The mean total lung capacity in one of our studies was around 68 % and forced vital capacity 64 % of expected. The ratio of forced expiratory volume in one second to the forced vital capacity was 87 %. This was not a longitudinal study, and therefore, it was not possible to determine whether the intrathoracic stomach was detrimental to lung growth. Of interest was that patients undergoing an uncomplicated primary gastric transposition had greater lung volumes than those subjects having a more complicated course involving multiple thoracotomies. We are aware that a bulky stomach in the chest of a child with borderline lung function may be a problem, and under these circumstances, gastric transposition may not be the optimal oesophageal substitute.

While most of our patients were in the lower centiles for weight, their heights remain within the normal range; we were unclear if this was related to their underlying problem or to the operation. Children who had caustic injury followed their previous percentiles.

Gastric emptying studies have shown that more than 50 % of both solid and liquid components of a test meal had left the stomach by the time of completion of the meal indicating that the transposed stomach act as a conduit rather than a reservoir. There is no correlation between diarrhoea or dumping symptoms and gastric empting.

It remains to be determined whether Barrett's metaplasia in the proximal oesophagus will be a longer-term problem. We have not encountered this so far but are aware of the problem when gastric tubes are used [10]. As the stomach has been vagotomised, the amount of acid produced may be insufficient to induce metaplasia.

We remain unsure of the best approach for those with CHARGE association, complete laryngeal clefts and caustic injuries to the upper

oesophagus and pharynx, as bolus gastrostomy feeds may be necessary in the long term in these children. Colonic interposition may be a better option under these circumstances.

We are encouraged that at least after the first two decades, there is no symptomatic deterioration in function of the transposed stomach.

Gastric transposition has replaced colonic interposition as the oesophageal replacement procedure of choice in many centres [5, 11, 12]. The excellent blood supply of the stomach, the fact that only one anastomosis is required and the relative technical ease of the procedure are clear advantages. In addition, the long-term follow-up of our patients has shown good growth and development and that the function of the replacement continues to be satisfactory in the immediate future.

Quality of Life Following Gastric Transposition

Previous research had shown that a significant proportion of children who underwent major neonatal surgery for life-threatening congenital abnormalities experienced psychosocial problems during childhood and early adolescence [13–16]. Since the outcome for children undergoing oesophageal replacement with gastric transposition for failed repair of oesophageal atresia has not previously been reported, we carried out a descriptive study in 2002 to assess in-depth functional outcome, psychosocial adjustment and health-related quality of life of patients following gastric transposition (GT) [17].

The rarity of the problem and the fact that many patients originated from a wide geographical area meant that our sample size was small. All the patients were resident in the United Kingdom and had undergone gastric transposition at Great Ormond Street Hospital for Children in London. Based on their operative history before gastric transposition, the 28 patients were divided into two groups. Group 1 consisted of 13 patients for whom gastric transposition was the primary reconstructive surgical procedure. The 15 patients in group 2 had undergone attempts at oesophageal repair or replacement, which had failed. Over two thirds of the patients in group 1, and more than half of those in group 2, had associated anomalies.

The total number of operative procedures for these 28 patients, including those performed in other institutions and those relating to procedures for associated anomalies, ranged from 2 to 91 (mean, 24 ± 22). The mean number of operative procedures in group 1 was 14 (SD, 15), and 32 (SD, 25) in group 2. The difference between the groups was significant ($p < .05$). In group 2, the mean number of operative procedures after gastric transposition was 19 (SD, 21) compared with a mean of 2 (SD, 2) in group 1 (Table 53.2).

Four patients (two in each group) were below school age, and eight patients (three in group 1,

five in group 2) had left school. One was at university, three are at college, three were employed, and one had recently given birth to a healthy boy. Of those at school, five patients were in a special unit or in special schools, and four required special needs within normal schools (9/17, 53 %); in addition, two of the older patients had been in a special unit, and two had moderate learning difficulties (13/28, 46 %). With one exception, all the older patients, including the young mother, were still living with their parent(s).

The design of the study included a clinical review, in-depth interviews with patients and their parents and the use of self-report standardised questionnaires. For psychosocial outcomes, we used the Child Behaviour Checklists (Achenbach [18]): a questionnaire completed by parents (CBCL for patients aged 2–18 years), the parallel Teacher Report Form (TRF for patients aged 4–18 years) and the Youth Self-Report Form (YSR for patients aged 11–18 years). These Achenbach questionnaires [18–21] are designed to measure competencies and behavioural/emotional problems as seen by parents, teachers and youth, respectively, and make it possible to compare data from different respondents on a common set of problem items and scales. They have been used extensively in child/adolescent mental health research. Reliability and validity are well established. Health-related quality of life (QOL) was measured using a modified version of the Eypasch Gastrointestinal Index (GIQLI) [19, 22].

Behavioural and Emotional Outcome

The overall mean scores based on the parents' and teachers' report were similar to the norms. However, the distribution of the individual scores indicated a significant proportion of the patients in group 2 with scores in the clinical range. For example, based on the parents' report, only one (1/10, 10 %) patient in group 1 had scores in the clinical range on the total problem score, compared with 3/12 (25 %) patients in group 2 on both the total problem and internalising scales; externalising disorder scores were low in both groups. The teachers' views of their pupils differed from that of the parents. Although overall mean scores were similar to the normative data, the distribution of the individual scores indicated a significant proportion of the patients in both groups with scores in the clinical range. Depressive symptoms were foremost among patients in group 1 (3/7 43 %) and externalising disorders among patients in group 2 (3/7 43 %) [20]. The parents' and teachers' findings did not appear to be related to the presence of associated anomalies or the length of time since GT.

Twelve patients completed the Youth Self-Report Form—six in each group—and, with only one exception, they all rated themselves as functioning well within the normal range.

To sum up, based on these findings, a significant proportion of patients who underwent GT, after other procedures had failed, were judged by the adults who knew them well to have psychosocial adjustment problems. Disturbed behavioural adjustment, principally internalising disorders, was noted by teachers for a proportion of the patients in group 1.

Health-Related Quality of Life Outcomes

Nineteen patients aged between 10 and 22 years, ten in group 1 and nine in group 2, completed the questionnaire. The only difference between the groups was on disease-specific symptoms. For example, fewer patients in group 1 experienced dysphagia (30 % vs. 67 %) or pain after eating (20 % vs. 33 %), compared with patients in group 2. Similarly, a smaller proportion of patients in group 1 had gastro-oesophageal reflux symptoms such as heartburn or regurgitation during the day or at night compared with those in group 2 (40 % vs. 67 %). Some breathlessness was experienced during the day by over half the patients in each group, but breathlessness at night was more frequent in group 2. Differences between the groups were not related to the length of time since gastric transposition. These data were supported by the parents' perception of the QOL of their children. Based on parental responses, patients in group 1

experienced fewer disease-specific symptoms such as dysphagia, dumping symptoms and pain after eating. In addition, with the exception of psychological and physical/social symptoms, parents in group 1 perceived the health-related QOL of their children to be significantly better than did parents of patients in group 2.

QOL of the Young Children

The parents' responses to the questionnaire showed that they perceived the overall QOL of the five young patients, aged 2–4 years, especially for those in group 2, to be adversely affected by difficulties relating to all aspects of eating—their enjoyment of food, restrictions in types of food they could eat and the amount they were eating. However, these problems are often reported about healthy children of this age. One patient in each group (50 % vs. 33 %) experienced dysphagia, and one child (50 %) in group 1, compared with two in group 2 (67 %), experienced pain after eating. Both patients in group 1 and one patient in group 2 (33 %) were reported to have gastro-oesophageal reflux symptoms. Similar proportions experienced some breathlessness during the day. Almost half of this small group of young children (44 %) had associated anomalies, and this was an important factor affecting their lives.

Physical Characteristics

The physical growth characteristics of the 28 patients showed that, with the exception of one patient in each group, all the patients were below the 50th centile for weight, but five patients in group 1 (41 %) and two (12 %) in group 2 were above the 50th centile for height. When the standardised body mass index (z scores), adjusted for age and gender, was calculated, all the patients had a BMI below zero, ranging from –0.10 to –3.91.

Conclusion

In this study, we examined the psychological adjustment and the QOL of a small group of patients following GT for repair of long-gap oesophageal atresia. Based on the responses of the adults who knew them well, we found that psychological maladjustment was more prevalent among the patients who had unsuccessful reconstructive surgery prior to GT. Additionally, the parents of these patients viewed their overall QOL as less satisfactory compared with those for whom GT was the primary reconstructive procedure. They were said to cope less well when eating and experienced a greater number of symptoms such as dysphagia, regurgitation and dumping symptoms. The patients themselves reported greater difficulty swallowing. However, in contrast to their parents' perceptions, they viewed their overall quality of life and psychological adjustment as normal.

With one exception, all the patients and the families in this study reported that they were extremely satisfied with the outcome following gastric transposition. Based on the interviews with the patients and their parents, the patients without debilitating conditions led relatively normal lives, and many enjoyed sporting activities. However, they tended to be less socially and emotionally independent than their peers.

The Follow-Up of the Gastric Tube

54

Gabriel O. Ionescu, Simona Gavrilescu,
and Sandu Gabriel Aprodu

Introduction

In paediatric surgery, final outcomes can only be assessed by the quality of life enjoyed by patients who have reached adulthood, and there have been several recent reports of the long-term results of oesophageal replacement performed in childhood [2, 6, 8, 10, 12, 13, 15, 25, 30, 33, 41, 47].

Our experience of 109 patients who have undergone gastric tube oesophageal replacement (GTER) during the last 34 years forms the basis of this discussion on the follow-up of patients into adulthood [5, 22, 28–31].

Principles of Long-Term Assessment Following Gastric Tube Oesophageal Replacement

After the initial post-operative period – the first 6 months – most patients are able to eat normal food without any special precautions. Particular attention is paid to the early detection of a stricture at the cervical anastomosis that might need dilatation. The establishment of normal feeding is usually rapid in those children who had surgery for intractable strictures due to caustic ingestion but can be more difficult if surgery was performed for oesophageal atresia.

All patients should be followed according to a strict protocol.

Assessment Protocol

In the first 6 months, a clinical examination should take place every 2 months at an outpatient consultation, then twice a year for the next 4 years and then annually for life.

Weight and height should be accurately recorded and compared to reference charts. Anaemia, particularly megaloblastic anaemia, should be sought and treated.

In the first 6 months, a contrast swallow with follow-through should be performed every 3 months, or earlier if there are symptoms suggesting a stricture formation, and then twice a year for 2 years. As the child grows, outpatient endoscopy might become a reasonable alternative to these contrast studies. Reflux within the gastric tube has been noticed in many contrast studies but is asymptomatic in most patients [22].

The threat of metaplastic changes in the proximal oesophagus justifies regular endoscopy with biopsies. This should be performed by an experienced endoscopist. With the gastric tube in the posterior mediastinal position, endoscopy is usually

easy; however, if the tube has been placed retrosternally, the examination is difficult and should be done under general anaesthetic using a small calibre flexible scope. It may not be possible under these circumstances to view the entire tube, and examination of the gastric reservoir and pylorus may be impossible. Bleeding and perforation of the tube during endoscopy have been reported [4].

In the first 3–6 months, post-operative endoscopy is focused on the recognition and management of early stricture formation at the upper anastomosis but may also detect congestion or gastritis. True peptic ulcers are occasionally seen.

Reflux within the gastric tube can be demonstrated in most patients but is frequently asymptomatic. Twenty-four-hour pH monitoring is unreliable as it cannot differentiate between refluxing acid and acid secretion within the tube [22].

In our experience pH monitoring was only used on ten occasions. These patients complained of unpleasant regurgitation of partially digested food during the night. In three patients this was severe enough to awaken the patient but caused chronic cough due to micro-aspiration in the remainder. These symptoms were controlled by sleeping in the semi-Fowler position, and they tended to improve with time. We found no benefit from the use of H_2 receptor antagonists, proton pump inhibitors, or prokinetic agents. Alkaline bile reflux, so common after total gastric transposition, was not detected following RGTER.

Late Complications Following Gastric Tube Oesophageal Replacement

Rare complications such as bronchogastric tube fistula [1, 22, 42] have been reported, and in one case this occurred many years after operation [1]. A stricture progressing to complete obstruction [40], perforation of an acquired diverticulum [40], and mucocele of the unresected injured oesophagus [31, 32] have also been reported (Figs. 54.1 and 54.2).

There have also been reports of peptic ulceration within the gastric tube [4, 11, 39, 46, 49] or peptic ulceration within the gastric reservoir [46]; most of these patients, as were three of our own patients, were successfully treated with proton pump inhibitors.

In our experience one patient presented with peptic ulceration within the gastric tube. One further patient had true gastric ulceration, and one

Fig. 54.1 Mucocele within the unresected injured oesophagus with retention of a foreign body inside (small metallic ring). Specimen of resected oesophagus by right thoracotomy)

patient had Zollinger-Ellison syndrome which presented many years after successful RGTER for caustic stricture with multiple recurring peptic ulcers, a perforated duodenal ulcer and a gastrocolic fistula with further ulceration in the fundus. After several operations, she finally had a gastrectomy with anastomosis of the tube to the jejunum. A preoperative celiac trunk angiography has been performed to identify the vessels of the gastric tube.

Post-operative adhesive obstruction occurred in five patients 6 months to 7 years after surgery. All were successfully treated by simple laparotomy and adhesiolysis. All five patients were seen early in our experience when, as Pr. D. Gavriliu originally recommended, we performed extensive mobilization of the splenic flexure and spleen. We no longer consider this step necessary.

In one patient 8 months after successful RGTER, progressive dysphagia occurred. This appeared due to angulation of the intra-abdominal portion of the tube that had been made too long. An anastomosis was created between the lower part of the tube and the gastric fundus after which normal feeding was restored (Fig. 54.3).

Lindhal [35] and Bornon [11] have both reported the presence of Barrett's oesophagus in mucosal biopsies above the oesophagogastric anastomosis. This would suggest that surgery has created a pre-malignant condition. However, Barrett's oesophagus, and its attendant risk of cancer, is defined as columnar-lined intestinal epithelium with various degrees of maturation and dysplasia [45]. Linthal [35] Bornon's [11] reports recognize the migration of gastric cells into the cervical oesophagus which, without dysplasia, is not associated with an increased risk of malignancy. To date there are no reports of cancer occurring either in or in relation to a successful gastric tube.

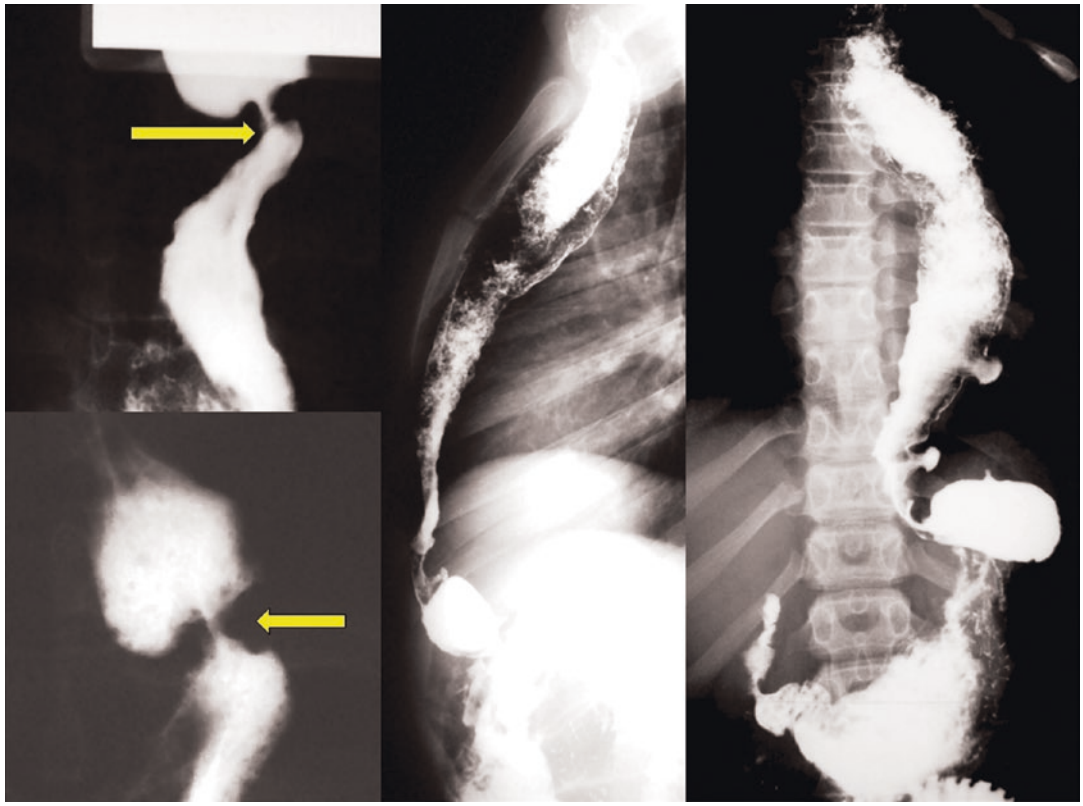

Fig. 54.2 Severe anastomotic stenosis with multiple diverticula 11 years post RGTER

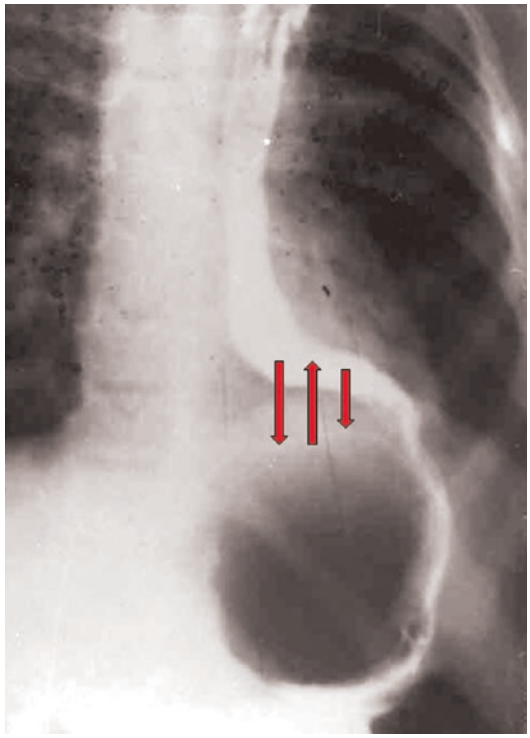

Fig. 54.3 Dysphagia due to too long angulate intra-abdominal GT

The Gastric Tube: Long-Term Follow-Up

Unlike a colon graft which tends to dilate and become redundant with time, often leading to late malfunction [19, 26], the gastric tube remains remarkably constant. Clearly the gastric tube should be constructed to match the calibre of the native oesophagus as there is a direct relationship between the width of the tube and the quality of swallowing [9] (Figs. 54.4 and 54.5).

Dilatation of the gastric tube was observed in only three of our patients, all of whom had retro-sternal placement of the tube. Dilatation was identified on routine radiological studies and was asymptomatic (Fig. 54.6).

In 18 patients oesophageal diverticula were identified on contrast swallows, but on endoscopy only 6 could be directly observed. Most developed in retro-sternal tubes that had been handsewn. Their cause and significance remain unclear, but there have been reports of bleeding and perforation related to diverticula [20, 21]. No gastric tube created with stapling devices has resulted in diverticulum formation.

Lengthening or Growth of the Gastric Tube

Despite the growth spurts of adolescence, the gastric tube appears to grow in proportion to the patient, although it is not clear that this is true growth rather than stretch. Gastric tubes can be expected to lengthen by about 1 cm per year in both the thoracic and abdominal components.

In a young girl operated upon at the age of 6 years for caustic injury, the gastric tube kept pace with her growth to an eventual 1 m 79 cm in height (Fig. 54.7).

The Gastric Reservoir: Long-Term Follow-Up

It is crucial to the success of the operation that the gastric reservoir retains its size, capacity and function after creation of a gastric tube, and this is difficult when the operation has been performed in infancy. The gastric phase of digestion, Vitamin B_{12} absorption and normal gastric emptying are all essential to normal nutrition. Both gastric tube oesophageal replacement and colonic interposition retain a gastric reservoir. Total gastric transposition greatly impairs reservoir function, particularly when augmented by a pyloroplasty or other gastric drainage procedure, resulting in a gastric phase reduced to 5 or 10 min [17, 36, 41]. A large stomach that allows creation of a gastric tube whilst leaving an adequate reservoir is an essential precondition to GTER and in patients with oesophageal atresia, in whom the stomach is initially small, may considerably delay surgery (Fig. 54.8).

Although in some patients the stomach may appear small after creation of a gastric tube, and this may be reflected in symptoms of diarrhoea and failure to thrive, growth results in normalization of gastric capacity within a year. During this transitional phase, dietary manipulation under

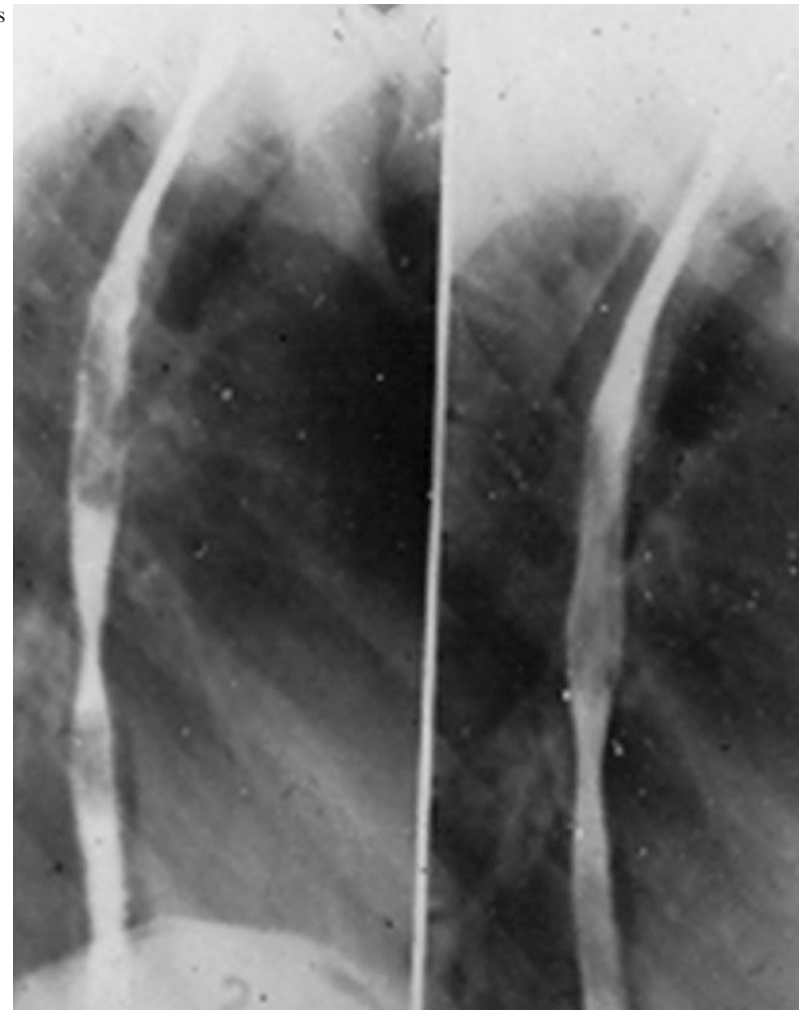

Fig. 54.4 Ideal GT 11 years post RGTER within post mediastinum

the supervision of a dietician may control symptoms. In patients with oesophageal atresia, despite sham feeding, oral feeding can be difficult to establish. Assistance can be gained from an experienced speech therapist.

Quality of Life in Adults Who Had Gastric Tube Oesophageal Replacement in Childhood

Introduction

There is copious literature to define the quality of life after oesophageal replacement performed in adults for benign or malignant disease [15, 34, 37, 48, 49]. In children several recent reports define the long-term effects of colon interposition [10, 16, 25, 38, 43, 47], gastric tube oesophageal replacement [4, 5, 15, 20, 22, 23, 30, 34], gastric transposition [17, 24, 36, 41, 44] and small bowel interposition [14].

Our experience of 109 gastric tube replacement and 37 colonic interpositions is presented.

Summary of Authors' Experience

From 1975 to 2009, we performed 109 GTER operations for long-gap oesophageal atresia

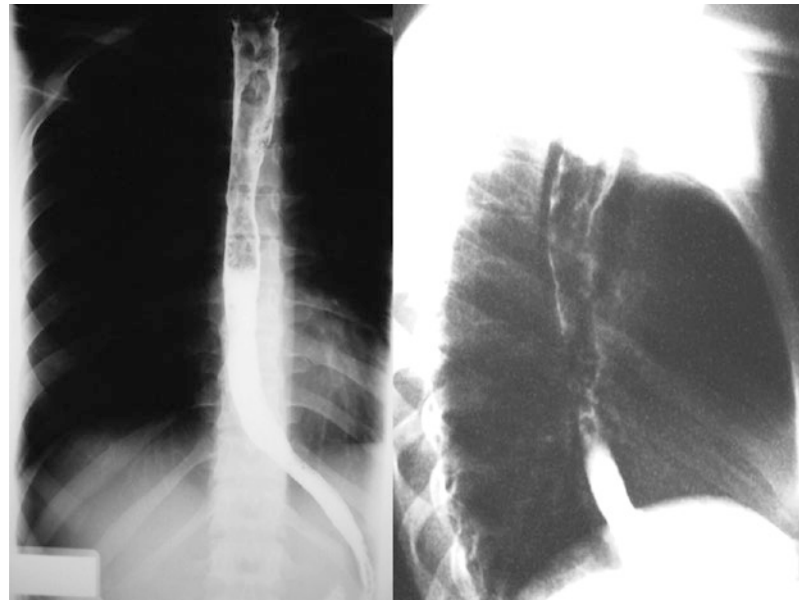

Fig. 54.5 The GT maintains the same calibre 16 years post GTER posterior mediastinum

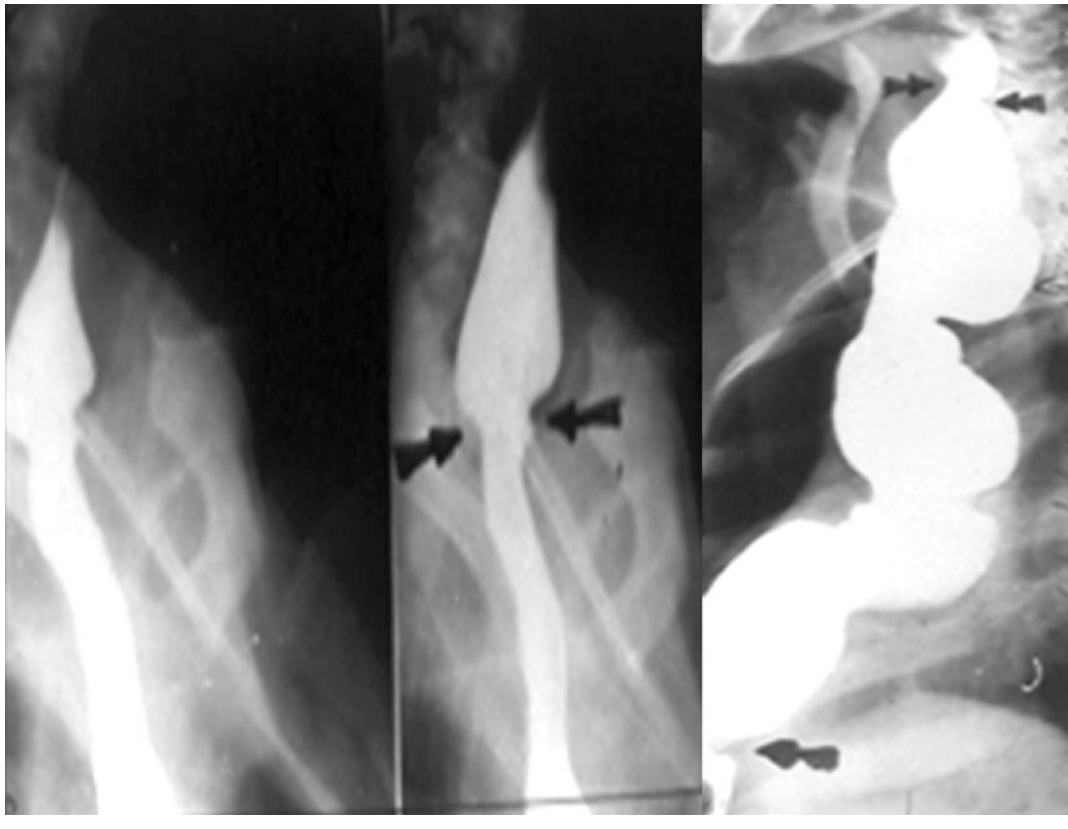

Fig. 54.6 Progressive dilatation of retro-sternal GT

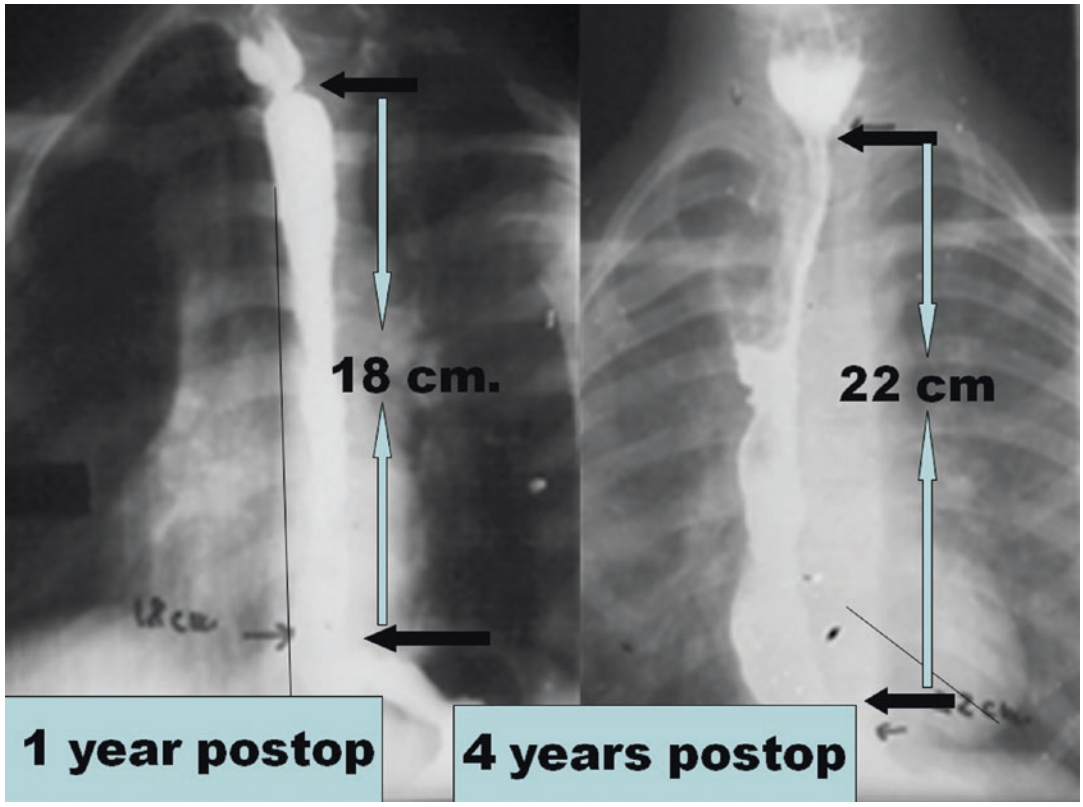

Fig. 54.7 Growth of the GT

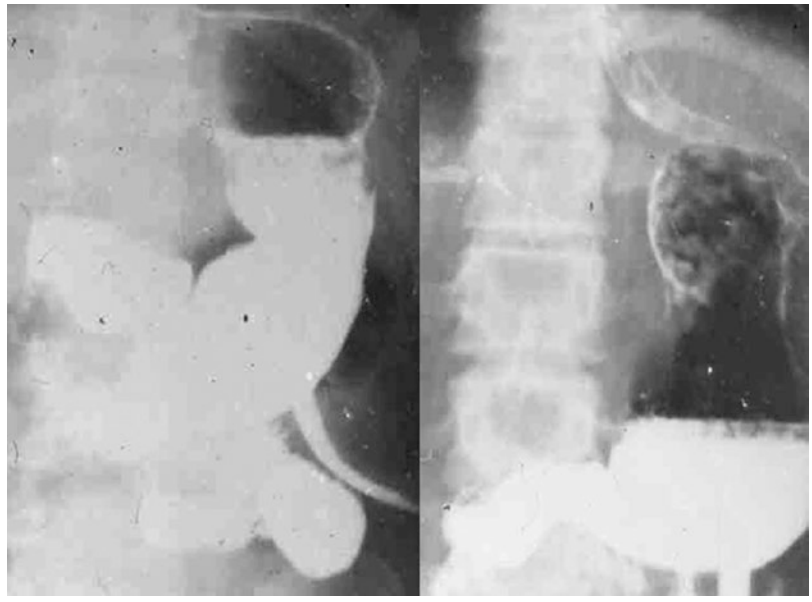

Fig. 54.8 Contrast study of the stomach immediately after GT shows good volume

(23, 21 %), severe caustic stricture (85, 78 %), including one attempted suicide, and one due to severe stricture secondary to gastroesophageal reflux.

In the first 19 patients, the tubes were sited retro-sternally without oesophagectomy, but the last 90 patients had posterior mediastinal placement with simultaneous transhiatal oesophagectomy for those with an injured oesophagus.

Two gastric tubes were isoperistaltic and 107 reversed. The detailed technique of the operation, as well as the potential complications, has already been presented.

The post-operative course was uneventful in 62 patients (53 %). Thirty-six patients (30 % suffered minor complications, and 11 (17 %) had major complications.

The most frequent complication was fistulation from the upper anastomosis, but this decreased from 37 % when the tubes were placed retro-sternally to 6 % when the tube was placed through the posterior mediastinum.

Complete failure of the gastric tube occurred in two patients: on one occasion due to the creation of an atypical tube when scarring of the greater curve due to the original caustic ingestion was identified at surgery. This ischaemic tube was removed from the posterior mediastinum on the seventh post-operative day and replaced with a retro-sternal colon interposition. One failure, in a child with severe developmental problems and hydrocephalus, who weighed just 3,5 kg at 2 years of age, was due to a breakdown of a retro-sternal tube. The child died of systemic sepsis after an attempt to repair the gastric tube via a median sternotomy.

Overall there were 7 (6 %) deaths in our experience. Five patients died following post-operative complications in the early period of the series (last 1982), and two patients died unexpectedly on day 14 and day 45 post-operatively whilst at home on full oral feeds. One of these children had Down's syndrome, and both operations were done for long-gap oesophageal atresia. It is likely that both deaths were due to aspiration during sleep.

One patient with a successful pharyngoesophageal replacement died of complications of his tracheostomy 2,5 years after a reversed duodenogastric tube for pharyngoesophagoplasty.

Prospective Study of QOL of Adults After Oesophageal Replacement Performed During Childhood

The gastrointestinal quality of life index [18] has been utilized but has proved inadequate for the assessment of quality of life after GTER. We therefore designed a questionnaire assessing the following features:

1. Medical assessment on an outpatient basis
2. Long-term follow-up
3. Social and family life
4. Extra-professional activities
5. Self-assessment of quality of life

Using this template, 86 patients were serially reviewed in 1992, 1996, 2002 and 2009. The detailed results were published as part of a doctoral thesis defended in 2009 [22].

To be included patients had to be more than 10 years post-operative and older than 16 years. From the cohort of 86 patients, 37 (41 %) fulfilled all the inclusion criteria. Nine adult patients now live and work abroad, but all completed the questionnaire and underwent clinical evaluation at their place of residence. Of the study group, the mean follow-up is 19 years. Too few patients who had GTER for long-gap atresia are represented, and it was not possible to compare outcomes for the two major surgical indications.

Questionnaire for long term follow up of patients with gastric tube esophageal replacement:

Pt. No…… Year……

Pt details……..…

……..…

Short summary……..

Age at operation……Year…….RGTER Type I /II Years from operation……..

Complications minor / major: Yes /No. If yes which one? ……

Secondary surgery for complications:

……

Follow up. Admission…….. Telephonic interview……

Weight……..Kg (under weight / normal / overweight)

Height…….cm (underweight / normal)

Swallowing /eating. Normal……..Dysphagia: minor, major, intermittent, and continuous for solid food or liquid food. Other abdominal G-I symptoms/complains……..

Dumping syndrome -Yes /No. Details……

Stool, G-I motility: normal, constipation, diarrhea, other symptoms or complaints:

……

Other minor / major health problems unrelated to the RGTER……

Did your operation in childhood influence your orientation as career choice: Yes/ No

……

Have your choice of profession been influenced by the operation: Yes /No. ……..

Have you been able to study or specialize in what you wanted without difficulty related to the operation? Yes/ No……

Profession: What is your present job?

How long have you been in this position?

Have some symptoms or other inconvenience related to the operation and are they any negative effects on your profession? Yes /No……..

Have you had to take sick leave due to the previous operation; Yes /No/ If yes, why?

……

Social and family life.

Are you married Yes /No. For how many years?.....Do you have children Yes /No……..

How many……Do you think that your family life has been influenced in any way by the previous operation Yes /No……

If unmarried do you think it is due to your previous operation Yes ?No……

Do you have a partner Yes /No……..

Do you have a normal sexual life (voluntary answer) Yes /No……

Your sexual life was or is in any way influenced by the previous operation Yes /No……

Do you have psychological or psychiatric problems which could be explained or correlated with your previous operation Yes/No: ……

Extra professional activities

What are you doing and enjoying outside of your professional work: Reading Yes/No…… Listening to music Yes /No……. Watching movies on grand screen Yes /No……..

Watching matches Yes /No…… Do you attend live theatre Yes / No. ……

Other activities……..

Are these extra-professional activities in any way influenced by your previous operation?

Yes /No…… Do you think that the fitness activity or sport are in any way influenced by your previous operation Yes /No……

Do you have a driver license Yes /No…….. Do you drive a car Yes/ No……..

