt signaling in EC growth and morphogenesis (35,36). A list of mice transgenic for Wnt pathway components and exhibiting a vascular phenotype is given in Table 85.2.

The role of  $\beta$ -catenin in the endothelium has been investigated by the conditional inactivation of  $\beta$ -catenin using the Cre/loxP system (19). Mice with floxed  $\beta$ -catenin were crossed with transgenic mice expressing Cre recombinase under the control of the endothelial-specific *Tie2* promoter.

**Table 85-2: Mutation or Deletion of Wnt Components in Mice Exhibiting a Vascular Phenotype**

Surprisingly, ECs do not require  $\beta$ -catenin for the early phases of vasculogenesis and angiogenesis, but do require the molecule for correct vascular patterning and maintenance of vascular integrity at later stages of development. The absence of  $\beta$ -catenin in ECs leads to lethality at midgestation, due to an altered vasculature in the head, vitelline umbilical vessels, placental defects, and frequent hemorrhages (19). Moreover, in many regions, the vascular lumen is irregular, with lacunae and bifurcations and fluid extravasation in the pericardial cavity. In EC lines derived from mutant mouse embryos, we found a different organization of intercellular junctions with a decrease in  $\alpha$ -catenin in favor of desmoplakin (19). These molecular changes lead to an overall alteration of the balance between the recruitment of  $\alpha$ -catenin and desmoplakin in endothelial intercellular junctions, with a decrease of the number of strong, actin-based AJs to weak, more dynamic, vimentin-based *complexus adherens* (see Figure 85.2). Interestingly, this junctional reorganization correlates with an increase in paracellular permeability measured in vitro. Although desmoplakin and vimentin are present in other types of endothelia, *complexus adherens* are preferentially observed in lymphatics, where junctions are relatively weak, permitting a dynamic passage of cells and solutes. It has consistently been reported previously that  $\beta$ -catenin is reduced in lymphatics as compared with vascular endothelium (37). We hypothesize that the weakness of cell-to-cell junctions can account for the high occurrence of vascular dilatation and hemorrhages found in vivo in mutant embryos.

It is not clear to what extent the phenotype observed in the absence of  $\beta$ -catenin can be attributed to a block of Wnt signaling rather than to an alteration of AJ organization. By using a transgenic reporter mouse strain for canonical Wnt

signaling (17), only a transient and localized activation of  $\beta$ -catenin transcriptional activity in the developing vasculature was observed (S. Liebner, unpublished observations).

Interestingly, the conditional deletion of  $\beta$ -catenin in the endothelium resulted not only in a severe defect in placental development and organization and remodeling of blood vessels in the yolk sac and perineural plexus, but also in the heart, revealing in particular a lack of heart cushion formation. The heart cushion evolves during ontogeny from an acellular structure called the cardiac jelly, which consists of ECM components; it is located around the atrioventricular canal and between endo- and myocardium. The cardiac jelly is overrun by cells derived from the endocardium, which undergo EMT during this process, leading to the formation of the heart cushion and, later in development, to the valves. EMT does not occur in endocardial cells or ECs lacking  $\beta$ -catenin, explaining the observed phenotype in the heart. Heart EMT has been shown to depend upon several pathways, including TGF- $\beta$ , bone morphogenic protein (BMP), VEGF, and Notch, raising the intriguing possibility that the Wnt pathway was also involved. The use of a reporter mouse for canonical Wnt signaling (17) showed that cells do, in fact, undergo Wnt signaling during EMT (23). Further support for an involvement of the Wnt signaling pathway in heart EMT came from work in zebrafish, demonstrating that a loss-of-function mutation of APC leads to increased  $\beta$ -catenin signaling and excessive cellularity of heart cushions. Although it seems confirmed that canonical Wnt signaling is involved in endocardial EMT, it remains to be elucidated at which time point during EMT the Wnt cascade becomes active, and whether and how cooperation with other pathways is necessary for proper heart cushion formation.

The involvement of Wnt signaling in endothelial EMT might have further implications. It was reported previously that, during the formation of arteriosclerotic plaques, the proliferation of vascular smooth muscle cells (VSMCs) is dependent on canonical Wnt signaling, which cooperates with the NF- $\kappa$ B pathway (Table 85.3) (38). Furthermore, embryonic as well as adult ECs can transform into VSMCs through an EMT-related process. Collectively, these data suggest a role for  $\beta$ -catenin in the etiology of the arteriosclerotic phenotype, acting on ECs and VSMCs.

## CLINICAL AND THERAPEUTIC IMPLICATIONS

As already mentioned, the Wnt pathway regulates proliferation, migration, differentiation, and apoptosis in a variety of cell types. Therefore, it is not surprising that the development of numerous organ systems depends on Wnt signaling, including the central nervous system, the female reproductive tract, mammary glands, kidney, limb, placenta, hair, and teeth. Wnt signaling also has been implicated in cardiogenesis and in directing hematopoietic cell fate. Uncontrolled Wnt signaling, resulting from mutations in  $\beta$ -catenin, inactivation of  $\beta$ -catenin phosphorylation, or the destruction complex has been shown to directly cause cell transformation and lead to different types of tumors. Increased Wnt signaling may also play a role in the pathologies of rheumatoid arthritis and Alzheimer disease. An increasing body of evidence also indicates that the Wnt pathway plays an important role in the correct development and in the pathological state of the vascular system. During human embryonic development, when vessels proliferate, nuclear and/or cytoplasmic  $\beta$ -catenin can be detected in placental villus capillaries, fetal capillaries (particularly in the brain), and in arteries and veins, whereas cells of the normal adult vasculature rarely if ever accumulate  $\beta$ -catenin in the cytoplasm or nucleus (13). On the other hand, cytoplasmic and nuclear  $\beta$ -catenin is frequently observed during vessel remodeling in disease states, such as myocardial infarction, where it correlates with neovascularization and increased endothelial proliferation.

$\beta$ -catenin accumulation has been associated with angiogenesis in cancer, in particular in the brain, both in a mouse model of gliomas, and in neovascular ECs of human glioblastoma multiforme, medulloblastoma, and other tumors of the central nervous system (39). Several human genetically inherited diseases appear to be caused by mutations in Wnt signaling (see Table 85-2). Chromosomal duplication of Wnt-4 in humans, for example, leads to an intersex phenotype (14). Consistent with this clinical finding, Wnt-4 transgenic mice have abnormal testicular vasculature, and their testosterone synthesis is inhibited. Although the mechanism of action of Wnt-4 in this system is not clear yet, it is likely that Wnt-4 acts as an anti-male factor by interfering with  $\beta$ -catenin functions.

Loss of function mutations in Fz-4 and the Wnt coreceptor LRP-5 are linked to familiar exudative retinopathy (FEVR), an inherited disorder of the retinal vasculature in which peripheral capillaries fail to grow, resulting in compensatory neovascularization, leakage, bleeding, and scarring, leading ultimately to blindness. Recently Norrin, a new ligand for Fz/LRP complex, has been identified and shown to be mutated in the hereditary ocular Norrie syndrome, an X-linked retinal dysplasia that presents similar features to FEVR (40). Wnt signaling has been implicated in the maintenance and self-renewal of various pluripotent stem and progenitor cells. Whether Wnt signaling also may play a role in the regulation of EC progenitors, as well as in endothelial specification in arterial, venous, and lymphatic endothelium is an important unsolved issue.

Given the deleterious consequences of uncontrolled Wnt/ $\beta$ -catenin signaling in humans, it is no surprise that a considerable number of inhibitors of this pathway are in consideration or under development for clinical studies. Candidate approaches include small-molecule inhibitors that block the interaction of  $\beta$ -catenin with TCF or CBP, as well as small interfering RNAs (siRNAs) and the therapeutic use of antibodies against Wnts.

## KEY POINTS

- The current understanding of  $\beta$ -catenin in the endothelium points to a fundamental role in vascular development and maintenance.
- In particular,  $\beta$ -catenin is crucial for the organization, regulation, and stability of AJ architecture, and for the control of vascular permeability.
- Growing evidence suggests an important involvement of  $\beta$ -catenin as a key player in the Wnt pathway, in normal vascular development, as well as in the pathological state of the endothelium.
- Although a challenging task, the growing scientific interest in  $\beta$ -catenin and Wnt signaling, mirrored by the numerous recent publications, fosters a rapid increase of our knowledge.

## Future Goals

- To determine which components of the Wnt pathway become active in the endothelium during vasculo- and angiogenesis, remodeling, and pathological neovascularization, and whereas and when these events take place
- To determine if Wnt signaling in the endothelium create cross-talk with other signaling pathways in order to exert a site-specific effect on vascular differentiation
- To determine whether insights into Wnt signaling accumulated over the past 20 years might be translated into tangible therapies for some of the diseases discussed here

## Nuclear Factor- $\kappa$ B Signaling in Endothelium

Kaiser M. Bijli and Arshad Rahman

*School of Medicine and Dentistry, University of Rochester, New York*

Nuclear factor (NF)- $\kappa$ B is perhaps the most intensely studied eukaryotic transcription factor, mainly because of its pivotal role in controlling varied biological effects ranging from inflammatory-, immune-, and stress-induced responses to cell fate decisions such as proliferation, differentiation, tumorigenesis, and apoptosis. The mammalian NF- $\kappa$ B family consists of five members: RelA (p65), RelB, c-Rel, NF- $\kappa$ B1 (p50 and its precursor p105), and NF- $\kappa$ B2 (p52 and its precursor p100). These proteins share a conserved N-terminal 300-amino acid Rel homology domain (RHD) that contains a nuclear localization signal (NLS) and is responsible for dimerization, sequence-specific DNA binding, and interaction with inhibitory I $\kappa$ B proteins (Figure 86.1A). A critical feature of RelA, RelB, and c-Rel that distinguishes them from p50 and p52 is the presence of a transactivation domain (TAD) within the carboxy-terminal region of these proteins (Figure 86.1A).

The diverse biological effects of NF- $\kappa$ B are mediated, in part, by the ability of NF- $\kappa$ B proteins to form numerous homo- and heterodimers that differentially regulate target genes (1). For example, p50 and p52 homodimers serve as repressors, whereas dimers containing RelA or c-Rel are transcriptional activators. Heterodimers of RelB with either p50 or p52 display a greater regulatory flexibility, and function both as an activator and a repressor (1,2). Accumulating evidence suggests that activation of specific dimers is mediated by distinct upstream signaling pathways, which in turn are activated in a stimulus- and cell-specific manner (2,3). This chapter begins with an overview of the current state of knowledge about NF- $\kappa$ B, and then discusses the role for this fascinating transcription factor in the endothelium.