In a stress condition (at home or at work) do you have symptoms related with your previous operation (i.e. difficulty in eating, true dysphagia) Yes /No ……

Any other medical or non medical problems which you think are related with the operation and not mentioned above, please comment: ……..

……

What is your own perception about the quality of your life (related or unrelated to the operation of esophageal replacement): Normal (very good), Good, Satisfactory, Poor.

Thank you for your participation.

Summary of Long-Term Results

Thirty-two (86 %) of our patients have normal swallowing, and five complain of occasional "sticking". One patient complains of symptoms of dumping but with normal gastric emptying on contrast studies. Eleven patients (30 %) were underweight and six (16 %) were short or stunted. Nine patients complained of easy fatigue that they ascribe to their surgery, and four patients reported feeling "stressed" by their situation.

Thirteen patients (35 %) have a high school or university education; 22 (59 %) are employed in a variety of trades and professions (drivers, carpenter, construction industry, agriculture). They have no complaints concerning their previous surgery. Two patients are currently unemployed.

Four female patients are married with children, one of them being the patient who attempted suicide by caustic ingestion at the age of 14 years.

Only four patients (11 %) have regular extramural activities such as sport. From the entire group, only 2 (5 %) consider that the oesophageal replacement is having a negative effect on their quality of life.

Thus, overall 17 patients (46 %) have a normal life, and 16 (43 %) have intermittent minor complaints, but they consider themselves to be leading normal lives. Four patients (11 %) have various moderate problems related to their surgery, but they are still satisfied with the results. No patients are considered to have had a bad result or to be complete failures. All eat a full diet orally, and no patient has a residual gastrostomy.

Final Commentary on Oesophageal Replacement

It is clear that three techniques of oesophageal replacement dominate surgical practice around the world: colonic interposition, gastric tube oesophageal replacement and total gastric transposition. Surgeon preference and experience are the most important factors in selecting the procedure. In very few cases, usually after failure of the primary procedure, there are specific indications for an alternative.

It is also clear that oesophageal replacement is less frequently necessary today than in previous decades due to the success of oesophageal lengthening procedures (Foker's or Kimura's techniques) applied to children with long-gap atresia. Serial balloon dilatations and intralesional steroids have also allowed oesophageal salvage in some cases of caustic injury, the incidence of which has been reduced in developed countries by legislation on the purchase and storage of caustics.

Colonic Interposition

Around the world this is probably the most popular technique of oesophageal replacement in children [10, 13, 16, 25, 38, 43, 47]. Surgery can be performed early in life, even in the presence of a small stomach, because the gastric reservoir is fully retained. An initial feeding gastrostomy is only indicated if preoperative nutritional supplementation is necessary. Colonic interposition is a good salvage procedure following failure of gastric tube oesophageal replacement [25]. It is possible after a failed gastric transposition to relocate the stomach in the abdomen and to still perform a colonic interposition [25].

As in all techniques of oesophageal replacement, the commonest complications occur at the upper anastomosis. Complete failure of the interposition is still a threat but with experience is reduced to an occasional complication [3]. With colonic interpositions, concerns relate to the long-term changes within the graft; redundancy [26], hypoperistalsis and progressive dilatation [3], a non-functional conduit [19], stasis of food within the graft resulting in halitosis due to stagnant fermented food being retained and difficult endoscopy in redundant and particularly retro-sternal grafts are the most frequently reported difficulties. Peptic ulcers due to acid reflux into the conduit and the development of diverticula have also been described [43]. Of course in very specific circumstances, a colonic interposition would be inappropriate (associated Hirschsprung's disease, anorectal malformations or acquired colonic diseases), and an alternative replacement should be performed.

Total Gastric Transposition

This procedure is frequently performed in adults suffering from carcinoma of the cervical or thoracic oesophagus and has been used by Lewis Spitz in London [17, 24, 36, 41, 44] and quickly adopted by paediatric surgeons around the world as a safe and easy means of replacing the injured or absent oesophagus. It can safely be performed laparoscopically.

The long-term results are satisfactory in many patients [17, 36, 41], and after 20 years 90 % of patients have a good or excellent result [41]. However, total gastric transposition completely eliminates the gastric phase of digestion, and contrast studies show a 5–10 min gastric emptying time. Frequently, especially if a pyloroplasty or other gastric drainage procedure has been added, there is massive bile reflux into the stomach with episodes of bilious vomiting.

Our experience of patients who have had gastric transpositions performed elsewhere suggests a failure to grow normally, probably related to the functional gastrectomy and the alteration of the stomach's function from reservoir to conduit. In our practice total gastric transposition is a salvage procedure to achieve oral feeding [3].

Gastric Tube Oesophageal Replacement

From the literature approximately 4,000–5,000 children worldwide have had gastric tube oesophageal replacement over the last 60 years [4, 5, 15, 20–23, 30]. Most were performed as reversed antiperistaltic tubes and a few isoperistaltic [11]. Our experience, over 35 years, is amongst the largest reported, with follow-up into adulthood [5, 22, 29–31].

Advantages of the Gastric Tube

The gastric tube allows flexibility in its construction, both in terms of length and calibre, to produce a well-vascularized and reliable conduit that will retain its proportions but grow with the child. The risk of infection is reduced by acid secretion within the conduit.

Using mechanical stapling devices, the creation of the tube is quick and easy as well, and the risk of leakage from the long staple line is much reduced over the historical handsewn anastamosis.

The gastric reservoir and its physiological function are preserved, and when the conduit is placed in the posterior mediastinal position, the final radiological anatomy of the upper gastrointestinal tract is near normal.

Disadvantages of the Gastric Tube

The need for a large gastric capacity before creation of a gastric tube has been repeatedly emphasized. A feeding gastrostomy for a prolonged period is necessary in most cases, particularly in long-gap oesophageal atresia.

When the operation is done without a prior gastrostomy, the completed operation resembles a bariatric procedure (sleeve gastrectomy), but the stomach develops a reservoir function over the ensuing year or 2.

The major problem with gastric tube oesophageal replacement remains the upper cervical gastric tube oesophageal anastomosis with the risk of fistula, stenosis and occasionally necrosis of the distal 1–3 cm of the tube. Most of these complications can be reduced with care and experience.

A strict protocol of follow-up is required for the early detection of anastomotic stenosis, but up to 50 % of patients will, at some stage, require dilatation which we prefer to perform using balloon dilators.

Other rarely reported complications include megaloblastic anaemia, permanent small stomach, delayed gastric emptying, dumping syndrome and Barrett's oesophagus. Apart from one child with dumping syndrome following an isoperistaltic tube, none of these complications were seen in our experience.

What Is the Best Oesophageal Replacement in Children?

Several retrospective and prospective studies [12, 13, 15, 21, 27, 43, 44], including our own [22], have attempted to answer this question. In an

extensive literature review, Arul [7] found that in the absence of prospective randomized studies, no reliable answer could be proposed.

Several authors (Burgos for colonic interposition [12, 13], Tannuri for colonic interposition and gastric transposition [43, 44], Helardot for gastric tube oesophageal replacement and other methods of oesophageal replacement [27]) have tried to establish criteria for the selection of the technique for oesophageal substitution.

Collard [15] demonstrated experimentally advantages for gastric transposition over gastric tube oesophageal replacement, and Tannuri [44] in a clinical series found superior results with the use of whole stomach. However, all studies report only early complications such as fistula formation, the number of days that ICU care is required and the need for ventilatory support, time to oral feeding, etc. The true value of an oesophageal replacement must evaluate the long-term results.

However, it is clear that there is no ideal oesophageal substitute, and with the diminishing numbers of children requiring oesophageal replacement, certainly in developed countries, it is unlikely that prospective randomized trials will be possible.

Conclusion

In children who require oesophageal replacement for congenital or acquired diseases of the oesophagus, the reversed gastric tube oesophageal replacement, brought through the posterior mediastinum in a one-stage procedure following transhiatal oesophagectomy if necessary, is an excellent option. The operation itself, as well as the preoperative preparation and post-operative monitoring, should be performed in a specialist centre by a multidisciplinary team.

The initial good results are durable, as is the anatomy and function of the gastric tube. Follow-up into adulthood shows that quality of life for most patients is excellent.

Long-Term Follow-Up After Gastric Reconstruction of the Esophagus

55

Sarah E. Billmeier, David I. Soybel, and Michael T. Jaklitsch

Introduction

The stomach is one of the most commonly used conduits for esophageal replacement. Restoration of gastrointestinal continuity may be undertaken for a variety of underlying etiologies, including long-gap esophageal atresia in children or benign or malignant disease in adults. Regardless of underling etiology, the replacement esophagus must be able to adequately mimic the native esophagus over the lifetime of the patient. While the literature on long-term follow-up after esophageal replacement is somewhat limited, the published experience does highlight outcomes that result from the act of transposing conduit into the altered physiological environment of the chest. In this chapter we will review these outcomes, with particular focus on the results after gastric pull-up.

Indications

The majority of esophageal procedures in children and infants are performed for esophageal atresia or strictures caused by caustic ingestions. Between 92 and 97 % of esophageal atresia defects can be corrected by primary esophagoesophagostomy [1, 2]. While even patients with long-gap atresia, defined as a gap of more than 3 cm, can be repaired primarily, a small percentage of children with atresia will be treated with esophageal replacement, either as a first procedure or after primary repair has failed. Caustic ingestion strictures are usually managed with serial dilation; however in severe cases with multiple, long strictures, esophageal replacement may be the best option [3]. The median age of esophageal reconstruction in children is dependent on the underlying disease, but is 2 years old when all etiologies are included [4]. The goal of esophageal replacement in children is maintenance of function for 70 years or more.

In adults, 74 % of esophageal replacements are for malignant disease [5]. Despite overall 5-year survival rates of 23–31 % after esophagectomy for cancer, every patient undergoing esophagectomy for malignancy has the potential to be a long-term survivor [6]. Given that the median age of diagnosis of esophageal cancer is 68, the expectation of durability for the neo-esophagus has traditionally been less than in children [7]. With advances in surveillance and management of esophageal cancer, however, adult esophagectomy patients will

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_55

increasingly rely on an esophageal replacement for decades rather than years.

In benign disease, esophageal replacements are typically performed on younger patients with a lower risk of death from their underlying disease and thus also require long-term use of their esophageal replacement. Esophageal reconstruction for benign disease in adults is most often undertaken for esophageal strictures (42%), primary motility disorders (33%) including achalasia, perforation (14%), or paraesophageal hernias (6%). The median age of esophagectomy for end-stage benign disease is 44–55 years old [8, 9]. Esophagectomy in these patients can be technically challenging as patients have frequently had multiple previous endoscopies, dilations, or esophageal operations [9].

Characteristics of the Ideal Esophageal Replacement

The best choice of conduit for esophageal replacement has long been debated. Conduit choice must be adapted and optimized for each patient depending on the patient's anatomy, disease, and prior surgical history. The goal of the esophageal replacement conduit is to mimic the function of the native esophagus for the lifetime of the patient. An ideal conduit allows for swallowing without aspiration, eating and drinking at a normal rate, belching, and vomiting. Additionally, the conduit should form a barrier against reflux. Finally, the operation to replace the esophagus should have minimal associated morbidity and mortality [10]. Choices for conduit include stomach, colon, jejunum, revascularized free grafts of abdominal viscera, skin or myocutaneous flaps, and historically external bypass with a prosthesis. The first three options are the most common and will be discussed further here.

The Stomach as Conduit

Stomach is the most common source of conduit for esophageal replacement due to its relative operative safety and simplicity. In children, gastric transposition is associated with the least short-term morbidity and mortality relative to alternatives such as colonic transposition or gastric tubes [11–16]. With division of the left and short gastrics, the stomach can reach the level of the cervical esophagus with maintenance of blood supply via the gastroepiploic vascular arcade. Only a single anastomosis is required, and thus there is one site with the potential to leak or stricture. An illustration of esophagectomy with gastric reconstruction is shown in Fig. 55.1.

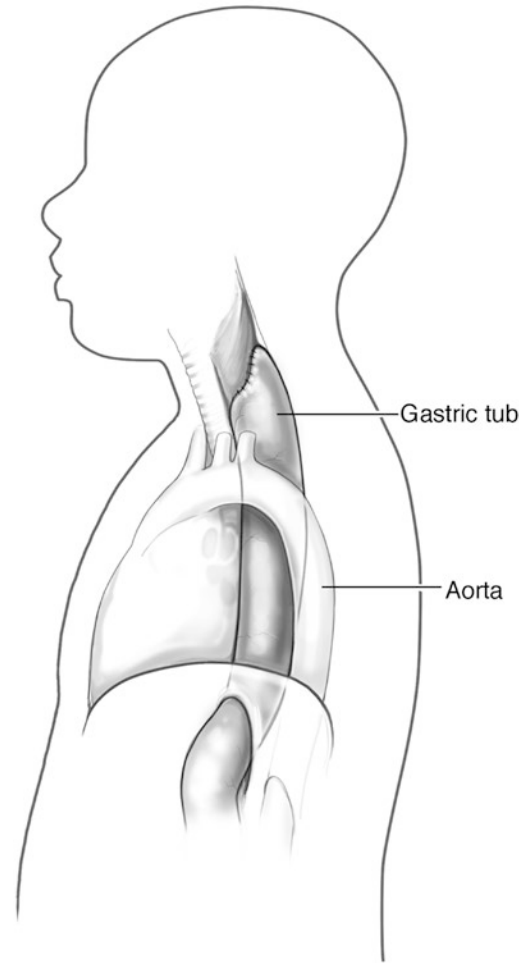

Fig. 55.1 Esophagectomy with posterior mediastinal gastric tube reconstruction and cervical anastomosis (Artwork by Marcia Williams)

The stomach has been used in a variety of configurations. Transposition of the whole stomach involves division of the left and right gastrics and left gastroepiploic and short gastric vessels and

mobilization of the pylorus and duodenum via a Kocher maneuver, followed by the creation of the anastomosis. Vascularization is based on the right gastroepiploic artery alone. A pyloroplasty or pyloromyotomy is commonly added, although this is controversial. The transposed stomach can be placed substernally or in its native bed in the posterior mediastinum.

Alternatively, a gastric tube created from the greater curvature of the stomach can be used. The gastric tube is less bulky than use of the whole stomach and passes with minimal compression through the diaphragmatic hiatus and the thoracic inlet into the neck. In our experience, the width of the gastric tube impacts the ability of the conduit to efficiently transport food, with a width of two fingers breadths conferring optimal function.

Disadvantages to the use of gastric conduit include the possibility of immediate morbidity due to vascular insufficiency at the level of the anastomosis. Over the longer term, the lack of a reflux barrier between the stomach and the esophagus can lead to complications such as aspiration, esophagitis, and stricture [17]. However, as originally observed by Sweet in 1945, the higher the anastomosis, the lower the incidence of significant reflux [18]. Disadvantages of gastric tubes include the possibility of leak along a long staple line and risk of injury to the spleen during preparation of the tube.

Alternative Conduits

Colon

Colon is a versatile conduit that can be used as an esophageal conduit for both malignant and benign disease. In adults, it is often used when stomach is unavailable due to previous operations, ulcers, or caustic burns. Reconstruction with colon is relatively common in children due to concerns of long-term complications with gastric transposition. A pedicled segment of left colon is most commonly used as it typically is of sufficient length the reach the neck, is of relatively small diameter, and has peristaltic ability.

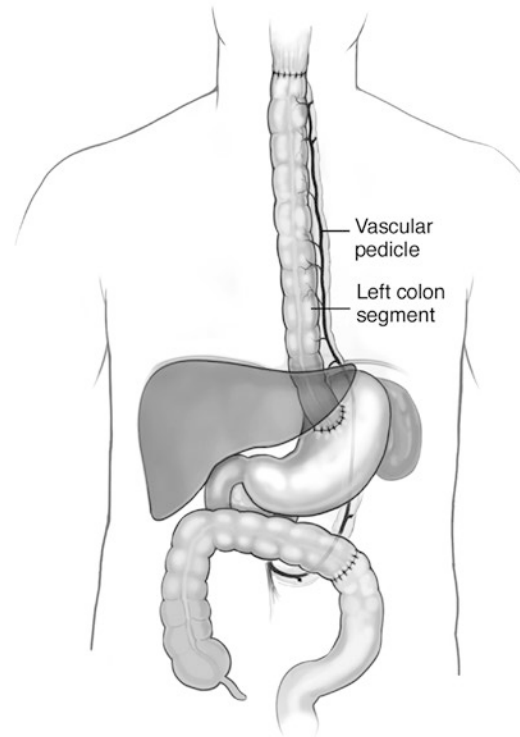

Fig. 55.2 Colonic interposition using pedicled left colon and a cervical anastomosis (Artwork by Marcia Williams)

An illustration of a colon interposition is shown in Fig. 55.2. The blood supply is maintained via an ascending branch of the left colic artery. In comparison, the right colon is shorter and larger in diameter, often lacks a marginal artery, and may be used when both the stomach and left colon are unavailable. The disadvantages of colon include the potential for leak of colonic contents in both the chest and abdomen, as well as the need for larger incisions for mobilization and the creation of three anastomoses. Patients with inadequate mesenteric blood supply due to atherosclerosis or an interrupted marginal artery or those with colonic disease are excluded as candidates. Over time the colon tends to dilate and lose tone and thus decline in function. In the long term, dilation and kinking can result in stasis and obstruction. Techniques to reduce dilation include minimizing conduit redundancy and eliminating sigmoid deformity at the time of the initial operation.

Jejunum

Jejunum is another option for esophageal replacement, particularly for distal esophageal resection or for replacement of the esophagus and stomach when malignancy involves both organs. Jejunum has been used as an intact loop, in a Roux-en-Y reconstruction, as an interposition between esophagus and stomach, and as a free tissue graft with use of microsurgical vascular anastomoses [10]. Advantages to the use of jejunum include the similarity of tube diameter to the esophagus, the ability of the graft to maintain peristalsis, and the ability to act as a barrier to reflux if of sufficient length. The use of jejunum is limited by the complexity of the mesenteric vessels. Obtaining a long segment of jejunum is often complicated by significant angulation and redundancy due to the tight radius of the blood supply. Careful dissection is necessary to prepare a long loop of jejunum that will reach the neck. To prepare the jejunal loop, the abdomen is typically opened via an upper midline incision and the small bowel is lifted out of the abdomen. The vascular anatomy of the small bowel is then inspected. In order for the jejunal loop to reach the neck, an average of four main jejunal branches from the superior mesenteric vessels need to be divided. Prior to division, bulldog clamps can be placed across the site of proposed transections to assess adequacy of the blood supply [19]. If mobilization creates excess intestine relative to the mesentery, redundancy can be overcome by excision and re-anastomosis of bowel [20, 21]. The jejunum can then be tunneled in an antecolic or retrocolic fashion, with antecolic reducing the risk of kinking of the vasculature. Figure 55.3 shows the tight

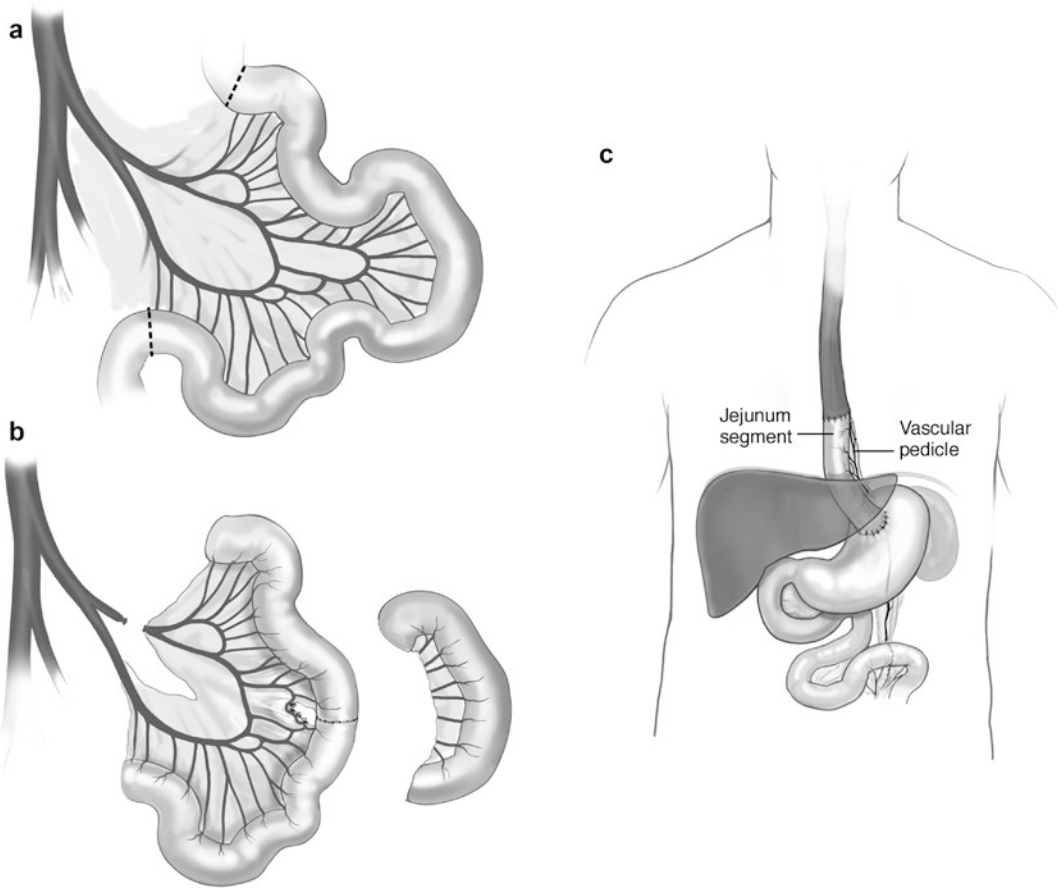

Fig. 55.3 Pedicled jejunal graft. (**a**) Illustrates the tight angulation of the jejunal vasculature, (**b**) excision of redundant bowel, and (**c**) anastomosis of the pedicled graft to the esophagus and stomach (Artwork by Marcia Williams)

angulation of the jejunal vasculature, excision of redundant bowel, and anastomosis of the pedicled graft to the esophagus. In patients with marginal vascular arcades, microvascular anastomosis of the internal mammary vessels has been used to augment blood supply [22].

Physiology of the Intrathoracic Stomach

The translocated stomach exists in an altered physiological environment. As described by Holscher, the blood supply is typically decreased by 10–20 % due to ligation of the left gastric and left gastroepiploic arteries [23]. Poor perfusion in the translocated stomach has been correlated with both increased rates of leak and stricture. Pierie et al. found that a reduction of perfusion below 70 % of pre-reconstruction values predicted anastomotic stricture formation [24]. Additionally, Ikeda et al. found that patients with low tissue blood flow by laser Doppler flowmetry were more likely to develop leaks than those with higher tissue blood flow [25].

Depending on the preparation of the stomach, the storage capacity and parietal cell mass are usually reduced due to partial resection of the fundus and corpus. The stomach's shape is changed by surgical manipulation and by stretching. Additionally, the transposed stomach is moved from the positive pressure environment in the abdomen to the negative pressure environment of the chest. In its new role as the neoesophagus, the usually receptive stomach is changed to a conduit of food and liquid boluses. A complete vagotomy permanently changes the stomach's innervation, as further discussed below. Gastric acid is at least temporarily decreased while gastrin levels are elevated [26].

The Vagal Nerve's Impact on Functional Outcomes

Many of the functional outcomes associated with esophageal reconstruction can be related to sectioning of the vagus nerve. The vagus broadly innervates structures in the head and neck, chest, and abdomen. Surgical division during resection and reconstruction of the esophagus results in predictable alterations to normal physiology. Injury or stretching of the vagus or the recurrent laryngeal nerve above the level of surgical division causes additional complications.

Anatomy of the Vagus Nerve

The vagus nerve exits the skull via the jugular foramen and descends within the carotid sheath into the mediastinum between the internal jugular vein and internal carotid artery. In the neck, the vagus branches to supply the larynx, pharynx, and heart. The superior laryngeal branch provides motor innervation to the cricothyroid muscle, which is responsible for control of vocal pitch. Pharyngeal branches provide motor innervation to all the muscles of the pharynx, with the exception of the stylopharyngeus muscle, and muscles of the palate except for the tensor veli palatini muscle. Cardiac branches descend into the mediastinum and provide parasympathetic innervation to the heart. The left and right vagi enter the mediastinum, where they give rise the recurrent laryngeal nerve (RLN) and divide into several branches around the esophagus. The recurrent laryngeal nerves run in the tracheoesophageal groves on both sides of the neck. The right recurrent nerve loops around the subclavian artery, while the left loops around the aortic arch. The RLN is main motor nerve of larynx. It also supplies the upper esophageal sphincter's cricopharyngeus muscle and thus plays a significant role in swallowing.

In the chest, the left and right vagal nerves descend parallel with the esophagus and form cardiac, pulmonary, and esophageal plexuses. The esophageal plexus forms between the level of the tracheal bifurcation and the level of the diaphragm. It is involved in motility of the esophagus and regulation of lower esophageal sphincter pressure [27]. The pulmonary vagal plexus is involved in pulmonary vasculature dilation and the cough reflex [28, 29]. Both left and right vagi contribute to parasympathetic innervation of the heart; however injury to the right, but not the left, increases heart rate via loss of attenuation of

activity of the sinoatrial node [30]. The esophageal plexus merges above the esophageal hiatus to form anterior (left) and posterior (right) vagal trunks that pass into the abdomen.

Once in the abdomen, each trunk separates into two divisions. The anterior trunk gives off the hepatic division that supplies the liver and gallbladder, with a branch reaching the pylorus and the duodenum. The anterior gastric division descends along lesser curvature of the stomach, giving branches to anterior gastric wall. The posterior trunk splits into the celiac division and posterior gastric division. The celiac division is the largest of the four divisions and leads to the celiac plexus, where it supplies parasympathetic fibers to the abdominal viscera [31].

Division of vagal branches to the fundus results in impairment of receptive relaxation, acceleration of gastric emptying of liquids, and decreased gastric acid production [32, 33]. Sectioning of the hepatic branch is associated with hypotonia of the gallbladder and the formation of gallstones [34, 35]. Division of the celiac branch is associated with impairment of motility and neuroendocrine disturbances [36, 37]. Multiple vagal branches supply the pylorus, with the hepatic plexus being most important [38]. An illustration of neck, chest, and abdominal vagal anatomy is shown in Fig. 55.4.

Vagal Injury During Esophageal Reconstruction and Its Consequences

In the neck, the recurrent laryngeal nerve is at risk of injury during circumferential dissection of the esophagus, if a cervical anastomosis is performed. During an extended resection with a formal lymph node dissection for cancer, the left RLN is additionally at risk during dissection of the aortopulmonary (AP) window lymph nodes or nodes along the left paratracheal groove. In this case, performing cervical incision on left reduces risk of bilateral RLN injury [39]. Recurrent laryngeal nerve injury results in vocal cord paralysis with hoarseness, impairment of coughing, swallowing and breathing, aspiration pneumonia, and, if bilateral, stridor and respiratory failure requiring reintubation or tracheostomy [39]. In a study of adults who underwent transhiatal esophagectomy for cancer, Hulscher reported a 22% rate of postoperative vocal cord paralysis and however found that this was permanent in only 4%. The authors concluded that most injuries were likely due to traction or stretching rather than transection [39].

Esophagectomy traditionally requires a truncal vagotomy with division of both the anterior and posterior vagal trunks. This results in loss of pyloric control of gastric emptying, gastric stasis, decreased gastric acid production, and dumping, as further described below [40–42]. An illustration of the abdominal vagal anatomy with truncal and highly selective vagotomy is shown in Fig. 55.4. A summary of consequences of vagal injury or division by location is shown in Table 55.1.

Alternatively, Akiyama et al. described the technique of a vagal-sparing esophagectomy for patients with benign disease or Barrett's esophagus with high-grade dysplasia. The vagi are identified and a limited, highly selective proximal gastric vagotomy is performed. The stomach is divided just below the GEJ, and the esophagus is inverted to remove the esophagus by invagination or eversion while preserving the esophageal plexus and the distal vagal trunks. The esophagus is then typically reconstructed with a colon interposition graft [43, 44]. Vagal-sparing esophagectomy has been shown to decrease dumping, diarrhea, and weight loss relative to transhiatal or en bloc esophagectomy in adult patients with high-grade dysplasia or intramucosal adenocarcinoma [45].

In total, the alterations introduced by placing the stomach in the chest, including division of the vagus nerve, affect gastric secretion, motility, gastric emptying, and gastroesophageal and duodenogastric reflux [23]. Many of the long- and short-term complications that occur after gastric pull-up are a direct consequence of these alterations. A summary of short- and long-term complications is shown in Table 55.2.

Perioperative and Short-Term Outcomes

In children, case series have established a 0–5.2% mortality rate for gastric transposition. The reported leak rate ranges from 12% to 36%.

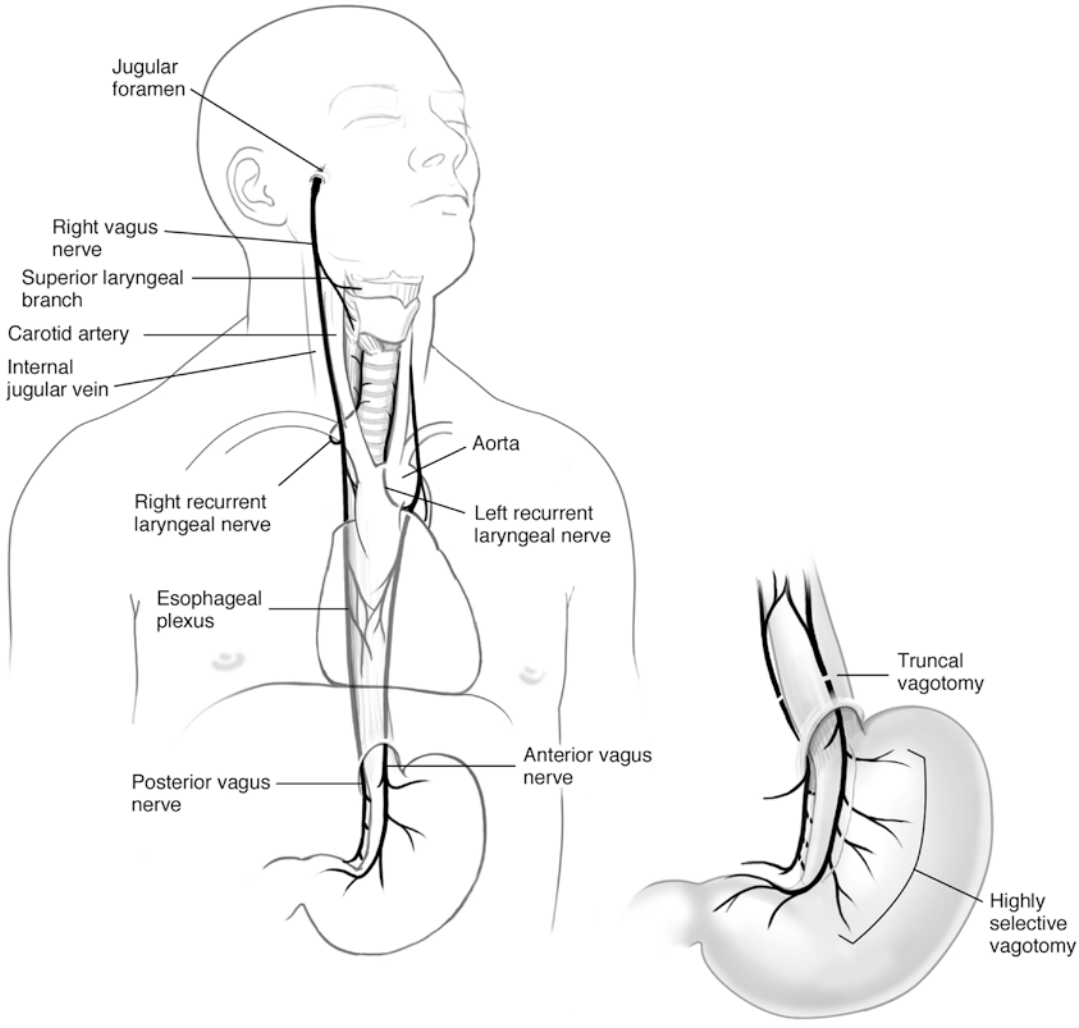

Fig. 55.4 Anatomy of the vagus nerve. *Inset* compares the divisions of a truncal vagotomy to those of a highly selective vagotomy (Artwork by Marcia Williams)

Table 55.1 Consequences of vagal nerve injury or division, by location

Location	Site of injury or division	Consequences of injury
Neck	Recurrent laryngeal nerve	Vocal cord paralysis with hoarseness, impairment of coughing, swallowing and breathing, stridor, respiratory failure requiring reintubation, aspiration pneumonia
Chest	Recurrent laryngeal nerve	Vocal cord paralysis as above
	Esophageal vagal plexus	Impairment of esophageal motility and LES pressure regulation
	Right cardiac vagus	Increase in heart rate via loss of attenuation of activity of the sinoatrial node
	Pulmonary vagal plexus	Impairment of pulmonary vascular dilation and the cough reflex
Abdomen	Hepatic/gallbladder branch	Hypotonia of gallbladder, increased rate of gallstone formation
	Gastric fundus branches	Acceleration of liquid emptying, impairment of receptive relaxation, and decreased gastric acid production
	Celiac branch	Impairment of bowel motility and neuroendocrine dysfunction
	Truncal vagotomy	Diarrhea, dumping, delayed gastric emptying

Table 55.2 Complications of gastric reconstruction of the esophagus

Short-term	Long-term
Leak	Decreased pulmonary function
Stricture (short- and long-term complication)	Dysphagia
Graft ischemia	Odynophagia
Graft loss	Weight loss/lack of weight gain
Vocal cord paralysis	Malnutrition
Chylothorax	Impaired gastric emptying
Aspiration	Dumping syndrome
Pneumonia	Anemia
Sepsis	Atrophic gastritis
Pulmonary embolus	Acid reflux
Death	Bile reflux
	Esophagitis
	Barrett's esophagus
	Esophageal stump dysplasia and cancer
	Diaphragmatic hernia
	Redundant conduit

Strictures formed in 19.6–49 % with one study approximating that 40 % of strictures formed in patients who were being treated for caustic ingestion. Other short-term complications include vocal cord paralysis, aspiration, chyle leak, effusions, and pneumonia [1, 4].

In comparison, series describing the outcomes of colonic transposition report a 0–4 % mortality rate, an 8–9 % rate of graft necrosis or ischemia, a 6–40 % leak rate, and a 28–50 % rate of anastomotic stricture [46, 47]. In 2007 Tannuri et al. published a comparison of esophagocoloplasty ($n = 115$, using transverse colon conduit with maintenance of a double blood supply via the left colic vessels and the marginal paracolic arcade via the sigmoid vessels) versus gastric transposition ($n = 34$) and found a 0.9 % mortality rate, 2.6 % major complication rate, and 85.2 % minor complication rate for esophagocolonoplasty versus a 5.9 % mortality rate, 23.5 % minor complication, and 52.9 % minor complication rate for gastric transposition [48]. The authors conclude that colon transposition is superior; however it should be noted that the two study groups were not comparable, with colon transposition representing the default operation.

In adults, overall mortality and survival have been similar between esophagectomy for cancer reconstructed with gastric transposition or colon; however some authors report higher morbidity for colonic transposition, with higher rates of anastomotic leaks and abdominal septic complications [49]. Reported 30-day mortality rates for esophagectomy with reconstruction for cancer range from 2.7 to 4.8 % and are not significantly different between colon and gastric interposition [49, 50]. Biel et al. reported that prevalence of endoscopically detected graft ischemia was similar with gastric and colonic reconstructions: 10.4 % versus 7.4 %, respectively. The prevalence of strictures was more common and more severe after gastric than colonic reconstruction [50]. At our institution, utilizing a three-incision esophagectomy technique with cervical esophagogastrostomy, the 30-day mortality for esophageal carcinoma patients is 3.6 % with a median survival of 25 months. Overall 3-year survival was 44 %. Recurrent laryngeal nerve injury occurred in 14 %, chylothorax in 9 %, and leak in 8 % [51].

Series reporting experience with jejunal interposition for esophageal replacement in patients of all ages found a 0–3.5 % mortality rate, 5–10 % leak rate, and 0–5 % rate of graft loss [52–54].

Long-Term Function and Complications

Studies of long-term functional outcomes in adults have been limited by the low survival rate of esophageal cancer; however there are multiple recent studies that illuminate the function and complications of esophageal replacement years after esophagectomy and reconstruction. In children, long-term results are obtained from published small case series. Regardless of the age of the patient, the published literature focuses on quality of life, swallowing function, gastric emptying and its consequences, nutrition status, and the long-term consequences of bile and acid reflux, as discussed below. Less reported findings

of impairment in pulmonary function and uncommon complications such as diaphragmatic hernia or redundant conduit are also discussed.

Quality of Life

There are limited numbers of studies comparing quality of life after reconstructions with different types of conduit. In children, quality of life was found to be generally unimpaired for patients who had gastric transposition for esophageal atresia, although the patients tended to be less socially and emotionally independent than their peers [55]. In adults at least 5 years after esophagectomy for cancer, physical function and level of energy SF-36 scores were significantly decreased from the national average; however the ability to work, social interaction, daily activities, emotional dysfunction scores, and perception of health were similar to national norms. Patients had significantly higher scores in mental health [56]. In patients who underwent esophageal reconstruction for benign disease (71.6% with stomach, 19.8% colon, and 9.6% small bowel), physical functioning, health perception, and social functioning were decreased compared to national norms a median of 9.8 years after surgery. Bodily pain, ability to work, energy level, emotional problem, and depression scores were similar to national norms [57].

Swallowing/Dysphagia

In a study of long-term effects of gastric transposition in children at least 5 years after surgery, Davenport et al. reported that 94% of patients had a normal, unmodified diet; however only 29% had asymptomatic swallowing [11]. Many children were noted to have developed a coping mechanism of drinking copious water when eating. In his series, Spitz et al. found that 30.6% had early postoperative swallowing problems, which persisted in half [4].

In a study of adults who were also at least 5 years after esophagectomy (93% with gastric reconstruction), 25% of 107 patients reported dysphagia to solid food and 9% had pain on swallowing. Nine percent reported dysphagia to pureed diet and 3% had dysphagia to liquids. Thirty-seven percent stated that they altered their food intake to eat smaller more frequent meals. Forty-three percent of these patients had undergone at least one postoperative dilation [56].

Gastric Emptying

Although the intrathoracic stomach (whole or gastric tube) is commonly thought to act as an inert tube after esophagectomy, with food emptying only by gravity, motor activity of the denervated stomach slowly recovers with time [58, 59]. Furthermore, motor recovery may be better in whole stomach transpositions relative to gastric tubes [60]. Accordingly, studies of gastric emptying tend to show improvement over time. In adults, Lee et al. found that 50% of patients had markedly prolonged gastric emptying of solid foods immediately after esophagectomy; however gastric emptying improved and the further patients were out from their operation [61]. Urshel et al. reported that pyloric drainage (pyloroplasty) reduced the occurrence of early postoperative gastric outlet obstruction and however had little effect on other early or late patient outcomes such as gastric emptying, nutritional status, or bile reflux [62]. Similarly, a study of children at least 5 years out from gastric transposition found that in 82%, more than 50% of solid and liquid contents left the stomach by the time of meal completion (5 min) [11].

Dumping

Dumping syndrome is a group of symptoms that result from rapid gastric emptying, including diarrhea, palpitations, pallor, abdominal cramps, weakness, sweating, dizziness, or the need to lie down after eating. Delivery of a large bolus of hyperosmolar contents to the duodenum causes a fluid shift from the intravascular compartment to the intestinal lumen, resulting in a decrease in circulating volume [63]. Increased release of several gastrointestinal hormones may also play a role. Late dumping symptoms that occur 1–3 h

after a meal are attributed to reactive hypoglycemia [64]. In children, Davenport et al. found that 12 % of children experienced postprandial weakness and dizziness. Twenty-three had significant episodes of diarrhea "at least once a week," precipitated by consumption of sweets, yogurt, or sugary foods. Interestingly, no correlation was found between the presence of diarrhea and dumping and radionuclide gastric emptying [11].

In adults 5 or more years after surgery, 50 % reported experiencing symptoms of postprandial dumping, including 24 % with diarrhea, 16 % with cramps, 8 % with nausea, 7 % with dizziness, and 6 % with diaphoresis [56]. In a comparison of symptoms in adults after vagal-sparing esophagectomy with colonic interposition, standard esophagectomy with colonic interposition and esophagectomy with gastric pull-up, Banki et al. found dumping symptoms in 1 of 15 (7 %), 3 out of 10 patients (30 %), and in 1 out of 10 (10 %), respectively [44]. In larger series, rates of dumping after gastric pull-up have been reported at 18–50 % [56, 65, 66] and typically decline with time [67]. Furthermore, Headrick et al. found that patients with a cervical anastomosis were more likely to have dumping symptoms relative to those with an intrathoracic anastomosis [68], possibly due to interruption of vagal fibers in the high thorax.

Feeding Intolerance

Feeding intolerance can result from lack of gastric emptying, pain with swallowing, strictures, or dumping symptoms. In a report of 42 children who underwent gastric transposition for esophageal reconstruction, 20 % had feeding tolerance necessitating jejunal feeds at a mean follow-up of 6.5 years, due to delayed gastric emptying in three, severe neurological impairment in four, and feeding aversion from esophageal atresia in one [1]. Prolonged jejunal feeding in adults is rarely reported.

Weight Gain/Loss

In children, restrictions in weight gain may result as both a result of other congenital anomalies or as a complication of esophageal reconstruction. At least 5 years after esophageal reconstruction for esophageal atresia, caustic ingestion or reflux, Davenport et al. found that only 65 % of children were above the third percentile of weight, and 76 % were above third percentile of height [11]. Similarly, Hirschl found that 40 % of children status post reconstruction with gastric pull-up for esophageal atresia were below the fifth percentile in weight [1].

In adults, most of whom undergo esophagectomy for malignant disease, maintenance of weight is related both to the function of their reconstruction and the status of their underlying disease. In a study of cancer patients at least 5 years after esophagectomy, Mclarty et al. found that 49 % never regained lost weight after the operation, 25 % maintained initial preoperative weight, and only 6 % gained weight [56]. In patients who underwent esophagectomy for high-grade dysplasia, assessment of those alive 2 years or more after surgery, 65 % had lost weight, 21 % had no change in weight, and 14 % had gained weight [68]. In contrast, a study of patients who underwent esophagectomy with gastric reconstruction for achalasia at a median follow-up of 43 months, postoperative weight was similar to optimized preoperative weight in men and women and did not change significantly with time [69].

Anemia

Iron absorption is facilitated by the presence of acid in the stomach, which aids in the conversion of ferric iron to ferrous iron and assists in the chelation of ascorbic acid for absorption in the duodenum. Truncal vagotomy results in loss of acetylcholine stimulation for gastric acid production. Correspondingly, basal and maximal gastric acid production is markedly decreased in most intrathoracic stomach patients, with associated elevations in serum gastrin [23, 36, 70]. The denervated stomach is able to recover intraluminal acidity over time; however [71] Tagami found that absorption of vitamin B_{12} is decreased immediately after esophagectomy but recovers after

about 1.5 years after operation [72, 73]. This transient decline in absorption has been found to be due to decreased excretion of intrinsic factor from parietal cells of the stomach [74].

In children at least 5 years after surgery, 33 % were found to be anemic, 47 % were found to have low mean corpuscular hemoglobin, and all patients tested had low serum ferritin, consistent with iron deficiency anemia. There was no evidence of B_{12} deficiency [11]. In adults, similar rates of anemia have not been found [23].

Atrophic Gastritis

Atrophic gastritis is found in 40–75 % of adult patients with an intrathoracic stomach [23, 26, 70, 75]. In addition to the histological changes induced by vagal sectioning, Okada et al. hypothesized that the high rates of postoperative gastritis may be due to the advanced age of most esophagectomy patients and the reduction of blood flow of the stomach [26]. Chronic proton pump inhibitor (PPI) use could also contribute to the high rates of postoperative atrophic gastritis. In non-esophageal replacement patients (without division of the vagus nerve), an increase in the rate of gastric body atrophic gastritis has been reported with proton pump inhibitor and H2 receptor antagonist therapy [76, 77]. There is no documentation, however, that long-term pharmacologic or surgical acid suppression produces the multifocal atrophic gastritis with the extensive intestinal metaplasia that is associated with increased risk of gastric adenocarcinoma [78, 79]. Rates of atrophic gastritis may also be confounded by *H. pylori* infection. A cohort study showed that patients with *H. pylori* treated with omeprazole were at increased risk of atrophic gastritis, and this was confirmed in a randomized trial with long-term follow-up [80, 81]. In the studies of esophageal replacement patients, the *H. pylori* infection rate and PPI use have not been reported. Multiple investigators have found no association between the extent of duodenogastric reflux and degree of gastritis [23, 75]. Similar endoscopic studies with children have not been published.

Bile Reflux

Up to 60–80 % of patients after esophagectomy experience symptoms of reflux and symptoms may originate from reflux of either bile or acid. Symptoms include regurgitation, heartburn, dysphagia, inability to lie flat, nocturnal cough, and nocturnal aspiration. The pressure gradient between the abdomen and the thorax promotes reflux of duodenal contents into the gastric conduit and across the diaphragm [82]. Furthermore, truncal vagotomy impairs the propulsive activity of the antrum [32, 71]. While pyloric drainage improves gastric emptying and therefore reduces acid reflux, pyloroplasty may facilitate reflux of duodenal contents. Notably, investigators have found intragastric bile regardless of whether a pyloroplasty was performed. Symptoms, however, were not correlated to intrathoracic bile concentrations [83]. Bile salts injure both the gastric and esophageal mucosa and their effects are increased in the presence of gastric secretions [84]. In a study of patients who underwent Ivor-Lewis esophagectomy with gastric tube esophagogastrostomy and digital dilation of the pyloric ring, 44 % of patients were found to have reflux of bile. Symptoms of reflux did not correlate with reflux esophagitis; however there was a correlation between acid or bile reflux and endoscopic esophagitis [85]. Patients with pyloric drainage had more reflux esophagitis [86].

Acid Reflux, Barrett's Esophagus, and Malignancy in the Esophageal Stump

Esophageal reconstruction with esophagogastrostomy causes disruption of the body's normal anti-reflux mechanisms. The gastroesophageal junction (GEJ) moves into the chest, the esophagogastric anastomosis lacks the valve-like activity of the native GEJ, sectioning of the vagus impairs the motility of the esophagus and stomach, and traditional surgical anti-reflux procedures are not an option. As previously mentioned, 60–80 % of patients after esophagectomy report symptoms of reflux [82]. Reflux not only causes

Table 55.3 Endoscopic findings after esophagectomy and gastric pull-up in 101 advanced achalasia patients

	1 year (%)	5 years (%)	5–10 years (%)	>10 years (%)
Normal	53.6	41.6	23.0	29.9
Esophagitis	45.9	71.9	–	70.0
Gastritis	20.4	31.1	–	40.0
Columnar epithelium	0	109	29.5	57.5

Adapted from Rocha et al. [97]

symptoms but over time results in esophagitis, metaplasia, dysplasia, and carcinoma in the remnant esophagus. Barrett's esophagus occurs when damage to the squamous esophageal epithelium results in development of columnar metaplasia or potentially premalignant specialized intestinal metaplasia [87]. While the exact molecular events that effect this transformation are unclear, studies suggest a pathogenic role for *Cdx2* genes [88]. These genes are known to mediate the differentiation of intestinal epithelial cells and are not normally expressed in the esophagus and stomach. In mice, intestinal metaplasia could be induced by forcing gastric epithelial cells to express *Cdx2*. In humans, 100 % of biopsy specimens with Barrett's specialized intestinal metaplasia stained positive for *Cdx2* [89]. The continued molecular changes involved in the evolution from Barrett's metaplasia to adenocarcinoma are also poorly understood; however genetic analyses revealed chromosomal losses and gains, as well as gene amplifications [90–92]. In patients who do not have a history or esophageal reconstruction, the risk of progression of Barrett's metaplasia to dysplasia and cancer is between 0.2 and 2.9 % per year [93, 94].

The American College of Gastroenterology recommends that patients with Barrett's esophagus without dysplasia undergo surveillance endoscopy every 3 years. Those with low-grade dysplasia are recommended to undergo endoscopy annually. Patients with high-grade dysplasia should undergo endoscopy every 3 months and be considered for esophageal resection [95].

In endoscopy studies of adult patients after esophagectomy with whole stomach or gastric tube reconstruction, rates of esophagitis ranged from 30 % to over 70 % [84, 96, 97]. As determined by Rocha et al. rates of esophagitis increase with time since surgery. In his study of patients who had undergone esophagectomy with cervical esophagogastrostomy for achalasia, the incidence of esophagitis in the esophageal stump was 45.9 % at 1 year, 71.9 % at 5 years, and 70.0 % at 10 years follow-up. Furthermore, the occurrence of ectopic columnar metaplasia and Barrett's esophagus in the esophageal stump was none before year 1, 10.9 % between years 1 and 5, 29.5 % between years 5 and 10, and 57.5 % at 10 or more years follow-up. H_2 blockers and proton pump inhibitors did not avoid the occurrence of Barrett's esophagus; however there was a tendency for medical acid blockers to delay the appearance and size of columnar epithelium. Of the patients with intestinal metaplasia, 2 of 23 (8.7 %) developed high-grade dysplasia 13 and 19 years after their initial operation. In both patients, this later developed into in situ adenocarcinoma 1 and 3 years after the diagnosis of dysplasia. Of patients followed for more than 5 years, 5 of 61 patients (8 %) developed cancer of the esophageal stump. Three patients developed squamous cell carcinoma and two patients developed adenocarcinoma. These later two patients developed cancer 22 and 34 years after their initial operation [84]. A table summarizing Rocha et al.'s endoscopic findings is shown in Table 55.3. Similarly, in a study of 48 adult patients who underwent esophagectomy with esophagogastrostomy primarily for cancer, O'Riordan et al. reported a 50 % incidence of columnar metaplasia above the anastomosis at a median 26 months post surgery. Of these patients, specialized intestinal metaplasia was detected in 54 %. The magnitude of acid or bile reflux was not found to be related to the prevalence of metaplasia; however duration of reflux was significantly correlated [98].

In children, a study of 14 patients who had undergone gastric tube reconstructions most commonly for esophageal atresia, 10 patients (71 %) were found to have Barrett's esophagus on endoscopy at least 2 years after surgery. There was no intestinal metaplasia or dysplasia found. Clinical symptoms were a poor indicator of cervical esophageal pathology [99]. Adenocarcinoma has been reported in a patient 20 years after esophageal atresia repair [100].

Pulmonary Function

Davenport et al. reported the respiratory symptoms and pulmonary function of children at least 5 years after gastric transposition. Forty-one percent had no respiratory symptoms, such as episodes of breathlessness or tiredness; however 94 % had lung function indexes below predicted values for height. The median total lung capacity (TLC) was 68 %, and forced vital capacity (FVC) was 64 %; however the ratio of forced expiratory volume in 1 s to FVC (FEV1 to FVC) was normal, indicating normal airway resistance. There was no correlation between PFT results and reported respiratory symptoms. Many of these children had undergone multiple thoracotomies [11].

In adults, it is unclear if this decrease in pulmonary function is present. In patients who underwent pulmonary function tests 6 months after thoracoabdominal esophagectomy with esophagogastrostomy, only vital capacity and total lung capacity were significantly reduced after the operation, however not to a clinically relevant degree [101].

Diaphragmatic Hernia

Diaphragmatic hernia is a rare complication after esophagectomy. In a review of 1,075 esophagectomies over a 12-year period using either whole stomach or gastric tube conduit, Kent et al. estimated that the incidence of a diaphragmatic hernia was 2.8 % for minimally invasive esophagectomy and 0.8 % after open esophagectomy. The mean time to diagnosis was 32 months post esophagectomy. In 17 % this herniation was asymptomatic. Abdominal pain was present in 45 %, dyspnea in 15 %, and dysphagia in 15 % and nausea and constipation in 10 % each. Colon was the most commonly herniated organ. Operative repair was necessary in most patients [102].

Redundant Conduit

Kent et al. also determined the incidence of another rare complication after esophagectomy. The authors reported a 3.6 % incidence of redundant conduit after minimally invasive esophagectomy with gastric tube reconstruction with pyloroplasty. One patient (<1 %) developed redundant conduit after open transhiatal esophagectomy. Dysphagia (43 %) was the most common symptom, followed by regurgitation (30 %), reflux (26 %), vomiting (22 %), aspiration (22 %), and early satiety (9 %). The cause of redundant conduit was determined to be excess conduit left above the diaphragm at time of esophagectomy in 23 %, mechanical obstruction to emptying in 54 % (such as lack of drainage procedure, pyloric stricture, or a too small hiatal aperture), twisted conduit in 14 %, and no anatomical basis identified in 9 %. Revisional surgery was performed in all but one patient [102].

Conclusions

There are advantages and disadvantages with all conduit options for esophageal reconstruction, and there is no clear best choice for all patients. Stomach is commonly used because of the relative ease of operation and reduced operative times. Use of stomach for esophageal reconstruction can be performed with minimal perioperative morbidity and mortality. While long-term functional results and quality of life are satisfactory, the problem of duodenal and gastric reflux predisposes gastric reconstruction patients to strictures, esophagitis, Barrett's esophagus, and cancer of the esophageal stump. The high reported rate of endoscopic abnormalities indicates the need for regular endoscopic surveillance of patients after gastric transposition. In children

and young patients with benign disease, surgeons and patients should weigh the long-term risks associated with gastric reconstruction and consider the use of alternative esophageal conduits.

Late Follow-Up of Colon Interpositions

56

Terry Lynn Buchmiller
and William Hardy Hendren III

Introduction

Children with long-gap esophageal atresia who are otherwise healthy may have a normal life expectancy. Therefore, durability and function of an esophageal substitute is essential. Long-term follow-up is critical as problems may present decades after the original surgery.

There are several methods for bridging a gap of esophagus. These include (1) a reversed gastric tube, (2) bringing the stomach into the chest or neck, (3) a jejunal conduit, (4) using the right colon based on the middle colic pedicle, (5) using the transverse colon based on the left colic pedicle in isoperistaltic fashion, and (6) using the descending colon based on the left colic pedicle placed antiperistaltically.

Construction of an esophagus from an interposed segment of colon was first described by Lundblad in 1921 [1]. In 1955 Dale and Sherman described a retrosternal colonic interposition [2]. Waterston popularized the posterior mediastinal transthoracic approach in 1957 [3]. Many modifications have been introduced in efforts to promote normal function with great variation in both early and late morbidity and mortality.

Hendren and most other authors prefer the method described by Waterston for several reasons. It is more versatile than a substernal conduit which must reach the neck. The Waterston operation allows substitution of only that length of esophagus which is abnormal or absent. As these conduits empty principally by gravity, there does not seem to be significant functional differences between an isoperistaltic and an antiperistaltic segment [4]. The Waterston approach may be through a left thoracoabdominal incision although a transhiatal approach is also reported in large series [5, 6].

This current chapter recognizes the diversity of surgical approaches to colon interposition and that these approaches will not necessarily have identical results. Often, diverse approaches are included in case series. For example, Hendren's series of 32 patients included 28 having a left thoracoabdominal approach, with a transverse colon isoperistaltic graft typically based on the blood supply of the left branch of the middle colic. The lower anastomosis was performed in 24 patients into the stomach with 7 into the anterior wall and in 17 into the back wall. Most (28 of 32), but not all, had a pyloroplasty performed either previously ($N=3$) or at the time of colon interposition. Bassoinny used an isoperistaltic left colon graft with pyloroplasty in all, while Burgos used this approach in the majority with routine pyloroplasty [6, 7]. Kelly used mostly retrosternal grafts, while Lindhahl used both retrosternal and

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_56

intrathoracic grafts without a significant difference in complications [8, 9].

The timing of colon interposition should also be mentioned. Hendren reported the performance of a colon interposition in the first year of life, as shown by seven cases in his series [5]. However, he and others believe the operation should not be performed in the newborn, as the blood vessels are very small and the colon is quite small, especially in cases of pure esophageal atresia without tracheoesophageal fistula which would be the principal indication for consideration in the newborn period. As emphasized by others, it may give a slightly added margin of safety to wait until the patient is between age 1 and 2 years, since this is a formidable operative procedure.

Indications

The indications for esophageal replacement in children are typically from complicated or long-gap esophageal atresia, corrosive damage from caustic ingestion, or from severe gastroesophageal reflux disease. Hendren's series over 25 years notes the indications for operation to include 21, esophageal atresia; 5, caustic injury; 3, peptic stricture; 2, esophageal varices with previous splenectomy; and 1, cartilaginous hamartoma of the esophagus. There were six secondary cases (all done elsewhere and were referred for revision): three failed gastric tube with peptic esophagitis, bleeding, stenosis, and recurrent aspiration; one presternal jejunal conduit; one failed/sloughed colon esophageal interposition with transverse colon; and one extensive stenosis after primary repair of esophageal atresia as an infant [5]. This series which now includes 62 patients is being updated.

Other series report heterogeneity which may limit broad application. Ahmad's series includes 38 total patients: 24 with esophageal atresia repaired at a mean age of 17 months and 14 with caustic strictures repaired at a mean age of 7.4 years [10]. Coopman reported 17 esophageal atresia patients and 15 with corrosive strictures [11]. West reported 31 patients total with esophageal atresia in 23, caustic ingestion in 6, and acquired stricture in 2 with a follow-up of 1–15 years [8]. Kelly reported 23 total with esophageal atresia in 9 and caustic ingestion in 14 with a 12.8-year follow-up. Burgos had 65 total patients with 30 esophageal atresia and 32 caustic ingestions, and Khan had 25 patients with esophageal atresia in 23 and corrosive strictures in 2 [7, 12].

Three authors report series of exclusively caustic ingestion patients. Canty provides a series of 7 [13]. Bassiouny reported an initial 70 children in 1992 who were followed 6 months to 5 years, which was later updated in 2002 to 100 patients, of whom 60 have been followed 5–15 years, all undergoing a transhiatal approach at a mean age of 3.4 years. Lastly, Hendren reported an additional seven patients with caustic strictures to the pharynx [14].

Only one series reported exclusively esophageal atresia patients of whom 20 underwent a colonic interposition out of 34 total [9].

Long-Term Follow-Up

Length of follow-up is also crucial to interpretation of these reports as complications may manifest decades after the original operation. Waterston was the first to provide long-term follow-up in 14 of his patients in 1976 over a 12-year period [3]. Hendren's report in 1985 included cases from 1959 to 1984 and provided an average 15-year follow-up with 20 of the patients ranging from 12 to 25 years [5]. His experience since then totals 62 cases. The inclusion of the more recent cases in need of long-term follow-up will be reported in the near future. Interpretation of case series must take this into account as length of long-term follow-up into account as this ranges from 3 to 33 years [7, 8, 10–12, 15–17].

Complications

Late Complications

The incidence of late complications, defined as those occurring after the first year, is substantive and tends to be more frequent in those with

esophageal atresia versus other indications for colonic interposition [11]. There is a broad range of complication rates related to the definition, occurrence, and the intensity of scrutiny. Approximately 25 % undergo repeat surgical intervention [7].

Graft Failure

The ultimate survival and function of the original colon conduit with excellent function and durability is critical to the long-term satisfaction of adults who may live with their graft for 70+ years. Several authors report no graft loss in their long-term series [5, 13, 17, 18]. Waterston's original series reports one graft failure, with other series reporting graft failure rates of 3–18 % [19]. Burgos reports 2 of 65 which had significant dilation of the graft requiring replacement, while Khan reports one of 25 [7, 12]. Ahmad's series reported 18 % who required graft replacement due to various causes such as graft redundancy, tracheocolonic fistula, cervical anastomotic breakdown, and severe graft ulceration with bleeding. Graft perforation due to ischemia is a rare event [10].

Graft Redundancy

The placement of a colonic interposition, typically in infants or toddlers, is expected to grow "with the child" and serve as a passive conduit for the passage of food throughout life. There are reports of isoperistaltic sequential or propulsive waves promoting evacuation of the graft contents and the clearance of refluxed gastric fluid suggesting retention of some level of intrinsic colonic motility. However, most show that these contractions are ineffectual and the colon empties by gravity, or the so-called "cascade" effect.

Colonic interposition grafts are prone to both dilation and elongation of the conduit over time, which can create difficulties and lead to revisions and/or graft replacement if symptomatic (see Fig. 56.1). Several theories exist to explain this phenomenon, some intrinsic to the growth pattern of the colon, while some implicate a relative

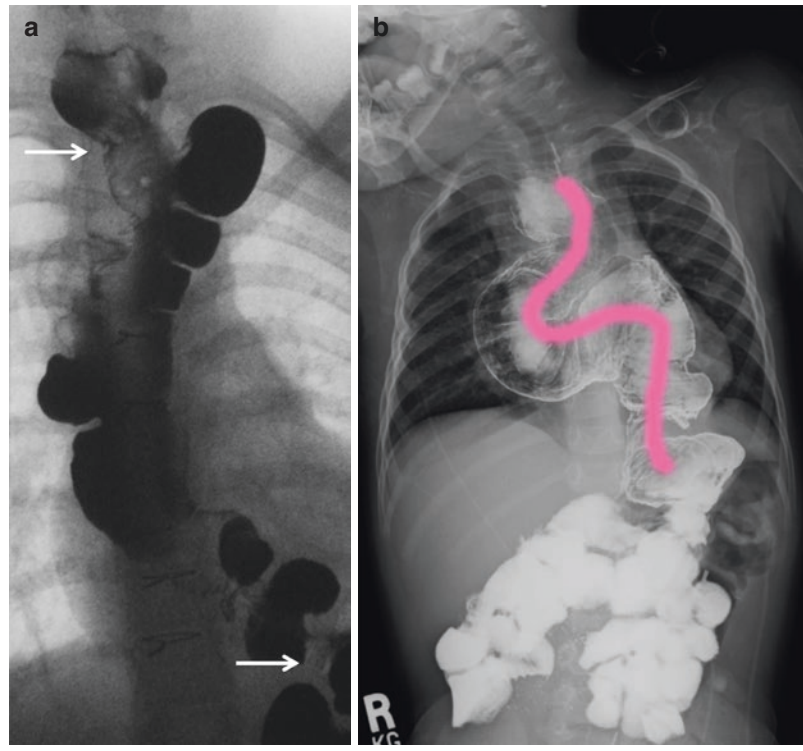

Fig. 56.1 (**a**) Normal "esophagram." Transverse colon with upper anastomosis in neck and lower anastomosis into back of stomach (*arrows*). Note satisfactory size of conduit and its straight course from neck via left pleural space to stomach. (**b**) Dilated colonic interposition years after the original surgery (Revision by partial resection of redundancy was ultimately required)

or acquired outlet resistance at the cologastric anastomosis as causative. Passive dilation may also occur above points of partial obstruction such as the thoracic inlet, main bronchus, diaphragmatic hiatus, or adhesions.

Overall rates of graft redundancy are typically 4–5 % in most series, but there are varied reports ranging from 0 % to 100 % as some authors report all radiographic dilation and others only report those whose symptoms require reoperation [12]. Canty reports no graft redundancy on contrast upper gastrointestinal studies in his seven patients although the follow-up is only modest at 2–7 years [13]. Lindhahl studied 14 of his patients with "esophagrams" noting the width of the colon was normal in 8 (57 %), dilated in 4 (29 %), and very dilated in 2 (14 %) with tortuosity in 3 [9].

Coopman reports a 17 % rate of dilation [11]. Conversely, Rode noted that all 16 of his patients had varying degrees of tortuosity of the interposed colon which was most marked distally. There was no spontaneous peristaltic movement seen under fluoroscopy, and the gastroesophageal junction was normal in all [16]. Others report more moderate rates of dilation. Of the 18 patients have contrast studies, Kelly noted that 4 (22 %) had redundancy, but only 1 was symptomatic [8].

Burgos noted 8 of 53 cervical redundancy of the graft in 8 of 53 patients which was a source of social embarrassment [8]. Six had episodes food impaction with several requiring endoscopic foreign body removal. He noted this was seen less with the transhiatal and retromediastinal location of the interposition.

Hendren reports 4 of 32 whose colon segment became redundant over years, causing partial functional obstruction (see Fig. 56.1b) [5]. This was remedied by shortening the lower bowel segment and altering its hiatus through the diaphragm to correct angulation as it passed from the thoracic gutter through the diaphragm to shorten and straighten the segments. He recommends that it is important to avoid redundancy and angulation in these colon segments as it can lead to functional obstruction [4, 5, 8]. The safest approach to shortening a conduit is at the cologastric anastomosis, dissecting along the bowel wall to avoid injury to the vasculature [5, 20].

Erdogan reports 4 of 15 patients who did not have an initial pyloroplasty who developed later graft redundancy (26.6 %) [15]. Only one required reoperation which resulted in a late mortality due to a leak. Ahmad noted an 11 % redundancy rate with all requiring revision due to severe redundancy which altered the vascular arcade; three had total graft replacement and one partial resection [10].

There are several authors whose series support the premise that symptomatic graft redundancy may take several decades to manifest. Domreis reports four patients with an average age of 37 years who developed symptomatic graft redundancy, an average of 16 years postoperatively [21]. Redundancy presented as dysphagia, regurgitation, pneumonia, or chest pain, and symptoms were improved after segmental resection. Dhir reports several patients with redundancy with an accompanying, and possibly causative, distal anastomotic stricture who underwent operative correction more than 20 years after their original surgery [22]. Basiounny noted minor increases in the occurrence of graft redundancy in his update reports, but none caused marked feeding problems [6, 18]. It should be noted these series have diverse patient populations and that those undergoing esophageal replacement at a later age due to corrosive ingestions may have a slightly favorable outcome.

Colonic Bacterial Overgrowth

The occurrence of bacterial overgrowth in the colonic conduit is rarely mentioned, with an incidence of 17 % noted by Coopman (2 of 17 patients) [11]. This is a potential source of malabsorption, so it should be considered in select patients.

Bezoars

The occurrence of bezoars is uncommon with only two series reporting this entity. Coopman noted the occurrence in 4 of 17, and Lindhal

noted that 2 of 15 required operative treatment for foreign body occlusion [9, 11].

Gastroesophageal Reflux

The occurrence of symptomatic "gastroesophageal" reflux (GER), or perhaps more correctly termed "gastrocolonic" reflux, is hypothesized to occur less frequently in colonic versus gastric interpositions as mucus production by the colon may be protective. The use of a pyloroplasty seems to be protective as Rode noted gastroesophageal reflux in four of seven (57%) without a pyloroplasty and in only 11% (one of nine) with a pyloroplasty [16]. Erdogan does not utilize a pyloroplasty and reports gastroesophageal reflux in 3 of 15 (20%). However, the absence of clinical symptoms and gastrointestinal hemorrhage in his cohort has lead him to suggest no pyloroplasty is needed [15].

In Hendren's series of 32 patients, 4 had symptomatic gastroesophageal reflux (12.5%). When reflux is seen on GI series, most patients are noted to have peptic distress, whereas asymptomatic patients do not seem to have significant reflux on contrast studies. Three pH testing and endoscopic biopsy showed alkaline gastritis which responded to medical therapy. Symptoms occurred in these patients 8, 10, 18, and 22 years postoperatively. One of the patients, now an adult, has nocturnal symptoms that suggest chronic aspiration pneumonitis.

Hendren noted the location of the anastomosis did not have a significant effect on the rate of reflux. GER occurred with the lower anastomosis into the rudimentary esophagus (12%), into the posterior stomach (12%), and to the anterior stomach (14%) [5].

Some authors report no gastroesophageal reflux [18]. Some have added an antireflux wrap in efforts to reduce GER. Vasseur Maurer evaluated patients with an esophagram with a reduction in GER from 48% down to 7.5% when a wrap was utilized. No difference in stasis within the graft was noted [23]. Canty reports a series of patients who had a Thal fundoplication who notes radiographic reflux into the conduit located within the abdomen, but no reflux above the diaphragm. All were asymptomatic.

Domreis reports severe late bile reflux in three which led him to convert the distal anastomosis into a Roux-en-y colojejunostomy combined with variable gastric resection [21].

Delayed Gastric Emptying

As emphasized by most authors, pyloroplasty appears to be an important adjunct in the performance of a colonic interposition [4–6, 13, 19, 24, 25]. As the integrity of the vagal nerves cannot be assured, pyloroplasty promotes gastric emptying and minimizes gastric reflux. Delayed gastric emptying is rarely reported. However, three patients who had pyloroplasty manifested alkaline gastritis many years later [17]. Further investigation of patients with peptic symptoms after colon esophageal replacement may uncover additional cases and screening is encouraged.

Dumping

Despite the common practice of performing a pyloroplasty during a colonic interposition, most authors provide no commentary on the occurrence of the gastric dumping syndrome. An incidence of 5% is noted by Ahmad (2 of 38) and 17% by Coopman (2 of 17) [10, 11]. Rode, however, reports normal gastric emptying on fluoroscopy in all [16]. Nuclear medicine gastric emptying studies are either not obtained or reported by most authors of large series.

Anastomotic Stricture

The occurrence of strictures at the proximal or distal interposition anastomosis is common, with up to 20% of all patients requiring surgical revision. Contributing mechanical factors must be considered such as compression at the clavicle or diaphragmatic hiatus.

Proximal strictures in the cervical esophagus are the more common and may manifest as

regurgitation of undigested food during meals or when recumbent. Reported occurrence rates vary from 4 to 28 % [7, 8, 10, 12, 15, 16, 18, 19]. Hendren reports one late anastomotic stricture at the proximal anastomosis which responded to steroid injection and cautious dilatation [5].

Many authors have noted that late strictures occur most frequently after initial leak or infection. A trial of dilation is warranted, with consideration of adjunctive steroid injection [5]. However, most authors report that ultimately one-third to one half of those with proximal strictures require late surgical revision at the cervical anastomosis [7, 10, 12, 16–19].

Distal strictures are diagnosed less frequently but may contribute to graft redundancy, even if subtle. Rates range from 13 to 20 % [9, 15]. Mechanical considerations must also be evaluated. Hendren reports one patient who had narrowing just above the distal anastomosis where her substernal conduit passed behind the xyphoid and over the liver causing extrinsic compression of the colon [5]. Distal strictures do not appear to be as amenable to dilation, with four of five requiring surgical revision in the series by Ahmad [10].

Late Gastrointestinal Bleeding

Reports of late gastrointestinal bleeding are likely related to the scrutiny of the individual author and are likely driven by significant symptoms warranting surgical attention. Bassiouny reports no occurrences, although no obvious surveillance program was utilized [6]. Lindahl found one anastomotic ulcer at routine follow-up when pallor was noted on physical examination and anemia confirmed by laboratory investigation [9]. Coopman reports anemia in 18 % of his cohort, and Ahmad notes one severe ulceration requiring graft replacement [10, 11].

Hendren details his experience with 7 patients out of 32 with late gastrointestinal bleeding [5]. Most had a vagotomy and pyloroplasty at their original operation. This included one duodenal ulcer at 12 years postoperatively and one gastric ulcer at 13 years. Both healed with appropriate medical therapy. One child developed gastritis 3 years postoperatively, with partial pyloric obstruction which was relieved by pyloroplasty. One patient developed bleeding from an anastomotic polyp 8 years postoperatively which was resected. One child developed a large paraesophageal hernia of the stomach into the chest 6 years postoperatively, which presented as bleeding which was repaired. Two patients had a small amount of gastrointestinal bleeding for which no source was discovered both ceasing spontaneously.

Interestingly, gastrointestinal bleeding has not been emphasized as an important complication in most series but is encountered in up to 25 % of cases followed long term. The etiology of bleeding has included paraesophageal hernia, gastric outlet obstruction with gastritis, peptic ulcer disease, and alkaline gastritis. If bleeding is encountered, the patient should be studied by upper gastrointestinal series, endoscopy with biopsy, and the measurement of gastric pH, to document possible alkaline gastritis which should be treated appropriately.

Intestinal Obstruction

The occurrence of bowel obstruction is on par with that expected from large series of patients undergoing laparotomy. Most authors mention bowel obstruction only when operation was required. The etiology is most commonly due to intestinal adhesions with rates ranging from 3 to 7 % [5, 8, 12, 15, 17, 18].

Hendren reports one obstructive episode due to small bowel intussusception [5]. Ahmad reports 4 patients of 38 who had an intrathoracic obstruction, of whom 3 required operative intervention [10]. The occurrence of volvulus in a retrosternal interposition has been reported in two [26, 27].

Pulmonary

Rigorous testing of pulmonary function is not commonly reported in most series. Coopman

notes that half of their population has either asthma, recurrent pneumonia, or recurrent bronchitis. However, these rates were equivalent to those reported in the overall esophageal atresia population and are not likely due to the colonic interposition itself [11]. Lung function testing was undertaken in 12 with only 5 (42 %) having normal function. Restrictive lung disease was noted in 50 % with a TL <20 %. Of these five had a spinal deformity and two had respiratory insufficiency with hypoxia and/or hypercapnia. Two of the 12 (16 %) had obstructive lung disease. Late pulmonary restrictive disease was noted in 20 % by West and was attributed to recurrent episodes of aspiration despite antireflux precautions. This was improved by the later addition of a gastric drainage procedure. The performance of pyloroplasty with the initial operation has greatly improved pulmonary sequelae.

Nutrition and Growth

Nutrition and growth data have been recorded in several series with variable findings. In general, patients with colon interpositions tend to be small and underweight. The underlying diagnosis leading to esophageal replacement has a clear impact. Kelly provided a 13-year follow-up in which those with caustic ingestion were in the 45–50th percentile and remained constant. Those with esophageal atresia were initially at 12 % and then increased to 33 % during the study, therefore demonstrating catch up growth [8].

Growth curves remained in the 5th–50th percentile over a 15-year follow-up in a series by West et al. [17]. Burgos noted 9 % (5 of 53) to be under the fifth percentile [7]. Rode noted 5 of 16 to be growth retarded, but 75 % had a normal growth velocity [16].

German/Waterston assessed long-term nutrition and growth in esophageal atresia patients who were greater than 10 years after operation, including those requiring esophageal replacement. Weight percentiles were 25 % in the EA group and 3 % in those with colon interpositions. However, diffuse overlap exists. In the 12 EA cases (eight of whom had other anomalies), seven had a preoperative weight below the tenth percentile. Six of these seven remained below the tenth percentile for weight. Four were below the tenth percentile for both height and weight. Three of them were above the tenth percentile for height. Five of the atresia cases were above the tenth percentile for weight preoperatively. Four of the five remained above the tenth percentile for both weight and height. Only one fell behind who had multiple anomalies. Six of the eight with another malformations remained below the tenth percentile. The four with three or more anomalies all remained below the tenth percentile for both height and weight on long-term follow-up.

In the eight non-atresia patients followed for more than 10 years, seven were at the same percentile or better than originally. Long-term growth correlated well with the preoperative status of the child. In atresia patients growth correlated with weight preoperatively and the presence or absence of associated anomalies. In the others, growth was excellent in all but one patient.

Coopman performed a dietary intake questionnaire in nine patients. Despite all meeting or exceeding the RDA (106 %), 25 % had undernutrition on growth metrics. No improvement in nutritional status was noted over time [11].

Therefore, this unique cohort may require increased energy intake from potential chronic respiratory disease or malabsorption due to colonic bacterial overgrowth, diarrhea, or vomiting. Lindhahl noted significant fat malabsorption in 2 of 15 [9].

Interrogation by sophisticated testing such as malabsorption screening and calorimetry may be considered in selected patients.