### HISTORY

NF- $\kappa$ B was first identified in 1986 by Sen and Baltimore (4) as part of an investigation that involved identification of proteins that bind to the immunoglobulin (Ig) heavy chain and  $\kappa$ -light chain enhancers in the nucleus of B cells. The nuclear factor found to be necessary for transcription of immunoglobulin

$\kappa$ -light chain in B cells was therefore named NF- $\kappa$ B (nuclear factor- $\kappa$ B). The inability to detect NF- $\kappa$ B by gel-shift assay in other cell types, including pre-B cells, led to the initial belief that NF- $\kappa$ B was restricted only to mature B cells. Later, identification of I $\kappa$ B proteins revealed the cytoplasmic retention of inactive NF- $\kappa$ B, explaining the absence of DNA-binding of NF- $\kappa$ B in other cell types. In 1991, the cloning of I $\kappa$ B $\alpha$  (5) showed that I $\kappa$ B $\alpha$  retains NF- $\kappa$ B in the cytoplasm through masking of the nuclear localization sequences. Further studies showed that stimulation of cells by a wide variety of agonists results in phosphorylation of I $\kappa$ B $\alpha$  (at Ser32 and Ser36), which then leads to proteasome-mediated degradation of I $\kappa$ B $\alpha$ , with release and nuclear translocation of NF- $\kappa$ B. The realization that protein synthesis-independent inducibility of NF- $\kappa$ B and its ability to translocate to the nucleus may allow rapid transmission of messages to their nuclear targets generated intense interest in this transcription factor. Investigations during the past 10 years have led to the discovery of I $\kappa$ B kinase (IKK) complex, alternate and classical pathways of NF- $\kappa$ B activation, and the post-translational modifications (phosphorylation and acetylation) of NF- $\kappa$ B subunits as well as histones surrounding the NF- $\kappa$ B target genes and their roles in nuclear regulation of NF- $\kappa$ B. These studies have established NF- $\kappa$ B as a central regulator of a wide spectrum of genes with critical functions in cellular physiology and pathology (Tables 86-1 and 86-2).

### THE CLASSICAL AND ALTERNATE PATHWAYS OF NF- $\kappa$ B ACTIVATION

NF- $\kappa$ B dimers are mostly sequestered in the cytoplasm by I $\kappa$ Bs, a family of inhibitory proteins that mask the NLS by virtue of their interaction with the RHD. These proteins, which include I $\kappa$ B $\alpha$ , I $\kappa$ B $\beta$ , BCL3, I $\kappa$ B $\epsilon$ , I $\kappa$ B $\gamma$  (Figure 86.1B), and the precursor proteins NF- $\kappa$ B2/p100 and NF- $\kappa$ B1/p105 (Figure 86.1A), contain five to seven ankyrin repeats that mediate association with the RHD. The presence of these repeats allows the precursors (NF- $\kappa$ B2/p100 and NF- $\kappa$ B1/p105) also to function

**A. NF- $\kappa$ B/Rel Family**

**B. I $\kappa$ B Family**

**C. IKK proteins**

**D. Processing of p100 to p52**

Figure 86.1. Schematic representation of NF- $\kappa$ B family members and their regulators. The number of amino acids in each protein is indicated on the right. (A) The N-terminal region (~300 amino acids) of NF- $\kappa$ B proteins has a Rel homology domain (RHD). The RHD contains a DNA binding domain and dimerization/I $\kappa$ B $\alpha$  binding domains, and a nuclear localization sequence (NLS) located on the C-terminal side of the RHD. In addition to an RHD, RelA, RelB, and c-Rel contain transactivation domains (TAD). The proteins p105 and p100 contain ankyrin repeats (*circles*) and a glycine-rich region (GRR). The ankyrin repeats render these proteins inactive, and the GRR is required for cotranslational processing of p105 to p50 and post-translational processing of p100 to p52 as indicated in (D). (B) Members of the I $\kappa$ B family contain ankyrin repeats (*circles*) that mediate their interaction with the RHD. Phosphorylation of indicated serines in these proteins is required for their degradation by the proteasome. Bcl3, by virtue of possessing ankyrin repeats, is frequently considered a member of the I $\kappa$ B family. However, Bcl3 also contains a TAD, and therefore complexes resulting from the interaction of Bcl3 with either p50 or p52 are transcriptionally active. (C) All three members of the IKK complex possess a leucine zipper (LZ) motif. Of these, only IKK $\alpha$  and IKK $\beta$  possess kinase and helix-loop-helix (HLH) domains. Phosphorylation of indicated serines is required for the activation of IKK $\alpha$  and IKK $\beta$ . IKK $\gamma$  (NEMO), which is unrelated to IKK $\alpha$  and IKK $\beta$ , possesses a zinc finger domain (Z), coiled-coil domains, and two  $\alpha$ -helical ( $\alpha$ ) domains. These domains are considered to mediate the regulatory function of NEMO and its association with NEMO binding domain (NBD) of IKK. (D) Processing of p100 to p52. The processing is initiated by phosphorylation of two serine residues at the C-terminus of p100 by IKK $\alpha$ , secondary to its activation by NF- $\kappa$ B inducing kinase (NIK). The presumed site of the cleavage for p100 (amino acid 447) is indicated. The sequences in GRR prevent further progression of the 26S proteasome, which digests the C-terminal half of p100 following its ubiquitination.

**Table 86-1: Phenotypes of IKK/I $\kappa$ B/NF- $\kappa$ B Knockout Mice**

Targeted Gene (Refs.)	Dominant Phenotypes
<i>RelA/p65</i> (59)	Embryonic lethality, liver cell apoptosis, granulopoiesis
<i>c-Rel</i> (60)	Defective in lymphocyte proliferation, humoral immunity, and IL-2 expression
<i>RelB</i> (61)	Lethal; multiple organ inflammation
<i>NF-<math>\kappa</math> B1/p50</i> (62)	Multiple deficiencies in B-cell function
<i>NF-<math>\kappa</math> B2/p52</i> (63)	Altered architecture of spleen and lymph nodes, deficiency in B cell function
<i>I<math>\kappa</math>B<math>\alpha</math></i> (64)	Lethal; skin defects, atrophic spleen and thymus, granulopoiesis
<i>I<math>\kappa</math>B<math>\epsilon</math></i> (65)	Reduction of CD44-CD25 <sup>+</sup> T-cell subspecies, enhanced Ig isotype switching, and cytokine synthesis
<i>Bcl-3</i> (66)	Altered microarchitecture of secondary lymphoid organs
<i>IKK<math>\alpha</math></i> (67)	Limb and skin abnormalities
<i>IKK<math>\beta</math></i> (8)	Embryonic lethality; severe liver damage due to apoptosis
<i>IKK<math>\gamma</math>/NEMO</i> (68)	Embryonic lethality; severe liver damage due to apoptosis
<i>NIK</i> (69, 70)	Impaired processing of p100 to p52, altered architecture of peripheral lymphoid organs

as I $\kappa$ Bs and retain their partners, the Rel proteins, in the cytoplasm (1,2). Crystallographic studies have revealed that I $\kappa$ B proteins mask only the NLS of RelA/p65, whereas the NLS of p50 remain accessible (1,6). The accessibility of the NLS on p50 and the presence of a nuclear export signal (NES) on I $\kappa$ B $\alpha$  and RelA/p65 allow constant shuttling of I $\kappa$ B $\alpha$ /NF- $\kappa$ B complexes between the nucleus and the cytoplasm. Despite this dynamic shuttling, the steady-state localization of I $\kappa$ B $\alpha$ /NF- $\kappa$ B is in the cytosol (1,7). Following signal-induced degradation of I $\kappa$ B $\alpha$ , which results in the removal of I $\kappa$ B NES and unmasking of RelA/p65 NLS, the steady-state localization of NF- $\kappa$ B is altered in favor of the nucleus.

Degradation of I $\kappa$ B is initiated through phosphorylation of I $\kappa$ Bs on specific serine residues by a macromolecular cytoplasmic IKK complex composed of the catalytic subunits IKK $\alpha$  and IKK $\beta$  and the regulatory subunit NEMO/IKK $\gamma$  (Figure 86.1C) (7). Phosphorylation marks I $\kappa$ Bs for polyubiquitination by the E3-SCF $\beta$ -TrCP ubiquitin ligase, which in turn targets them to degradation by the 26 S-proteasome (1,2). Degradation of I $\kappa$ B results in translocation of the released NF- $\kappa$ B dimer to the nucleus, where it activates transcription following its binding to the  $\kappa$ B-enhancer consensus sequences (5'-GGGRNYYYCC-3', where R is a purine, Y is a pyrimidine,

**Table 86-2: Some Diseases Associated with NF- $\kappa$ B**

Atherosclerosis
Rheumatoid arthritis
Inflammatory bowel disease
Asthma
Systemic inflammatory response syndrome
Ischemia–reperfusion injury
Cancer

and N is any nucleotide) in the promoter region of target genes.

There are two major signaling pathways by which extracellular stimuli mediate I $\kappa$ B degradation–dependent translocation of NF- $\kappa$ B dimers to the nucleus. In the classical NF- $\kappa$ B signaling pathway, the key event is the activation of IKK $\beta$  induced by proinflammatory cytokines and pathogen-associated molecular patterns (PAMPs) following engagement of receptors belonging to the tumor necrosis factor (TNF) receptor (TNFR) and Toll-like receptor (TLR)-interleukin-1 receptor (IL-1R) superfamilies, respectively (Figure 86.2A). Activated IKK $\beta$  (in association with IKK $\alpha$  and IKK $\gamma$ ) catalyzes the phosphorylation of I $\kappa$ Bs on two N-terminal serine residues (at sites equivalent to Ser32 and Ser36 of I $\kappa$ B $\alpha$ , and Ser19 and Ser23 of I $\kappa$ B $\beta$ ), polyubiquitination (at sites equivalent to Lys21 and Lys22 of I $\kappa$ B $\alpha$ ), and subsequent degradation by the 26 S-proteasome. The liberated NF- $\kappa$ B dimers (generally the prototypical heterodimer p50-p65/RelA in this pathway) undergo nuclear translocation and DNA binding to activate the transcription of genes involved in innate immunity and inflammatory responses (1,2,7). It should be noted that activated IKK $\alpha$  also can phosphorylate I $\kappa$ Bs; however, biochemical and genetic studies indicate that IKK $\beta$  is the dominant kinase involved in the phosphorylation of I $\kappa$ B proteins and, thus, is a crucial regulator of the classical NF- $\kappa$ B pathway (8,9).