Delayed Puberty

The onset of puberty was delayed in 22 % in a series by Coopman with an average onset at age 11 in girls and age 13 in boys [11]. His is the only series that provides information on sexual development, which may possibly be a surrogate for nutritional status.

Spinal Deformities

The prevalence of spinal deformities is not routinely reported but appears to be quite prevalent with chronic backache, the most prevalent symptom. Scoliosis is reported in 22–34 % and kyphosis in 6 % [7, 11]. The etiology is diverse and attributed to associated congenital vertebral anomalies, postsurgical changes, and idiopathic. Radiographic screening is supported.

Endoscopic Surveillance

Endoscopic screening for the early detection of colorectal cancers is recommended in many large populations. Hsieh described a metachronous adenocarcinoma in a colon conduit following treatment of an intra-abdominal colon carcinoma. The use of a colonic conduit with potential exposure to an acidic or alkaline environment has been thought to theoretically increase this risk. However, his literature review of nine cases reported only one at the cologastric junction, not supporting exposure to gastric and/or bile juice as playing a major etiologic role [28].

Khan performed endoscopy in 13 of 25. Mild histologic colitis was common, but none had metaplasia, aneuploidy, or colonic dysplasia [12]. Rode had one of four patients with multiple shallow ulcers in the colon just above the gastric junction and a small solitary single diverticulum. Significant diverticular disease has not yet been reported in colonic transplants. As the colon interposition population is aging, consideration for routine screening protocols is encouraged [11].

Oral Diet and GI Symptoms

The ability to support one's nutrition on solely oral feeds is perhaps the metric or yardstick by which one measures the ultimate success of an esophageal interposition. Hendren reports that the ultimate ability to swallow and eat a normal diet is the rule after colonic substitution and is supported by other authors [5, 13].

Other authors report mixed results. Ahmad report that 91 % achieve oral feeds by discharge, with the remainder dependant on gastrostomy supplementation [10]. However, 45 % in his series required further surgery to achieve and maintain a good functional result.

Minor symptoms are quite prevalent and are likely the results of close scrutiny.

Dysphagia in the absence of an anatomic stricture is not uncommon. Most have mild dysphagia to certain foods and report a sensation of food "catching" which is relieved by water ingestion. These symptoms tend to improve with time. Endoscopy for food impaction is occasionally required. Coopman queried 20 patients, and all but one had persistent swallowing difficulties with feeding difficulties in half [11]. Kelly reported that 86 % had no dietary restrictions and were able to eat food at relatively rapid rates. However, 9 % ate small meals, 9 % had bloating after a large meal, and 9 % reported a subjective "sticking" of food in the throat despite normal contrast studies [8]. Lindhahl reported normal swallowing in 9 of 15 (60 %), with four having difficulty with meat and oranges, and one with occasional regurgitation in the supine position [9]. Hendren and others note bulging in the left neck in most patients during passage of the food bolus. Most become quickly accustomed to it and some massage their neck to promote swallowing [5, 12, 15].

Notable borborygmi occurs during and after meals in 62 % [16]. Other minor symptoms can include abdominal pain (60 %), dysphagia (50 %), and a prolonged time to ingest meals. Khan emphasizes the need for all patients to maintain an upright posture particularly when eating, drinking, and sleeping and suggest gravity is the most important mechanism for conduit emptying. A substantial number of patients have coughing while eating (40 %), diarrhea (40 %), substernal postprandial heartburn (35 %), halitosis (20 %), and regurgitation/vomiting (20 %). Nearly one quarter of patients remain on medical treatment.

Khan studied 19 patients with a barium swallow. All had rapid transit of the liquid bolus and emptying without any significant delay or holdup [12]. Fluoroscopy shows that the ingested bolus is transported more by gravity than by the rapid

peristaltic activity seen in a normal esophagus. Rode also studied the transit time from bolus ingestion to reaching the stomach. For fluids, this varied from a few seconds to 2 min in an unobstructed conduit. Transit time for solids ranged from 2 to 25 min on average, with one taking nearly 2 h to completely clear. Transit time for solids was greatly improved by taking fluids with the meal [16].

Manometry

Manometric evaluation of the colon conduit has been reported by Rode in three patients with excellent results. Basal colonic pressures were 14 cm of water, but no spontaneous peristaltic activity was observed [16].

Late Mortality

Late mortality is exceedingly rare and has not been related to GI pathology or complications of the conduit [5, 10].

Quality of Life

Assessment of the overall quality of life has been increasing reported. Overall subjective assessment of children by parents stated that 17 of 20 were doing "well" [11].

The completion of schooling and the quality of social life was essentially normal in a series reported by Ahmad [10], with almost all achieving age appropriate goals; none claimed social limitations. Burgos studied the Karnofsky Performance Status Index which was originally applied to cancer patients. This tool assesses functional performance, side effects of treatment, and disease-specific symptoms and utilizes a quality of life (QOL) questionnaire to query subjective perception of well-being and familial and professional adaptation. All patients were over age 18 with a median age 38 years. In a mean follow-up of 33 years, 60 % were healthy with a good/excellent functional outcome. Thirty-six percent had a fair outcome with mild lifestyle limitations, and 4 % had a poor outcome, typically due to persistent dysphagia and/or chronic respiratory disease. Overall, there was good functional outcome and a perception of good health. He noted that symptoms improve over time and that there was, importantly, no correlation of immediate postoperative complications to the long-term QOL [7].

Ure provides one of the most extensive QOL reviews [29]. He examined 58 esophageal atresia patients; 50 had a primary anastomosis and 8 underwent a retrosternal colon interposition. Three assessment instruments were used: a global QOL scale, the Spitzer Index, and the Gastrointestinal QOL Index. A lower QOL was noted in interposition pts, with the QOL in primary anastomosis patients equivalent to healthy controls. Similar scores were demonstrated between healthy controls, those having a primary anastomosis, and colon interposition patients in physical and social functions and emotional state. Interposition patients suffered more overall from various gastrointestinal complaints (eating habits, meal capacity, and the requirement of liquids with meals). Five of eight had a sensation of holdup; some had pain and choking with swallowing, nocturnal regurgitation, and respiratory symptoms. All interposition patients subjectively felt short of breath. A restricted meal capacity was seen in 62.5 % versus those with a primary anastomosis, but they led an otherwise normal life. Overall, lower scores were attributed to GI symptoms. The long-term QOL was acceptable, suggesting those with congenital malformations may acquire coping habits.

Lastly, Khan measured functional outcome according to a classification scheme proposed by Ahmed and Sptiz. Overall 52 % had excellent results (asymptomatic, tolerating a regular diet), 28 % had good results (asymptomatic with minor dysphagia), and 20 % had fair results (significant dysphagia) [12]. Long-term follow-up of these challenging pediatric patients is essential far into adult years.

Conclusion

Colon interposition surgery is technically challenging and is reserved for the rare case in which the native esophagus cannot be

preserved. Colon interposition is a safe operation with rare mortality and low morbidity which requires meticulous surgical technique and diligent follow-up. Complication rates may reach greater than 80 % and are related to the length of follow-up. Perseverance in the management of complications is necessary as many present in the decades following the initial operation. Surgical revisions are often required. Follow-up, which extends to 25 years in some series, have shown very satisfactory long-term results [5]. In Hendren's experience, the colon conduit provides an excellent substitute esophagus for pediatric patients. The operation should have relatively low rate of major complications, most of which are avoidable and most of which can be corrected to give quite good to excellent long-term results in the majority [5, 8, 10, 11].

57 The Long-Term Follow-Up from the Parents' and Patient's Perspective

J. Trompelt

Situation in Germany

The German healthcare system offers good surgical and postoperative care to children born with esophageal atresia (EA). If the diagnosis is made early, mortality from isolated EA, with or without tracheoesophageal fistula (TEF), is nowadays very low. Death of a child suffering from EA is mostly due to severe associated malformations, primarily cardiac defects, or chromosomal anomalies that are incompatible with life or prematurity [1–4].

EA, as a rule, does not represent a lethal malformation today. This heightens the significance of other qualitative aspects: incidence and management of potential complications, morbidity and quality of life of patients during their childhood, adolescence, and adult life.

Local medical care, as pursued in Germany, is positive for the parent-child relationship, but in rare malformations may also prove to be disadvantageous. In Germany, about 220 EA patients are born per year (incidence, approx. 1:3000, about 670,000 births annually). These will be admitted to a total of almost 100 pediatric surgical wards and departments as well as a few clinics for adult care. There are only a small number of wards and hospitals caring for more than one to three newborns with EA per year. This means that only few physicians have the opportunity of deepening their academic knowledge by personal experience. Personal experience, on the other hand, influences the surgical outcome, the quality of follow-up care, and the assessment of complications or sequelae [5–7]. Limited routine or lack of experience on the part of the medical staff may mean that complications and sequelae are not followed thoroughly or at all. Further, the treatment implementation could be delayed or the scope of treatment is suboptimal. This, in turn, may lead to increased risks, especially of gastrointestinal or respiratory complications, which may affect a patient's physical and psychosocial development. This experience is shared by the Patient Support Organizations (PSOs).

PSOs are not merely an important source of information for families and patients. Families also experience the relief of knowing that they are not alone and they are able to profit from the knowledge of other people, who are in the same situation.

Over time, PSOs gather profound experience on pertinent subjects, like malformation, sequelae and associated disease, treatment options, and the individual effects, which EA will have on the everyday lives of patients and their families. On this basis, PSOs offer counseling, orientation, and assistance in coping with the disease and its consequences. The German PSO (KEKS e.V.) was established in 1984. The experience gathered

by this organization is also available to the medical profession.

Prevalence of Frequent Complications as Well as Secondary and Associated Diseases, According to the KEKS Database

Many physicians presume that it is only the severely affected patients or those suffering from medical malpractice who gather in PSOs. They suspect that the experience accumulated in our organizations may tend to have a negative tinge.

For that reason, the KEKS e.V. PSO carried out a member survey and evaluation of their member database (out of 780 member families, 236 questionnaires were returned in 2004). The prevalence of EA types, complications, sequelae, and secondary surgical interventions as recorded by the PSO was analyzed against data in the literature [8–16]. The percentage of long-gap atresia in the PSO was twice as high as that given in the literature (Fig. 57.1). While some complications or secondary interventions in the PSO slightly outnumbered those in the literature, others were underrepresented by comparison or largely corresponded to the data in the literature (Fig. 57.2).

A high percentage of PSO children suffering from tracheomalacia were subjected to aortoventropexy (35 % of those affected). It is possible that cases of low-grade tracheomalacia were not included in the diagnosis or, given the EA, were considered normal. The prevalence of typical associated malformations was rather lower than was expected (Fig. 57.3). It is likely that families primarily seek the help of a PSO for malformations that appear to them as being the most menacing – medically or personally – for instance, they might consult an organization for children with cardiac disease in the case of severe concomitant heart abnormality.

Long-gap atresia is essentially overrepresented in the member database. This fact, notwithstanding, the excess of serious complications and sequelae in the member population is quite low, meaning that complication rates among PSO members were not greatly increased.

Impact of Complications and Secondary Diseases on the Everyday Life of Patients and Their Families

Family Education

The personal experience of the surgeon or the physician providing aftercare will influence the state of information of the family and thus their ability to cope with potential problems [18–20]. PSO observations indicate that a patient's or family's handling of an existing malformation depends on their state of information and education on the subject. Their tolerance of complications hinges upon prevailing expectations: Families, for instance, to whom even grave difficulties in swallowing were described as being normal, may accept considerable constraints for a (too) long time without seeking help.

Case Report

By way of an internship, a 17-year-old, considerably underweight girl with EA came into closer contact with the PSO. It was noticed that she was able to only take in small amounts of food, she needed to be washed down with drinks, and she preferred soft mushy food. When asked about it, she said that she had always had difficulty swallowing and that this was normal since she had esophageal atresia. She agreed to undergo endoscopy upon the recommendation of the staff. Findings showed severe stenosing of the anastomosis. After repeated bouginage, the young woman is now able to enjoy completely normal food and experiences substantial weight gain.

If, on the other hand, expectations are raised that a child will be completely well after the surgery, complications are often seen as parent or surgeon failure, and their existence may be denied for as long as possible by one party or the other. This makes it difficult to keep up a trustful relationship between doctors and parents.

Parents' Report

We were told that our child would be completely well after the surgery and that in case of any problems, they would be experienced enough to deal with them. However, they could not offer any solutions when our child had repeated episodes of apneic spells. Instead, we were told that it was not known what caused them and that this was not an issue of pediatric surgery, anyway. It was only in another hospital that our daughter was diagnosed with severe tracheomalacia.

In no case information of the family must be limited to the preoperative or immediate postoperative discussion. Parents and patients are personally affected and fearful, so that they often will not be able to immediately realize the significance and implications of findings and diagnoses for their lives. It is indispensable to continue having sympathetic and caring conversations with a child's parents. The potential or existing complications and problems typical of the child's age need to be discussed without discouraging his parents.

When problems arise at home, many families seek additional information beyond what they receive from the doctors. Today, the Internet is the information source of choice but unfortunately not all websites are trustworthy. Therefore, PSOs have improved their communication efforts. By and by an increasing number of patients are being guided to appropriate PSOs. In turn, they can contribute to patient information and education based on their respective, extensive experience.

Parents and patients need to know that after successful surgery the esophagus will not be completely normal, even if no postoperative complications occurred. They need to be informed that there is a risk of complications and sequelae, which may be treated or must be treated, depending on the situation. It is only informed families who are able to be relevant and competent partners

in the timely diagnosis of potential esophageal and respiratory functional impairment secondary to EA.

In Hospital and Back Home

Shortly after birth and during the immediate postoperative time, the family's concern about the life and future of their child is in the foreground. The initial joy of having a child rapidly gives way to great anxiety: "Will my child survive the surgery? Will any damage remain? Will my child ever have a normal life?" Most parents cling to the hope that the surgical intervention will solve all problems and that their child will be restored to perfect health. Medical statements to this effect are gratefully absorbed. Should complications occur, the parents' confidence in the doctor will be severely shaken.

Accepting that a child has a health problem that will stay with it all its life is a difficult process. Any complications or new findings (e.g., additional malformations) will inevitably throw parents back to the beginning of their adaptation process. It is only by repeated sympathetic and honest discussions of the individual perspectives of a child that a trusting patient-doctor relationship can be build and that families are able to confront themselves in a timely (though painful) manner with the significance of the malformation for their lives.

As a first step, the child needs to undergo surgery so that the continuity of the alimentary canal is restored. The child may have to go through potential complications, such as anastomotic leakage, infections, pneumothorax, and recurrent tracheoesophageal fistula that may develop immediately after the surgery. The subsequent target is the complete oral feeding of the child and its discharge from the hospital unless this conflicts with additional malformations or health problems.

Parents often feel insecure when their child is discharged from the intensive care unit with all its continuous monitoring to the regular ward. Depending on the child's history, release from hospital may also create a considerable amount of ambivalent feelings for the family: On the one hand, there is that natural desire to take responsibility for one's own child and its feeding and recovery which up to that point were mostly provided by doctors and nurses. On the other hand, parents are afraid that they may not be competent to meet the special needs of their child. The situation is aggravated by the parents' sadness over a child with compromised health:

Family Report

"Home at last!" was our first thought. Our son had overcome many complications and I was even able to nurse him. But we were unable to find our peace of mind for fear that we'd have to get him back to the hospital if he would not feed properly. We had been told to weigh him before and after breast-feeding. But how do you weigh a hungry crying baby with some precision? So I felt tense all the time which did not contribute, of course, to proper nursing.

PSOs and sociopediatric aftercare institutions (e.g., in Germany "Bunter Kreis") offer support to families in this situation.

The problems each family will face at home vary with their children's preconditions.

Feeding Problems

Feeding and nursing represent the elementary forms of maternal attention to a child and therefore are a core topic for the family concerned.

EA conflicts with the natural desire of a mother to feed her child. Complications following anastomosis surgery or replacement of the esophagus may contribute to difficulties in oral feeding as well. Mothers often consider that drinking and feeding problems, frustrating tube weaning, or unsatisfactory weight gain are their personal failure. This may put a massive strain on the mother-/parent-child relationship. An understanding approach, therefore, is necessary when dealing with the families of EA children who do

not drink or feed adequately. Psychological support of a family may be helpful, especially during the period of tube weaning and establishment of full oral feeding. It is important to not only focus on weight gain but also to consider the complete picture of a child's development. Families feel considerable relief when – during tube weaning – the child's general condition and advances in development are included in the assessment of its medical status.

Feeding and food texture should be as normal as possible for a child's age. A child, who under medical aspects is able to eat and drink, will do so or learn to do so very soon. A physical cause will probably be at the root of failure to thrive or eating disorders, if a child refuses oral food intake as a matter of principal, avoids age-appropriate food, or fails to thrive properly. This holds particularly true in children with EA. Psychosocial causes of refusal are more likely in children growing up under highly unfavorable socioeconomic circumstances [21–23].

The German PSO carried out a study into the development of eating attitudes among their members [24]. It showed that the time to reaching so-called milestones (complete oral feeding, liquid food, mushy food, and adult diet) depended on the severity of the EA and accompanying malformations, complications, and sequelae (Fig. 57.4). The same is true for the enjoyment of food and the pace of food intake (Figs. 57.5 and 57.6). Depending on the history and complications, complete oral and age-appropriate feeding of an EA child may be delayed, but remains the defined and almost always attainable goal of treatment.

Infant Drinking Problems

Causes for drinking problems after early correction are to be found among the complications that are typical of a given EA pathology, such as massive anastomotic stricture, TEF or recurrent TEF, gastroesophageal reflux (GER), or tracheomalacia. These causes need to be tracked down, even where other factors, like prematurity, accompanying malformations, or disorders, are present at the same time. The exact history of drinking behavior is essential for tentative and differential diagnosis, and specific attention to gagging, drooling, coughing, increased stridor, or dyspnea including apnea is required.

Tube Weaning

After short-term tube feeding in early uncomplicated esophageal anastomosis, tube weaning will pose no problems in most cases. Difficult drinking and tube weaning problems mostly concern children, in whom oral food intake was not possible for a prolonged period of time (e.g., long-gap atresia, prematurity, complications, or additional malformations precluding any attempts to establish oral feeding). In these cases the time span to achieving age-appropriate nutrition is distinctly longer than in uncomplicated cases or healthy children (Fig. 57.4).

Results of our PSO survey, which were confirmed by many families, showed that sham feeding had a sustained positive effect on eating attitude. This approach combines tube feeding with the oral feeding of fluid draining via a collecting tube or esophagostoma (Fig. 57.5). Since sham feeding without an esophagostoma may be problematic, careful weighing of the expected benefits against the potential risks (aspiration!) is indicated. As a minimum requirement, oral stimulation – e.g., by a pacifier dipped in sugar solution or tea – should be possible.

Without sham feeding or oral stimulation, the baby can neither train his sucking reflexes nor his oral motor skills. Disagreeable oral experience like manipulations such as intermittent suction or elongations without analgesic sedation or anesthesia will make the change to oral feeding even more difficult.

For tube weaning to be successful, the child must have an incentive to eat and drink. In children, who were exposed to negative oral experience, fears and unpleasant associations may often outweigh the pleasure gained from tasty food or repletion. Hunger and thirst are the strongest physiological stimulation to take in food and drink. Trivial as this statement may be, it is often not considered by parents or doctors for fear of a weight loss.

In the experience of the German PSO, parents and doctors misunderstand that weaning attempts fail, if at the same time, the energy demands of a

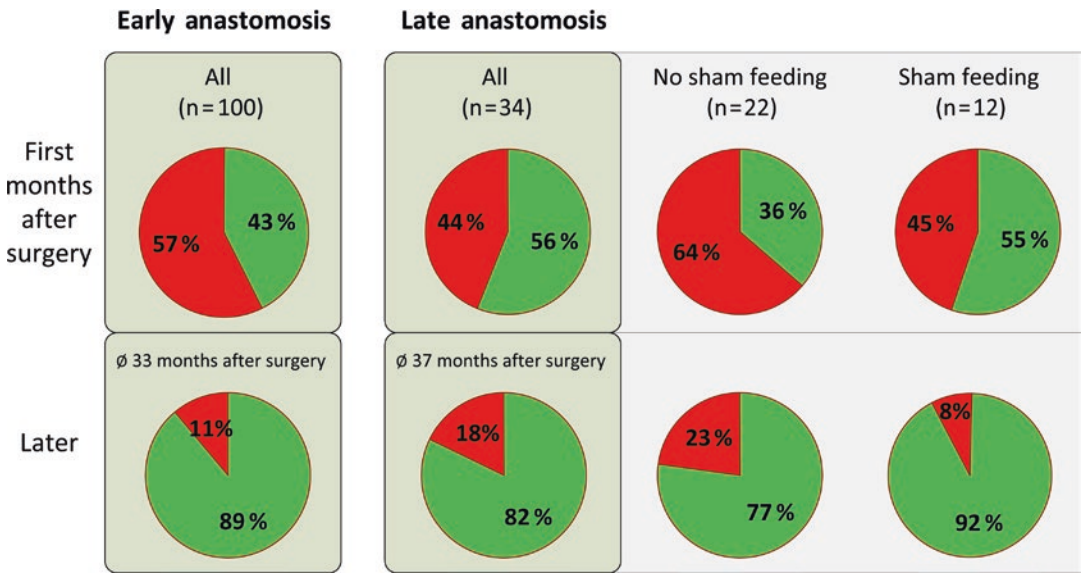

Fig. 57.5 Attitude to oral nutrition of EA children after anastomosis (According to Trompelt et al. [24]). Unwillingly/only forced. With pleasure/willingly

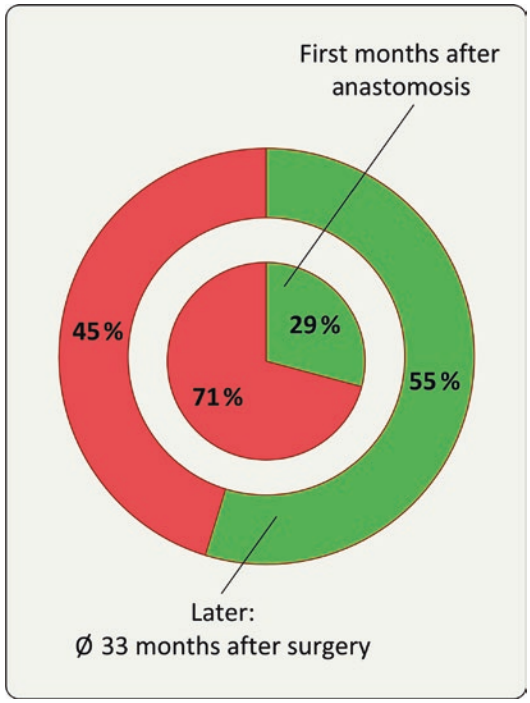

Fig. 57.6 Duration of meals (According to Trompelt et al. [24]). Child needs substantially more time than its peers. Child needs about the same time like its peers

child are fully met by feeding via a tube or gastrostomy. It is often presumed that a child eats sufficiently before tube feeding is being reduced or discontinued. But weaning can only be expected to succeed if the child is allowed to feel hungry.

To promote its oral motor skills and normal social development, it is necessary that the child should feed orally as soon as possible. Especially in small infants, the nasogastric tube itself can possibly impair swallowing. Once the medical obstacles have been cleared, the pediatric surgeon and the pediatrician should work together to provide an individually tailored concept for tube weaning to be implemented as soon as reasonably possible.

In its initial phase, tube weaning will be associated with weight loss. An infant with long-term tube feeding has not been able to experience the causal connection between oral food intake and repletion. Hence many children do not feed at all or food uptake is clearly not enough during the first stage of tube weaning. In the experience of the PSO, weight loss is all the higher if preceded by attempts to overnourish the child. Pediatric care is required for the medical monitoring of the child during tube weaning. Psychological guidance may help parents in stages of feeding refusal.

If the problems with tube weaning persist, the concept needs to be revised, so that new medical obstacles may be identified and handled, if possible. If tube weaning at home fails, inpatient weaning with an experienced team may be considered.

Problems Arising When Feeding Is Switched

As for any child, normal age-appropriate nutrition is also aimed at for children who underwent EA surgery. Problems arise especially when a child is switched to semisolid or solid food: Food refusal, which is more pronounced than in normal children during an adjustment process, gagging, vomiting, or respiratory distress has a medical background in most cases [9, 25–28].

Experience shows that in infants, anastomotic strictures may often go unnoticed since milk is a thin fluid and will pass even narrow strictures. Only thickened milk or switching the feeds to semisolid or solid food will lead to clinically manifested swallowing problems or can result in food-bolus impaction, which might be resolved endoscopically, if necessary.

Even in older children or adults, anastomotic strictures can go undetected for a long time. Sometimes patients prefer rather fluid food and their environment does not realize that there might be a problem behind it. Therefore, a regular and specific inquiry into eating habits and food consistence is needed.

Early radiological and endoscopic follow-up evaluations of the esophagus are recommended to avoid negative swallowing experience. Experience shows that bougienage is achieved more easily if the scarring is relatively new. Follow-up examinations, therefore, are helpful even in the absence of clinical signs and prior to feeding being switched, i.e., at the age of 4–6 months at the latest.

Depending on their level of information and their personal experience, some families tend to be overcautious. A timely follow-up may help to reduce fears associated with the switch in feeding.

Swallowing disturbances may often deteriorate only very gradually and go unnoticed since the

children and their families are adapted to impairments of swallowing, due to motility disorders that are present in most cases. This experience is shared by the PSO as well as by the author and her son. Irrespective of complaints of deterioration by the patient himself/herself, regular follow-up checks are recommended and need to include meticulous anamnestic recordings of swallowing as well as observation of a child's eating behavior.

Failure to Thrive

When an EA child fails to thrive, there are typical causes that must be considered, more or less pronounced swallowing disturbances, frequent bronchopulmonary infections due to gastroesophageal reflux, tracheomalacia, or a recurrent TEF, but also increased breathing effort in severe tracheomalacia should be evaluated.

Dumping syndrome is also to be taken into account in EA patients with antireflux surgery (fundoplication) [12, 25, 27] and patients with gastric transposition [29]. Recent reports show that – as a rare incident – this syndrome may occur in postoperative EA even without fundoplication [28]. PSO experience shows that the signs and symptoms may not be understood for a prolonged period of time. Sometimes such misinterpreted symptoms are revealed only after more examinations became necessary due to the random finding of postprandial glucosuria or if malabsorption-induced iron deficiency anemia, osteoporosis, or hypovitaminosis occurred.

Many parents have experienced that increasing caloric density has little effect on the thriving of EA children. They just eat less to compensate. It is important to search for the underlying causes and subsequently provide adequate treatment.

Gastroesophageal Reflux (GER) and Gastroesophageal Reflux Disease (GERD)

GER is a typical and very frequent complication of postoperative EA [30, 31]. Thickening the food may offer some relief of the GER cardinal symptom "chronic recurrent vomiting" which frequently affects infants. It is often absent in older children where nocturnal coughing and recurrent respiratory disease are in the foreground in most cases. GER, in particular in infants, also may be associated with life-threatening episodes due to reflex apnea and massive aspirations. Typical differential diagnoses in EA patients (esp. with TEF) include tracheomalacia and an additional or recurrent TEF.

In children and adults who underwent EA surgery, the cardinal symptom "heartburn" often is absent because innervation of the distal esophageal segment is diminished.

GER may be the reason of recurrent anastomotic strictures and ineffective bougienage. Therefore it must be ruled out or treated in these cases. Furthermore, GER may increase the risk of Barrett's esophagus and esophageal adenocarcinoma [2, 26, 32–34].

Additionally, GERD-induced chronic esophageal hemorrhage can induce anemia.

In most cases, GERD becomes evident in the first years after esophageal repair, but may also develop in later years. It is conceivable that a surgically treated esophagus is particularly prone to develop GER-induced mucosal lesions due to its reduced clearance [33]. Regular monitoring of the esophagus including endoscopy with biopsies is therefore recommended as a long-term measure to be followed into adulthood.

Surgical management of GERD in EA patients must consider the restricted motility of the distal esophagus segment [34, 35]. A tight fundoplication, especially Nissen's fundoplication, may make oral nutrition very difficult, since due to its compromised motility, the esophagus segment that is distal to the anastomosis is hardly able to assist in the passage of food. This increases the risk of dysphagia, which may result in failure to thrive or problems in tube weaning as experienced by the PSO.

Respiratory Problems

Impaired swallowing due to anastomotic strictures and compromised motility may entail aspirations. Aspirations also may be caused by undiagnosed or recurrent TEF and by GER (see also section "Gastroesophageal Reflux (GER) and Gastroesophageal Reflux Disease (GERD)").

These conditions may precipitate pneumonia or pulmonary damage as well as cyanotic and apneic attacks, and a careful search for such causes is mandatory in frequent, severe bronchopulmonary infections requiring antibiotic treatment.

In infants and small children, frequent infections, especially of the respiratory tract, are normal physiological occurrences. Most children with congenital EA are suffering form tracheomalacia of a varying degree, especially if they had a TEF [13]. In this case, severe respiratory infections are more likely. The dominating symptom of tracheomalacia is a more or less audible stridor (usually more evident during meals). As a rule, low-grade or moderate tracheomalacia will hardly affect the child. Unless vascular malformation is the cause of tracheomalacia, the stridor resolves as the tracheal lumen of the growing child widens and the tracheal cartilages consolidate. However, the more pronounced the tracheomalacia is, the more tracheal clearance will be reduced compared to that of a healthy child, and expectoration of bronchial mucus must be accomplished against increased resistance. This produces bubbling breathing noises that typically persist till late infancy and intensify in infections and during meals. These children are prone to have severe pathologies when they contract respiratory infections, which may include pneumonias or require antibiotic treatment. Again, the intensity and duration of this susceptibility are determined by the severity of the tracheomalacia [36, 37].

Experience shows that mucolytic therapies do not considerably facilitate expectoration in EA children. They often lead to overproduction of mucus which will make breathing rather more difficult. From parental experience it is more helpful if the children receive a consistent respiratory physiotherapy similar to that received by children with cystic fibrosis guided by a well-versed physiotherapist. This should be completed by a consistent inhalation therapy, e.g., with saline solution.

The increased proneness to infections and the potentially higher breathing effort in tracheomalacia may lead to an increase in nutrient requirements. If there are simultaneous swallowing problems, proper thriving of a child may be at risk.

EA children with tracheomalacia have an extremely noisy and barky cough in particular in infections or allergic reactions. They, therefore, tend to attract negative attention, and explanations need to be given frequently informing people that coughing is a largely normal occurrence for the child considering the circumstances.

In general, tracheomalacia does not trigger life-threatening events. In a small number of cases, it may, however, be so severe that cyanosis or even obstructive respiratory arrest may occur [38, 39]. These attacks may be initiated by food passing the esophagus – especially if passage is affected (dorsal pressure on the trachea), in elevated blood pressure due to, e.g., crying (ventral pressure on the trachea) or infections (lumen is further reduced by mucosal swelling). Typically, children with severe tracheomalacia recline their heads in an attempt to widen the trachea. If stridor is present in combination with acute cyanotic or apneic episodes (also) during meals with or without head reclination, tracheoscopy under spontaneous breathing should be performed to exclude or confirm severe tracheomalacia. Once severe tracheomalacia has been confirmed, surgical intervention (aortopexy) should be considered even after the first occurrence of life-threatening conditions [38–41].

Experiencing life-threatening conditions like cyanosis or even apnea in their own child triggers extreme anxiety in parents. They will then adopt a particularly anxious and protective attitude toward their children in such situations:

Family Report

My son used to turn blue in the face over and over again, and even had episodes of respiratory arrest at home. Each time I ended up thinking: “That’s it, now he is dead.” When it was over, we would observe him anxiously for signs of any changes. We were extremely apprehensive that his respiratory arrests might leave him with cerebral damage. Our hearts would jump into our throats, whenever he turned blue. He had a

very noisy stridor that could be heard all day long and even in his sleep. He would always lie in bed with his little head far reclined. Whenever his breathing noise stopped, we knew he was in respiratory distress again. During nighttime we did not feel so bad since he was on the pulse oximeter. But during daytime, I felt that I had to keep an eye or rather "an ear" on him, always. I never dared to use the vacuum cleaner when I was alone with him because I would not have been able to hear him breathe. Aortopexy worked miracles: he was able to sit upright in his buggy and sleep with his head on his chest. He never turned blue again, not even when food got stuck in his throat.

Unless surgery is performed, a child in this condition is at risk to incur brain damage, if prolonged apnea occurs. Even if a child survives such episodes of oxygen deficiency, it is likely to suffer severe respiratory infections over many years (if not throughout life) due to its compromised bronchial clearance and is at risk for secondary lung damage.

In severe tracheomalacia GER following surgical EA repair represents an extra-challenge. The dorsal pressure on the trachea that is produced by vomiting or the reflux of food into the esophagus may trigger obstructive cyanosis or apnea. Moreover, surgical management of the reflux by fundoplication may impair esophageal passage to the extent that obstructive cyanosis or apnea is triggered or exacerbated. Documented evidence of three cases is available with the German PSO. In cases of severe tracheomalacia with obstructive cyanosis and apnea in comorbidity with significant GER or GERD, the indication for aortopexy should, therefore, be considered *prior* to an inevitable fundoplication.

As a result of rib synostosis, e.g., after thoracotomy, restrictive ventilation problems may impair physical fitness all throughout a patient's life [36, 42–44].

Esophageal Motility Problems

In EA children, the correction of the malformation entails esophageal motility impairment of varying degree. Most children quickly learn to accelerate the food passage through the esophagus mainly by "washing down." Bolus events due to impaired esophageal function are particularly likely if concomitant stenosis of the esophagus (predominantly in the area of the anastomosis) is present. While in most cases these "food catches" are associated with respiratory distress of a mild form, the severity of tracheomalacia determines the degree of respiratory distress. If there is high-grade tracheomalacia, food-bolus impaction may trigger life-threatening episodes.

The fear of bolus impaction may cause children and their families to be excessively apprehensive when eating, but also in everyday life. Some families shy away from offering their child solid food for a long time. They exercise extreme caution far beyond infancy and at least through the phase where small children put everything into their mouths. This attitude, however, may lead to social problems and to avoiding social contacts.

Orthopedic Problems

Associated skeletal malformations (primarily affecting vertebral bodies, ribs, or limbs) may call for conservative or surgical treatment.

Orthopedic problems may also occur as a consequence of one or more thoracotomies for EA correction. However, in patients without additional congenital deformities of the skeleton, scapula winging, chest wall deformities, or scoliosis, for instance, rarely reach a degree where they present more than a cosmetic problem [42]. This corresponds to PSO experience.

Social Problems

Young Children and Their Families

The problems occurring in the wake of EA may constitute a considerable burden for the family and the child.

Swallowing problems may cause failure to thrive. Eating a meal under these circumstances takes much more time and is exhausting for the child. The remaining time and energy to enjoy positive activities of the family and child and for playing are diminished. Preparing food and meals takes much more time than with a normal child.

Most children do not look sick, so that failure to thrive is often met with a lack of understanding in the child's environment. Advices like "have you tried porridge, mashed almonds, or this or that … yet," "don't distract your child's attention while his or her is eating" or "distract his or her attention," "you ought to make sure your child is getting more food," etc. may be to the despair of mothers involved. The only solution lies in a systematic search for causal factors; treatment of any medical causes, where possible; and honest and prospective information. The understanding that families receive from other affected people, e.g., in a PSO, is very helpful.

In certain situations, it is not advisable to intensify the therapy or there is no therapy available yet. In some cases, improvements will only be visible after healing or further growth of the patient. The empathy and support of other affected families and PSOs are of special value in these circumstances.

While eating primarily serves the uptake of nutrients, it also should be a pleasurable process. The worries whether the child's intake of food is sufficient, a mother's concern that her child might actually starve to death, may create a tense situation around every meal. This keeps a child from enjoying his drink and food.

Eating is also a social activity. Eating together makes food tastier; meals serve social exchange. If a child is not able to eat or suffers from vomiting portions of its meal repeatedly, this will constitute a burden for its social life and that of its parents. Family or friends may not always be sympathetic of lingering over meals or of the absorption of an EA child's family with meals. Some of these families finally tend to withdraw from all situations in which they and their child would have to eat in public.

Apart from the concern for their child's health, its @@proneness to contract infections adds to social isolation and means increased nursing care including physiotherapy and breathing therapy. Many children have noisy breathing even though they are not suffering from an infection. On an on-and-off basis, parents will have to defend themselves and explain that their child has no contagious disease and therefore does not need to stay home.

Especially during the flu season, many families seal themselves off and avoid or limit their contacts with other people and children in particular. Normal activities of mothers with small children, such as attending toddler groups or meeting other mothers with children of the same age, are drastically curbed or canceled altogether. Some parents hesitate to take their child to a day nursery or kindergarten, in order to avoid infection.

The increased attention and care given to the child with EA are a considerable burden for his or her siblings. In addition, not every marriage will stand the stress of a massive change in the couple's relationship that comes with the care for a chronically ill child.

Food-bolus events give rise to strong fears not only in parents but also in external caregivers. The families of the child's friends hesitate to invite the EA child over, because they are afraid of potential bolus complications.

Babysitting by friends and the close or extended family often is feasible only on a reduced scale during the child's first months or years. "You better take the kid with you, his breathing is funny," *or* "I'd rather not be responsible, if…"; those are sentences parents hear very often in this situation.

Depending on their personality, nursery teachers and school teachers may show concern or be afraid to admit a child. This means that families have to put in a lot of effort into convincing and reassuring people in charge, so that the child may attend a day nursery, kindergarten, or regular school. This may restrict the parents' options of working or finding help in dealing with their daily challenges.

Older Children and Adolescents

As with all chronic diseases, the restrictions associated with EA may have negative repercussions on the children's free time, on their social contacts, and also on their school performance.

In EA, it is predominantly the length of time needed for meals and the reduction in physical

performance due to respiratory diseases or lung involvement that may negatively affect free time, leisure activities, and social life.

Depending on a child's social environment, abnormal eating, barky cough, or restricted physical fitness may provoke offensive peer reactions or lead to social exclusion of the affected person. Experience obtained in the PSO shows that an open and confident attitude toward the malformation and the resulting limitations will increase the social acceptance of deficits or abnormalities:

Patients Report

In my new class, it was one student, in particular, who would always bark, if I coughed loudly. I attended a full-time school, and nobody wanted to sit with me for lunch, because I was eating so slowly and sometimes couldn't help gagging. I felt very unhappy. At one point, my parents proposed that I should present a paper during my biology class about esophageal atresia and the problems involved. That's what I did. My fellow students were impressed that I talked about it so freely. After that, the badgering grew less and by and by I even made friends.

Recurrent bronchopulmonary infections or frequent hospitalization may account for long times of absence from school which may have a negative influence on a student's performance and in turn may affect his further education and career opportunities.

Aftercare of Patients with Repaired Esophageal Atresia

Problems Arising from the Lack of a Consistent and Standardized Aftercare

While most late complications are evident only in the first years of life, they may also become manifest during growth spurts and even at adult age [2, 8, 12, 44–48].

If no aftercare is available, families are left alone with the problems that may occur. Whether and when medical help is sought for swallowing problems, failure to thrive or the signs and symptoms of GER will then largely depend on personal tolerance, settling in with the situation, and the level of information present in the family and the local pediatrician. Since this malformation is rare, most office-based pediatricians may see one affected child, if any, during their entire life as a practicing doctor. They can very rarely draw upon their own experience with this malformation and its implications.

Like in healthy children, the frequency and severity of bronchopulmonary infections are found to decrease as immunocompetence increases toward school age. But in many affected patients, the susceptibility to such infections persists into adulthood. This is due to bronchial dyskinesia and possibly tracheomalacia, which may entail secondary complications like scarring, emphysema, and bronchiectasis. A barky cough will accompany many patients into their adult years [44, 45, 47].

It is important to note that the esophagus is not a healthy organ after surgical correction. There will be impairment of esophageal motility and clearance in almost all cases, which may go unnoticed by the patients as they are used to it. These problems may be the underlying cause for GERD or respiratory disease developing beyond the patients' childhood and youth. Since swallowing problems are considered normal to some extent by many patients with EA repair, they may be late in noticing any deterioration. Late complications of anastomotic strictures or peptic stenosis include dilation of the prestenotic esophagus – and in the worst case diverticular pouch formation.

Without follow-up monitoring, EA patients may not become aware of GER or GERD for a long time. Due to the malformation and the dissection required for surgical repair, the function of the distal esophagus is poor. Acid reflux, therefore, may not cause discomfort or heartburn, and early Barrett's syndrome or peptic stenosis may go largely unnoticed.

It has been for a few decades only that medical progress has allowed patients with complications or long-gap atresia to survive and grow to reach

adulthood. Hence it is not yet possible to give an evaluated statement on the risk of complications that may occur after a very long period of time (>30 years). An increasing number of adolescents or adults present at PSOs with a first onset or recurrent history of swallowing disorders, GER, or changes of the esophageal mucous membrane. Investigations show that the esophageal mucosa has an increased risk of developing metaplasia and dysplasia [49]. There are case reports of esophageal carcinoma after EA repair in patients who are much younger than the average of patients who are usually affected by this cancer [32, 33, 50]. This underlines the necessity of lifelong aftercare. To date, it has not been possible to clarify the very long-term risk of esophagus substitution, of biliary reflux associated with dumping syndrome as a complication of fundoplication with or without pyloroplasty, or of reduced esophageal clearing with or without acid reflux [14, 25, 33, 51].

Advantages of Structured and Standardized Aftercare from the Patients' Point of View

Many of the typical complications and sequelae of EA develop slowly and subtly. This attributes particular significance to consistent aftercare. Even though patients may see no reason to complain about existing symptoms or their deterioration, because they have grown accustomed to their condition, specific questioning as part of the aftercare procedure may help to reveal complications and sequelae that require treatment. The use of structured and standardized checklists to achieve a complete inquiry into relevant symptoms will increase the confidence of the examiner as well as patient safety. This will allow even the less experienced examiner to identify problems, which require further investigation or treatment.

In the opinion of the PSO, patients and/or their families need early information that consistent and lifelong aftercare is necessary even if corrective surgery was successful. This will reassure the patients and families that everything will be done to discover complications at an early stage and avoid secondary lesions. Moreover, the family is not left alone after discharge from hospital.

Contribution of Patient Support Organizations to the Long-Term Care and Aftercare of Patients with Surgical Repair of Esophageal Atresia

It is the traditional approach of Patient Support Organizations to provide aid on the basis of their members' personal experience. Interlinking patients, education, information about support options in problems after EA repair, and counseling in questions of everyday life are the cornerstones of patient self-help.

Over the years of their existence, the PSOs have been able to accumulate "living competence," which can be shared by all people with an interest in EA. This accumulated experience is also integrated into guidelines for the diagnostics, treatment, and aftercare of EA and its complications [52].

On this basis the German PSO strives to provide active support and improved aftercare for patients with EA correction and their families. Further political activities are undertaken to increase the awareness for the need to implement qualified aftercare at experienced and specialized healthcare centers.

As yet, recommendations for the aftercare of EA patients in hospitals are not evidence based, but are built on doctors' assessments and experience. Advice ranges from "not necessary," "should problems occur," and "occasional follow-up evaluations in the first years of life" to "regular monitoring – possibly throughout life."

Any opinion as to which condition requires treatment and which condition can be treated has a subjective bias. This explains the importance of guidelines for systematic and structured aftercare, which makes sure that the examiner inquires about all symptoms of typical accompanying diseases and complications. That is the only way to ensure that no relevant questions are forgotten during the doctor-patient consultation.

Reviewing the patient records may be difficult in between the daily routine of a hospital. PSO experience shows that sometimes awareness of a patient's history is incomplete. A short survey of patients' medical history in addition to their follow-up documents proves helpful to all parties and facilitates communication between attending doctors.

The German PSO KEKS e.V. developed a three-part concept to support a lifelong standardized aftercare of patients with EA repair:

1. KEKS e.V. defined follow-up appointments and the scope of follow-up examinations. The PSO developed standardized and structured questionnaires facilitating complete inquiries into all symptoms of typical complications and sequelae. Since no evidence-based standards of aftercare are available yet, the scheduling and volume of aftercare as well as the design of questionnaires were based on the experience gathered in the PSO and that of the medical experts of the PSO scientific advisory board. Thus the Aftercare Folder issued by the German PSO offers a guideline for lifelong standardized aftercare.
2. The structures and standardized questionnaires make documentation of follow-up evaluations easier for patients and doctors and facilitate communication between doctors.
3. Recent publication revealing a lacking consensus about management of esophageal atresia at last in Europe underlines the advantages of a registry about therapies and sequelae [53]. Entering the data as documented in the questionnaires of the German Aftercare Folder into a multicenter database will make it possible to evaluate both aftercare and treatment concepts. The German PSO is working to set up a database of that type. Analysis of the data will help to continuously evaluate and optimize the aftercare concept. In addition, the observation of long-term outcomes achieved with different therapeutic regimens will contribute to identifying the best treatment options.

PSOs in other European countries also are committed to regular and standardized aftercare and documentation in support of patients with EA repair. The Dutch PSO "VOKS" provides a concept for patient-controlled documentation of patient history. The French PSO "AFAO" supports the reporting of data from follow-up evaluations to a reference center. The AFAO also contributed to the guideline for interdisciplinary aftercare issued by the HAS (Haute Autorité de Santé). Their recommendations for a follow-up strategy are largely identical with those given in the German Aftercare Folder.

All PSOs principally have identified the necessity of consistent and lifelong follow-up as an important objective. PSOs are committed to supporting and developing appropriate concepts and guidelines. Hence, beyond providing traditional patient support, PSOs may help to optimize the medical care of patients after esophageal atresia repair.

Part XI

Acquired Esophageal Problems

Esophageal Injuries and Foreign Bodies

58

Filippo Torroni, Paola De Angelis, and Luigi Dall'Oglio

The ingestion of foreign bodies (FBs) is a frequent occurrence in children, especially in early childhood. The risk period is between 6 months and 6 years, with predominance in males. The maximum peak incidence is between 1 and 2 years of life when the age of exploration of their environment begins. The ingestion is almost always an accidental event (93 % of cases) – excepting patients with neurological deficit and psychiatric patients. Generally an FB passes through the digestive tract without causing damage – in children about 80 % of FBs ingested are eliminated spontaneously within a week [1, 2].

It is of extreme importance to verify the shape and chemical characteristics of the FB, as well as the impaction area. FBs smaller than 2 cm usually pass spontaneously into the stomach. FBs are categorized by size and considered large in diameter if ≥2 cm in children younger than 1 year or if ≥3 cm in children older than 1 year. These are less likely to progress beyond the stomach or may even stop in the middle third or the esophagus where it is compressed by the aortic arch – alternatively these may stop at the level of the lower esophageal sphincter or pylorus [3, 4].

luigi.dalloglio@opbg.net

The symptoms are related to the location and to the typology of the FB: refusal to eat, dysphagia, odynophagia, chest pain, regurgitation, retching, and vomiting. Rarely stridor may occur in the case of arrest of an FB in the upper esophagus. Cough, laryngeal stridor, and cyanosis may occur in cases of laryngotracheal compression or inhalation. The different types of ingested FBs can be schematically listed, both on the basis of morphological categories and in relation to their potential hazard:

- Foods: meat boluses, large pips, bones (especially those of fish), cartilage
- Objects: harmless (e.g., coins or similar) or dangerous (pins, sticks, paper clips, long or bulky objects)
- Toxic containers (disk batteries, items containing lead, containers of drugs)

The radiological examination is a very important, and often decisive, step in the assessment of a patient with an ingested FB. A chest X-ray without contrast is generally sufficient to verify the presence and localization of a radiopaque FB. If radiopacity of the FB is questionable, it can be very useful to assess a twin object, when present. As radiolucent objects can escape first detection, the use of an adequate contrast can be useful. The X-ray examination should be performed erect, including the neck, the chest (anterior and lateral projection), and the abdomen. The radiological examination is also essential in the identification

DOI 10.1007/978-3-642-11202-7_58

Fig. 58.1 Coin impacted in the cervical esophagus (cricopharyngeus muscle)

of possible complications, such as pneumomediastinum or pneumoperitoneum [5, 6].

The most frequent impact site described in literature is the cricopharyngeus muscle, while the middle part of the esophagus is the least frequent (Figs. 58.1 and 58.2). The patients who have esophageal abnormalities such as tracheoesophageal fistulae, previous surgery of esophageal atresia, and caustic ingestion are at risk of entrapment in atypical locations. Indication and timing of endoscopic removal in the management of pediatric patients who accidentally swallow an FB depend on many factors: the type of FB, the site in which the FB is trapped in, and the general conditions of the patient and the clinical picture. Management of the child with an esophageal coin has typically included an invasive coin removal procedure, usually endoscopy. Coins in the distal esophagus, however, often pass spontaneously into the stomach in the first 24 h after the

Fig. 58.2 Light bulb impacted in the cervical esophagus

ingestion, suggesting that conservative management alone may be effective. There is no agreement in the literature concerning the management of asymptomatic patients. In 2005 a prospective randomized trial which considered only asymptomatic and risk-free patients with esophageal coin localization demonstrated a good probability (about 30 %) of spontaneous passage toward the gastric cavity [7, 8].

In the literature, foreign bodies are most often fish bones, metal objects such as batteries and coins, and fragments of broken tooth [9]. Tissue response depends on the composition of the FB and also any associated bacterial infection. Organic fragments can cause an acute inflammation greater than those caused by pieces of metal, plastic, or bone. Button batteries are particularly dangerous for children – the frequency of ingested button batteries is about ten per million population per year. Battery ingestion causes serious injuries, and hence immediate endoscopic removal of esophageal batteries is warranted, i.e., an endoscopic emergency. The mechanism of injury that occurs includes direct corrosive action due to leakage, toxic effect due to absorption of substances, low-voltage burns, and necrosis. Necrosis, and perforation, can occur in 4–6 h after a disk battery is lodged in the esophagus, while tracheoesophageal fistula and esophageal stricture/stenosis within 10 h have been described [10–12] (Figs. 58.3 and 58.4). There have been reports of tracheoesophageal fistulae and Meckel's diverticulum perforation secondary to

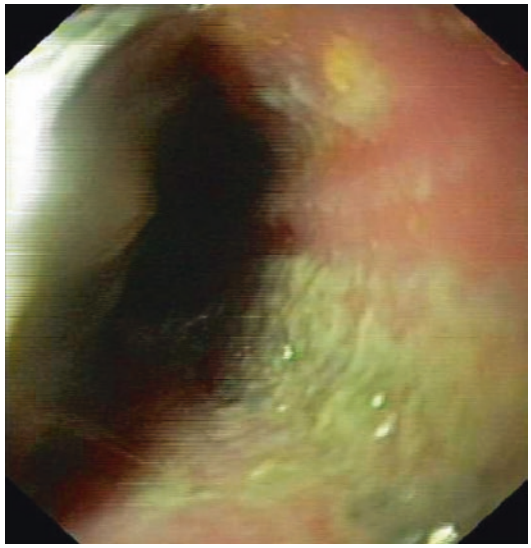

Fig. 58.3 Disk battery impacted in the esophagus

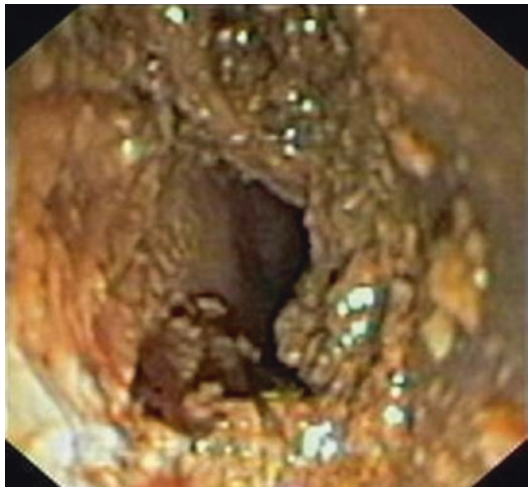

Fig. 58.4 Disk battery ingestion: esophageal injuries (necrosis)

Fig. 58.5 Abdominal X-ray: two magnetic objects lying in different intestinal loops with intestinal perforation

disk battery ingestion [13, 14]. Endoscopic emergency is the gold standard for all complicated situations or high risk, particularly for sharp and pointed foreign bodies, such as dentures with protruding hooks, razor blades, and open safety pins, which increase the risk of perforation. Esophageal lesions are particularly dangerous because of the proximity to major vessels and organs including the heart. The ingestion of magnets is a frequent occurrence in children. Singly ingested magnets do not cause specific problems and have to be considered as not dangerous foreign bodies. Two or more magnetic objects lying in different intestinal loops may produce a considerable attraction force with consequent crushing and fistulization between intestinal lumen. Severe damage such as ulceration, fistulae, hemorrhage, and perforation can occur [15–17] (Fig. 58.5).

In one pediatric patient who had had endoscopic removal of a foreign body in the lower esophagus, a few months after removing the foreign body, persistence of dysphagia was observed. An X-ray examination with contrast was performed and revealed an esophageal diverticulum (Fig. 58.6). The common wall was cut with a precut needle knife (*Boston Scientific*®), resulting in patency between the diverticulum and the esophageal lumen (Fig. 58.7).

In approximately 95 % of cases, underlying esophageal pathology contributes to impaction – such as peptic injuries, previous caustic ingestion, and postoperative strictures or stenosis. Eosinophilic esophagitis (EE) represents another

Fig. 58.6 X-ray examination with contrast: esophageal diverticulum

Fig. 58.7 Endoscopic image: esophageal diverticulum

Fig. 58.8 Esophageal diverticulum: section of the common wall

Fig. 58.9 Esophageal food impaction

common pathology recognized more recently (Fig. 58.8) [18]. Typical features include circular rings – "trachealization," white specks, linear furrowing, and associated motility disorders (Fig. 58.9). It would seem that the natural evolution of this disease at a mucosal level is toward stricture (Fig. 58.10).

In congenital stenoses a preliminary radiological assessment is useful to exclude the presence of bony fragments or cartilage. Endo-ultrasound (EUS) can be helpful.

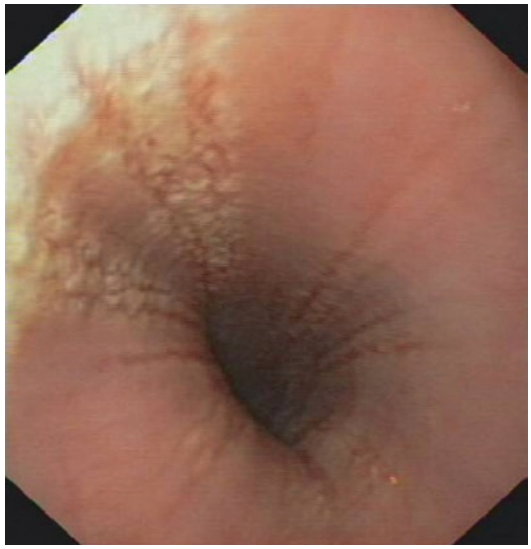

Fig. 58.10 Eosinophilic esophagitis

Recourse to the surgeon becomes mandatory in cases where it is necessary to solve an unexpected situation or an unexpected complication at the time of endoscopic removal or in cases where foreign bodies are too large or potentially harmful to predict a complete and safe endoscopic removal [19]. The literature contains a significant number of observations regarding serious consequences resulting from the ingestion of two or more magnetic elements, able to attract also through distant segments of the alimentary canal leading to intestinal perforation. In the situation of multiple ingestions, removal must be quick [20, 21].

It is important to highlight the concept of known malformations of the digestive tract or situations that may determine difficulty in gastrointestinal transit.

In summary, FB ingestion may compromise the esophagus and lead to stricture formation, but importantly the ingestion of batteries and magnets merits the most urgent endoscopic examination.

Caustic Ingestions

59

Mário César Vieira
and Paulo Fernando Souto Bittencourt

Introduction

Caustic injury to the digestive tract remains a significant medical concern despite efforts to minimize the hazards of caustic household products in various countries. The ingestion may be harmless or it may have severe effects, and there are divergent opinions on how to diagnose and treat pediatric patients who ingest caustic agents.

Epidemiology

Corrosive ingestion is a widespread problem in many parts of the world. In the United States, a decline in the incidence of caustic injuries has been observed, but despite all the new laws and precautions, there is an incidence of approximately 5,000–15,000 cases per year [1]. Nevertheless, an increase has been reported in other countries such as Turkey and India [2, 3]. In developed countries, alkaline material accounts for most cases of caustic ingestion, whereas acid ingestion may be more common in some developing countries, like India, where sulfuric acid and hydrochloric acid are easily accessible [4].

The ingestion of caustic agents occurs most commonly accidentally in children less than 6 years of age and especially in those between 12 and 48 months. Although children in this age group account for 51 % of toxic exposures, they account for only 2.3 % of fatalities (fatality rate of 0.0022 %) primarily due to low-volume ingestion of caustic agents [5, 6]. This is in distinction to ingestions in adolescents and adults, the majority of which are deliberate as part of a suicide attempt. The significantly higher fatality rate in adolescents and adults results from the different outcomes associated with an intentional ingestion of a high volume, and high concentration, of a caustic or other poisonous products [6]. A concept of "accidental-deliberate" ingestion was proposed by Betalli et al. referring to the well-recognized situation where the child drinks a high volume of caustic substance which is contained in a bottle of apparently drinkable fluid, e.g., juice or mineral water, unaware of its content [7].

DOI 10.1007/978-3-642-11202-7_59

A number of studies tried to assess the importance of the educational level of parents, as well as social economic aspects that could be related to the incidence of caustic ingestion in children. Turkish investigators studied families of 50 children that ingested caustic material and 60 controls using a questionnaire, which included sociodemographic data and questions about their knowledge, attitude, and behavior toward corrosive ingestion. The level of education of both mothers and fathers in the corrosive group was lower than that of the controls. Families in the corrosive group had three or more children (42 %), and the socioeconomic status of this group was lower than the controls. In the corrosive group, these substances were purchased unlabeled (64 %) and kept mainly in soft drink bottles. The authors concluded that both level of education of parents and socioeconomic factors play an important role in predisposing to corrosive ingestion in children [8].

Etiology

A variety of substances are responsible for caustic injuries ranging from alkaline agents with pH greater than or equal to 12, to acidic substances with pH as low as 2, as well as bleaching substances where the pH is around 7 (Table 59.1).

High concentrations of alkali are found in lye-based (NaOH, KOH) agents as drain and oven cleaners, dishwashing detergents, as well as cosmetics which may be freely accessible to children in the home environment. Unfortunately, these products may not be perceived by families as a potential hazard due to their ubiquitous nature and lack of childproof packaging.

Granular forms of caustic substances are associated with a higher rate of injury in comparison with liquid forms because of their potential for localized contact. Crystalline alkali drain cleaners may result in deep injury due to adherence in areas of anatomic narrowing [3, 9, 10].

Button batteries, containing high concentrations of sodium and potassium hydroxide, can also cause severe injuries.

Acids are available in battery fluids (sulfuric), toilet bowel cleansers (sulfuric, hydrochloric), antirust compounds (hydrochloric, oxalic), and swimming pool cleansers (hydrochloric) [3, 10].

Milder injuries are usually caused by sodium carbonate, ammonium hydroxide, and bleaches (sodium and calcium hypochlorite and hydrogen peroxide). Bleaches are relatively pH neutral and are seldom associated with severe injury.

Legislation to reduce the concentrations of various household caustics and childproof packaging are not in place in many countries, and therefore injury following unintentional ingestion

Table 59.1 Common caustic substances

Caustic substance	Type	Commercial product
Alkali	Sodium hydroxide Potassium hydroxide sodium carbonate	Drain cleaner Oven cleaners Soap manufacturing Washing products Disc batteries Drying fruit on farms
Acids	Sulfuric Oxalic Hypochloric phosphoric	Batteries Paint thinner, toilet cleaner Solvent Metal cleaner
Detergents/bleach	Sodium hypochlorite Sodium polyphosphate	Household bleach Industrial detergent
Condy's crystals	Potassium permanganate	Hair dye Disinfectant
Ammonia	Ammonium hydroxide	Household cleaners

may be more frequent and severe in such places [5]. The use of "non-original" containers such as juice or soft drink bottles to store cleaning products increases the risk of accidental ingestion substantially.

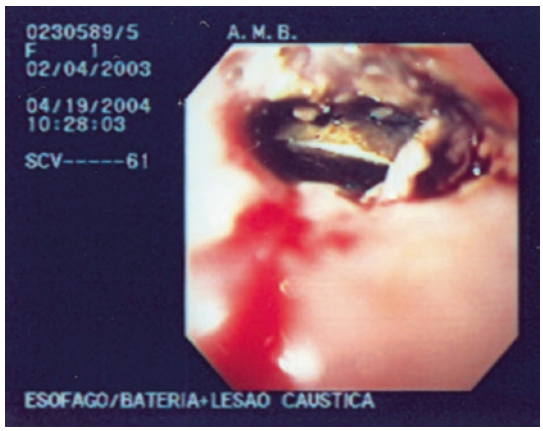
Mechanisms of Injury

The pathogenesis of injury varies among different products [11]. Acids cause coagulation necrosis, which results in a self-limiting burn pattern with the formation of a somewhat protective coagulum layer at the site of injury. Acids are more often associated with gastric injury, with less extensive injuries to the esophagus. Their specific gravity and viscosity are lower than liquid alkalis resulting in rapid transit to the stomach and leading to injuries especially in the prepyloric area and even in the duodenum. Their noxious taste and pungent odor may limit the amount ingested. Gastric injury following ingestion may result in gastric outlet obstruction or perforation frequently in the area of the gastric antrum or pylorus [12]. Chlorine bleaches are considered irritants only and are less likely to cause severe pediatric injury.

Disc batteries found in watches, toys, remote controls, and hearing aids among other places can become impacted in the esophagus with subsequent leakage of alkaline material around its seal. These contain high concentrations of KOH or NaOH and can cause damage if they remain in the esophagus even for brief periods (Figs. 59.1 and 59.2).

Alkalis induce liquefaction necrosis with saponification of fats, solubilization of proteins, and deep diffusion of the substance into the tissues with more extensive and deeper burns. Only neutralization of the substance by the tissue itself will cease the reaction. Because of increased tissue adherence, alkalis also cause more damage to the esophagus; however, deliberate ingestion of large quantities of alkali may injure the stomach and even the small intestine. The initial contact of the agent will produce immediate and progressive changes in the mucosa. The injury evolves in three phases: acute phase (minutes to 72 h) with intense inflammatory reaction that causes erythema and edema of the superficial layers associated with necrosis, bacterial infiltration, and vascular thrombosis; subacute phase (3 days to 3 weeks) with ongoing inflammation, granulation tissue formation, and collagen formation; and chronic phase (>3 weeks) in which vigorous collagen deposition by fibroblasts results in thickening and scarring of the wall. Stricturing is the end result of cicatrization.

The severity and extent of injury depend on multiple factors, such as the volume ingested, the concentration of the agent, duration of contact with mucosal surfaces, and pH of the solution (damage is greatest when the pH is >12). Solid



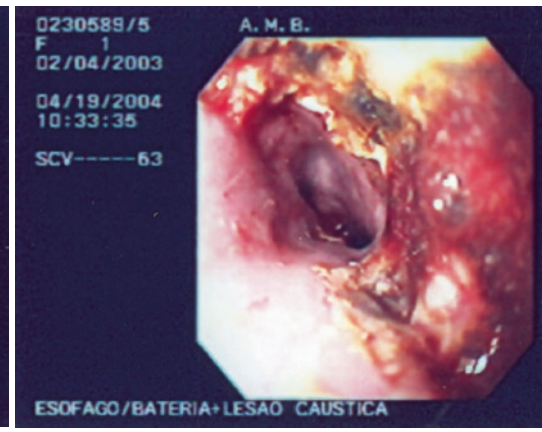


Fig. 59.1 and 59.2 Caustic injury caused by a button battery lodged in the esophagus for 6 h

preparations and viscous liquids produce more severe injury owing to a longer contact time with the oral mucosa. The amount ingested is usually limited by the pain experienced by the child upon accidental exposure but even small quantities can cause significant lesions. A correlation between the depth of lesion and the concentration of sodium hydroxide (NaOH) solution has been shown in animal experiments. When a solution of 3.8 % contacts the esophagus for 10 s, it produces necrosis of the mucosa and submucosa. A 10 % solution extends the injury to the muscular layers of the esophagus. Transmural injury occurs with a few seconds of exposure to a 22.5 % NaOH solution [3, 5, 9, 12].

Clinical Manifestations

After the ingestion of a caustic agent, patients can present from having few symptoms to a frankly toxic state with evidence of visceral perforation.

A burning pain in the mouth and substernal or epigastric areas with swelling of the lips may occur. The most common symptoms are dysphagia, excessive salivation, feeding refusal, and vomiting. These symptoms may develop rapidly or be delayed for several hours and usually last days to weeks.

Symptoms involving the airway are less common and include hoarseness, stridor, and dyspnea, and if there is perforation, a shock-like picture may occur.

Despite this, guidance of treatment by signs and symptoms is not always adequate. Several studies have shown that signs and/or symptoms do not adequately predict the presence or severity of a pediatric lesion although an increased number of symptoms correlate with a greater likelihood of significant injury [3, 13]. In a Turkish study of 473 pediatric caustic ingestions, primarily of alkaline agents, 240/389 (61 %) children without oral burns had lesions found at endoscopy. In that study, 80 % of patients had an esophageal injury and 17 % of patients had gastric injury [14]. In a review of 378 pediatric caustic ingestions, 12 % of asymptomatic patients had severe esophageal burns, whereas 82 % of symptomatic patients had no esophageal injury [15]. Other series have also demonstrated the discordance between oral and esophageal burns [3].

Emergency Management

An adequate initial management is directed at maintaining an adequate airway and ensuring cardiovascular stability and depends on accurate diagnosis. Very often the causative agent is unknown, and a careful history detailing the time, modality of ingestion, type, brand name, and amount of ingestion of the substance should be obtained. Asking the parent to bring the original product container may help to identify the chemical properties of the agent that can influence the severity of gastrointestinal lesions. It is also important to know whether vomiting occurred as this can increase the length of time of esophageal exposure.

Most children do not present any symptoms and do not have any lesion because the caustic has not really been ingested but only tasted. Patients may be asymptomatic, but may also have varied signs and symptoms. They may present with burns on the lips, chin, chest, and hands. There may be burns in the mouth and pharynx, which should be examined with proper lighting. It is essential to bear in mind that signs and symptoms are not always reliable as some patients with moderate-to-severe esophageal injury can have few of these complaints [5, 10, 13].

Inducing emesis and gastric lavage should not be encouraged as this determines a risk of further injury on reexposure of the esophagus to the caustic agent. Neutralization of alkali with vinegar and sodium bicarbonate for acids is inappropriate because an exothermic reaction may result in further damage to the tissue [16].

Analgesics are indicated for patient comfort. There is no clear evidence of a direct effect of medical treatment on the prevention of strictures [17].

Some advocate that the placement of a nasogastric tube can be useful in severe esophageal injuries to avoid stricture formation by preventing luminal adherence. This can be placed with caution in the first 24 h either under fluoroscopic guidance or at

the time of endoscopy. In their usage in 32 patients with severe circumferential burns, Wijburg et al. had stricture development in only two patients [18]. Nevertheless it is essential to bear in mind that there is a risk of perforation and that vomiting may be induced with the passage of the tube.

Protection of burned esophageal mucosa from gastric acid reflux is generally considered important although not proven in human studies. H_2 blockers or proton pump inhibitors and sucralfate may help prevent further esophageal damage [3, 10, 19, 20].

Different investigators have demonstrated the effectiveness of the use of corticosteroids in reducing the inflammatory response, fibrous tissue proliferation, and stricture formation, particularly in grade 2 injuries [21, 22].

A prospective randomized study over an 18-year period, involving 60 children with pediatric caustic injury, concluded that steroids are not beneficial in preventing strictures in children after caustic ingestion [23]. A meta-analysis of studies between 1991 and 2004 and an analysis of the literature on corticosteroid use between 1956 and 2006 also failed to demonstrate a benefit of steroid administration in terms of stricture prevention [24, 25]. Despite the absence of conclusive data, when steroids are used, treatment must be started within the first 8 h for maximal effectiveness in case of grade II lesions [26]. In third-degree burns, steroid use may be contraindicated because of a theoretical higher risk of developing perforations, although this risk has not been well documented. Dexamethasone (1 mg/kg/day) appears to be more effective than prednisone (2 mg/kg/day) [27]. Further prospective studies are needed in order to demonstrate the efficacy of the steroids in changing the natural history and reducing the risk of stricture.

Antibiotic use is controversial in the treatment of serious injuries. Theoretically, decreasing bacterial counts in the burned tissue would lead to a reduction in granulation tissue formation with less chance of stricture formation. Others would argue that antibiotics may mask the signs of more serious infection. If prophylactic antibiotics are used, third-generation cephalosporins or ampicillin at 50–100 mg/kg/day is recommended [3, 10, 17].

A radiographic exam of the neck, chest, and abdomen is indicated especially if any symptom of respiratory distress or visceral perforation is suspected. Contrast radiographic study is of little use in the acute phase since it only delays endoscopy and may not reveal first- or second-degree damage.

The role of biochemical markers of injury is not certain, although some parameters such as neutrophilic leukocytosis and metabolic acidosis can give an indication of the severity of clinical condition [28]. Metabolic acidosis (pH <7.22), arising mainly from tissue necrosis, may indicate serious damage with poor prognosis [28, 29]. Different biochemical abnormalities have been studied in acute caustic ingestion in an attempt to identify markers of injury. Otçu et al. conducted a prospective study in 78 children with caustic ingestion performing an extensive biochemical analysis, blood gas estimations, chest radiography, and endoscopy. Blood pH level was decreased in patients who ingested household bleach but did not differ in patients with or without injury. These authors identified increased levels of uric acid and decreased levels of phosphate and alkaline phosphatase in patients with caustic lesions of the esophagus [30].

Recently, a grading system using computed tomography (CT) was proposed as a useful noninvasive modality on a retrospective study of 49 patients with caustic ingestion. The authors found CT to be as effective as endoscopic findings in order to estimate the occurrence of complications including esophageal stricture suggesting that this diagnostic method could be useful particularly in cases in which larger doses of caustics were ingested, vital signs were unstable, or an early stage endoscopy could not be performed [31].

Endoscopy

Routine evaluation by endoscopy after caustic substance ingestion is still a matter of debate particularly in asymptomatic patients [7, 32, 33]. However, endoscopy may prove to be particularly valuable in the event of large amounts of

substance ingested, attempted suicide, or persistent symptoms.

Since signs and symptoms are not accurately predictive of esophageal damage, a routine upper gastrointestinal endoscopy is traditionally recommended by most authors on suspicion of caustic ingestion, except for asymptomatic children in whom the ingestion is dubious. Nevertheless, there are no strict guidelines as to when endoscopy is indicated and on how much to advance with the endoscope.

The procedure should only be done by an experienced endoscopist. Flexible endoscopy has made this procedure safer, once perforations are more likely to occur with rigid instruments. In the severely affected patient, maintenance of airway to prevent obstruction as well as hemodynamic stabilization may be crucial, and abdominal and chest radiographies should be taken to detect perforation or pulmonary complications. Some authors suggest that, based on endoscopic findings, one can individualize the management preventing unnecessary treatment or allowing early intervention when there is a serious case [3, 7].

A classification system for mucosal damage was proposed in 1989 and latter modified by Zargar et al. in order to standardize the description of injuries (Table 59.2) [34]. Patients with minor (grade 1) or no esophageal injuries would be discharged once they are able to take oral fluids. Those with more extensive injuries (grades 2 and 3) would be given intensive hospital care. Grade 2a (superficial, non-circumferential) lesions rarely progress to esophageal stricture although some patients may require dilation. Grade 2b and 3 lesions are associated with an increased risk of stricture formation [3, 7, 34]. In general it is suggested that endoscopy is carried out within 24–48 h (some authors recommend 72 h) of ingestion for better demarcation of the degree of injury. After this period, there may be an increased chance of iatrogenic perforation due to structural weakness in the esophageal wall. Some authors recommend to terminate the endoscopy at the level of the most proximal circumferential burn to avoid perforation, and others advocate that a full examination of the esophagus, stomach, and duodenum should be performed [5, 17, 21, 28, 35, 36].

On the other hand, there are some researchers who are against early esophagoscopy because of the risk of esophageal perforation. A retrospective study evaluating the need for early endoscopy in 124 adult patients who have ingested a corrosive agent showed that early endoscopy appears to be unnecessary in adult patients who ingested the corrosive agent accidentally. Based on their findings, these authors state that the most important point in patients who had ingested a caustic agent is to detect whether there is a perforation in the acute stage. They suggest that after ruling out perforation, radiography with water-soluble, nonionic contrast material may be performed for the assessment of the severity of esophageal and stomach burns. If there is no perforation, a treatment should be planned for a stricture that may develop in the future [19].

Another recent prospective study involved 350 children with a history of caustic ingestion where no patient underwent an early endoscopy and were followed up for at least 24 h in hospital. Patients tolerating oral feeding well were discharged with advice on progression in symptoms and deterioration in vital signs to be observed over a 48–72-h follow-up. A contrast study of the upper gastrointestinal tract was performed in all patients with persistent dysphagia within 3 weeks after injury. In case of a stricture, a dilatation program was initiated. These authors state that, in practice, the endoscopic findings do not bring useful data to change the modality of treatment and that it would lead to unnecessary general anesthesia and possible com-

Table 59.2 Zargar's classification of mucosal caustic injuries [34]

Grade 0	Normal
Grade 1	Mucosal edema and erythema
Grade 2a	Superficial ulceration, erosions, friability, blisters, exudates, hemorrhages, whitish membranes
Grade 2b	Grade 2a plus deep discrete or circumferential ulcerations
Grade 3a	Small scattered areas of multiple ulceration and areas of necrosis with brown-black or grayish discoloration
Grade 3b	Extensive necrosis

plications associated with the procedure at the most fragile period of esophageal damage [37].

Based on these data and on the absence of proven therapy to prevent stricture, the recommendation of early endoscopy in patients with caustic ingestion still remains an issue of controversy. Large prospective studies with clearly defined protocols are needed to resolve this question.

Late Management

Stricture Dilatation

Despite adequate early management, when healing is occurring, stricture formation is the major complication following caustic ingestion in 10–40 % of esophageal burns depending on the grade of the initial injury [7, 36]. Because the contractile phase of the healing process begins around 2 weeks after injury, in the majority of cases, the strictures develop within 2–8 weeks after the ingestion [5].

Endoscopic dilatation is required as a primary treatment for esophageal strictures and should always be undertaken slowly and carefully, as a planned procedure where possible, in patients who have been adequately prepared with previous clinical and radiological assessment.

Dilation is accomplished by application of expansible forces against a luminal stricture. Dilation devices can be organized into two categories: fixed-diameter push-type dilators and radial expanding balloon dilators [38]. Fixed-diameter push-type dilators exert axial as well as radial forces as they are advanced through a stricture. Balloon dilators exert radial forces when expanded which is thought to be less likely to result in a tear of the esophagus than the other methods. Despite these mechanistic differences, no clear advantage of either balloon or bougie (Savary-Gilliard) dilation has been demonstrated [39–42].

Dilators can be placed at the stricture site in different ways, based on the dilator design and operator experience, including with or without endoscopic, fluoroscopic, and/or wire guidance. Fixed-diameter and balloon dilator devices include through-the-scope (TTS) and non-TTS types. Through-the-scope dilators must be placed by the endoscope accessory channel. Most push-type dilators are non-TTS devices and are introduced over a guidewire which is initially positioned under endoscopy followed by subsequent endoscope removal. Both anterograde and retrograde esophageal dilation are widely used in different centers. Push dilators may be mercury filled (Maloney), solid (Jackson), or wire guided (metal olives, Celestin-type bougies, or polyvinyl dilators). Eder-Puestow dilators comprise a series of graduated metal olives (6.6–19.3 mm diameter) mounted on a flexible shaft. In the past it was the only system available for dilating resistant or complicated strictures. The system is believed to be useful in patients with tortuous strictures or small stomachs. Retrograde dilation is felt to be safer by some and was originally described by Tucker. In this method, a continuous loop of string is kept in the esophageal lumen and brought out of the nose superiorly and a gastrostomy inferiorly. A Tucker dilator is tied to the lower end of string and pushed and pulled out of the patient's mouth [43].