The recently described alternative NF- $\kappa$ B signaling pathway has provided a second evolutionarily conserved mechanism of NF- $\kappa$ B activation. This pathway is unique in that it does not require participation of IKK $\beta$  and IKK $\gamma$  and is strictly dependent on IKK $\alpha$  (Figure 86.2B). The IKK $\alpha$  homodimers selectively phosphorylate the two C-terminal serines of NF- $\kappa$ B2/p100 associated with RelB (2,3) (Figure 86.1D). The phosphorylation of these sites is essential for p100 processing to p52. Thus, processing of p100 releases a subset of transcriptionally active NF- $\kappa$ B dimers, consisting mainly of p52 and RelB (3,10). Processing of p52 also is dependent on ubiquitination and proteasomal degradation of p100 (11). However, unlike complete degradation of I $\kappa$ Bs, the phosphorylation-dependent ubiquitination of p100 leads only to degradation of its inhibitory C-terminal half. This releases the p52 polypeptide containing the N-terminal RHD associated with RelB, and

Figure 86.2. The classical and alternative pathway of NF- $\kappa$ B activation. (A) The classical pathway is activated by a host of stimuli including viruses, proinflammatory cytokines, antigen receptors Toll-like receptors (TLR), and G-protein-coupled receptors (GPCR). This pathway is mediated by IKK $\beta$ , which catalyzes the phosphorylation of I $\kappa$ B $\alpha$  and leads to its ubiquitination and degradation. The released NF- $\kappa$ B translocates to the nucleus and activates expression of multiple inflammatory and innate immune genes. (B) The alternative pathway is mediated by IKK $\alpha$  following its activation by NIK in response to cytokines such as  $LT\beta R$ , BAFF, and CD40L. Activation of this pathway leads to phosphorylation and processing of p100, generating p52:RelB heterodimers. Following nuclear translocation, p52:RelB activates the genes mainly involved in the development and maintenance of secondary lymphoid organs. BAFF, B-cell-activating factor; BLC, B-lymphocyte chemoattractant; ELC, Epstein-Barr virus-induced molecule-1 ligand CC chemokine; GlyCAM, glycosylation-dependent cell adhesion molecule;  $LT\beta R$ , lymphotoxin- $\beta$  receptor; PNA, peripheral lymph node addressin; SLC, secondary lymphoid tissue chemokine; SDF-1, stromal cell-derived factor-1.

the p52-RelB heterodimer translocates to the nucleus, where it activates the transcription of genes involved in the development and maintenance of lymphoid organs (2).

**REGULATION OF I $\kappa$ B KINASE: THE POINT OF CONVERGENCE IN SIGNALING TO NF- $\kappa$ B**

Activation of IKK is the central event in the mechanism of NF- $\kappa$ B activation. (One possible exception is the casein kinase 2 [CK2], which has been shown to mediate ultraviolet [UV]-

induced NF- $\kappa$ B activation by catalyzing the phosphorylation of I $\kappa$ B $\alpha$  at a cluster of C-terminal sites [12]). The majority of extracellular signals causing activation of NF- $\kappa$ B converge on this high-molecular-weight kinase IKK complex, which is composed of at least three subunits: IKK $\alpha$ , IKK $\beta$ , and IKK $\gamma$  (Figure 86.1C). The IKK $\alpha$  and IKK $\beta$  are the catalytic subunits and share 52% overall amino-acid sequence identity in their primary structures and 65% identity in their catalytic domains (7). The characteristic features of these kinases include an N-terminal kinase domain, a C-terminal helix-loop-helix (HLH) domain, and leucine zipper (LZ) domain (Figure 86.1C). The

HLH domain is required for full IKK $\beta$  activity, because deletion mutants lacking this domain possess diminished kinase activity following overexpression or stimulation (1,7). IKK $\alpha$  and IKK $\beta$  dimerization depends on a leucine zipper domain, which is therefore required for kinase activity (1,7). Unlike IKK $\alpha$  and IKK $\beta$ , IKK $\gamma$  (also termed NEMO, or NF- $\kappa$ B essential modifier) has no catalytic activity but plays a critical regulatory role in protein-protein interaction by virtue of its long stretches of coiled-coil sequence and C-terminal leucine zipper domain. Gene targeting experiments in mice have shown that the IKK subunits are differentially required for NF- $\kappa$ B activation, depending on the stimulus and the cellular context (1,2,7) (Figures 86.2A and 86.2B).

Activation of the IKK complex involves the phosphorylation of two serine residues in the activation loop within the kinase domain of IKK $\alpha$  (Ser 176 and Ser 180) or IKK $\beta$  (Ser 177 and Ser 181) (Figure 86.1C). IKK $\beta$  also is phosphorylated at multiple serines in the C-terminal of the HLH motif, most likely through autophosphorylation following its activation. Deletion mutants lacking the C-terminal serine-rich segment show normal activation upon challenge with TNF- $\alpha$ , but remain active for longer periods. This suggests that autophosphorylation or *trans*-autophosphorylation of IKK $\beta$  may be a negative regulatory mechanism (1).

The molecular mechanisms by which signaling from cell surface receptors lead to phosphorylation and thereby activation of IKK are still poorly understood. Among the multiple upstream kinases suggested to act as IKK kinases, most have failed to yield the expected results in knockout mice. NF- $\kappa$ B inducing kinase (NIK), a critical component of alternative pathway of NF- $\kappa$ B signaling provides the strongest proof of being an upstream IKK kinase. NIK, a mitogen-activated protein kinase kinase kinase (MAP3K) family member, directly phosphorylates and activates IKK $\alpha$  following activation of the alternative pathway through select members of the TNFR family including lymphotoxin  $\beta$  receptor (LT $\beta$ R) and B cell-activating factor receptor (BAFFR) (Figure 86.2B) (1,2,11). Despite the reports that NIK associates with IKK $\beta$  and NEMO, and thus participates in classical signaling pathway (11–13), the phenotype of *NIK*<sup>-/-</sup> mice, namely severe deficiency in lymph node development, is consistent with NIK functioning only in the alternative pathway. These findings have led to the prevailing view that each receptor system utilizes a distinct set of adaptor molecules and signaling enzymes to construct a unique pathway that mediates IKK activation in a signal- and cell-specific manner.

## REGULATION OF NUCLEAR FACTOR- $\kappa$ B TRANSCRIPTIONAL ACTIVITY

### Role of RelA Phosphorylation

Apart from I $\kappa$ B $\alpha$  degradation and nuclear translocation of NF- $\kappa$ B, the transcriptional activity of NF- $\kappa$ B also is regulated by post-translational modifications, particularly phosphorylation and acetylation (14,15). Studies have shown that phos-

Figure 86.3. RelA phosphorylation and acetylation sites. (A) RelA phosphorylation sites. The phosphorylation sites in RelA include serines 276 and 311 in RHD, and serines 529 and 536 in TAD. These phosphorylation sites are targeted by multiple kinases following activation by distinct stimuli as indicated. (B) RelA acetylation sites. The acetylation sites in RelA include lysines 122/123, 218/221, and 310. These acetylation sites regulate distinct functions of RelA. The DNA-binding affinity of RelA to  $\kappa$ B enhancer is increased upon acetylation (*ac*) of Lys221 by p300 or CREB-binding protein (CBP), and simultaneous acetylation of Lys218 prevents the association of RelA with I $\kappa$ B $\alpha$ . Acetylation of Lys310 is required for full transcriptional activity but has no effect on the DNA binding and I $\kappa$ B $\alpha$  assembly. Acetylation of Lys122 and Lys123 by p300/CBP- and p300/CBP-associated factor reduces the transcriptional activity of RelA by interfering with its binding to  $\kappa$ B enhancer.

phorylation of RelA/p65 at serine 276 and 311 in the RHD or serine 529 and 536 in the TAD increases the transcriptional capacity of NF- $\kappa$ B in the nucleus (14,15). Moreover, phosphorylation of RelA also decreases its affinity for its negative regulator, I $\kappa$ B $\alpha$  (14,15). Unlike I $\kappa$ B $\alpha$  phosphorylation, the RelA phosphorylation site and the kinase involved vary in a stimulus- and cell type-specific manner (14,15). For example, phosphorylation of RelA at Ser 276 following lipopolysaccharide (LPS) challenge is mediated by the catalytic subunit of protein kinase A (PKA<sub>c</sub>), whereas TNF- $\alpha$ -induced phosphorylation at this residue is catalyzed by mitogen- and stress-activated kinase (MSK)-1 (Figure 86.3A). Interestingly, PKA<sub>c</sub> phosphorylates RelA in the cytoplasm, whereas MSK1 functions in the nucleus. TNF- $\alpha$  also induces phosphorylation of serine 311 within the RHD of RelA, and this phosphorylation requires the participation of yet another kinase, protein kinase (PKC)- $\zeta$  (Figure 86.3). Phosphorylation of serine 529 is mediated by CK2, whereas serine 536 is phosphorylated by IKK $\alpha$  and IKK $\beta$ . Other kinases that phosphorylate RelA include glycogen synthase kinase (GSK)-3 $\beta$ ,

phosphoinositide 3-kinase (PI3K), and NF- $\kappa$ B-activating kinase (NAK; also known as TANK binding kinase [TBK]-1, and TRAF2-associated kinase [T2K]) (14,15). Recently, an additional phosphorylation event at serine 254 in the RHD has been implicated in the regulation of nuclear NF- $\kappa$ B function (Figure 86.3A) (16). This phosphorylation facilitates the binding of peptidyl-prolyl isomerase PIN-1 to the Thr254-Pro motif in RelA. The binding of PIN-1 by this mechanism inhibits RelA binding to  $\kappa$ B and enhances RelA nuclear localization and protein stability. The biological significance of PIN-1 regulation of RelA was evidenced by the findings that PIN-1-deficient mice and cells are refractory to NF- $\kappa$ B activation by cytokine signals and that the RelA-T254A mutant that cannot act as a PIN-1 substrate is extremely unstable and fails to transactivate NF- $\kappa$ B target genes (16). Given the multiplicity of phosphorylation sites and the kinases involved, it is likely that concurrent phosphorylation of multiple sites has cooperative functional effects on the transcriptional activity of NF- $\kappa$ B.