Polyvinyl dilators have become more widely used in recent years. Savary-type dilators consist of a range of flexible taper-tipped polyvinyl chloride cylinders (5–20 mm diameter) with a central channel for passage over a guidewire. Savary-Gilliard dilators (Wilson-Cook Medical Inc., Winston-Salem, NC) have a long tapered tip and a radiopaque band at the widest point for radiological localization. The American Dilation System dilators (C. R. Bard, Inc., Billerica, Mass.) are similar but dilators have a shorter taper tip and are radiopaque throughout their length [40].

Balloon dilators may also be used and may be passed through the scope or be wire guided. They are positioned at the narrowest part of the stricture under direct view and then inflated with water to a pressure that corresponds to a specific diameter. The principal disadvantage of balloon dilators is their cost.

Both Savary-Gilliard and balloon dilators are currently by far the most frequently used dilators, but these need to change to esophageal balloons as soon as possible [38, 40].

The efficacy and safety of endoscopic dilation without fluoroscopy have been shown in several studies [44, 45]. However, it is generally recommended to use fluoroscopic guidance to enhance safety during dilation of complex strictures [38].

Frequency and timing are individualized and based on symptoms, nutritional status, and general health conditions. Dilatations may be performed at weekly or fortnightly intervals with a very gradual increase in dilator size. The need for repeated dilatations is based on clinical judgment until the maintenance of adequate nutritional status with appropriate swallowing and normal oral feeding can be established. The period of dilatation may be extended over months or years with progressively longer intervals between procedures. Patients should be closely observed following the procedure in order to identify symptoms and signs of possible iatrogenic perforation as a result of therapeutic dilatations. Most perforations occur in complex strictures that have been dilated without fluoroscopic guidance.

If a patient develops pain, breathlessness, fever, or tachycardia, perforation should be suspected and chest radiography should be performed urgently. The consequences of perforation may be significant and include pneumothorax, pneumomediastinum, need for esophageal or gastric surgery, or death. Minor perforations have been treated with intravenous nutrition and antibiotics without surgery and resumption of dilation in 4–8 weeks [46–48].

Many patients with caustic esophageal strictures have GERD due to motility changes and to the shortening of the esophagus [49, 50]. Although there are no clinical studies to document the effectiveness of the use of anti-reflux medication, this treatment is recommended empirically in reducing stricture formation. The use of sucralfate to coat and protect the esophageal ulceration may be also recommended empirically especially after dilatations.

Stenting

The development of self-expanding and removable plastic stents (Polyflex®) may be promising in reducing the number of dilatation sessions and keeping the patency of the esophageal lumen for longer periods. Broto et al. conducted the largest experiment in pediatrics, in which ten patients with esophageal strictures unresponsive to endoscopic dilatation were submitted to esophageal stenting, with good results [51]. Recently, the use of a biodegradable esophageal stent in a child was reported with a favorable outcome [52].

Steroids

Intralesional triamcinolone (TAC) injections may reduce the risk of recurrent stricture formation in patients with corrosive esophageal stricture [53]. Although the steroid injection seems to be superior over regular dilatation, this needs to be determined by controlled studies. In addition, it remains to be defined what the optimal injection technique and frequency are and at what dose triamcinolone should be injected.

Mitomycin C

Mitomycin C is an antifibrotic agent derived from the Actinobacteria *Streptomyces*, which acts by interfering with RNA synthesis, thus inhibiting fibroblast proliferation and consequent reduction in the amount of scar formation. Local application of mitomycin C may be performed by using different endoscopic techniques. A cotton pledget held by endoscopic forceps and soaked in a 0.1 mg/ml solution of mitomycin C can be applied topically under direct vision, either using an overtube or a standard cap used for band ligation of varices attached to the end of the endoscope, the agent from touching the normal mucosa [54–56]. A recent report has described the use of injections at the site of stricture with promising results [57]. The ideal concentration, duration, or frequency of application is unclear.

Although there is a theoretical increased secondary long-term risk of malignancy associated with the use of mitomycin C and there is a need for controlled trials confirming its efficacy, this substance should be considered as a promising

adjunct in the management of esophageal strictures in children.

Surgery

Failure to respond to dilatation is an indication for esophageal replacement [58]. Colonic interpositions, jejunal interpositions, and gastric pull-ups are options. However, the definition of "failure" is not clear when deciding to perform a replacement surgery [37, 59]. As other colleagues we believe esophageal replacement in caustic strictures should be exceptional. These are extensive surgical procedures, and scarring often remains a problem, with strictures most commonly occurring at the cervical anastomosis.

Surveillance for Esophageal Cancer

An important consideration relates to the 1,000-fold increased risk of esophageal carcinoma (both adenocarcinoma and squamous cell carcinoma) with a latency period of 15–40 years in patients with histories of caustic ingestion. This association is supported by the location of the cancer at the site of the stricture and the younger age of patients with caustic ingestion-related carcinomas [3, 10, 60]. Dysplasia screening is recommended for patients following a severe caustic ingestion to allow for the early detection of premalignant changes. Guidelines from the American Society for Gastrointestinal Endoscopy in 2006 recommend that endoscopic surveillance should begin 15 years after ingestion, with endoscopy performed every 1–3 years [61].

Psychosocial Implications

An important part of management is continuous support to the child's parents and other caregivers at the time of injury. Manifestations of anxiety or even aggression reflecting a sense of blame or guilt are common at initial presentation. Long-term psychosocial impact may include the development of educational problems, such as school avoidance, antisocial behavior, and feeding difficulties even after successful dilatation. There may be a higher risk of family breakups and abandonment often associated with financial implications and parental absenteeism from work [10, 21].

The involvement of a clinical psychologist is important to help the child as well as the family in coping with the long-term psychosocial consequences of caustic ingestion.

Esophagitis: Causes Other Than Reflux

60

Mike Thomson

Inflammatory processes in the pediatric esophagus have received a disproportionately small amount of attention until recently, when appreciation of their pathophysiology and concordant clinical importance has been highlighted. This increase in interest and exposure is probably a phenomenon secondary to a number of important factors, which include improved diagnostic yield from relatively recent technical advances in areas such as infant and pediatric endoscopy; advances in fields such as mucosal immunology, allowing for the realization that etiopathologic mechanisms for esophagitis are more complex than simple luminal chemical damage; and a shift in clinical opinion recognizing esophageal pathology as a major cause of nonspecific ubiquitous symptoms such as infant colic, feeding disorders, and recurrent abdominal pain among others. A state of knowledge such as this has made pediatric esophagitis, until recently, a relatively underdeveloped area of research and clinical understanding, but this is rapidly changing [1].

It is now clear, therefore, that esophagitis in infants and children has many responsible etiologic pathways that may have complex interactions and hence requires equally complex diagnostic and therapeutic strategies. Such causative factors are now known to include cow's milk protein (CMP) intolerance or allergy, pH-dependent and pH-independent gastroesophageal reflux (GER), dysmotility of various causes, and infective, traumatic, and iatrogenic causes, among others. Hence, the term "esophagitis" can be used to describe chemical, infectious, inflammatory, ischemic, immunologic, and degenerative abnormalities [2]. Nevertheless, there remains a minor degree of controversy regarding the definition and significance of esophagitis, as assessed by the standard diagnostic techniques, including endoscopy and biopsy [3, 4]. This chapter attempts to describe basic etiologies other than reflux-related esophagitis and does not deal with eosinophilic esophagitis which is dealt with in subsequent chapters.

Etiology and Pathophysiology

The etiologies of esophagitis in infancy and childhood can usefully be divided into the following groups:

1. Chemical:
   (a) Owing to refluxed contents from the stomach and duodenum such as gastric acid, pepsin, bile, and trypsin
   (b) Owing to swallowed substances, either intended such as medications or accidental caustic ingestion such as dishwasher liquid

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_60

2. Immunologic: owing to specific responses to specific antigens such as CMP or multiple food intolerance or allergy
3. Infective: associated with organisms as diverse as *Helicobacter pylori* (with associated reflux), *Candida*, cryptosporidiosis, herpes simplex, and *Cytomegalovirus* (CMV)
4. Traumatic: secondary to intraluminal trauma (e.g., long-term nasogastric tube) or irradiation (e.g., as part of bone marrow transplant conditioning)
5. Systemic disease manifestation: associated with conditions such as Crohn's disease and chronic granulomatous disease
6. Miscellaneous: such as that associated with passive smoking or that occurring in fictitious or induced illness (Munchausen syndrome by proxy)
7. Idiopathic: eosinophilic esophagitis

The etiopathologic role of each of these situations can therefore be usefully discussed under each heading, bearing in mind that an individual child or infant may, of course, have more than one factor contributing to the esophageal insult at any one time (e.g., GER and cow's milk-associated esophagitis).

Chemical

Chemical esophagitis owing to swallowed substances.

Ingested materials are usually household or garden substances and are usually markedly alkaline; the common one was dishwasher fluid, often with a pH of 9 or above. However, fortunately, in most countries, this has been replaced with powder, which is less easy to swallow, and even individually wrapped tablets of powder. Acute perforation, mediastinitis, and subsequent esophageal stricture have frequently been seen. The possibility of non-accidental injury should not be forgotten in this context. It is notable that the rate of subsequent stricture formation is high, and more recently, a potentially effective post-dilation topical application of an anti-fibrotic, mitomycin C, has shown promise in preventing restenosis and long-term repeated stricture dilation [5].

Restenosis post-dilation of strictures due to many variable pathologies has now been successfully prevented by the use of this substance applied topically at endoscopy – the only pathology which may be refractory to its effect is in epidermolysis bullosa [6] (Fig. 60.1).

Many medications have been associated with esophageal damage and symptoms of esophagitis, and these include tetracyclines (not recommended under the age of 12 years, of course), drugs used in acne therapy, and nonsteroidal anti-inflammatory drugs [7–10].

Immunologic

Although it is now clear that multiple food antigens may induce esophagitis [11, 12], the most common precipitant is CMP. Standard endoscopic biopsy and histology do not reliably distinguish between primary reflux esophagitis and the emerging clinical entity of cow's milk-associated reflux esophagitis. This variant of cow's milk allergy appears to be a particularly common manifestation in infancy, with symptoms indistinguishable from primary GER but that settle on an exclusion diet [13]. Some dif-

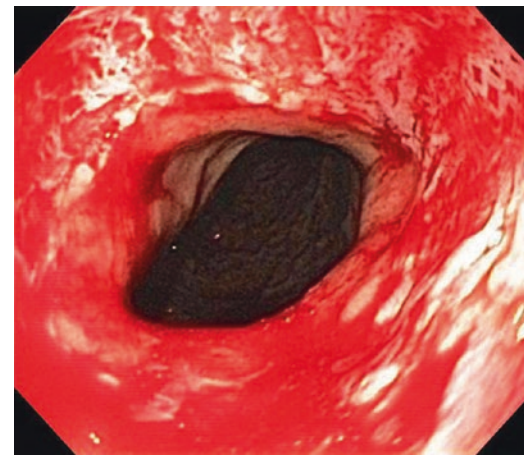

Fig. 60.1 Example of caustic injury to the esophagus

ferentiation from primary reflux has been suggested on the basis of an esophageal pH testing pattern and an α-lactoglobulin antibody response, although the former has not been substantiated by more than one center [13, 14]. There is recent evidence that this esophagitis is becoming a more common presentation of infant food allergy within the developed world and, in fact, may be induced by a variety of antigens in addition to cow's milk [11, 12]. Many affected infants have sensitized while exclusively breastfed, and a defect in oral tolerance for low doses has been postulated as the underlying cause [15, 16].

Esophageal mucosal eosinophilia has been described in both suspected cow's milk-associated [11] and primary reflux esophagitis (Fig. 60.2) [17], as well as in other conditions, such as idiopathic eosinophilic esophagitis (EE) [18]. A variety of immunohistochemical markers have been used to examine the esophageal mucosa, including eotaxin, a recently described eosinophil-specific chemokine (Fig. 60.3) [19], and markers of T-cell lineage and activation. Despite the mild histologic abnormality in CMP-associated esophagitis, an increased expression of eotaxin co-localized with activated T lymphocytes to the basal and papillary epithelium has been shown [20], distinguishing this from primary reflux esophagitis. The molecular basis of the eotaxin upregulation in cow's milk protein-sensitive enteropathy (CMPSE) is unknown. However, there is evidence from murine models of asthma that antigen-specific upregulation of eotaxin expression can be induced by T cells and blocked by anti-CD3 monoclonal antibodies. This suggests the possibility of a distinct mechanism in CMPSE, in which mucosal homing to the esophagus occurs of lymphocytes activated within the small intestine. This may explain the seemingly counterintuitive finding of the basal, as opposed to superficial, chemokine expression, and the common occurrence of mucosal eosinophilia in this condition. The esophageal motility disturbance of CMPSE-associated esophagitis is thus suggested to occur as a neurologic consequence of the inflammatory infiltration induced from lamina propria vessels into the epithelial compartment [21]. This proposed mechanism contrasts with the current concept of luminally induced inflammation found in primary reflux esophagitis and is consistent with the characteristic delayed onset and chronic nature of cow's milk-associated reflux esophagitis. It has also been suggested that increased numbers of mucosal mast cells allow a distinction to be made between allergy-induced and reflux-induced esophagitis [22]. Much work is required in this area and is ongoing.

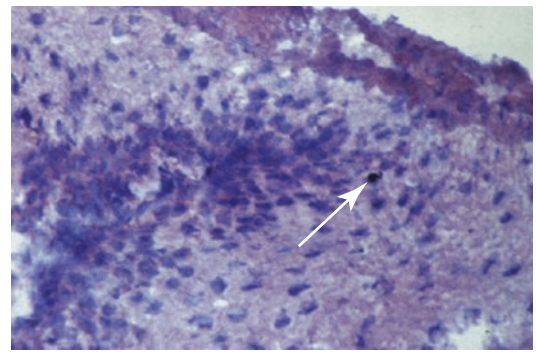

Fig. 60.3 Eotaxin, a recently described eosinophil-specific chemokine. (Darker staining area marked by an *arrow)*

Infective

The majority of infective esophagitis that occurs is in the immunocompromised child and is due to such agents as herpes simplex, CMV, *Candida*, and others. Mucosal damage owing to physical or chemical causes may predispose the patient to opportunistic infection. Oral herpes or *Candida* may offer some clue to etiology, and the older child will often complain of odynophagia or dysphagia. Diagnosis may be made on endoscopy with biopsy, but brushings may offer a greater diagnostic yield.

Viral esophagitis is usually due to herpes simplex, CMV, and, occasionally, *Varicella zoster* [23–25]. Herpes simplex esophagitis can occur in those with normal immune function [26], but is more often seen in those who are immunocompromised. In one series, 10% of the liver or kidney transplant recipients had herpes or CMV esophagitis [27], and it is also commonly seen in pediatric human immunodeficiency virus (HIV) infection [28]. The use of prophylactic acyclovir/ganciclovir is conjectural but may be of some benefit.

The diagnosis of herpes esophagitis is often difficult because the characteristic nuclear inclusions and multinucleate giant cells may not be seen in endoscopic biopsies; however, a prominent mononuclear cell infiltrate is described as characteristic (Fig. 60.4) [29]. It may be that the esophagus is particularly vulnerable in the GI tract owing to affinity of the herpes virus for stratified epithelium. Typically, roundish distinct disseminated lesions with yellowish borders are seen and have been termed "volcano ulcers" (Fig. 60.5) [30] although early in the presentation, vesicles may be noted. Although the inflammation can resolve spontaneously in the immunocompetent, in those with poor immune function, acyclovir and a high index of suspicion are recommended [30]. Resistance to acyclovir has been described, in which case, foscarnet is the agent of choice [31]. CMV esophagitis is confirmed by basophilic nuclear inclusions on biopsy of the edge of the ulcers, which are similar in appearance to herpetic ones. CMV is predominantly found in immunocompromised individuals, and treatment is with ganciclovir or foscarnet [25]. Hemorrhage, fistulae, and esophageal perforation in adults with viral esophagitis are described [32, 33]. Acute HIV infection can also cause esophagitis [34].

Candida, the most common infectious cause of esophagitis, has the classic appearance of white plaques on the mucosa, which cannot be washed or brushed off, unlike food or milk residue, and which often extends up to the upper

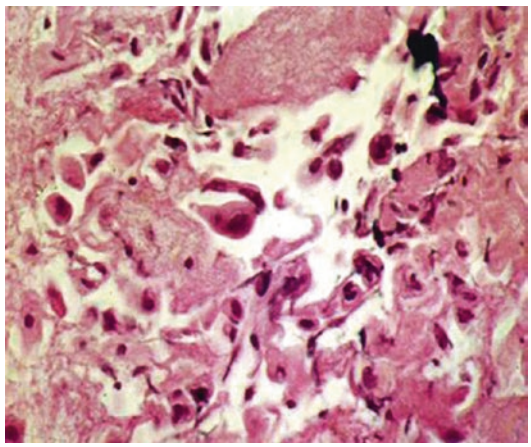

Fig. 60.4 Herpes esophagitis with nuclear inclusions, multinucleate giant cells, and a prominent mononuclear cell infiltrate

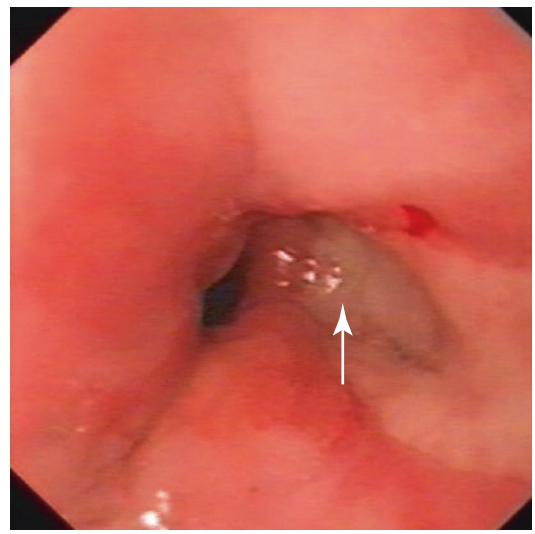

Fig. 60.5 Macroscopic appearances of herpes esophagitis. Roundish distinct disseminated lesions with yellowish borders are seen and have been termed "volcano ulcers" (*arrow*)

third of the esophagus (Fig. 60.6) [35]. Oral *Candida* is not predictive of esophageal involvement except in the immunocompromised host, but even in these children, extensive esophageal involvement is seen in the absence of oral candidiasis [36]. Mucositis and a white cell count less than 0.5×10^6/L predispose patients with leukemia to candidal esophagitis [37]. Steroid use (even poor technique with inhaled steroids for asthma) or acquired or congenital immunocompromise may be etiologic and may have the appearance of white focal lesions on the esophageal surface (Fig. 60.7). This appearance may be difficult to distinguish from eosinophilic esophagitis. Apart from the macroscopic appearances, diagnosis is confirmed by the presence of hyphae in biopsies (Fig. 60.8). Culture is not helpful because coexistent oral *Candida* can confuse the assessment. Complications include fistulae, perforation, painless stricture formation, esophageal dysmotility, transient achalasia [38], and systemic candidiasis. A 2–6 week course of oral nystatin can be effective in those with normal immune function, but it is more convenient to give fluconazole. Fluconazole or liposomal amphotericin is required, and both are effective in the immunocompromised child. Esophageal resection and diversion for necrotizing candidal esophagitis have been successful in a 10-year-old [39].

Eradication of *H. pylori* in adults has been associated with increased acid production and hence more noxious gastroesophageal refluxate. However, there does not seem to be any increased incidence of esophagitis in the presence of, or following, the eradication of *H. pylori* in children [40]. Because *H. pylori* affects gastric epithelium, it is not surprising that it has been identified in Barrett epithelium in a child, in whom symptoms

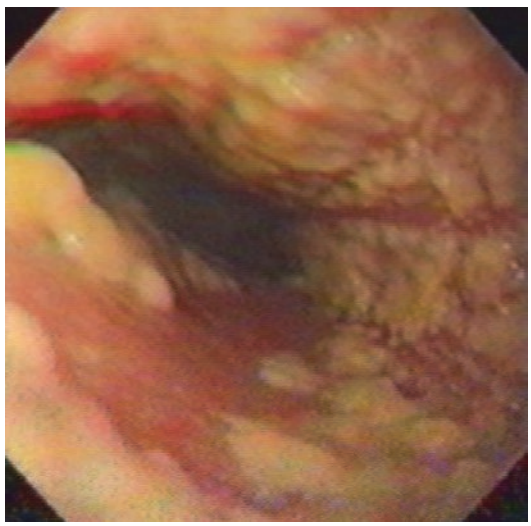

Fig. 60.6 Candidal esophagitis has the classic appearance of white plaques on the mucosa that cannot be washed or brushed off

Fig. 60.7 Candidal esophagitis may have the appearance of white focal lesions on the esophagus, which may be difficult to distinguish from allergic esophagitis

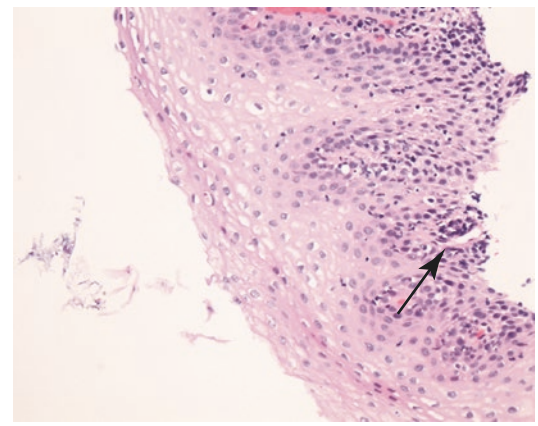

Fig. 60.8 Candidal hyphae (*arrows*)

resolved only with addition of amoxicillin to anti-reflux therapy [41]. Primary bacterial esophagitis is described in immunocompromised patients and may be successfully treated with long-term ciprofloxacin, metronidazole, or penicillin – or a combination dependent on bacteria and sensitivity [42].

Other opportunistic organisms causing esophagitis, such as *Cryptosporidium* and *Acremonium*, have been reported [43, 44].

Traumatic

Trauma causing esophageal pathology could, of course, be accidental, intentional, or iatrogenic. The presence of a nasogastric tube may be associated with abrasive esophagitis, and it has been postulated that the severe esophagitis found in newborn infants in one study, in the absence of other etiologic factors, may have been secondary to enthusiastic upper GI suction at birth [45]. Of particular note was the severity of the esophagitis in the face of relatively minimal symptomatology, such as feeding refusal. Radiation-induced esophageal strictures are described in children receiving mediastinal irradiation (usually greater than 4,000 cGy) and doxorubicin, occurring between 1 and 10 years post-therapy [46]. Radiation-associated esophagitis following bone marrow transplant conditioning is known to occur in the subsequent 1–2 weeks but is usually amenable to medical therapy.

Systemic Disease Manifestation

GER occurs more commonly in diverse conditions such as cystic fibrosis, severe combined immunodeficiency, cerebral palsy, raised intracranial pressure, celiac disease, and conditions associated with impaired gastric emptying [47, 48]. Certain diseases are, however, associated with esophagitis, which is not via the pathogenetic pathway of reflux. Crohn's disease is a prime example, and Crohn's lesions in the esophagus are usually distinct rounded ulcers, although diffuse disease may also occur (Fig. 60.9). Endoscopic examination with biopsy of the upper GI tract should be part of the diagnostic workup of a child with suspected Crohn's disease [49]. Relapse of the disease may be associated with recurrence of esophageal manifestations [50]. Type 1b glycogen storage disease may present with similar phenotype to Crohn's disease, and severe esophageal involvement has been noted in childhood in this condition [51]. Inflammation and stricturing of the esophagus can occur in chronic granulomatous disease and can involve most of its length, making balloon dilation difficult [52]. Scleroderma and vasculitic conditions such as polyarteritis nodosa have significant esophageal pathology in adults but are very rare in pediatric populations. Graft-versus-host disease may present in the esophagus although this is less likely than other GI areas such as the stomach and rectum. Epidermolysis bullosa is a debilitating disease that may also involve the esophagus, as are other dermatological conditions which affect the esophagus such as lichen sclerosus et atrophicus.

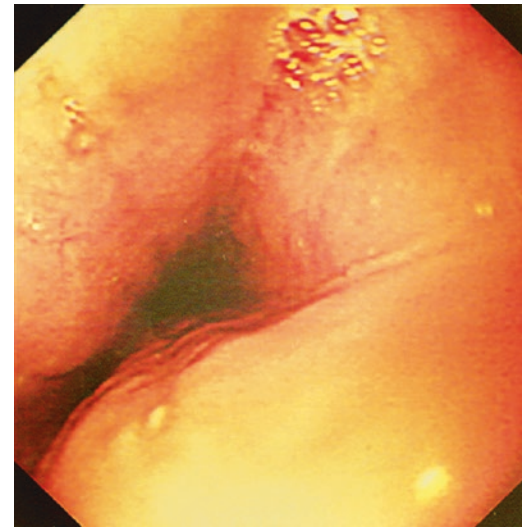

Fig. 60.9 Distinct round ulcers of Crohn's esophagitis

Miscellaneous

Passive smoking has a strong association with esophagitis in childhood. The reasons behind this are not completely understood, but nicotine is

known to relax the LES and may decrease mucosal blood flow. The nicotine levels in swallowed saliva may directly injure the esophagus or render it more susceptible to injury from acid exposure. Also, free radicals present in tobacco smoke may reduce antioxidant defenses [53].

Fictitious or induced illness (Munchausen syndrome by proxy) can be at the root of esophagitis in children, but this is usually due to the deliberate introduction into the esophagus by the perpetrator of caustic or irritative substances [54].

Idiopathic: Eosinophilic

Eosinophilic esophagitis (EE) is the subject of a subsequent chapter.

Management and Prognosis

Management of esophagitis must, of course, be dictated by its etiology, which further underlines the vital nature of obtaining an accurate diagnosis based on upper endoscopy and histologic assessment.

Because the vast majority of cases of esophagitis in infants and children will be due to GER, then treatment of GER and treatment of GER-related esophagitis will be very closely linked. Treatment of GER is also dealt with in other chapters. Other specific treatments for specific pathologies are also dealt with.

Infective causes of esophagitis in pediatrics require specific therapies. Viral esophagitis is usually due to herpes simplex, CMV, and, occasionally, *Varicella zoster* [23–25]. Although the inflammation can resolve spontaneously in the immunocompetent, in those with poor immune function, acyclovir and a high index of suspicion are recommended [30]. The use of prophylactic acyclovir is conjectural but may be of some benefit posttransplant. Resistance to acyclovir has been described, in which case, foscarnet is the agent of choice [31]. CMV esophagitis is predominantly found in immunocompromised individuals, and treatment is with ganciclovir or foscarnet [25]. Hemorrhage, fistulae, and esophageal perforation in adults with viral esophagitis have been described [32, 33].

Acute HIV infection can also cause esophagitis, and antiretroviral regimens are needed [34].

Candida is the most common infectious cause of esophagitis. A 2- to 6-week course of oral nystatin can be effective in those with normal immune function, but it is more convenient to give fluconazole. Fluconazole and liposomal amphotericin are both effective and are necessary in the immunocompromised child.

Eradication of *H. pylori* is not likely to improve coexistent esophagitis, and, indeed, in adults, eradication has been associated with increased acid production and hence more noxious gastroesophageal refluxate. However, there does not seem to be any increased incidence of esophagitis in the presence of or following the eradication of *H. pylori* in children [40]. Primary bacterial esophagitis is described in immunocompromised patients and requires appropriate antibiotics dictated by sensitivity testing [42]. Other opportunistic organisms causing esophagitis, such as *Cryptosporidium* and *Acremonium*, have been reported and require appropriate therapy [43, 44].

Treatment of caustic esophagitis is initially conservative, with barium swallow at 4–6 weeks post-ingestion, endoscopic assessment, and, if necessary, stricture dilation. The place of steroids in stricture prevention is controversial and not routine in many centers. Recently, the use of an anti-fibrotic, mitomycin C, applied topically to the mucosa post-stricture dilation has been used successfully in patients who have required multiple stricture dilations, with prevention of restenosis (Fig. 60.1) [5]. Antibiotic therapy for mediastinitis and judicious use of surgery may be employed.

Older children whose esophageal stratified epithelium is exposed to long-term acid may, as with adults, develop gastric metaplasia, eponymously termed Barrett's esophagus [55–57]. This increases the lifelong risk for esophageal adenocarcinoma approximately 30- to 40-fold. Debate surrounds the relative merits and success rates of anti-reflux surgery or long-

term proton pump inhibitor use, and this is dealt with in greater detail elsewhere in the book.

Prognostication in infant and childhood esophagitis is wholly dependent on etiology, however, fortunately, the most common causes, reflux and allergy, are relatively self-limiting, with a natural improvement and recovery by 18 months to 2 years in the vast majority. This is dealt with in greater detail at the beginning of the section on treatment. It is the responsibility of the pediatrician to prevent avoidable complications such as peptic strictures occurring during the period of vulnerability until such an age has been reached. A low threshold for diagnosis and intervention is therefore sensible in this population.

Treatment of EE is dealt with in detail in a seperate chapter.

In summary, pediatric esophagitis is no longer regarded as a unidimensional reflux-related condition, and the main reason cited by the recent conjoint ESPGHAN-NASPGHAN working group on reflux and esophagitis for endoscopic assessment in this group of patients is diagnostic differentiation of reflux esophagitis from other conditions such as eosinophilic esophagitis and other inflammatory and infective etiologies [58]. The developments in physiologically appropriate tools such as impedance and the rapid rise in comprehension of issues such as neurohumoral interactions controlling esophageal function, combined with the recent apparent explosion in incidence of new esophageal diseases in children – for example, eosinophilic esophagitis – suggest that the study and clinical care of children with esophageal inflammatory disorders are likely to be of expanding interest to the pediatric gastroenterology community as each year goes by.

Eosinophilic Esophagitis (North America)

61

Aileen Har and Sandeep K. Gupta

Introduction

Eosinophils are involved in and mediate a variety of disease processes including parasitic and fungal infection, allergic reactions, hematologic malignancies, autoimmune diathesis, and endocrine disorders [97]. Eosinophils can also be part of normal/baseline histological makeup of certain organs. For example, in the gastrointestinal tract, there is a variation in the eosinophil load in the healthy state where a relatively high number of eosinophils are present in the cecum, but are strikingly absent in the healthy esophageal epithelium.

Eosinophilic esophagitis (EoE) involves eosinophilic infiltration restricted to the esophagus without evidence of gastroesophageal reflux (GER) [28]. Eosinophilic infiltration is limited to the esophageal epithelium with concomitant epithelial changes such as vascular papillae elongation and basal cell hyperplasia [71]. This entity had been sporadically reported in the literature with limited attention until 1995 when Kelly et al. published a series of 12 children who had significant eosinophilic inflammation of the esophagus that was unresponsive to standard anti-reflux therapy including six children who had underwent Nissen fundoplication [43]. Patients with EoE may present with a variety of symptoms, several of which may be similar to gastroesophageal reflux disease (GERD) including regurgitation, nausea, feeding intolerance, and epigastric pain. Others may present with more specific symptoms such as dramatic and recurrent dysphagia and food impactions. The diagnosis of EoE has increased in recent years, which may be due to both increased recognition of the disease and actual increase in incidence [11, 48, 67, 95].

As of now, our understanding of EoE is still in its infancy with much to be discovered in this relatively new entity. This chapter will discuss the pathogenesis, epidemiology, diagnosis, treatment, and long-term outcomes of EoE.

Other Causes of Eosinophilia in the Esophagus

While eosinophils are present in the healthy state in most parts of the gastrointestinal tract, they do not normally reside in the healthy esophagus [79]. Other than EoE, there are a variety of conditions that may lead to eosinophilic infiltrate of the esophagus with the most common being GER (Table 61.1) [17]. In GERD, exposure of the esophageal epithelium to gastric contents containing pepsin, trypsin, and gastric acid results in nonspecific inflammatory infiltrate with involvement of a variety of cytokines and chemokines, along with other inflammatory mediators [20]. While the exact pathways involved are not completely understood, it is postulated that the direct exposure of esophageal epithelial cells to gastric contents causes secretion of pro-inflammatory mediators as well as activation of mesenchymal and endothelial cells leading to an upregulated immune response [76]. A mixed infiltrate consisting of neutrophils, eosinophils, mast cells, and macrophages is seen in the esophageal epithelium of patients with GERD, but the degree of eosinophilia is generally less than that seen in EoE and is usually limited to the distal esophagus.

Fungal infections of the esophagus are more common in the setting of immunocompromise, broad-spectrum antibiotic use, inhaled corticosteroid usage with improper technique, malignancy, or chronic metabolic disease [13]. *Candida sp*. are the most frequently isolated fungal organisms from the esophagus. Patients most commonly present with dysphagia or odynophagia and may have abdominal pain, globus sensation, nausea, vomiting, dyspepsia, and in severe cases upper gastrointestinal bleeding. The endoscopic picture of esophageal candidiasis can be similar to that of EoE with adherent white plaques, though the plaques with candidiasis are of a "cheese-like" appearance. Histology and fungal brushings are useful to differentiate between the two conditions as hyphae can be identified in candidiasis.

Table 61.1 Causes of esophageal eosinophilia

Gastroesophageal reflux disease
Eosinophilic esophagitis
Infection – parasitic and fungal
Connective tissue disease
Eosinophilic gastroenteritis
Hypereosinophilic syndrome
Inflammatory bowel disease/Crohn disease
Drug-induced injury

Connective tissue diseases such as scleroderma intrinsically cause an elevation of eosinophils in the esophagus due to generalized inflammation. Systemic scleroderma affects the esophagus in 75–90 % of patients [15] leading to dysmotility and abnormal functioning of the lower esophageal sphincter thereby causing a predisposition to GERD with further increase in inflammation.

Other inflammatory conditions where there is recruitment of eosinophils to the esophagus include injury due to medications. Pill esophagitis occurs when there is prolonged contact of medication with the esophageal surface. Medication-induced esophagitis has been reported with nonsteroidal anti-inflammatory drugs, alendronate, quinidine, tetracycline, doxycycline, potassium chloride, ferrous sulfate, and mexiletine with higher risk in patients with esophageal dysmotility and decreased salivation [30]. Large or sustained release pills as well as ingestion in the supine position or ingestion with insufficient water predisposes to injury. Endoscopy may reveal erythema, erosions, and/or ulcerations; strictures or perforation could be seen with severe cases.

Eosinophilic gastroenteritis typically involves the stomach and small bowel, but may expand to the esophagus or colon [106]. It is a rare condition and even less common in the pediatric age group with the typical presentation in the 30–50-year age range [31]. Eosinophilic inflammation may be limited to the mucosa and submucosa or may involve the muscle layers to the extent of full-thickness inflammation [52]. Clinical presentation is varied and depends on the location and depth of tissue inflammation; symptoms can include diarrhea, abdominal pain, weight loss, failure to thrive, protein losing enteropathy, iron

deficiency anemia, and eosinophilic ascites [27]. These patients may have a history of atopy and peripheral eosinophilia. The pathophysiology is unclear, but in infants, the trigger may be milk-protein intolerance, and in older children, there may be associated IgE-mediated hypersensitivity to food [42].

Hypereosinophilic syndrome (HES) comprises of sustained peripheral eosinophilia >1,500 eosinophils/mm^3 for 6 months, absence of other eosinophilic syndromes or identifiable etiology for eosinophilia, and end-organ involvement [14]. HES is a group of heterogeneous syndromes with a male predominance of 9:1, and age of diagnosis ranged from 20 to 50 years [103]. Organ systems that may be affected include cardiovascular, dermatologic, pulmonary, gastrointestinal, and ocular. Gastrointestinal involvement can include esophagitis, gastroenteritis, and colitis as well as hepatitis and Budd-Chiari syndrome.

Pathogenesis

The exact molecular mechanisms underlying eosinophilic infiltration of the esophageal epithelium are poorly understood and remain incompletely defined. The infiltration in EoE is thought to be secondary to an allergic process, and patients with EoE have an increase in overall genetic dysregulation with an elevation of eosinophil-directed cytokine expression in the esophagus [8, 34, 91]. There is a noted increase in T cells and mast cells [46, 54] within the esophageal epithelium as well as an upregulation of interleukin (IL)-5, IL-13, interferon (IFN)-γ, and tumor necrosis factor(TNF)-α production that does not involve the stomach, duodenum, or peripheral circulation [34, 91]. T-helper 2 (Th2) cell-associated cytokines have been implicated in the recruitment of eosinophils to the esophagus.

A genetic variant of the eotaxin-3 gene, an eosinophil-specific chemoattractant, also known as CCL26, may predispose to development of EoE [8]. Patients with histological diagnosis of EoE have a highly conserved esophageal transcriptome seen on genome-wide transcription analysis of biopsy specimens. The highest induced transcript in EoE patients is reported to be eotaxin-3, and its induction is not seen in patients with chronic esophagitis due to other causes or in healthy individuals. In fact, esophageal transcriptomes of non-EoE esophagitis patients were similar to that of those without esophagitis. Eotaxin-3 levels correlated with EoE disease severity and were expressed in EoE patients with and without known food or aeroallergies. Deletion of the eotaxin-3 receptor, CCR3, in mouse models has been shown to be protective of EoE development [60, 61]. In vitro experiments on esophageal tissue treated with IL-13 induced production of CCL11 and CCL26 at levels sufficient to cause eosinophil migration [64].

Epidemiology

EoE has been described in both pediatric aged and adult patients. The mean age of diagnosis in children is 8.6 years with a range of 0.5–21.1 years, and there is a striking gender bias to EoE with two thirds of patients being male [28]. Epidemiologic data is wanting, but limited studies indicate an incidence around 1:10,000 yearly and prevalence is estimated around 1:2000 [11, 48, 67, 95]. Several centers, including those in the United States, have noted a steady increase in yearly diagnosis of EoE [87]. It is unclear if incidence of EoE is truly increasing or if it is partially due to increased recognition. EoE has been described throughout most of the world except Africa, but there is a lack of data looking at ethnic predilection. There may be a familial preponderance for the disease, but it is unclear if the link is genetic vs. environmental exposure [59, 72, 95]. Up to 8 % of patients with EoE have parents with esophageal biopsies consistent with EoE, and 10 % of the parents have a history of esophageal strictures [67]. Fifty to 80 % of patients with EoE may have a personal and/or family history of atopy [50, 70]. There is evidence showing a seasonal variation in diagnosis, which may differ depending on the geographical location and the type or level of aeroallergens [24, 62, 74]. A published case involving a 21-year-old female

diagnosed with EoE showed clear variation of symptoms and histology correlating with spring and winter months [24]. Springtime and grass pollen counts also correlated with EoE diagnosis in a single center involving 127 patients – 33 % of diagnoses were made in spring and 16 % in winter [62]. In another study, 68 % of cases of EoE were diagnosed in spring/summer versus 27 % in winter [3].

Table 61.2 Presenting symptoms of EoE

Infants	Failure to thrive
	Feeding difficulties
	Gastroesophageal reflux symptoms
	Vomiting
School age	Abdominal pain
	Gastroesophageal reflux symptoms
	Vomiting
Adolescence	Dysphagia
	Food impaction

Diagnosis

EoE is defined as presence of ≥15 eosinophils in at least one high-power field (hpf) on esophageal mucosal biopsies, clinical symptoms of esophageal dysfunction, and absence of GERD as evidenced by persistent inflammation on high-dose PPI or normal 24-h continuous intraesophageal pH monitoring (pH probe) [28]. The most specific variables for diagnosis of EoE are loss of mucosal vascular pattern and vertical furrows in the esophageal mucosa on esophagogastroduodenoscopy (EGD); patients with improved symptoms on either an elemental diet or swallowed fluticasone are 160 times more likely to have EoE than GERD [48].

History and Physical Examination Presenting symptoms in the pediatric population vary by age. Patients with EoE can be difficult to recognize, and the time to diagnosis may range from 13 to 60 months from symptom onset [22]. Younger patients tend to present with feeding intolerance, refusal to feed, and failure to thrive, while children who present when they are older may have emesis, regurgitation, heartburn, and abdominal pain. As they enter adolescence, patients tend to have symptoms similar to adults – recurrent dysphagia and food impaction (Table 61.2). In a retrospective study of pediatric patients with follow-up period of over 10 years, 82 % of the patients presented with GER symptoms and only 18 % presented with dysphagia [50]. The presence of dysphagia and anorexia/early satiety may help differentiate patients with EoE from those with GER alone [2]. There is a dissociation between severity of symptoms and histological severity in the pediatric population making it difficult to predict histological findings based on symptoms alone [73]. Atopy, the tendency for an individual to have an IgE-mediated response to allergens resulting in asthma, atopic dermatitis, or allergic rhinitis, is found in 50–80 % of children with EoE [38, 50, 85]. In addition to personal history of atopy, patients have a family history of atopy and EoE at 43 % and 12 %, respectively [50]. The physical examination for EoE is nonspecific, but eczema or other signs of allergy may be elicited as may those of failure to thrive. Clinical evaluation of EoE is further challenged by coping mechanisms utilized by patients, and efforts to uncover these should be part of the evaluation. Coping mechanisms most commonly seen are texture avoidance/preference, excessive use of liquids at mealtime to assist passage of food bolus, excessive chewing of food, very small bites of food, and prolonged mealtimes.

Laboratory Data and Biomarkers Currently there is no ideal biomarker that accurately predicts the diagnosis, severity, remission, and relapse of EoE. Identification of a biomarker that could substitute for endoscopic examination and histological assessment would be exceedingly beneficial to both patients and health-care provider as it would substantially reduce the time and costs associated with repeated endoscopic procedures. The ideal biomarker would be sensitive, be specific, be reproducible, correlate with EoE state, connect with severity of disease, reflect changes caused by therapy, be obtained from specimens that are easily and noninvasively collected, and be cost-effective [33]. Potential

biomarkers for EoE include mast cell products, peripheral blood eosinophils, cytokines and chemokines, serum IgE and CD 23 levels, and eosinophil granular proteins such as eosinophil-derived neurotoxin (EDN).

The role of mast cells, and their products including leukotrienes and histamine, in the pathogenesis of EoE has yet to be conclusively delineated [39, 83, 100]. Leukotriene levels in esophageal mucosa in children with and without EoE are similar to those seen in controls [35]. N-methylhistamine, a stable metabolite of histamine which can be measured in urine, has been evaluated in inflammatory bowel disease, but not yet in EoE [104].

Mild peripheral eosinophilia (600–1,600 cells/μL) [97] is seen in 20–100 % of children with EoE [23, 45, 66, 70, 80, 98, 102]. The level of peripheral eosinophilia may decrease once treatment for EoE is initiated, but there is insufficient evidence to use it as a surrogate marker of disease activity [23, 47]. Patients may have an elevated total IgE level, but it is unclear if this is related to underlying atopy or specifically to EoE itself [51]. CD23 is a membrane protein that serves as an IgE receptor and is present on various cells including enterocytes and eosinophils. CD23 expression is induced by cytokines involved in allergic processes and may be a potential biomarker for EoE [105]; CD23 has been detected in stools of children with food allergies, but not in controls [49].

Cytokines and chemokines that mediate eosinophilic inflammatory processes include IL-5, which is crucial to eosinophil life cycle, and eotaxin-3, a eosinophil chemoattractant. IL-5 is intimately involved in eosinophil proliferation, maturation, trafficking, stimulation, degranulation, and recruitment [89]. Eotaxins are a family of chemokines that attract eosinophils and promote their degranulation and may also be involved in eosinophil homing to the gastrointestinal tract [58]. In a genome-wide microarray expression analysis, the gene-encoding eotaxin-3 (CCL26) was found to be the most highly induced gene in patients with EoE compared to normal individuals [8]. Eotaxin-3 levels in blood and esophageal tissue may also correlate with esophageal eosinophil density in pediatric patients [8, 47] though other studies have shown eotaxin-3 levels in esophageal tissue of EoE patients to be similar to controls with instead upregulation of TNF-α, eotaxin-1, IL-5, and IFN-γ in EoE subjects [34, 91]. Furthermore, eotaxin-1, eotaxin-2, and IL-5 in the peripheral blood have not been shown to correlate with esophageal eosinophilic inflammation [47]. More studies need to be performed looking at cytokines and their relation to EoE as information from studies to date have been conflicting [8, 34, 47, 91].

EDN is a toxic mediator released on degranulation of eosinophil cytoplasmic granules [36]. It is elevated in serum and urine of children with allergic atopic dermatitis and asthma [37, 47]. Plasma and stool EDN levels may correlate with eosinophilic esophageal inflammation and be useful as a noninvasive biomarker [10, 47, 75].

Radiological Studies An upper gastrointestinal (UGI) contrast study is useful to determine if there is any narrowing or any other gross anatomic changes associated with EoE. Narrowing of the esophagus, though uncommon in clinical practice, has been reported in up to 6 % of children with EoE [50]. Other findings include Schatzki's ring, corkscrew esophagus, and small-caliber esophagus [50]. The study may help map out the length and approximate positioning of strictures. Having information from an UGI study prior to endoscopy is helpful for planning the procedure – selection of endoscope size, caution for increased risk of mucosal tearing, and availability of dilation instruments. However, even in pediatric patients with documented food impaction, the UGI findings may be normal and not suggestive of luminal stricturing [7].

Esophagogastroduodenoscopy Signs of EoE seen on endoscopy include edema, loss of vascular pattern mucosal thickening, vertical lines, furrowing, white specks/plaques, and circular rings or trachelization of the esophagus. Up to 12 % of patients will have rings in their esophagus on initial endoscopy [50]. Strictures may require

dilatation, though the mucosa tends to be friable and associated with increased risk of deep mucosal tears and perforation. Abnormal endoscopic findings are not limited to the distal esophagus as may be the case with GERD but rather in the mid- and proximal esophagus too. Interestingly, patients with active EoE may have endoscopically normal-appearing mucosa; about one third of patients with normal endoscopic findings have severe eosinophilia on histology [50].

Histology Mucosal biopsies should be obtained from all patients with suspected EoE undergoing EGD. Obtaining biopsies from both the distal and mid-esophagus helps to differentiate the diagnosis from GER as changes in EoE are generally not limited to the distal segment [28]. Histological changes associated with EoE include intraepithelial eosinophilia, eosinophil microabscess, eosinophil degranulation, basal cell hyperplasia, vascular papillae elongation, mucosal edema, and lamina propria fibrosis [28]. The actual intraepithelial eosinophil cutoff number to differentiate EoE from GERD has been variable and of debate [18] – commonly >20 eosinophils/hpf has been employed; however, consensus recommendations are that ≥15 eosinophils/hpf should be used [28]. When correlating eosinophils with GERD, patients with < 5 eosinophils/hpf were more likely to have abnormal pH probe results than those with ≥20 eosinophils/hpf [80]. The number of eosinophils found in esophageal epithelial biopsies may vary depending on a number of confounding factors such as the size of hpf, number and site of biopsies, use of corticosteroids, sampling error, and seasonal variation [24, 69]. Eosinophilic microabscesses are clusters of 4 or more eosinophils and have been seen exclusively in patients with EoE [71, 102]. The eosinophilic infiltrate often is concentrated in the superficial epithelium [19, 102]. Special staining for eosinophils, Luna eosinophil granule stain, may be more sensitive in detecting eosinophils and can be useful in cases where the eosinophil count is indeterminate, i.e., 5–15 eosinophils/hpf [48]. A small study showed an increase in esophageal EDN on immunofluorescence staining in EoE patients by [44]. It is important in patients being evaluated for EoE to biopsy the stomach and duodenum in order to differentiate from other disease entities such as eosinophilic gastroenteritis.

pH Probe Extended intraesophageal pH monitoring may be performed to help differentiate EoE from GERD, though approximately 10 % of patients with EoE may have coexisting GERD [80, 90, 102]. Patients without evidence of pathological acid reflux on pH probe and persistent clinical symptoms as well as histological eosinophilia (≥20 eosinophils/hpf) are likely to have EoE [90, 102]. The degree of esophageal eosinophilia does not correlate with the degree of measured GER, and those with ≥20 eosinophils/hpf have an increased likelihood of a normal pH probe. Children with EoE may actually have increased alkaline reflux with pH values >8.0 occurring during 19 % of probe time vs. 0.9 % in age-matched controlled ($p<0.01$) [80]. Alkalization of the esophagus may be secondary to dysmotility causing delay of saliva passage or perhaps due to bicarbonate production from damaged submucosal glands [84, 99].

Endoscopic Ultrasound (EUS) Limited data is available for the utility of EUS in the diagnosis of EoE although thickening of the mucosa, submucosa, and muscularis propria is seen compared to children without EoE [26]. In this single study, 11 patients were diagnosed with EoE based on four criteria: (1) endoscopic and histological appearance consistent with EoE, (2) extended esophageal pH probe results, (3) nonresponse to twice-daily proton pump inhibitor (PPI) therapy, and (4) symptomatic and histopathological response to swallowed fluticasone. EUS measurements were obtained 3–5 cm from the gastroesophageal junction, and layers measured were (1) total wall, (2) mucosa + submucosa, (3) muscularis propria, and (4) circular muscle. All layers except the circular muscle were statistically thicker in the EoE patients compared to controls.
Esophageal Manometry – Patients with EoE may experience dysphagia, without evidence of strictures or other anatomic abnormalities, suggesting esophageal dysmotility though it is unclear

whether esophageal manometry is useful for evaluation and/or management of EoE. One study using prolonged (24-h) esophageal manometry measured an increase in ineffective peristalsis and isolated and high amplitude contractions in pediatric patients with EoE compared to patients with GERD and controls [68]. It should be noted that traditional esophageal manometry may not show any motility abnormalities in the pediatric population [12]. Adult manometry studies have been inconclusive, but 10–57 % of patients may have nonspecific esophageal motor disorders [6, 16, 53, 55].

Treatment

The end point of EoE treatment is unclear, the long-term impact of the disease is still unknown, and there is dissociation between symptoms and objective data. Should the end point be based on symptoms, endoscopic findings, histological abnormalities, or a combination of these or some other criteria? A patient who is asymptomatic/has nonspecific symptoms may have endoscopic findings consistent with EoE. Another patient with normal/unremarkable endoscopic appearance may have severe eosinophilic infiltration on histology. Various treatment options for EoE are available and include dietary modification, systemic and topical steroids, biologic agents, and esophageal dilation.

Dietary Modification A broad-brush elemental diet, consisting of amino acid (AA)-based formula only, can be very successful in the motivated patient and family (88–97.6 % response [40, 43, 50, 56]). In the original article by Kelly et al. [43], ten children were placed on an elemental diet for a minimum of 6 weeks, of which eight showed clinical resolution and two had improvement. The number of esophageal epithelial eosinophils decreased from a median of 44 eosinophils/hpf pretreatment to 0.5/hpf on treatment. In a review of 60 pediatric patients with EoE (35 patients on a six-food elimination diet, 25 on an exclusive AA-based formula diet), 74 % of the patients on the six-food elimination diet and 88 % of the patients on the AA-based formula diet showed a reduction in eosinophils to ≤10/hpf [40]. Expected clinical improvement occurs within 1–2 weeks of strict adherence to an elemental diet; in 51 EoE patients on an elemental diet, 8.5 ± 3.8 days was the time to clinical improvement with endoscopic and histological improvement by 1 month [56]. Foods can be reintroduced slowly after confirmation of histological improvement, though the reintroduction may result in disease recurrence which then necessitates repeated endoscopies.

More liberal diets guided by results of allergy testing are termed directed-elimination diets. In treatment of 146 children with EoE, skin prick test (SPT) and atopy patch testing (APT) were performed to guide elimination diet [85]. In this report, 75 % of patients responded in 6–8 weeks to elimination of positively tested foods with clinical and histological improvement. Many patients however relapsed with reintroduction of allergic foods [85]. Interestingly younger children are more likely to respond to dietary elimination. The likelihood of identifying a food allergy depends on the number of foods tested, and most commonly identified food allergies on SPT are milk, eggs, soy, wheat, fish, and peanuts, and APT most commonly identified positive reactions to milk, wheat, corn, beef, egg, potato, chicken, soy, barley, oat, and rice in patients with EoE (Table 61.3) [86]. SPT is aimed at identification of IgE-mediated allergies, whereas APT identifies T-cell-mediated, non-IgE-mediated allergens. Since EoE is likely due to a combination of both IgE- and non-IgE-mediated allergy, performing both SPT and APT may increase the likelihood of identifying

Table 61.3 Six most commonly allergenic foods seen with EoE

Dairy
Eggs
Wheat
Soy
Peanuts
Fish/shellfish

Table 61.4 Riley hospital diet for EoE

Food or beverage	Avoid	Allowed
Beverage	Milk, soy milk, juice drinks, all fruit juice except pure juice from 5 selected fruits, tea, coffee, all formulas other than Neocate, Neocate One+, Neocate Jr., pediatric EO28, or Elecare	Water, Neocate, Neocate One+, Neocate Jr., pediatric EO28, or Elecare, rice milk, pure fruit juice from 5 selected fruits[a]
Animal protein sources	Cheese, eggs, poultry, fish, all meats except lamb	Lamb
Vegetable protein sources	Soy milk, soybeans, all beans, lentils, peas, peanuts, peanut butter, all nuts, bean sprouts	None
Grains/starches	Wheat, corn, oats, barley, rye, millet, wild rice	White potato, buckwheat, sweet potato, yams, rice, tapioca, arrowroot
Vegetables	Peas, tomatoes, corn, green beans, lima beans, cucumber, summer squash	Limit to 5 choices from the allowed vegetable list
Fruits	Citrus fruit (orange, tangerine, grapefruit, lemon, lime), all berries, cherries, kiwi, canned fruits in syrup	Limit to 5 fruits from the allowed fruit list[a]. Fruits may be fresh, frozen, juice, or canned in water or juice
Sweeteners	Powdered sugar	Cane or beet granulated sugar, maple syrup, honey, corn syrup, molasses, brown sugar
Fats/oils	Butter, all margarines except milk-free, nonspecific shortening, fats of animal origin	Coconut oil, corn oil, safflower oil, soy oil, milk-free margarine[b]
Other	Chocolate, malt, cornstarch, baking power	Salt, pepper, spices (limit total number to 5), vanilla extract, lemon extract baking soda, cream of tartar. Yeast, distilled vinegar, soy, lecithin[b]

[a]See Table 61.5
[b]No corn is allowed except corn oil, no soy is allowed except soy oil and soy lecithin, and oils must be hot pressed

Table 61.5 Riley hospital diet for EoE

Allowed vegetables	Allowed fruits
Asparagus	Apple
Beets	Apricot
Broccoli	Banana
Brussel sprouts	Cantaloupe
Cabbage	Grapes (seedless)
Cauliflower	Mango
Celery	Peach
Green pepper	Pear
Lettuce	Pineapple
Onion	Plum
Spinach	Raisins (seedless)
Turnips	
Winter squash	

offending foods. Using SPT alone may be insufficient in identifying all potential allergens, leading to treatment failure [66, 98]. Empiric food elimination of the six most commonly allergenic foods, namely, milk, eggs, soy, wheat, fish, and peanuts, has been successful in 74 % of children with both clinical and histological improvement [40]. While patients may test positive for food allergies on radioallergosorbent testing (RAST), no studies have shown successful treatment using RAST as a guide for food elimination [70, 98]. The elimination diet we offer our patients, in addition to directed-elimination and elemental diets, is listed in Tables 61.4 and 61.5. Many EoE patients have coexisting allergic rhinitis and aeroallergies [3, 62, 69] which should be appropriately managed and treated.

Systemic Corticosteroids Oral prednisone induces both clinical and histological remission in >95 % of pediatric EoE patients [50] though there is a risk of disease relapse (as with dietary modification) after weaning of

treatment. Dosing for prednisone is 1–2 mg/kg/day, divided twice a day, with a maximum of 60 mg/day [50, 81]. The risks associated with using systemic corticosteroids for EoE are the same as with any other indication (Table 61.6). There is no identified optimal weaning strategy to decrease incidence of relapse, though a slow taper is indicated for patients who have been on prolonged treatment due to risk of adrenal insufficiency and to perhaps delay likelihood of symptom relapse. In a study of 80 pediatric EoE patients randomized to oral vs. topical corticosteroids, there were no significant differences in the rate and progression to disease relapse among the two therapies [81].

Topical Corticosteroids Corticosteroids are delivered into the esophagus topically by swallowing formulations typically used as inhaled treatment for asthma. The major benefit of using topical therapy is the avoidance of side effects caused by systemic corticosteroids. Fifty two to 100% of patients treated with swallowed fluticasone had improvement of their symptoms [50, 98]; significant histopathological improvement is also induced by topical corticosteroid treatment. Treatment dosing of swallowed fluticasone from a metered dose inhaler (MDI) has ranged from 220 to 440 μg two to four times daily for a duration of 6–12 weeks. No standard treatment protocol has been developed to date, but dosing listed in Table 61.7 can be used as a prototype. Patients are to place the inhaler directly in their mouth with a tight seal, administer two puffs, swallow, and abstain from rinsing or oral intake for 30 min. After 30 min, patients should take a drink of liquid to "wash down" the medication due to the risk of candidal overgrowth. Unlike treatment for asthma, a spacer should not be used. Oral viscous budesonide mixed with sucralose has also been used successfully in treatment of EoE with 80% of patients responding in one study [1]. Budesonide may be an option for children who are unable to coordinate use of a MDI.

Histopathological reassessment should be performed after 4–12 weeks of therapy, specifically after 4 weeks with fluticasone treatment and 12 weeks with budesonide therapy to demonstrate efficacy. As with systemic steroids, there is no standard weaning schedule, but patients may be weaned slowly over approximately 3 months with close clinical monitoring for disease relapse. The major side effect seen in patients using topical steroid therapy is candidal overgrowth of the esophagus [98]. There is the possibility of adrenal suppression, growth impairment, and other end-organ damages such as osteoporosis with chronic topical corticosteroid exposure though objective data is wanting.

Table 61.6 Side effects of systemic prednisone

Central nervous system	Headache, mood disturbances, psychosis, pseudotumor cerebri, intracranial hypertension
Ocular	Increased intraocular pressure, cataracts, glaucoma
Cardiovascular	Hypertension, edema
Gastrointestinal	Nausea, vomiting, peptic ulcer disease
Endocrine	Cushing syndrome, electrolyte disturbances, hyperglycemia, growth suppression, weight gain, hypothalamic-pituitary-axis suppression, menstrual irregularities
Musculoskeletal	Osteoporosis, fractures, muscle weakness
Immune system	Immunosupression
Dermatologic	Acne, impaired wound healing, skin atrophy, bruising, petechiae

Table 61.7 Topical steroid therapy dosing prototype for pediatric EoE

Medication		
Fluticasone propionate	Age 1–10 years – 110 μg, 2 puffs swallowed, 4 times daily	Age ≥11 years – 220 μg, 2 puffs swallowed, 4 times daily
Budesonide mixed with 5 g sucralose	Age 1–9 years – 1 mg daily	Age ≥10 years – 2 mg daily

Leukotriene Receptor Antagonists There have been no studies to date using leukotriene receptor antagonists in children for the treatment of EoE. No difference in cysteinyl leukotriene levels in esophageal mucosal biopsies was found between pediatric patients with and without EoE [35]. Eight adult patients with EoE and symptoms of dysphagia were treated with 20–40 mg of montelukast for a median of 14 months; six had symptomatic resolution but histopathological remission was not investigated, and all had symptoms relapse within 3 weeks of discontinuing treatment [5].

Cromolyn Sodium No formal studies have been published using cromolyn sodium in children with EoE. Fourteen pediatric patients who had been trialed on oral cromolyn (100 mg/dose four times a day) did not have clinicopathological improvement after 4 weeks of treatment [50].

IL-5 IL-5 is the primary cytokine responsible for eosinophil proliferation, maturation, and recruitment among other eosinophil-directed functions [4, 89]. A fully humanized anti-IL-5 antibody, mepolizumab, has been used with success in treatment of HES with significant sparing of systemic steroid usage [29, 57, 78]. An open-label phase I/II study conducted on four adult patients with EoE showed decrease in peripheral and esophageal eosinophilia with 750 mg mepolizumab infusions administered once a month for 3 months [88]. Peripheral eosinophilia, esophageal eosinophilia, and patient quality of life were compared prior to initiation of mepolizumab and 1 month after treatment. There was a decrease in peripheral eosinophilia by 6.4-fold and esophageal eosinophilia by 8.9-fold with therapy as well as improvement in patient symptoms scores and quality of life using the Validated Short Form Health Questionnaire SF-36. Adverse events noted with mepolizumab were headache and upper respiratory tract infections with one patient experiencing hypotension during the third infusion, which was successfully treated with volume expansion. In a double-blind, randomized trial, 11 adults with EoE were treated with mepolizumab or placebo – while a significant decrease in the number of eosinophils/hpf was reported, none of the biopsies fell below 15 eosinophils/hpf and clinical remission was not attained at the end of the trial [93]. Patients in this study were treated with mepolizumab 750 mg infusion or placebo 1 week apart for two infusions. Four weeks after the initial infusion, a repeat EGD was performed – none of the patients attained a eosinophil count of <15/hpf. Patients were then given mepolizumab 1,500 mg or placebo for two additional doses 4 weeks apart and EGD re-performed 4 weeks after the last infusion. Again no patient had an esophageal eosinophil count of <15/hpf, and side effects were minimal and included upper respiratory tract infection and fatigue.

While there is potential for anti-IL-5 to be used as targeted therapy in EoE, further study is needed and clinical trials are currently being conducted. An open-label study of three doses of mepolizumab in children with EoE having prior inadequate response or intolerance to other EoE therapies was recently completed [32]. Pediatric patients had a pharmokinetic profile similar to that of adults and 31 % of subjects achieved <20 eosinophils/hpf on esophageal mucosal biopsies. Another anti-IL-5 agent reslizumab is currently being evaluated in children with EoE.

Omalizumab This is a recombinant monoclonal IgG1 antibody, which binds IgE, and it has been used for the treatment of asthma and allergic rhinitis [9]. Nine adult patients with eosinophilic gastroenteritis were trialed on omalizumab with decrease in gastric and duodenal eosinophils, but the numbers did not reach statistical significance [25]. Of these nine patients, seven also had eosinophilic infiltration of the esophagus with >25 eosinophils/hpf. The study did not show decrease in esophageal eosinophils, and instead there was a statistically insignificant trend toward increasing number. No published trails exist for use of omalizumab specifically for EoE.

Acid Suppression The use of acid-suppressive agents including PPI in EoE is a matter of much debated. In one retrospective study, 43 pediatric patients with esophageal eosinophilia of ≥15/hpf were treated with a PPI [21]. On repeat endoscopy,

17/43 (40%) of the patients had ≤5 eosinophils/hpf, while 86% reported symptomatic response. Abnormal pH probe, reported symptoms, endoscopic appearance, baseline eosinophil count, and season of presentation did not have statistically significant correlation to PPI response, and hence it is difficult to clinically predict who will demonstrate histological response to acid-suppressive therapy. Acid suppression may be of benefit if the patient has overlapping EoE and GERD since up to 10% of patients with EE have this coexisting GERD [80, 90, 102]. In a case series of three patients with esophageal eosinophilia of ≥20/hfp, treatment on PPI alone induced histological remission in all patients (eosinophils of 0–3/hpf) after 4–8 weeks [65]. Although the patients in this case series met histological criteria for diagnosis of EoE, it is important to note that reflux esophagitis may well cause significant eosinophilic infiltration as one patient did have an abnormal reflux index on pH probe and the other two did not have a pH probe performed. PPI treatment may also be useful in diagnosis of EoE since nonresponse along with eosinophilic infiltration of the esophagus is virtually diagnostic of EoE in the appropriate clinical situation.

Infliximab Infliximab is a chimeric TNF-α inhibitor used in the management of chronic inflammatory conditions such as rheumatic arthritis and inflammatory bowel disease. A single study involving three adult patients with corticosteroid-dependant EoE used infliximab as a therapeutic option [92]. All other EoE treatments were discontinued for a 4-week period followed by infusion of infliximab 5 mg/kg for two doses spaced 2 weeks apart. There were no statistically significant results with regard to symptoms score, number of eosinophils/hpf, esophageal inflammatory mediators, TNF-α levels, or eotaxin-3 levels.

Esophageal Dilatation Non-pharmacologic intervention for EoE may be needed in patients who have strictures unresponsive to medical management, but data on the use of esophageal dilation in the pediatric population is limited. In a retrospective review of a single center over a 5-year period, balloon dilation was performed in 31% of their pediatric EoE patients [77] with symptomatic improvement in the patients and no reported major complications. Although esophageal perforation is rarely reported, care must be taken while performing the procedure as there is increased risk for deep mucosal tearing and significant postoperative pain [41, 63, 82, 101]. Most adult series have used bougienage dilatation, and 7–50% required repeated dilation for stricture recurrence [63, 94, 96]. Deep mucosal tears and renting can occur with introduction of the endoscope alone, and therefore care must be taken to select an appropriately sized endoscope if narrowing is suspected. There is no data available to determine if pretreating dilation medically will improve outcomes or decrease risk of trauma, though we do prefer this approach in our clinical practice. Given the risks of complications, surgical management should be reserved for those failing medical therapy or for those with a critical stricture.

Long-Term Outcomes

It is difficult to maintain histological remission after discontinuation of dietary or medical therapy, and it appears that EoE is a chronic disease and prone to relapse off-therapy. In a population of 562 patients with EoE, only 11 (1.9%) were able to maintain remission off-treatment [24]. Untreated disease can be complicated by esophageal narrowing and stricture, and younger children may have persistent feeding intolerance or failure to thrive. Patients may remain asymptomatic despite recurrence of esophageal eosinophilia though in-depth questioning including for coping mechanisms should be performed. There currently is no evidence for increased incidence of metaplasia, adenocarcinoma, or progression to any other gastrointestinal diseases in patients with EoE, though more longitudinal data is needed.

Conclusions

Eosinophilic esophagitis is a complex and currently incompletely understood entity though rapid and significant advances in our

understanding of this disease have been made over the last decade and half. The pathogenesis is an interplay of genetic predisposition with environmental and dietary contributions, but the pathways and triggers to disease expression have yet to be elucidated. Diagnosis is complicated by nonspecific symptomatology as well as comorbid conditions such as gastroesophageal reflux. Selecting the type and duration of treatment can be a dilemma for the clinician as response, treatment dependence, and risks for disease relapse are unpredictable and inconsistent. Treatment tolerability is also an issue since systemic corticosteroids have significant side effects and strict dietary modifications are difficult to adhere to chronically. Inhaled corticosteroids are better tolerated but not scientifically studied in EoE therapy, and novel therapeutic agents are being investigated. EoE is a chronic disease with potential for esophageal fibrosis, and restructuring and longitudinal studies are needed to better define these complications and disease natural history. Many aspects of EoE remain unknown to date, but much research is ongoing and the results will surely prove fascinating and enlightening.

Eosinophilic Esophagitis (Europe)

62

Juan A. Tovar, Ana Lourdes Luis,
and Cristina Riñón

Introduction and Definition

Eosinophilic esophagitis (EE) is an emergent disease suffered by patients of any age, often bearing allergic symptoms, who experience abdominal pain, vomiting, heartburn, dysphagia or food impaction associated with heavy eosinophilic infiltration, edema, and inflammation of the esophageal mucosa. The fact that some of its symptoms and the main histologic features are also observed in gastroesophageal reflux disease (GERD) makes diagnosis between both conditions confusing. However, the normalcy of pH studies and the lack of response to acid suppression in many EE patients together with the favorable effects of anti-inflammatory medication and dietary restrictions and elemental diets in them [36] allowed its recognition as an individual disease with its own clinical, endoscopic, and histologic features. EE is increasingly prevalent both in children and adults and indeed deserves separate study.

History

EE was first described as an independent disease by Atwood et al. in 1993 [5], and the number of publications on this topic increased over the last two decades in parallel with its amazingly growing prevalence. It should be pointed out that, at the same time, other eosinophilic gastrointestinal ailments became accordingly frequent, revealing a common background. The intensity of the eosinophilic infiltration required for diagnosis has been a matter of debate [21] until cutoff values of eosinophils were set for diagnosis [47] in order to separate true EE from reflux esophagitis with eosinophilic infiltration. These cutoff values are relevant because until then, it had been accepted that one of the histologic criteria for the diagnosis of reflux esophagitis was eosinophilic infiltration of the mucosa [33]. Experienced pathologists soon concurred in that the intensity of this infiltration in EE was well beyond what it was seen in GERD. EE occurrence in children was pointed out simultaneously with its description in adults, and, although there are differences in clinical expression, analysis and recommendations for

diagnosis and treatment have been shared by adult and pediatric gastroenterologic associations [25].

Etiology and Pathogenesis

The origin of EE remains unknown, although an allergic mechanism is more than likely. All ethnic groups are affected, but the disease is more prevalent in white individuals, and it is definitely more frequent in males (3:1 in children) [25] with some familial predisposition [13, 49, 64]. Differences in reporting could account for the apparent regional discrepancies in prevalence, but there is no doubt that blind retrospective studies in developed countries demonstrated a substantial increase over time [17, 57].

The amazing concentration of eosinophils in the esophageal mucosa was found to be related to increased levels of the chemoattractant eotaxin 3 [11], and it was shown later that EE patients had a unique genetic profile with highly induced eotaxin 3 (or CCL26) gene. In addition, knockout mice for this gene were immune to experimental EE [12], and increased eotaxin 3 messenger could be demonstrated by RT-PCR in esophageal biopsies of individuals with EE in contrast with both controls and GERD patients [7]. The Th-2 cytokine interleukin IL-5 seems to participate also in this eosinophil chemoattraction together with eotaxin 3 since IL-5 overexpressing transgenic mice under the control of a T cell (CD2) have increased eosinophils in the esophagus that decrease in the absence of eotaxin 3 [51]. Other interleukins like IL-3 and IL-13 play also a role in EE [8, 10], and increased T cell and mast cell numbers were found within the epithelium of EE patients together with increased expression of IL-5 and TNF-alpha [81]. The obvious interpretation is that EE is of allergic nature, and there is ample evidence of the participation of alimentary allergens in human EE since restriction and/or elemental diets improved the disease [36]. On the other hand, aeroallergens may also unchain these allergic reactions. Mice challenged with respiratory allergens (but not with gastrointestinal ones) developed marked esophageal eosinophilic infiltration [50]. It has also been shown that sensitization to both food and aeroallergens participate in the pathogenesis of EE in children [66].

Recently, an association between celiac disease (CD) and EE [62, 90] was confirmed [42]. The prevalence of EE in esophageal biopsies of CD patients was 4% or higher, and infiltration persisted in some children after duodenal histologic recovery under gluten-free diet [42]. This association is intriguing because EE is a Th-2-mediated disorder, whereas CD is a Th-1-mediated condition. The increased permeability of the intestinal mucosa in CD could allow exposure of the immune system to various antigens and generate distant hypersensitivity responses like EE [42].

The allergic nature of EE was unveiled when dietary management with either elemental diets [36] and/or elimination of six foods (cow-milk protein, soy, wheat, egg, peanut, and seafood) cured the symptoms and the eosinophilic infiltration in children [34]. At the end of dietary treatment, infiltration reappeared in some cases [36]. Allergic symptoms like atopic dermatitis, eczema [43], rhinitis and/or sinusitis, laryngitis, or bronchial spasm-asthma are frequent in children with EE [30, 63, 89].

The inflammatory reaction of the esophageal wall impairs in some way the propulsive function of the organ. Edema and narrowing, the cytokines themselves, changes in intrinsic innervation or secondary muscular disorders explain defective peristalsis and symptoms like dysphagia or food impaction [58, 59].

Pathology

Basal layer thickening [52, 79] and papillar lengthening [65] are present in EE. These features, together with infiltration of the mucosa by eosinophils [31, 41], had been considered indicative of reflux esophagitis in children. However, in recent years, heavy infiltration in excess of 20 eosinophils per high power field (hpf) (or better $\geq$15 per hpf) in at least one mucosal biopsy was set as a diagnostic threshold for the diagnosis of EE [25]. Apparently, peak count of eosinophils in the most involved hpf correlates with highest

average count per hpf count. This, together with the use of specific Luna eosinophil granule stain, could simplify diagnosis [40]. The absence of eosinophilic infiltration of the mucosa of other parts of the GI tract has been included into the diagnostic criteria for EE [15].

Thickening of the mucosa, friability, and even narrowing of the lumen observed upon endoscopic assessment attest the transmural involvement of the esophagus in the disease. These features may correspond to subepithelial fibrosis [52] which was present in children with EE but absent in those with either eosinophilic gastroenteritis or GERD [16]. The increased collagen in the lamina propria was only visible with Masson trichrome stain in relatively deep biopsies and was constant in children with food impaction. It was not associated with increasing numbers of either eosinophils or mast cells in the mucosa, but it was associated with activation of eosinophils as shown by degranulation [16]. Ulcers are not seen in EE, but abundant desquamation and exudates may be present.

Clinical Features in Children

The main symptoms of EE in infants and young children are refusal to feed, vomiting and abdominal pain, or dysphagia expressed as discomfort. Later on life, when the patient becomes able to describe his symptoms, abdominal or epigastric pain, vomiting or regurgitation, heartburn, dysphagia, or food impaction become the leading features [18, 20, 28, 43, 63, 68, 88]. Patients have to swallow water to pass solid food, and eventually the bolus impacts itself into the esophageal lumen and blocks any attempt at swallowing. This brings sometimes the patient to the emergency room and triggers the diagnostic work-up [46]. Failure to thrive or diarrhea may be experienced sometimes by children with EE. With these symptoms, except when food impaction or obvious allergic disease occurs, the first diagnostic suspicion and hence the first treatment measures are directed to treat GERD. Only after endoscopic assessment will failure of pH probe to demonstrate GERD or persistence of the symptoms in spite of energetic acid suppression the possibility of EE be considered. Schatzki rings [60] and spontaneous rupture of the esophagus (Boerhaave syndrome) [82] have been occasionally observed in this condition.

Most children with EE, up to 60–80 %, have allergic symptoms like rhinitis, laryngitis, asthma, or eczema, indicating the atopic nature of the disease [43]. This should raise the level of suspicion and prompt diagnostic work-up. Blood eosinophilia may also be present in EE [68], and to a certain extent, it correlates with the intensity of esophageal eosinophil infiltration [73].

It was recently pointed out that EE or intermediate esophagitis (IE), a minor form in which the intensity of infiltration does not reach diagnostic levels, may occur in patients operated upon for esophageal atresia and tracheoesophageal fistula [61]. In these individuals, GERD is extremely frequent, and, since they have often dysphagia due to the original condition and its surgical repair, the diagnosis of EE may be missed and the appropriate treatment never undertaken.

Diagnosis

Except in cases with obvious atopic symptoms and perhaps when food impaction occurs, the diagnosis of EE is only made after excluding other possible conditions and particularly GERD. This implies that pH monitoring and fiber-optic endoscopy with biopsy are necessary, often after more or less prolonged attempts at acid suppression with high-dose proton pump inhibitors (ppi). In a number of EE patients, true GERD occurs at the same time, and this creates some confusion.

Barium meal may show narrow esophageal lumen, dysmotility, or Schatzki rings [60]. Computed tomography has shown thickened esophageal walls in a few children with EE [68] and so did esophageal ultrasonography which demonstrated thickened mucosal, lamina propria, and submucosal layers [24].