Phosphorylation of RelA also serves an important function in promoting the recruitment of various transcriptional coactivators. Studies have established that phosphorylation of RelA at serine 276 by PKA<sub>c</sub>, MSK1, or serine 311 by PKC- $\zeta$ , facilitates the interaction of cAMP-response-element-binding protein (CREB)-binding protein (CBP) and p300 to RelA (1,14). The RelA-CBP complex effectively displaces the transcriptionally repressive histone deacetylase complexes, especially p50-histone deacetylase (HDAC)-1 complexes that frequently occupy  $\kappa$ B enhancers of target genes under unstimulated conditions (1,14,15). It remains unclear whether phosphorylation of serines 529 and 536 within TAD also promotes association of RelA with CBP and p300. Nevertheless, it appears likely that the phosphorylation of RelA at these residues facilitates its interaction with other components of basal transcription machinery, thereby controlling the transcriptional responses.

### Role of RelA Acetylation

Acetylation of RelA, in addition to phosphorylation, is implicated in regulating the nuclear function of NF- $\kappa$ B. Acetylation of RelA by CBP/p300 prolongs NF- $\kappa$ B DNA binding, and this effect is the result of impaired interaction of acetylated RelA with  $\kappa$ B $\alpha$  (14,17). Deacetylation of RelA by HDAC-1, -2, and -3 restores the interaction with  $\kappa$ B $\alpha$ , which results in a rapid chromosomal-region maintenance 1 (CRMI)-dependent nuclear export of the NF- $\kappa$ B complex, thereby terminating the transcriptional response. It has been suggested that the reversible acetylation of RelA serves as an intramolecular switch critical for determining the strength and duration of the NF- $\kappa$ B response (17). Although the sites of acetylation in RelA have been identified (14), they seem to have differential effects on NF- $\kappa$ B transcriptional activity (Figure 86.3B). Although acetylation at Lys 221 stabilizes RelA binding to the  $\kappa$ B site and interferes with  $\kappa$ B binding, acetylation at Lys 310 enhances transcriptional activity without influencing binding to DNA or  $\kappa$ B (14). In contrast to

these transcriptional-promoting effects, acetylation of RelA by both CBP and p300/CBP-associated factor (PCAF) on Lys 122/123 was shown to exert a negative effect on RelA transcriptional activity by reducing its binding to the  $\kappa$ B site (14).

### Role of Histone Acetylation and Deacetylation

Acetylation and deacetylation of histone, like RelA, has important implications in gene regulation (14,18). Histone proteins (histone-H1, -H2, -H3, and -H4), which form nucleosomes associated with DNA, are the fundamental components of chromatin. In general, histones in the transcriptionally active segments of chromatin are acetylated, whereas deacetylated forms are concentrated in the transcriptionally repressed regions of chromatin. Acetylation by histone acetyltransferase (HAT) of specific lysine residues on the N-terminal tail of core histones is associated with uncoiling of the DNA that renders the promoters accessible for binding to RNA polymerase II and other cofactors. Conversely, histone deacetylation by HDAC represses gene transcription by promoting DNA winding, thereby limiting promoter accessibility to transcription factors. Chromatin remodeling associated with the acetylation or /deacetylation of histone plays an important role in regulating NF- $\kappa$ B responses. For example, acetylation of histone-H3 and -H4 is associated with increased NF- $\kappa$ B signaling and activation of genes encoding interleukin (IL)-6, IL-8,  $\kappa$ B $\alpha$ , manganese superoxide dismutase (MnSOD), granulocyte macrophage colony stimulating factor (GM-CSF), macrophage inflammatory protein 1 $\alpha$  (MIP1 $\alpha$ ), and MIP2 (19,20).

In contrast, histone deacetylation renders the cells refractory to NF- $\kappa$ B activation. Inhibition of NF- $\kappa$ B-dependent gene expression by glucocorticoids is primarily ascribed to the ability of these hormones to induce histone deacetylation by facilitating recruitment of HDACs or by direct inhibition of HAT activity (14,21). Other mechanisms involving induction of  $\kappa$ B $\alpha$  synthesis and interaction between glucocorticoid receptor and NF- $\kappa$ B subunits are believed to contribute to the inhibitory effects of glucocorticoids (22). Similarly, the function of p50 homodimers in repressing NF- $\kappa$ B-dependent genes is consistent with its ability to recruit the HDAC1-containing complex (1,14). Recruitment of HDAC1 by this mechanism leads to histone deacetylation in regions bound by p50 homodimers. These findings highlight the importance of chromatin remodeling secondary to the acetylation or deacetylation of histones in controlling the expression of NF- $\kappa$ B target genes.

### Role of Histone Phosphorylation

Recent studies have identified phosphorylation at serine 10 of histone H3 as a novel regulatory step in the mechanism of NF- $\kappa$ B activation (23,24). The kinase implicated in this phosphorylation is nuclear IKK $\alpha$ . However, it remains to be determined whether IKK $\alpha$  catalyzes histone phosphorylation directly or requires the participation of a downstream kinase.

Chromatin immunoprecipitation (ChIP) studies showed that stimulation of cells with TNF- $\alpha$  resulted in the recruitment of IKK $\alpha$  to the *IL-6* promoter (23,24). The kinetics of IKK $\alpha$  recruitment was similar to phosphorylation of histone H3 at serine 10. Consistent with the observation that several inflammatory stimuli that induce phosphorylation at serine 10 also promote acetylation at lysine 14 of histone H3, CBP also was recruited to the promoter. RelA appears to have a key nucleating role in the assembly of this complex and in recruiting the IKK $\alpha$  and CBP components to the promoter. The sequence of events include translocation of IKK $\alpha$  to the nucleus, where it interacts with CBP and in conjunction with RelA; these proteins are collectively recruited to NF- $\kappa$ B-responsive promoters and mediate the cytokine-induced phosphorylation and subsequent acetylation of specific residues in histone H3. These studies define a new nuclear function of IKK $\alpha$  in facilitating the recruitment of CBP in a histone H3/serine-10 phosphorylation-dependent manner, which in turn catalyzes the acetylation of histone H3, and thereby promotes transcription of NF- $\kappa$ B target genes. However, given that activation of *TNF- $\alpha$*  and *MIP-1 $\alpha$*  genes occur independently of histone H3 phosphorylation, this does not appear to be a general mechanism in controlling NF- $\kappa$ B-dependent responses (25).

#### NUCLEAR FACTOR- $\kappa$ B AS AN IMPORTANT REGULATOR OF ENDOTHELIAL CELL RESPONSES

By serving as sensors and transducers of signals within the circulatory microenvironment, endothelial cells (ECs) play an integral role in several physiological processes, including the trafficking of cells and nutrients, the control of vasomotor tone, the maintenance of blood fluidity, the regulation of permeability, and the formation of new blood vessels (26). The components of the NF- $\kappa$ B/I $\kappa$ B system, as well as the IKK complex (as described earlier), are present in ECs. The role of NF- $\kappa$ B in ECs has been well documented, especially in the context of inflammation, apoptosis, and angiogenesis. The following section summarizes the key events regulated by NF- $\kappa$ B in ECs; it should, however, be noted that most studies (unless otherwise stated) are based on cell cultures.

#### Expression of Adhesion Molecules

Adhesion of leukocytes to the endothelium is a crucial step in transendothelial trafficking of leukocytes during inflammation and involves the sequential activation of adhesive proteins on ECs and their counter-receptors on the surface of leukocytes (27). Leukocyte adhesion begins with “capture” and “rolling” of leukocytes along the vessel wall, followed by firm adhesion to the endothelium. Rolling is mediated by binding of endothelial-bound E-selectin and P-selectin to their respective ligands on the surface of leukocytes, whereas firm adhesion involves the binding of vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 to

very late activation antigen (VLA)-4 and  $\beta$ 2-integrins, respectively (27–30).

Previous studies have shown that activation of NF- $\kappa$ B is essential for the expression of these adhesion molecules in response to a variety of proinflammatory mediators including thrombin, TNF- $\alpha$ , IL-1 $\beta$ , LPS, phorbol esters (PMA), vascular endothelial growth factor (VEGF), interferon (IFN)- $\gamma$ , and shear stress. Promoter analyses have revealed that the number and sequence of NF- $\kappa$ B sites, as well as the DNA sequence context in which they are present, are different in these genes. While the *E-selectin* and *P-selectin* promoters each contains three NF- $\kappa$ B sites, the promoters of *ICAM-1* and *VCAM-1* are characterized by the presence of one and two functional NF- $\kappa$ B sites, respectively (31,32). Consistent with sequence variation in the NF- $\kappa$ B sites, these promoters are occupied by different NF- $\kappa$ B dimers following TNF- $\alpha$  or thrombin challenge of ECs (31,33,34). For example, NF- $\kappa$ B sites in *E-selectin* and *VCAM-1* promoters are preferentially bound by p50/RelA heterodimer, whereas *ICAM-1* promoter is predominantly activated by RelA homodimer. Moreover, NF- $\kappa$ B sites in these genes either overlap with or are in close proximity to the binding sites for other transcription factors. These features are consistent with the findings that NF- $\kappa$ B despite being essential for the expression of these adhesion molecules, requires the cooperation of other transcription factors for maximal response, and it also explains why these genes have distinct patterns of expression in ECs (31,32). Thus, the activation of these genes is influenced by the number and arrangement of NF- $\kappa$ B binding sites as well as by codependency on other transcription factors, such as CAAT enhancer binding protein (C/EBP) in case of *ICAM-1*, interferon response factor (IRF) in case of *VCAM-1*, and high-mobility group-1[Y] (HMG-1[Y]) in case of *E-selectin* (31,32).

Unlike the requirement of NF- $\kappa$ B for the expression of human as well as murine *ICAM-1*, *VCAM-1*, and *E-selectin* genes, only the murine *P-selectin* gene relies on NF- $\kappa$ B activation. Murine *P-selectin* – but not the human analogue – contains two tandem  $\kappa$ B elements and a reverse-oriented  $\kappa$ B site. As expected, TNF- $\alpha$  or LPS stimulation results in *P-selectin* expression in murine, but not human ECs. Agonist-mediated induction of the murine promoter is mediated by the binding of NF- $\kappa$ B p50/p65 heterodimers and p65 homodimers to the two tandem  $\kappa$ B elements, and binding of p65 homodimers to the reverse-oriented  $\kappa$ B site (35).

#### Expression of Chemokines

Chemokines are small (8–14 kDa), structurally related molecules that interact with seven-transmembrane-spanning G-protein-coupled receptors and, in conjunction with cell adhesion molecules, play an important role in the process of leukocyte recruitment and activation at sites of inflammation (36). IL-8 and monocyte chemoattractant protein (MCP)-1 are among the chemokines predominantly induced in ECs following activation of NF- $\kappa$ B by inflammatory mediators such as TNF- $\alpha$ , IL-1 $\beta$ , LPS, VEGF, and thrombin (36). IL-8, a

potent activator and chemoattractant of neutrophils belonging to the CXC chemokine family, was the first chemokine to be characterized. The promoter of *IL-8* is reminiscent of *ICAM-1* in that the NF- $\kappa$ B site is in close proximity to the C/EBP binding site and therefore requires the cooperation of C/EBP and NF- $\kappa$ B for maximal IL-8 induction by TNF- $\alpha$ . MCP-1, the prototype C-C chemokine, is a major regulator of monocyte and T-lymphocyte recruitment to sites of inflammation. In addition, MCP-1 is associated with many biological and disease processes, such as atherosclerosis and angiogenesis (36). Studies by Denk and colleagues (37) used retroviral-mediated expression of transdominant (TD) mutants of I $\kappa$ B $\alpha$ , I $\kappa$ B $\beta$ , or I $\kappa$ B $\epsilon$  and dominant negative (DN) versions of I $\kappa$ B kinases (IKK)- $\alpha$  or - $\beta$ , as well as constitutively active version of IKK $\beta$  to address the role of NF- $\kappa$ B in mediating the expression of *IL-8* and *MCP-1* in ECs. Using this approach, expression of TD-I $\kappa$ B $\alpha$ , -I $\kappa$ B $\beta$ , or -I $\kappa$ B $\epsilon$  inhibited the activation of NF- $\kappa$ B and expression of *IL-8* and *MCP-1* in response to TNF- $\alpha$  challenge of ECs. Expression of DN-IKK $\beta$  prevented TNF- $\alpha$ -mediated upregulation, whereas DN-IKK $\alpha$  showed only partial inhibition of expression of these molecules. In related experiments, expression of a constitutively active IKK $\beta$  mutant induced the expression of *IL-8* and *MCP-1* in the absence of TNF- $\alpha$  challenge. In another study, selective inhibition of NF- $\kappa$ B by adenoviral-mediated transfer of I $\kappa$ B $\alpha$  impaired the expression of these chemokines as well as transendothelial migration of leukocytes by shear flow (38). Similarly, overexpression of RelA/p65 in ECs resulted in the transactivation of the *MCP-1* promoter. Collectively, these data indicate that the IKK/I $\kappa$ B/NF- $\kappa$ B pathway is not only necessary but also sufficient to induce *IL-8* and *MCP-1* expression in activated endothelium.

### Expression of Cytokines

Cytokines are small secreted proteins that mediate and regulate immunity, inflammation, and hematopoiesis. The ability of ECs to produce cytokines, in addition to adhesion molecules and chemokines, further underscores the critical involvement of these cells in orchestrating the inflammatory processes. ECs, upon stimulation with such diverse stimuli as hypoxia and bacterial infection, produce a wide range of cytokines including TNF- $\alpha$ , IL-1, IL-5, IL-6, IL-18; and colony stimulating factor (CSF); granulocyte CSF (G-CSF); macrophage CSF (M-CSF); and GM-CSF (39,40). Activation of NF- $\kappa$ B is a critical determinant of the expression of these cytokines (40–42). TNF- $\alpha$  and IL-1 thus released or secreted by infiltrating inflammatory cells can act on ECs in an autocrine or paracrine manner to induce the expression of several of these cytokines, in addition to the adhesion molecules and chemokines, which act in concert to promote adhesion and the migration of leukocytes across endothelial barrier. Recent studies have demonstrated that the adhesive interactions between ECs and recruited inflammatory cells also can signal the activation of NF- $\kappa$ B in ECs, resulting in the secondary secretion of inflammatory cytokines and further induction of adhesion molecules

(43,44), thus creating a positive feedback loop that may serve to amplify the inflammatory responses. Indeed, cross-talk between inflammatory cells and the endothelium may be critical to the development of chronic inflammatory states. EC-derived cytokines have been implicated in cellular chemotaxis and recruitment, hematopoiesis, coagulation, and acute-phase protein synthesis. The involvement of these processes in the maturation of an inflammatory and reparative state suggest a crucial role for endothelial-derived cytokines in several disease states such as atherosclerosis, graft rejection, asthma, vasculitis, and sepsis. These findings highlight the importance of NF- $\kappa$ B in controlling the production of multifunctional cytokines from activated endothelium.

### Expression of Antiapoptotic Genes

Several lines of evidence have suggested that NF- $\kappa$ B is an important cell survival factor. Targeted deletion of the *RelA/p65* gene in mice leads to embryonic lethality at 15 to 16 days of gestation, concomitant with a massive degeneration of the liver by programmed cell death or apoptosis (45). In addition, cells with functionally inactive NF- $\kappa$ B undergo apoptosis when challenged with a host of stimuli (46). The antiapoptotic effect of NF- $\kappa$ B primarily is ascribed to its ability to activate the transcription of antiapoptotic genes. In ECs, NF- $\kappa$ B has been shown to induce the expression of antiapoptotic molecules such as Bcl2 homologue A1, the zinc finger protein A20, cellular inhibitor of apoptosis 1 and 2 (c-IAP1 and c-IAP2), TNF receptor-associated factor (TRAF)-1, and MnSOD (46,47). Interestingly, Levkau and colleagues (48) showed that NF- $\kappa$ B is activated soon after growth factor deprivation, and that the ability of an EC to maintain this NF- $\kappa$ B activity determines whether it survives or undergoes apoptosis. These studies demonstrate that surviving viable cells exhibit increased NF- $\kappa$ B activity, whereas in apoptotic cells, NF- $\kappa$ B is inactivated by a mechanism involving caspase-mediated cleavage of RelA/p65. This cleavage results in the loss of the carboxy-terminal transactivation domain, rendering RelA/p65 transcriptionally incompetent. The truncated RelA/p65 thus generated promotes apoptosis by acting as a dominant negative inhibitor of NF- $\kappa$ B, whereas the intact RelA/p65 rescues cells from undergoing apoptosis. The caspase-dependent cleavage of RelA/p65 may serve as a regulatory switch that commits the cells to apoptosis by turning off the antiapoptotic genes (48). However, it remains to be determined whether this is a general mechanism of apoptosis or whether its activation is stimulus- and/or cell-type-specific.

Intriguingly, NF- $\kappa$ B activation also is implicated in facilitating EC apoptosis. Recently, Chandrasekhar and colleagues (49) reported that IL-18 induces apoptosis of human cardiac microvascular ECs (HCMECs) by promoting the expression of proapoptotic genes *Fas* and *FasL* in a manner dependent on NF- $\kappa$ B activation. Interfering with NF- $\kappa$ B signaling by siRNA-mediated knockdown of RelA/p65 or expression of dominant negative IKK $\alpha$  or IKK $\beta$  mutant inhibited IL-18-induced HCMEC death (49). The paradoxical effects of NF- $\kappa$ B

on apoptosis raises the following important questions: (a) What determines whether the activated NF- $\kappa$ B mediates expression of pro- or antiapoptotic genes and thereby promotes or inhibits EC apoptosis? and (b) Are there specific adaptor proteins that are activated in a stimulus-specific manner to link NF- $\kappa$ B to pro- or antiapoptotic pathways?

### Expression of Proangiogenic Genes

Clues for a role of NF- $\kappa$ B in angiogenesis were provided by the protective effect of NF- $\kappa$ B on EC apoptosis. Evidence indicating the involvement NF- $\kappa$ B in mediating angiogenesis came from the finding that the expression of several proangiogenic genes depends on the activation of NF- $\kappa$ B. Studies by Yoshida and colleagues (50) showed that expression of proangiogenic factors, IL-8 and VEGF, and their receptors was associated with activation of NF- $\kappa$ B following TNF- $\alpha$  challenge of human microvascular ECs. Neutralizing IL-8 and VEGF by their respective antibodies inhibited TNF- $\alpha$ -induced tubular morphogenesis in vascular ECs plated onto collagen gels as well as neovascularization in the rabbit cornea *in vivo*. Another important angiogenic mediator induced by TNF- $\alpha$  in an NF- $\kappa$ B-dependent manner is endothelium-specific receptor tyrosine kinase, Tie2, which has been shown to mediate TNF- $\alpha$ -induced angiogenesis in a mouse corneal assay (51). Inhibition of NF- $\kappa$ B activation also prevented angiogenesis as determined by tubular morphogenesis in human microvascular ECs in response to hypoxia-reoxygenation. Angiogenic activities of such diverse stimuli as LPS, estrogen, reactive oxygen species (ROS), and 12(R)-hydroxyeicosatrienoic acid [12(R)-HETE<sub>r</sub>E], an arachidonic acid metabolite, involve activation of NF- $\kappa$ B. These studies identify NF- $\kappa$ B as an important mediator of angiogenesis. Consistent with this, the administration of NF- $\kappa$ B inhibitor pyrrolidine dithiocarbamate (PDTC) resulted in suppression of retinal neovascularization in mice (52).

### Cell Growth, Inflammation, and Tumorigenesis

Recent studies have provided evidence for an important role of IKK/NF- $\kappa$ B in promoting cell growth and tumorigenesis and also in linking inflammation to tumorigenesis (53). In an elegant study, Greten and colleagues (53) used a colitis-associated cancer (CAC) model to demonstrate that tissue-specific deletion of IKK $\beta$  in intestinal epithelial cells and macrophages was associated with a dramatic decrease in the formation of inflammation-associated tumors. The mechanism by which IKK $\beta$  exerts its tumorigenic effect differs between cell types. For example, in enterocytes, IKK $\beta$  contributes to tumor initiation and promotion by suppressing apoptosis, but is not required for inflammation *per se*, whereas in myeloid cells IKK $\beta$  is involved in the production of inflammatory mediators that promote tumor growth (53). Similarly, using a mouse model of hepatocellular carcinoma, a prototype of inflammation-associated cancer, Pikarsky and colleagues (54)

have shown that NF- $\kappa$ B plays an essential role in promoting such cancers. These studies further demonstrate that activation of NF- $\kappa$ B in hepatocytes in this model depends on TNF- $\alpha$  secreted by endothelial and recruited inflammatory cells. The identification of IKK/NF- $\kappa$ B as a key link between inflammation and tumorigenesis points to the existence of a mechanism that ensures proper growth of normal cells by tightly controlling IKK/NF- $\kappa$ B activation.

Mammalian target of rapamycin (mTOR), alternatively termed FKBP12 and rapamycin associated protein (FRAP) or rapamycin and FKBP12 target (RAFT), is a central controller of cell growth. Minhajuddin and colleagues (55) have recently demonstrated that inhibition of mTOR by rapamycin, an immunosuppressive drug that complexes with high affinity with its cellular receptor FK506-binding protein 12 (FKBP12) with the resulting rapamycin-FKBP12 complex specifically binding to mTOR and inhibiting mTOR-dependent downstream signaling, promoted thrombin-induced NF- $\kappa$ B activation in ECs. Conversely, overexpression of mTOR inhibited NF- $\kappa$ B activation by thrombin. Analysis of the NF- $\kappa$ B signaling pathway revealed that inhibition of mTOR potentiated IKK activation and resulted in a rapid and persistent phosphorylation and degradation of I $\kappa$ B $\alpha$ . Consistent with these data, inhibition of mTOR resulted in a more efficient and stable nuclear localization of RelA/p65 and subsequently, the DNA binding activity of NF- $\kappa$ B in response to thrombin. As expected, mTOR inhibition was associated with augmented ICAM-1 expression by thrombin. These data define a novel role of mTOR in downregulating thrombin-induced ICAM-1 expression in ECs by controlling a delayed and transient activation of IKK/NF- $\kappa$ B. Given the role of IKK/NF- $\kappa$ B and ICAM-1 in tumor promotion and metastasis, the negative regulation of IKK/NF- $\kappa$ B activation by mTOR may be a mechanism of ensuring proper cell growth.

### DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

The activation of NF- $\kappa$ B is implicated in the pathogenesis of a variety of human diseases (Table 86-2). The apparent association of NF- $\kappa$ B activation with various diseases raises the possibility that detection of "expression levels" or "activation states" of the IKK/I $\kappa$ B/NF- $\kappa$ B system can serve as an important tool to predict or diagnose the onset of these disease states. Indeed, studies by Hajra and colleagues (56) have shown the presence of activated NF- $\kappa$ B and induction of NF- $\kappa$ B-dependent genes in atherosclerotic lesions using a mouse model of atherosclerosis. These studies showed that expression of RelA/p65 and I $\kappa$ B $\alpha$  was five- to 18-fold higher in ECs in regions of proximal aorta with high probability (HP) for atherosclerotic lesion development. Moreover, in response to systemic inflammatory stimuli, NF- $\kappa$ B was preferentially activated in the HP region. The increased expression of NF- $\kappa$ B/I $\kappa$ B components suggests that NF- $\kappa$ B in aortic ECs is primed for activation in

regions predisposed to atherosclerotic lesion formation. These studies also provide a rationale for the development of strategies for determining the steady-state expression of IKK/I $\kappa$ B/NF- $\kappa$ B components to localize atherosclerotic lesions or regions prone to developing such lesions.

Consistent with discrete steps involved in NF- $\kappa$ B activation, different agents have been shown to block NF- $\kappa$ B activity by targeting different events in the NF- $\kappa$ B activation pathway (57). For example, nonsteroidal anti-inflammatory agents such as aspirin, sodium salicylate, and sulindac exert their effects, at least in part, by inhibiting IKK $\beta$  activity. Similarly, naturally occurring flavonoids such as quercetin, resveratrol, and myricetin are thought to mediate their various biological effects including suppression of inflammation, cancer chemoprevention, and protection from vascular disease through inhibition of IKK activity. The anti-inflammatory effects of glucocorticoids such as dexamethasone and prednisone are attributed to their ability to inhibit NF- $\kappa$ B activation by promoting the expression of I $\kappa$ B $\alpha$  to increase cytosolic retention of NF- $\kappa$ B, disturbing the interaction of RelA/p65 with the basal transcription machinery, or competing for the limiting amounts of the coactivators CBPs, depending on the cellular context (57). Other compounds such as peptide aldehyde MG132, lactacystin, and the immunosuppressive drug cyclosporine A (CsA) prevent NF- $\kappa$ B activation by inhibiting the protease activity of the proteasome. Tacrolimus (FK506), another immunosuppressive drug, which, like CsA, is used to prevent the rejection of organ transplants, inhibits NF- $\kappa$ B activation by preventing translocation of c-Rel from cytoplasm to the nucleus. Thus, a number of widely used anti-inflammatory, anticancer, and immunosuppressive agents inhibit the NF- $\kappa$ B pathway, at least in part, as one of their targets.

One of the concerns about inhibiting several of these components of the NF- $\kappa$ B pathway is the specificity of such drugs and the potential for toxicity because prolonged NF- $\kappa$ B blockade could interfere with host defense response and result in liver apoptosis. In view of these challenges, an effective strategy for the therapeutic interventions of diseases associated with chronic or dysregulated NF- $\kappa$ B activation depends on achieving a delicate balance between suppressing NF- $\kappa$ B activity and interfering with normal cellular functions. Conditional targeting of specific NF- $\kappa$ B subunits, I $\kappa$ B proteins, or IKKs in a cell-specific manner will be a useful strategy to achieve this goal. For example, using *E-selectin* promoter, it will be possible to direct the expression of super repressor I $\kappa$ B $\alpha$ , dominant negative mutant of IKKs, or short hairpin RNA (shRNA) in targeting specific NF- $\kappa$ B subunits in an EC- and inflammation-specific manner, thus providing a control over the strength and duration of NF- $\kappa$ B signals and thereby ensuring therapeutic efficacy and minimizing systemic toxicity. Such a strategy has been used to induce conditional and EC-specific expression of neutrophil inhibitory factor (NIF), a  $\beta_2$ -integrin antagonist, which in turn prevents lung neutrophils infiltration and vascular injury in a mouse model of gram-negative sepsis (58).

## KEY POINTS

- Endothelial NF- $\kappa$ B plays a key role in controlling varied biological effects ranging from inflammation, angiogenesis, and cell fate decisions.
- NF- $\kappa$ B contributes to inflammation by inducing the expression of cytokines, adhesion molecules, and chemokines in ECs.
- NF- $\kappa$ B contributes to angiogenesis by promoting the expression of proangiogenic genes such as *VEGF*, *IL-8*, and their receptors in ECs.
- Activation of NF- $\kappa$ B in ECs influences cell fate decisions by mediating expression of pro- or anti-apoptotic genes.

## Future Goals

- To identify the proximal signaling components of the IKK/I $\kappa$ B/NF- $\kappa$ B pathway in ECs
- To determine the mechanisms responsible for dysregulated NF- $\kappa$ B activation in EC in disease states
- To conditionally target NF- $\kappa$ B in endothelium to limit the pathological effects of dysregulated NF- $\kappa$ B without interfering with host defense response

## Peroxisome Proliferator-Activated Receptors and the Endothelium

---

Jonathan D. Brown and Jorge Plutzky

*Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts*

The endothelium is a biologically active, dynamic transducer of diverse inputs to the arterial wall and indeed the entire organism. In perhaps an analogous manner, peroxisome proliferator-activated receptors (PPARs) are biological integrators linking various proximal signals to multiple, specific cellular responses through transcriptional regulation (1,2). PPARs perform this function as nuclear receptors that are ligand-activated transcription factors (3). Through PPAR activation, inputs such as lipid metabolism, dietary intake, and drug therapy are coupled to nuclear responses, thus regulating entire cassettes of PPAR target genes (4). The complexity of the PPAR system allows this programmed response to be specific, carefully controlled, and integrated into feedback loops that coordinate systemic responses. The evidence for PPAR expression and activity in the endothelium identifies these biological transcriptional integrators as important contributors to endothelial biology (5). Given known PPAR control of pathways such as lipid metabolism, insulin sensitivity, adipogenesis, and energy balance, as well as recent data for PPAR involvement in inflammation and atherosclerosis (6), their relevance to endothelial cell (EC) transcriptional responses is apparent. After briefly reviewing PPARs in general, this chapter considers more recent data regarding endothelial PPAR responses.

### HISTORY AND EVOLUTIONARY CONSIDERATIONS

The discovery of the nuclear hormone receptor family, beginning with the identification of the growth hormone receptor (GHR) in 1985, unearthed a critical molecular link between hormonal signaling cascades and the transcriptional control of specific gene cassettes (7). The following decade was marked

by an explosion in the field of nuclear hormone receptor biology due to the realization that this superfamily of receptors regulates a broad array of physiologic processes ranging from reproduction to bone metabolism to nutrient control of carbohydrate and lipid metabolism. Moreover, interest in this arena was fueled by the realization that these nuclear receptors could be targeted for drug therapy. In 1990, shortly after the discovery of the GHR by Evans and his laboratory, Issemann and Green cloned the first PPAR nuclear receptor (now known as PPAR $\alpha$ ) as part of their search for the molecular target of chemicals known to induce hypolipidemia and peroxisome proliferation in rodents (8). Interestingly, the rodent peroxisome organelle contains the enzymatic machinery required for  $\beta$ -oxidation of lipids. Homology mapping between this first PPAR and other known steroid nuclear receptor family members, including the retinoic acid receptor, thyroid receptor, and vitamin D<sub>3</sub> receptor, revealed significant similarity spanning a wide range of eukaryotic organisms including *Drosophila melanogaster* and *Homo sapiens* (8). Functional studies confirmed that the activation of this PPAR directly upregulates the expression of acetyl co-A oxidase (ACO), an enzyme involved in the  $\beta$ -oxidation of fatty acids (9). The subsequent observation that fatty acids can activate PPARs revealed a link between nutritional input and the transcriptional regulation of genes responsible for crucial metabolic processes. These findings were of obvious relevance to many areas such as diabetes and cardiovascular disease, an intersection that was heightened by the discovery of many of these nuclear receptors in other tissues – for example, the estrogen receptor in vascular smooth muscle cells (VSMCs) and the PPARs in ECs, the latter being the focus here. The conserved homology among PPARs in eukaryotes suggests a mechanism has likely evolved for the dynamic molecular adaptation to nutritional states in these organisms.

Figure 87.1. PPARs are members of the steroid hormone nuclear receptor family. Like other such nuclear receptors, PPARs are ligand-activated transcription factors with five main domains including the ligand-binding domain (LBD) and the DNA-binding domain (DBD). In response to specific ligands, the PPAR is activated and forms a heterodimeric complex with another nuclear receptor retinoid X receptor (RXR). This functional transcriptional complex, which also involves the release (corepressors) or recruitment (coactivators) of small accessory molecules, can then bind to specific PPAR response elements (PPRE) in the promoter region of target genes.

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS – LIGAND-ACTIVATED NUCLEAR RECEPTORS REGULATING GENE EXPRESSION

The three known PPAR isoforms –  $\alpha$ ,  $\gamma$ , and  $\delta$  – are all members of the steroid hormone nuclear receptor family (10). Like other steroid hormone receptors, such as the estrogen receptor and the thyroid hormone receptor, PPARs contain both ligand-binding (LBD) and DNA-binding domains (DBD) (1) (Figure 87.1). The binding of a cognate agonist to the PPAR LBD induces a conformational shift that activates the receptor, allowing formation of a heterodimeric complex between the PPAR and another nuclear receptor, the retinoid X receptor (RXR), which is activated by its own distinct ligand, namely 9-*cis*-retinoic acid. Like many other steroid hormone receptors, PPARs are obligate heterodimeric partners with RXR, requiring the presence of RXR for functional activity. The cognate interaction between a specific PPAR agonist and its PPAR partner regulates PPAR-responsive genes *in vitro* and *in vivo*. The exact mechanics through which PPAR and RXR heterodimerization actually occur *in vivo* remain incompletely defined. For example, insight into the order of steps, the action of unliganded receptors, and the control of RXR homodimerization versus its heterodimerization with its multiple other nuclear receptor partners all remains largely obscure. Regardless, ligand binding induces a conformational change involving the PPAR AF2 domain that allows the ligand/PPAR/RXR complex to recognize and bind to specific PPAR response elements (PPREs) in the promoter regions of specific target genes. PPREs are classically a direct DNA repeat separated by a single nucleotide. More recently, the PPAR field has focused on the importance of small accessory molecules, known as *coactivators* and *corepressors*, that must be respectively recruited

or released in order for functional PPAR responses to occur (11). Importantly, PPAR activation can either induce or repress gene expression. Although the mechanism for so-called trans-repression remains incompletely understood, one recent line of investigation implicates the stabilization of a corepressor-bound state through sumoylation may contribute to anti-inflammatory effects of PPAR $\gamma$  (11). Recent scientific evidence suggests PPARs can activate transcription in a ligand-independent manner through stochastic changes in LBD conformation (12). Although many advances in the PPAR field have been derived from the serendipitous discovery of synthetic PPAR ligands, the precise identity of natural PPAR agonists remains somewhat obscure (see the following sections for further discussion). Furthermore, the fate of these ligands, once bound to the PPAR, is unclear. Although the three PPARs share common mechanisms of action, each isoform has unique biological attributes and functional roles. We review current insight into each PPAR isoform, focusing on its role in endothelial biology.

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\gamma$ – TRANSCRIPTIONAL REGULATOR OF ADIPOGENESIS AND INSULIN SENSITIVITY

PPAR $\gamma$  was initially identified in adipocytes with subsequent work establishing a critical role for PPAR $\gamma$  in the adipogenic differentiation program, for example through induction of aP2, leptin, and adiponectin (2,13–15). The discovery that synthetic PPAR $\gamma$  ligands identified through chemical screening could improve insulin sensitivity and lower glucose established the role of PPAR $\gamma$  in metabolic homeostasis (1,15). Thiazolidinediones (TZDs), a class of drugs in clinical use as antidiabetic medications in the form of pioglitazone (Actos) and rosiglitazone (formerly BRL49653, now Avandia), were found to exert their effects by binding to PPAR $\gamma$  (16). PPAR $\gamma$  also participates in lipid metabolism through the regulation of target genes such as cholesterol transporters and lipoprotein lipase (17). Homozygous PPAR $\gamma$ -deficient mice die *in utero* due to placental malformation (18–20) (Table 87-1). Although the identity of naturally occurring ligands remains elusive, several candidate endogenous PPAR $\gamma$  ligands have been proposed, including oxidized linoleic acid, in the form of 9- or 13-hydroxyoctadecadienoic acid (HODE) derivatives (21,22) (which also activates PPAR $\alpha$ ) (23); nitrooleic acid; and the prostaglandin metabolite 15-deoxy-D12,14-prostaglandin J<sub>2</sub> (15d-PGJ<sub>2</sub>) (24,25). The enzyme 15-lipoxygenase may be a way of generating PPAR $\gamma$ -activating HODEs and is a general pathway for the production of endogenous PPAR ligands (26).

### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\gamma$ IN THE ENDOTHELIUM

PPAR $\gamma$  transcript and protein is expressed in human ECs both *in vitro* and *in vivo*, as demonstrated by Northern blot and

**Table 87-1: Genetic Mouse Models**

<i>Gene</i>	<i>-/- (Refs.)</i>	<i>Synthetic Agonists (Refs.)</i>	<i>Endogenous Agonists (Refs.)</i>	<i>Expression and Function Role in ECs (Refs.)</i>
<i>PPAR<math>\gamma</math></i>	Embryonic lethal (18)	TZD (rosiglitazone, pioglitazone) (16)	HODE, 15d-PGJ <sub>2</sub> (24)	Inhibits IFN- $\gamma$ -mediated induction of CXC chemokines, but not MCP-1 (29); inhibits CCR2; ET-1 (34, 35); variable results with PAI-1 in vitro and in vivo (46); <sup>+/-</sup> effects on VCAM-1, ICAM-1 (69); CuZn-SOD; decreased p22 <sup>phox</sup> and p47 <sup>phox</sup> (71,72); Increased nitric oxide bioavailability (41); inhibits angiogenesis (43)
<i>PPAR<math>\alpha</math></i>	Viable; altered lipid profile (56)	Fibric acid derivatives, the research compound WY14643 (1)	HODE, eicosanoids, long-chain fatty acids; leukotriene B <sub>4</sub> ; LPL-treated VLDL (1)	Inhibits IL-1 $\beta$ and TNF $\alpha$ -induced VCAM-1 expression (65); CuZn-SOD; decreased p22 <sup>phox</sup> and p47 <sup>phox</sup> (71); activation in vivo reduces atherosclerosis in mice (83)
<i>PPAR<math>\delta</math></i>	Predominantly embryonic lethal; surviving animals with less adiposity (76)	Research compound GW501516 (19)	LPL-treated VLDL, prostanoid derivatives (89)	Present in ECs (19); function unclear

immunohistochemical staining of human carotid and coronary artery specimens (27,28). Subsequent work has identified various PPAR $\gamma$  target genes and secondary responses important to endothelial biology (5). For example, PPAR $\gamma$  agonists have been shown to repress chemokine expression (29). Chemokines – short for chemoattractant cytokines – are a large complex family of proteins produced by various tissues including ECs that can recruit inflammatory cells to sites of injury (30). Chemokines, strongly implicated in the pathophysiology of atherosclerosis (31,32), are categorized into subfamilies based on the primary sequence relationship of the first two of four invariant cysteine residues (30): so called “CC” or “CXC” chemokines. CXC chemokines are further defined by the presence or absence of an amino-terminal ELR (Glu-Leu-Arg) sequence. ELR-containing CXC chemokines include interleukin (IL)-8 and platelet factor 4 (PF4). Non-ELR CXC chemokines include interferon (IFN)-inducible protein of 10 kDa (IP-10), monokine induced by  $\gamma$ -IFN (Mig), and IFN-inducible T-cell  $\alpha$ -chemoattractant (I-TAC). Inflammatory cytokines such as IFN- $\gamma$  or tumor necrosis factor (TNF)- $\alpha$  can induce the expression of both CC chemokines, such as monocyte chemoattractant protein (MCP)-1, and CXC chemokines. Consequently, this network of chemokines can recruit numerous and distinct types of inflammatory cells to sites of injury, including T cells, monocytes or macrophages, and neutrophils (31).

Experimentally, synthetic PPAR $\gamma$  activators were shown to repress certain cytokine-induced chemokine expression in ECs cultured from human saphenous vein specimens. PPAR $\gamma$

activation inhibited mRNA expression in a subset of IFN- $\gamma$ -induced CXC chemokines including IP-10, ITAC, and Mig. In contrast, in this experimental system, IFN- $\gamma$  induction of the CC chemokine *MCP-1* mRNA (29) was unchanged by PPAR $\gamma$  stimulation, suggesting a selective effect of PPAR $\gamma$  activation. Extended further, PPAR $\gamma$  activation inhibited *IP-10* promoter activity in vitro in response to IFN- $\gamma$  via a nuclear factor (NF)- $\kappa$ B-dependent mechanism. Functionally, the transcriptional effect on chemokine expression also attenuated chemotactic responses in cell culture (29,33). Despite the lack of effect on MCP-1, the receptor for MCP-1 (known as CCR2) is repressed by PPAR $\gamma$  agonists, which would still be consistent with a net repression of MCP-1 signaling. Although complete elucidation of all PPAR regulation of chemokines and their receptors remains to be worked out, other studies have implicated PPARs in chemokine regulation in the gut, suggesting possible benefits in inflammatory bowel disease. To date, ligand-mediated trans-repression of transcription remains poorly understood, but may involve the upregulation of cytoplasmic NF- $\kappa$ B inhibitors such as I $\kappa$ K or the direct recruitment of corepressors to the transcriptional apparatus, as noted earlier (11).

PPAR $\gamma$  has other effects in ECs. PPAR $\gamma$  activation can suppress both basal levels and induced levels of insulin-stimulated or thrombin-induced expression of the potent vasoconstrictor endothelin (ET)-1 in cultured ECs (34,35). Other investigators have found that PPAR $\gamma$  can limit the hypertension induced by angiotensin II infusion in rats and restore EC-dependent vasodilation in response to acetylcholine (36).

These mechanisms may contribute to the modest but consistent decrease in blood pressure observed in patients treated with thiazolidinediones (37). Although causation has not been established, angiotensin receptor blockade using some of the currently available pharmacologic antagonists can bind and activate PPAR $\gamma$  within physiologic dose ranges (38). To define more precisely the role of PPAR $\gamma$  in blood pressure regulation in ECs, mice with a targeted disruption of the *PPAR $\gamma$*  gene in ECs (EC- $\gamma$  KO) have been engineered. At baseline, these EC- $\gamma$  KO animals possessed no significant phenotypical, biochemical, or hemodynamic differences as compared with wild-type animals. However, after exposure to high fat diet, the EC- $\gamma$  KO mice developed an exaggerated hypertensive response (39). Treatment with the TZD rosiglitazone reversed hyperinsulinemia in the EC- $\gamma$  KO animals, but did not lower their blood pressure. These data implicate EC PPAR $\gamma$  specifically in the pathophysiology of high-fat diet induced hypertension. In contrast, a high-salt diet provoked hypertension in both knockout and wild-type mice to the same degree. Taken together, these findings suggest that the direct activation of EC-derived PPAR $\gamma$  modulates the hypertensive phenotype in the setting of insulin resistance; and the data also may explain why TZD therapy in humans can modestly lower blood pressure, independently of their well-described insulin-sensitizing effects. Further studies in these genetically altered mice will likely provide other important mechanistic insights into PPAR $\gamma$ -dependent endothelial biology.

Other in vitro studies have revealed enhanced nitric oxide (NO) bioavailability after treating cultured ECs with various PPAR $\gamma$  agonists (40,41), although PPAR $\gamma$  stimulation did not change gene expression or protein levels of endothelial NO synthase (eNOS), which is the enzyme responsible for basal and shear stress-mediated NO production in EC. Thus, the precise mechanism for PPAR $\gamma$ /NO interaction remains obscure and may occur indirectly through eNOS cofactor expression, activation, or degradation. Intriguingly, laminar shear stress (LSS) activates PPAR $\gamma$  in ECs in vitro (42). Moreover, the conditioned media from ECs exposed to LSS also can activate PPAR $\gamma$ , correlating with the upregulation of *CD36* gene expression – a known PPAR $\gamma$  target. Shear stress represents an important anti-inflammatory stimulus in vascular EC. In these in vitro experimental systems, pretreatment of cultured ECs with the conditioned media from LSS antagonized the IL-1- $\beta$  induction of intercellular adhesion molecule (ICAM)-1. Targeted knockdown of PPAR $\gamma$  by small interfering RNA (siRNA) partially abrogated this effect, which implicates PPAR $\gamma$  as one anti-inflammatory mediator of shear stress in ECs. Other, variable PPAR $\gamma$  effects on adhesion molecule expression have been reported (discussed later, in conjunction with PPAR $\alpha$ ). PPAR $\gamma$  agonists may have antiangiogenic effects (43,44), but they also have been reported to induce vascular endothelial growth factor (VEGF) in certain cells such as VSMCs, and the results in other angiogenic models have varied (45). We have found that putative, naturally occurring PPAR $\gamma$  ligands induce in vitro

mRNA and protein levels of plasminogen activator inhibitor (PAI)-1, an important endogenous inhibitor of fibrinolysis that has been found to be predictive of risk for myocardial infarction. PPAR $\alpha$  ligands had no such effect (28). In contrast, other in vitro reports have found that synthetic PPAR $\gamma$  agonists modestly downregulate basal and cytokine-induced *PAI-1* mRNA and protein expression (46–48). Finally, synthetic PPAR $\gamma$  agonists clearly decrease serum PAI-1 levels in patients, although these changes also may derive from the metabolic effects of these drugs, including improved insulin sensitivity, decreased glucose levels, or lowered triglycerides levels, which may contribute to these responses. This discordance in the scientific literature likely reflects the use of distinct experimental systems, the use of different PPAR $\gamma$  agonists (synthetic versus natural), and the complexity of dissecting the multiplicity of potential PPAR $\gamma$  molecular targets from in vivo models. Translational studies in humans also have reported PPAR $\gamma$ -mediated improvements in endothelium-dependent vasoreactivity, assessed by forearm blood flow measurements with bradykinin stimulation, although it is not clear if this is through direct endothelial versus smooth muscle cell effects (49,50). Taken together, these endothelial PPAR $\gamma$  effects are congruent with reports of PPAR $\gamma$  action in other vascular and inflammatory cells and may account for a putative role of PPAR $\gamma$  in limiting inflammation and atherosclerosis (51–53).

#### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\alpha$ – TRANSCRIPTIONAL SENSOR FOR FATTY ACID METABOLISM

Issemann and Grossman first identified PPAR $\alpha$  in 1990, while screening a murine cDNA library (8). They were searching for the molecular target of a group of chemical compounds that induced peroxisomal proliferation and carcinogenesis in rodents. Peroxisomes are intracellular organelles that participate in detoxification and fatty acid oxidation in rodents. This proliferation of peroxisomes does not occur in humans (54). PPAR $\alpha$  is expressed in a variety of tissues, including heart, liver, skeletal muscle, and kidney. PPAR $\alpha$  plays an important role in lipid metabolism and energy balance (55). PPAR $\alpha$  target genes include enzymes important for  $\beta$ -oxidation of fatty acids. Moreover, PPAR $\alpha$  regulates many metabolic pathways, including activation of fatty acids to acyl coenzyme A derivatives, peroxisome  $\beta$ -oxidation, and apolipoprotein expression (A1, AII, and CIII) (1). Endogenous PPAR $\alpha$  activators likely include eicosanoids and certain long-chain fatty acids, although as with PPAR $\gamma$ , many aspects of endogenous PPAR $\alpha$  activation remain unclear. Synthetic PPAR $\alpha$  agonists include lipid-lowering fibric acids – fenofibrate, gemfibrozil, and the research compound WY14643 (6). The relative potency among various synthetic ligands for binding to PPAR $\alpha$  differs, which may explain the nonuniform effects of different fibric acids, as well as general biological differences among distinct PPAR agonists.

The PPAR $\alpha$ -deficient mouse developed by Gonzalez and colleagues has been an invaluable tool for studying PPAR $\alpha$  (56). Of note, PPAR $\alpha$  agonists fail to induce peroxisome proliferation in PPAR $\alpha$ -deficient animals (see earlier discussion). PPAR $\alpha$ -deficient mice do manifest altered lipid and lipoprotein profiles including increased total cholesterol, elevated Apo-AI, and mildly increased total high-density lipoprotein (HDL) levels, the latter apparently caused by decreased HDL metabolism (57). Triglyceride levels were not significantly different between wild-type and knockout animals. Although PPAR $\alpha$  activators lowered triglycerides in wild-type mice, they had no effect on PPAR $\alpha$ -null mice, implicating PPAR $\alpha$  directly in triglyceride lowering by fibrates. Extended to humans, the decrease in cardiovascular events with fibrate therapy observed in clinical trials such as the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial Study Group (VA-HIT) suggests that PPAR $\alpha$  activation in the vasculature, including the endothelium, may contribute to benefits in patient outcomes (58,59). More recent data from the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study with fenofibrate were less clear, perhaps in part due to a significant degree of statin drop-in treatment that occurred disproportionately more in the placebo group (60).

#### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\alpha$ IN THE ENDOTHELIUM

PPAR $\alpha$  is expressed in vitro and in vivo in ECs, as shown by several approaches, including northern blotting of cultured ECs and immunohistochemistry of human carotid specimens (61). Multiple PPAR $\alpha$ -regulated target genes relevant to endothelial function have been identified (62). Endothelial adhesion molecule expression is an early step in atherogenesis. We and others have found that synthetic PPAR $\alpha$  activators (WY and fenofibrate) inhibit TNF- $\alpha$  – or IL-1 $\beta$ – mediated induction of vascular adhesion molecule (VCAM)-1 expression in cultured ECs, as well as adhesion of fluorescently labeled monocyte-like cells (61,62). PPAR $\alpha$ -mediated repression of adhesion molecule expression may derive from NF- $\kappa$ B inhibition (61). The molecular mechanism underlying PPAR antagonism of NF- $\kappa$ B signaling remains elusive, but may involve the altered expression of the cytoplasmic inhibitor I $\kappa$ B $\alpha$ , which is known to occur in cultured VSMCs (63,64). Importantly, we have shown that these PPAR $\alpha$  agonist responses do not occur in microvascular ECs isolated from the hearts of PPAR $\alpha$ -deficient mice (23,65). PPAR $\alpha$  may regulate transcription in ECs through nutritional inputs (4,66). For example, certain forms of  $\omega$ -3 fatty acids can repress adhesion molecule expression and leukocyte adhesion in a PPAR $\alpha$ -dependent manner (67). Although our group identified no effect of PPAR $\gamma$  activators on VCAM-1, other investigators have reported inhibition of inducible VCAM-1 and ICAM-1 in various models (68–70). Not all PPAR $\gamma$  agonists limit adhesion molecule expression, an observation that underscores the potential complexity of

PPARs, including the impact of specific agonists and variables that may differ among experimental systems (68). Consistent with our in vitro findings, although synthetic PPAR $\gamma$  agonists reduced atherosclerosis in low-density lipoprotein (LDL) receptor-deficient mice fed a high-fat diet, VCAM-1 gene expression was unchanged in control and treated animals (53). These variable findings highlight the potential impact that the specific PPAR agonists used, the concentrations employed, cell type being studied, and the methodological approach and model system used can have on results.

PPARs also have been implicated in the endothelium's defense against oxidative stress (71,72). Inoue and colleagues found that both PPAR $\alpha$  and - $\gamma$  activators induced the expression of the superoxide scavenger enzyme Cu<sup>2+</sup>, Zn<sup>2+</sup>-superoxide dismutase (CuZn-SOD) in cultured vascular ECs (71). PPAR $\alpha$  and - $\gamma$  activators also decreased induction of p22<sup>phox</sup> and p47<sup>phox</sup>, two subunits of the superoxide generating enzyme nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) oxidase (71). PPAR $\alpha$  also has been suggested to play a part in feedback loops that help limit oxidative stress (73,74).

#### PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR- $\delta$ – TRANSCRIPTIONAL SENSOR FOR FATTY-ACID METABOLISM