Ambulatory pH metering may reveal excessive acid exposure in children with EE; although since it is used to exclude GERD in these cases,

this feature can be attributed to it. Excessive alkaline exposure has been observed in some patients [68].

Stationary and prolonged ambulatory esophageal manometry in children revealed that peristalsis is abnormal in terms of either poor or excessive amplitude of the waves, frequent tertiary waves, and abnormally propagated waves. Some of the abnormal motor events were accompanied by dysphagia [59], and they were particularly marked in the distal esophagus and during nighttime [46]. This pattern of dysmotility is quite similar to that described in adults, in whom, in addition, lower esophageal sphincter pressure has been found to be normal or slightly decreased [6, 44]. Combined pH and multichannel prolonged impedance studies in children with GERD and EE showed that, as expected, there was increased acid exposure in GERD that the mean number of nonacid refluxes was similar in both conditions and that no full-column reflux episodes were more frequent in EE than in GERD [67].

Endoscopy may show an apparently normal mucosa in one third of children and edema, friability, longitudinal furrows, and white plaques and exudates in the remaining two thirds [43]. In some patients, concentric rings give to the esophagus a "trachealized" [2] or "feline" aspect [35, 48] for it resembles what is common in the cat esophagus. True stenosis may occur in a few cases [19, 36], but in most, the instrument can be advanced along the esophagus although with frequent fissuration of the mucosa [53].

Biopsies should be taken at various levels and, ideally, also from other segments of the GI tract for involvement of the mucosa outside the esophagus is more likely due to eosinophilic gastroenteritis. The number of eosinophils per hpf authorizes diagnosis when the solid cutoff of $\geq$15 per hpf is attained in at least one of the specimens with an understandable increase in sensitivity when several biopsies show the infiltration [29]. Detailed observation of the sections can demonstrate the presence of groups of eosinophils and in some cases of micro-abscesses [86] made up of these cells.

Some diagnostic tests directed to unveil the allergic nature of EE are usually included in the work-up: blood eosinophilia, which is found in half of the affected children or more [68] and correlates to a certain extent with mucosal eosinophil count [38]; total IgE, which is usually elevated and falls after corticosteroid treatment; and aeroallergen and food-specific IgE radioallergosorbent testing (RAST) [91] which yield variable results. Plasma cytokines, like IL-5, IL-13, or the chemoattractant eotaxin-3, are elevated in EE [38] and usually decrease after treatment. Finally, skin prick testing [75, 76] and patch tests for atopy [76, 77, 85] may unveil sensitization to various allergens and guide food elimination treatment.

Natural History

EE is a chronic disease that may persist for years. A follow-up study of 30 adults showed that, after more than 7 years, majority still experienced dysphagia although without nutritional impact or apparently malignant potential [84]. Although this is reassuring, the chronic inflammation could have some unknown permanent impact on esophageal function [80]. The fact that EE is not a mucosal destructive condition like GERD explains why Barrett's esophagus and/or adenocarcinoma are not observed in this condition [25]. It has been questioned whether natural history would be the same in children and adults with EE [87]. Elimination and elemental diets, corticosteroids, and Montelukast are usually effective for alleviating symptoms and also for decreasing mucosal infiltration, but most studies do not include sequential biopsies able to rule out the persistence of the disease in the long run. An 8-year follow-up study of 89 children with EE showed that the vast majority of those responding to treatment relapsed [3]. In another study involving 330 children with EE followed up for more than 1 year, no progress to any other gastrointestinal disease was detected [78]. Personal or family anxiety is also a cause of concern in these chronically ill children [37].

Treatment

Due to the elusive nature of EE, it is difficult to assess the results of treatment that can aim at relieving the symptoms, reverting the mucosal

infiltration, or both. The clinical and pathologic features shared by EE and GERD tend to dilute the therapeutic aim: if persistence of symptoms after formal PPI treatment is required for the diagnosis of EE, it will be the disappearance of these symptoms, but if, on the contrary, the diagnosis is made upon finding of dense eosinophilic infiltration of the mucosa, it may be obviously different. Finally, if the leading symptoms are allergic, the aim may be the clearance of any cutaneous, respiratory, or biologic sign of the disease together with the symptoms.

The following treatment measures have been used in children with EE:

1. Acid suppression: The diagnosis of EE is done in most cases after ruling out GERD. The latter is often treated by acid suppression drugs prior to the performance of invasive tests, and therefore, a full course of PPI has usually been completed in all patients [70]. Persistence of the symptoms prompts the performance of diagnostic tests and allows the correct diagnosis. It is probably wise to treat all patients with PPI for some time.
2. Dietary food suppression has been very successful after skin prick and/or patch testing for food allergens and even without these tests [34, 69, 76]. Elimination of six usually taken foods (cow-milk, soy, wheat, egg, peanut, and seafood) improved EE in children [34] and is a good diagnostic and therapeutic test.
3. Elemental diets can be used when there is evidence of wide sensitization or when food elimination fails. This dietary management, which is highly effective and able to revert the esophageal eosinophilic infiltration [47], is less practical due to the limited acceptability by patients for prolonged periods of time, but it has been useful in numerous cases.
4. Systemic corticosteroids are dramatically effective as expected in an allergic condition like EE. However, the necessary doses (1–2 mg/kg/day of prednisone) prescribed for relatively long periods of time involve undesirable secondary effects that are prevented by topical treatment [71]. In addition, a rebound effect is possible after cessation of long-term treatment. In consequence, this medication should only be used in severe acute cases of after failure of nutritional or topical treatments [55].
5. Topical corticosteroids, administered in the form of aerosols (fluticasone propionate, 200–400 μg twice a day), were highly effective for alleviating the symptoms, decreasing esophageal infiltration by eosinophils and CD3 and CD8 lymphocytes [56, 88]. A randomized blind trial showed that fluticasone was significantly better than placebo in terms of disappearance of symptoms and decrease of infiltration on the mucosa by eosinophils and T(+) lymphocytes [39]. Candida overgrowth has been pointed out in a reduced proportion of patients after this treatment [71]. Budesonide in a viscous suspension produced good results in children with EE [1].
6. Leukotriene inhibitors like Montelukast at 20–40 mg/day during prolonged periods of time were successful in most cases, although relapses were seen after cessation of medication [4].
7. Other medications, like inhibitors of [32] or monoclonal antibodies [14, 26, 74] against IL-5, or immunomodulators [54] have been also used occasionally. There is experimental evidence of some effect of pretreatment with monoclonal antibodies against IL-13 of the esophageal effects of this cytokine [9].
8. Esophageal dilatation: In cases in which severe dysphagia is due to stenosis, formal dilatation is indicated [72]. However, the mucosa is particularly fragile in EE [83], and there are risks of tearing and even of perforation in adults [22, 45] and children [27]. If possible, endoscopy and dilatation should be deferred until after medical treatment has been instituted.
9. Impacted food bolus extraction may be necessary and is one of the operations leading to the diagnosis of EE in children [23, 68]. In all cases in which food impaction in the absence of stenosis occurs [46], esophageal biopsies and blood samples for peripheral eosinophilia and biologic markers should be taken in order to make diagnosis possible.

Effect of Systemic Illness, Medication, Radiation, and Infection on the Esophagus

63

Seema Mehta and Ryan W. Himes

Introduction

Injury to the esophagus can result from infection, medical therapy, or systemic illness. *Candida*, herpes simplex virus, and cytomegalovirus comprise the bulk of clinically encountered esophageal infections. Esophageal injury secondary to medical therapy is most often caused by retained pills; however, chemotherapy and radiation therapy are also associated with esophagitis. Systemic diseases involving the connective tissue, skin, and neuromuscular system may also affect the esophagus, usually giving rise to dysmotility or mucosal injury. Although these etiologies of esophageal injury occur less frequently in the pediatric population, physicians and surgeons charged with the care of children should nonetheless be aware that esophageal symptoms may be the presenting feature of one of these systemic conditions.

Infectious Esophagitis

Three organisms account for most cases of infectious esophagitis, *Candida* spp., herpes simplex virus (HSV), and cytomegalovirus (CMV), and are discussed in detail below. Primary bacterial infections of the esophagus are uncommon [146]. There is considerable symptomatic overlap in infectious esophagitis of any etiology, underscoring the value of upper endoscopy as the gold standard in their diagnosis.

Candida

Epidemiology and Pathophysiology

Candida albicans is a normal commensal in the gastrointestinal tract. Because of its ubiquity *C. albicans* is the most commonly encountered esophageal pathogen [140]. While most cases of *Candida* esophagitis occur among the immunocompromised, widespread availability of highly active antiretroviral therapy has heralded a declining prevalence of this once extraordinarily common complication in the human immunodeficiency virus (HIV) population [101]. *Candida* esophagitis may also be the initial manifestation of autoimmune polyendocrinopathy-candidiasis-ectodermal

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_63

dystrophy (APECED) syndrome (OMIM 607358) in children.

The pathophysiology of *Candida* esophagitis is a two-step process, colonization of the esophagus followed by invasion and more rarely dissemination [9]. Factors favoring this process include esophageal stasis, lack of competitive inhibition from microbial communities, and defective lymphocyte and granulocyte function. In addition to primary immunodeficiency states, risk factors for *Candida* esophagitis are corticosteroid use (both inhaled [54, 95, 137] and systemic [24, 95]), antibiotic therapy [24], presence of underlying esophageal injury (e.g., caustic ingestion) or motility disorder, gastric hypochlorhydria (e.g., proton pump inhibitors) [24, 65, 95, 137], as well as chemotherapeutics and immunosuppressants in the context of bone marrow or solid-organ transplantation.

Clinical Manifestations

In a series of immunocompromised pediatric patients with esophageal candidiasis, odynophagia was present in 80 %, retrosternal pain in 57 %, and dysphagia in 45 %; nearly all episodes (94 %) presented with concomitant oropharyngeal candidiasis [23]. Rare complications of advanced disease that have been described include esophageal stricture and perforation as well as systemic dissemination. In infants the main symptom may be a refusal to eat.

Diagnosis

Endoscopically, esophageal candidiasis usually presents with white plaques that will not wash away upon irrigation on an erythematous and friable background. Edema, cobblestoning, and linear confluence of the plaques, which are comprised of fungal elements and sloughed cellular debris, are common. Discrete ulcers, on the other hand, should raise the question of a coexistent, usually viral, infection.

Mucosal biopsies should be obtained for cytological examination. Yeast, hyphae, and pseudohyphae are readily demonstrated with routine stains. Culture is not useful unless susceptibility testing is desired (i.e., when a resistant organism is suspected).

Under the right circumstances (e.g., immunosuppressed child with odynophagia, chest pain, and oropharyngeal candidiasis), some clinicians would empirically treat for *Candida* esophagitis and reserve endoscopy for those who did not respond to an appropriate agent.

Treatment

Mild cases in hosts with a reversible or transient risk factor such as swallowed corticosteroids for eosinophilic esophagitis or antibiotic use may respond to cessation of that agent. Oral fluconazole has the advantage of once-daily dosing and is the mainstay of treatment in patients capable of swallowing medications [1]. Treatment is continued for 2–3 weeks after symptomatic improvement [1]. Amphotericin B should be used parenterally for patients with neutropenia and fever or disseminated disease [146]. Caspofungin is an alternative; it was shown to be as efficacious as amphotericin B in a randomized trial among predominantly HIV-positive adults with *Candida* esophagitis [138].

The Infectious Disease Society of America recommends fluconazole for prevention of fungal disease in neutropenic patients undergoing chemotherapy or bone marrow transplantation and for all recipients of liver, pancreas, and small bowel transplants [108].

Clinicians using fluconazole in solid-organ transplant recipients should be mindful of its inhibition of the cytochrome P450 system and monitor therapeutic drug levels accordingly.

Herpes Simplex Virus

Epidemiology and Pathophysiology

The esophagus is the most common site of visceral HSV infection among the immunocompromised [116] and the second most common esophageal pathogen (behind *Candida*) in the immunocompetent. In a study of >1300 consecutive autopsies, HSV esophagitis was identified in 1.8 %, the overwhelming majority of whom were

immunocompromised [61]. Males [61, 116], the HIV infected, and patients receiving antineoplastic, corticosteroid, or immunomodulator medications (e.g., solid-organ transplant recipients, inflammatory bowel disease patients) are more frequently afflicted. In case reports, HSV esophagitis has been associated with eosinophilic esophagitis. One hypothesis is that HSV-related mucosal damage may allow ingested allergens a portal of entry for sensitization [130]. Alternatively, treatment of eosinophilic esophagitis with topical fluticasone may predispose to HSV esophagitis [82].

HSV esophagitis may arise as a primary infection or as reactivation of disease latent in the neuroganglia. The virus has a tropism for stratified epithelium, and it has been suggested that this may explain why the esophagus is the preferred site in the gastrointestinal tract for infection [140].

Clinical Manifestations

The majority of patients present with an acute onset of esophageal symptoms including odynophagia (76 %), heartburn (50 %), dysphagia (21 %), and fever (24 %). They may experience a prodrome that may include fever, myalgias, and weight loss owing to decreased oral intake [116]. Concomitant orolabial lesions are uncommon in contrast to *Candida* esophagitis.

Diagnosis

At endoscopy, friable mucosa, discrete "volcano" ulcers, and exudates are seen in the mid and distal esophagus. Vesicles, if present, are typically confined to the upper third of the esophagus. The diagnosis is ascertained by histopathology, culture, and polymerase chain reaction (PCR). Brushings obtained from the ulcer edge are more likely to yield diagnostically helpful information in contrast to specimens from the center of the lesion, where few infected epithelial cells are present [146]. Microscopic findings include multinucleated giant cells, ballooning, and eosinophilic nuclear inclusions (Cowdry type A) limited to the mucosal layer. When typed, most HSV esophagitis is associated with HSV-1 [146].

Treatment

HSV esophagitis is self-limited in immunocompetent children. Treatment with intravenous acyclovir is undertaken when severe odynophagia or dysphagia precludes oral hydration and alimentation. Though controlled trials have not been conducted, most clinicians treat milder cases with oral acyclovir with the belief that the duration or severity of symptoms may be attenuated. Immunocompromised patients will not clear the infection themselves and treatment with acyclovir is indicated. Recurrent infections are uncommon in immunocompetent but may be encountered in the immunocompromised patient.

Cytomegalovirus

Epidemiology and Pathophysiology

In contrast to HSV, cytomegalovirus esophagitis has only rarely been described in the immunocompetent host. It is a ubiquitous virus; the vast majority of people are seropositive by late childhood or early adolescence. In those with intact immune function, an appropriate response is mounted upon initial exposure, and the virus becomes latent in the leukocytes. Like HSV, many cases of CMV esophagitis result from reactivation of latent infection under conditions of immunosuppression (e.g., HIV, immunomodulator medications).

Clinical Manifestations

The spectrum of presenting symptoms in CMV esophagitis depends largely on whether the episode represents primary infection or reactivation and which other parts of the gut are affected. CMV esophagitis is more likely to present with nausea, vomiting, fever, epigastric pain, and weight loss in addition to odynophagia and dysphagia than other esophageal infections; some speculate this is due in part to a viral syndrome that accompanies primary infection [9]. The onset of these signs and symptoms is generally more indolent than with HSV esophagitis. When CMV disease coexists in other parts of the gut, symptoms such as lower abdominal pain or diarrhea may predominate. It should also be

remembered that multiple pathogens may coexist in the immunosuppressed child.

Diagnosis

Serology is neither sensitive nor specific for CMV esophagitis. On upper endoscopy, there are classically large ulcers in the mid to distal esophagus with a linear orientation. Biopsies should be directed to the ulcer base because unlike HSV, CMV viral cytopathic effect is most prominent in the fibroblasts and endothelial cells rather than the squamous epithelium. Brushings add little to the diagnosis of CMV [143], and culture is also inferior to biopsy and immunohistochemical staining. Molecular diagnostics are increasingly available and attractive owing to their rapid turnaround time.

Treatment

Intravenous ganciclovir and foscarnet are equally efficacious and safe [109]; 2 weeks of treatment is advocated. Relapse is common among the profoundly immunosuppressed, and consideration should be given to prophylaxis until cell counts are restored (in the case of HIV) or immunosuppression can be liberalized (when iatrogenic). Routine serological testing of organ recipients and donors and targeted prophylaxis have reduced the incidence of transplant-associated disease.

Iatrogenic Esophageal Injury

Our ability to treat both complex and simple diseases has grown by leaps and bounds in the last century. And while these therapies are life enriching and prolonging, some can cause esophageal injury. From the pain reliever taken to assuage low-back pain to the chemotherapeutic agents used to condition for bone marrow transplantation, iatrogenic esophageal injuries are important and not infrequent complications of medical treatment.

Pill-Induced Esophagitis

Epidemiology and Pathophysiology

Pills are designed to deliver pharmaceutical compounds to the stomach or intestine; their inappropriate retention in the esophagus can result in injury. The widespread use of liquid medications for infants and children means that most cases of pill esophagitis occur in older children and adolescents. In adults, women are more often diagnosed with pill esophagitis than men, and this has been attributed to their increased exposure to frequently implicated pills [71]. Antibiotics (e.g., tetracycline, doxycycline), nonsteroidal anti-inflammatories (NSAIDs), ferrous sulfate, potassium chloride, and alendronate have repeatedly been associated with esophagitis in the medical literature.

Pill esophagitis can result from the caustic [13], hyperosmolar [71], or direct cytotoxic effect [71] of the medication on the esophageal epithelium. Risk factors for pill-induced esophagitis include pill characteristics (e.g., large size, sustained-release formulations, pill coating), patient characteristics (e.g., anatomical or motor anomalies of the esophagus), and administration characteristics (e.g., taking pills without a fluid bolus or before lying down) [48]. Experimental evidence suggests that substantial variability in the tendency of a pill to adhere to the esophagus exists among the same medication depending on the manufacturer [122]. This underscores the importance of the physical properties of a pill independent of its active ingredient.

Clinical Manifestations

Most often the patient will present with sudden onset of odynophagia, retrosternal burning pain, and dysphagia. Older children frequently volunteer that the onset of symptoms followed pill swallowing; the sensation of something stuck in the esophagus is not uncommon. Personal experience, however, suggests that this is seldom the case. Rarely, hematemesis can be the presenting symptom; this may be a clue to NSAID-induced esophagitis [2].

Diagnosis

In many cases, history will be sufficient to make the diagnosis. Contrast studies of the upper gastrointestinal tract are less sensitive than endoscopy to diagnose pill esophagitis but are the preferred modality to evaluate for a possible

anatomical predisposition to retained pills. Endoscopy usually reveals a discrete ulcer surrounded by normal esophageal mucosa. Occasionally remnants of the pill may still be adherent to the mucosa. Characteristically, like food bolus impactions, pill esophagitis occurs at areas of esophageal narrowing, low-amplitude contractile motility, or preexisting lesions (e.g., stricture, web, ring) [21]. Biopsies may be helpful to diagnose an underlying condition like eosinophilic esophagitis or gastroesophageal reflux disease (GERD)-related strictures.

Treatment

Though no trials have been conducted to evaluate their efficacy, most clinicians utilize histamine-2-receptor antagonists (H2RAs), proton pump inhibitors, or sucralfate to treat pill esophagitis. Where feasible, cessation of the offending pill or transition to a liquid form of the medication would prevent recurrence. Taking pills with an ample amount of fluid while standing or seated and remaining so for several minutes thereafter are good practices with evidence to support their routine implementation [13, 56].

Chemotherapy-Induced Esophagitis

Epidemiology and Pathophysiology

The prevalence of chemotherapy-induced esophagitis in children or adults is not known. Oral mucositis, on the other hand, is known to affect more than half of adults undergoing some chemotherapy regimens [128]. Esophageal disease is present in most of these patients [7], and it is cited among the most troubling symptoms experienced by patients receiving chemotherapy [12].

High rates of cell turnover predispose the entirety of the gastrointestinal mucosa to damage from chemotherapeutics. Though chemotherapy-induced mucositis can affect any portion of the gastrointestinal tract, its presence in the mouth and esophagus is an important determinant of complications including the need for parenteral nutrition, bacteremia, prolonged hospitalization, and interruption of therapy [127]. There is a dearth of literature that deals strictly with chemotherapy-induced esophagitis [128]. This may reflect the fact that it frequently coexists with much more readily observable oral mucositis [140] but may also indicate the complexity of teasing this entity apart from reflux disease and esophageal superinfection which are common in this population as well [146].

Risk factors for chemotherapy-induced esophagitis include the agent utilized, its dose and the frequency of its administration as well as concomitant radiation treatment. Conditioning regimens for autologous bone marrow transplantation as well as dactinomycin, bleomycin, cytarabine, 5-fluorouracil, methotrexate, and vincristine are commonly implicated in chemotherapy-induced mucositis [106].

Because chemotherapy is delivered systemically, its injury proceeds from the deeper basal layer through to the superficial epithelium. The primary event in chemotherapy-induced esophagitis is thought to be either endothelial dysfunction or DNA damage which activates cellular danger-signal pathways, the result of which is a feed-forward inflammatory loop culminating in ulceration [127, 129].

Clinical Manifestations

Dysphagia and odynophagia typically manifest within a week of starting chemotherapeutics and usually will resolve within 2 weeks after cessation of treatment. Coexistent oral mucositis may dominate the clinical picture, preventing oral alimentation and obscuring esophageal symptoms. A grave complication of esophageal mucositis is superinfection, usually with *Candida* [127] which can give rise to systemic fungemia, particularly in the neutropenic patient [7]. Case reports have indicated that esophageal strictures can be the presenting sign of upper gastrointestinal injury during chemotherapy in children [69].

Diagnosis

Awareness of the mucositic potential of specific chemotherapeutics and anticipation of this common side effect are usually sufficient for diagnosis. Superinfection with viral or fungal pathogens must be considered in the differential diagnosis, however. Endoscopy plays a minor role in

chemotherapy-induced esophagitis because patient factors (e.g., neutropenia, thrombocytopenia) usually tip the risk-benefit analysis against its application [146].

Treatment

Prevention of mucositis is an area of ongoing research [68, 127]. Adult guidelines published in 2007 by the International Society for Oral Oncology do not specifically address esophageal mucositis but recommend only that ranitidine or omeprazole be used for prevention of chemotherapy-induced epigastric pain [68]. This document is also specifically recommended against sucralfate for oral mucositis [68].

Because it is generally self-limited in nature [106], many experts treat esophageal mucositis expectantly with narcotic analgesics [128].

Radiation-Induced Esophagitis

Epidemiology and Pathophysiology

With advances in oncology, there are increasingly children who are treated for and who ultimately survive cancer. These data are evolving, but it is probably reasonable to infer that in the absence of preventive strategies, radiation esophagitis will continue to burden pediatric cancer survivors.

Radiation-induced esophageal injury can be categorized as acute and late [142]; each has a slightly different pathophysiology and presentation; therefore, they are discussed separately below. It should be noted that patients receiving radiation therapy are usually also at risk for infectious (particularly fungal or viral) esophagitis. Indeed both conditions may be present; therefore, the clinician should maintain a high index of suspicion.

Risk factors for radiation esophagitis include dose, schedule, and use of concomitant chemotherapy [33, 76, 85, 142].

Acute esophageal radiation toxicity typically manifests within 2 weeks of beginning treatment and is marked by capillary dilation and thrombosis, edema, and inflammation accompanied by endothelial proliferation [140, 142]. On the other hand, late radiation-induced esophageal injury comes to clinical attention weeks to months after cessation of treatment and tends to be referable to chronic inflammation and fibrosis of the lamina propria and submucosa giving rise to stricturing [140, 142]. Using clinically apparent strictures or perforations as endpoints, it has been estimated that 68–72 Gy delivered over one-third of the esophagus is necessary for 50 % of adult patients to develop these complications over 5 years [43]. Analogous data are not available for children.

Clinical Manifestations

Esophageal symptoms like dysphagia and odynophagia are almost universal among patients receiving radiation treatment that includes the esophagus in the therapeutic field [43, 148]. These symptoms in addition to retrosternal pain are characteristic of acute radiation esophagitis. Late-radiation esophagitis more frequently presents as only dysphagia which is usually related to esophageal strictures. On rare occasions, esophageal perforation or tracheoesophageal fistulae [76] complicate late-radiation esophagitis.

Diagnosis

Upper gastrointestinal contrast studies may demonstrate diffuse esophageal ulceration acutely and is sensitive for stricturing disease later. Disorganized peristalsis is frequently cited as a finding in late-radiation esophagitis [42]; however, at least one small adult study failed to document anomalous esophageal transit or motility in this setting [148]. Esophagogastroduodenoscopy has the benefit of allowing the physician to sample the esophagus (e.g., cytologic brushings, biopsy) and exclude coexistent *Candida* or viral esophagitis since these entities have considerable symptomatic overlap.

Treatment

There are no trials to substantiate the effectiveness of acid suppression, topical anesthetics (e.g., viscous lidocaine), diphenhydramine, or sucralfate, but they are routinely utilized. On the contrary, one placebo-controlled trial of sucralfate in adults beginning radiation therapy found no improvement in symptoms and a tenfold higher

rate of discontinuing the study treatment among those receiving sucralfate versus placebo [92].

When encountered, infectious esophagitis should be treated appropriately. Strictures are usually amenable to endoscopic dilation but may require several sessions to achieve clinically effective results [42, 76, 86].

Amifostine is a free radical scavenger that has been explored in adult studies to mitigate radiation and chemotherapy-induced esophagitis; some trials have shown benefit favoring its use [74, 75, 120], while others are equivocal [98]. Ongoing research seeks to establish the role for gastrointestinal-protective agents in the prevention of radiation-induced toxicity [15].

Esophageal Manifestations of Systemic Disease

Esophageal involvement occurs with many systemic diseases and can manifest as dysmotility or mucosal injury. The initial clinical presentation for these diseases may include esophageal symptoms, and therefore physicians should be familiar with the esophageal manifestations of various systemic diseases. The esophageal abnormalities associated with connective tissue diseases, cutaneous diseases, and neuromuscular disorders are described.

Connective Tissue Diseases

Scleroderma

Systemic sclerosis, the systemic form of scleroderma, is a multisystem disease of unknown etiology characterized by collagen deposition in the skin and internal organs [28]. Systemic sclerosis can be further classified into diffuse or limited, also known as progressive systemic sclerosis and CREST (calcinosis cutis, Raynaud's phenomenon, esophageal abnormalities, sclerodactyly, and telangiectasias) syndrome, respectively [28]. Childhood onset of systemic sclerosis is rare, representing less than 10 % of all cases. The male to female ratio is 3:1 for children 8 years of age or greater [149].

The gastrointestinal tract is commonly affected in both diffuse and limited systemic sclerosis [26]. Esophageal dysfunction, as revealed by diagnostic tests such as manometry, is present in 75–90 % of patients [27, 46, 104, 114]. The characteristic esophageal abnormalities include an incompetent lower esophageal sphincter (LES) and decreased smooth muscle peristalsis [27].

Symptoms of esophageal dysfunction are less prevalent and may be present in only 35–50 % of patients [67, 77, 136]. Dysphagia and symptoms of gastroesophageal reflux (GER) are the most common complaints [104]. Early satiety with resultant weight loss, regurgitation, and food impaction has also been reported [27, 104].

Diagnostic studies to assess for esophageal involvement include barium esophagrams, radionucleotide scintigraphy, esophageal manometry, and endoscopy [21, 104]. Barium esophagrams demonstrate esophageal dilation and reflux of contrast material into the proximal esophagus [21, 104]. Esophageal strictures can also be identified [104]. Diminished or absent peristaltic contractions can be visualized; however, in comparison to esophageal manometry, barium radiography is a less sensitive study for detecting motility abnormalities [21, 104, 141].

Radionucleotide scintigraphy is diagnostically useful to assess esophageal transit time and clearance [21, 67]. It is a noninvasive, sensitive, and an easy-to-perform test making it an ideal diagnostic modality to screen patients with systemic sclerosis for esophageal dysmotility. Esophageal manometry is needed for specific confirmation [21, 67].

Esophageal manometry is a highly sensitive test for esophageal dysmotility. As previously mentioned, in patients with systemic sclerosis, the characteristic findings on esophageal manometry include reduced LES tone and decreased frequency and amplitude of peristaltic contractions in the distal two-thirds, smooth muscle portion of the esophagus [21, 46, 47, 100, 125]. Of note, these findings are not limited to systemic sclerosis and may be seen less commonly in other rheumatologic disorders. The study is invasive and may cause discomfort to the patient; however, complications are rare [21].

Endoscopy is not utilized to diagnose esophageal dysfunction in patients with systemic sclerosis but to assess the mucosal damage that may occur as a consequence [104]. Mucosal changes consistent with reflux esophagitis can be seen in 60 % of patients with systemic sclerosis [104]. Chronic GER can result in columnar-cell replacement of the squamous cell layer of the esophagus, Barrett's esophagus [21, 66, 104]. This premalignant condition imparts an increased risk of adenocarcinoma; therefore, patients with Barrett's require careful endoscopic surveillance [21, 66, 104].

Currently, no treatment is available for the management of esophageal dysfunction in systemic sclerosis. Minimizing esophageal injury secondary to excessive esophageal acid exposure is the current standard of care [104]. Behavioral modifications include dietary changes (e.g., low-fat diet) and lifestyle changes (e.g., avoidance of smoking) [104].

Medical therapy consists primarily of inhibitors of gastric acid secretion, proton pump inhibitors and H2RAs, and prokinetic agents [104, 117, 124, 126]. Proton pump inhibitors when compared to H2RAs are more effective in reducing gastric acid secretion and improving mucosal changes secondary to GER [126].

Surgical management of GER is effective for the treatment of primary GER. In patients with systemic sclerosis, GER occurs secondary to esophageal dysfunction resulting from this progressive systemic disease [104, 134]. Patients with systemic sclerosis are at greater risk of complications related to general anesthesia and antireflux surgeries; therefore, surgery should be limited to patients with severe, intractable GER [104, 134].

Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD) is an overlap syndrome characterized by a combination of the clinical features of systemic lupus erythematous (SLE), systemic sclerosis, and polymyositis in addition to high serum titers of antibodies to the ribonucleoprotein component of extractable nuclear antigen, anti-RNP [123]. As in systemic sclerosis, esophageal dysfunction is common in MCTD. Esophageal symptoms include dysphagia, regurgitation, and symptoms of GER, but they are rarely spontaneously referred to by the patient [19, 32, 37, 53, 77, 89].

Characteristic esophageal manifestations in MCTD include LES incompetence and hypomotility of the smooth muscle portion of the esophagus [32, 37, 77, 89]. Total aperistalsis of the esophageal body may be seen in 17–53 % of MCTD patients [53]. Diminished upper esophageal sphincter (UES) pressure has also been variously identified in patients with MCTD; however, this abnormality has been observed in patients with polymyositis (PM) and SLE as well [53, 89].

It has been suggested that esophageal peristalsis in MCTD may improve with corticosteroid therapy [89, 111]. Evidence in support of this potential therapy is not definitive; therefore, further studies are needed to elucidate the benefit of corticosteroid therapy for the management of esophageal dysfunction in MCTD.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disease of unknown etiology that can affect any organ system of the body. The clinical manifestations of SLE vary widely and have a relapsing and remitting course [8, 57]. SLE may affect up to 10–15 % of children and adolescents. The clinical presentation of SLE in children is as variable as in adults and occurs at any age with an increasing prevalence after the first decade of life [8, 57, 80].

Esophageal symptoms occur in 2–25 % of patients with SLE [25, 53]. Dysphagia is the most common esophageal complaint followed by symptoms of GER [53, 132]. These symptoms are frequently attributed to esophageal hypomotility; however, a poor correlation exists between the presence of esophageal symptoms and esophageal manometry abnormalities [22, 118]. Lower esophageal dysmotility is most common in patients with SLE; however, involvement of the

upper one-third of the esophagus has been reported [53, 77, 118]. Unlike patients with systemic sclerosis, LES hypotension is mild or absent [77]. Authors have suggested that moderate to severe decrease in lower esophageal pressure may help to differentiate between systemic sclerosis and SLE [77].

Several studies have investigated the association between esophageal dysfunction in SLE and the presence of Raynaud's phenomenon [53, 97, 131]. Early studies report a positive relationship and a potential correlation with high titers of hnRNP protein A1 antibodies [53, 97, 131]. The results of a more recent study, however, did not support the association of esophageal dysfunction in SLE and Raynaud's phenomenon [77]. Further studies are needed to clarify this relationship.

There are currently no specific treatment measures for esophageal dysfunction in SLE [132]. Supportive management of esophageal symptoms with inhibitors of gastric acid secretion, H2 receptor antagonists and proton pump inhibitors, and reflux precautions may be of benefit [132]. Treatment of active SLE would be predicted to improve symptoms of esophageal dysfunction; however, this has not been specifically studied.

Polymyositis/Dermatomyositis

Dermatomyositis and polymyositis are autoimmune myopathies caused by an inflammatory infiltration of the skeletal muscle [14, 30]. Dermatomyositis is a complement-mediated small vessel angiopathy, while polymyositis involves a direct T-cell-mediated invasion of myocytes [14, 30]. Both are characterized by a proximal myopathy; however, patients with dermatomyositis also manifest cutaneous changes including heliotrope rash of the eyelids, erythroderma, and telangiectasias [39, 115].

In children, juvenile dermatomyositis is the most common inflammatory myopathy [91, 115]. The peak incidence is from 5 to 10 years of age, and girls are affected more often than boys. Juvenile polymyositis rarely occurs before the second decade of life and therefore accounts for only 3–6 % of juvenile inflammatory myopathies [94, 105, 110, 133].

The striated muscle of the pharynx, upper esophageal sphincter, and proximal esophagus are commonly affected in patients with inflammatory myopathies [35, 39, 44, 62]. Dysphagia is the most common gastrointestinal symptom. Other complaints include symptoms of GER, nasopharyngeal regurgitation, and aspiration [62, 107].

Diagnostic studies to evaluate proximal esophageal dysfunction include cine-esophagram and esophageal manometry [34, 77]. Radiographic findings demonstrate prolonged pharyngeal peristalsis, nasopharyngeal reflux, vallecular pooling of barium, and tracheal aspiration [39, 62]. Characteristic manometric abnormalities include decreased cricopharyngeal sphincter pressure and diminished pharyngeal and proximal esophageal peristaltic contractions [34, 77].

Smooth muscle dysfunction of the esophagus has also been described in patients with inflammatory myopathies [58]. Manometric findings include decreased LES tone and low-amplitude peristaltic contractions of the distal esophagus. Delayed esophageal emptying is another notable finding suggesting involvement of the smooth muscle portion of the esophagus [58]. The presence of delayed esophageal emptying has been shown to correlate with the severity of proximal muscle weakness [34, 62].

Corticosteroids are the initial treatment of choice for polymyositis and dermatomyositis [30]. Immunosuppressive medications are reserved as a second-line agent for patients with steroid-refractory inflammatory myopathies. Incidental improvement of esophageal symptoms with these therapies has been reported; however, there are no controlled clinical trials demonstrating their direct efficacy on esophageal dysfunction [39]. Intravenous immunoglobulin was found to be an effective therapeutic agent for patients with severe, steroid-resistant esophageal dysfunction in a double-blind placebo controlled trial [31, 88].

Other treatment options include medical therapy for GER symptoms with inhibitors of gastric acid secretion, H2 receptor antagonists

and proton pump inhibitors, as well as swallowing rehabilitation for dysphagia. Controlled clinical studies assessing the effectiveness of these interventions have not been conducted [21].

Cutaneous Diseases

The esophagus can be affected in various dermatologic diseases. Esophageal involvement may occur because the epithelium of the skin and upper one-third of the esophagus are both comprised of stratified squamous epithelium. The primary dermatoses include epidermolysis bullosa, bullous pemphigoid, and pemphigus vulgaris. Esophageal involvement of epidermolysis bullosa is discussed in detail in a later chapter. Bullous cutaneous lesion with involvement of the esophageal mucosa is also characteristic of Stevens-Johnson syndrome; therefore, it is covered in this chapter.

Bullous Pemphigoid

Bullous pemphigoid is an autoimmune disease characterized by bullous lesions [3, 10, 21]. The targeted antigens are components of the basement membrane zone of the skin, bullous pemphigoid antigen 1 (BPAG1) and 2 (BPAG2) [21, 84]. It rarely occurs in children and usually affects the elderly. The characteristic clinical manifestation is a widespread cutaneous bullous eruption involving the flexural areas, axillae, and groin [10]. Infants can have more pronounced involvement of their palms, soles, and face [10]. Oral and esophageal bullae present less frequently since mucous membrane involvement is not common. Oral lesions do tend to occur more frequently in children than adults [10].

Cicatricial pemphigoid is a variant of bullous pemphigoid characterized by more extensive mucosal membrane involvement and less cutaneous lesions [4, 21]. Esophageal involvement occurs in 5 % of patients and manifests as esophageal bullae, webs, and strictures secondary to scarring [4, 21, 99].

Endoscopy can be used to identify esophageal bullae but may cause further injury to the esophageal mucosa [21, 144]. Direct immunofluorescence of esophageal biopsies reveals immunoglobulin G (IgG) and complement (C3) deposition in the basement membrane [21, 139].

Systemic corticosteroids are the initial treatment for esophageal involvement in both bullous pemphigoid and cicatricial pemphigoid [21, 139]. Steroid-sparing immunosuppressive medications are also effective treatment options [11, 21, 55, 73, 93].

Pemphigus Vulgaris

Pemphigus vulgaris is also an autoimmune disease characterized by bullous lesions on the skin and mucous membranes [5, 6, 102]. The target antigen is desmoglein 3, an adhesion protein for keratinocytes in the epidermis [5, 6, 36, 102]. It occurs more commonly in children than bullous pemphigoid but is still rare [21]. Mucous membrane involvement is also more marked. Oral mucosal lesions are usually the initial clinical manifestation followed, up to several months later, by widespread cutaneous bullous lesions involving primarily the face, trunk, pressure points, groin, and axillae [10, 49, 51, 102]. Mucous membrane involvement can extend into the esophagus from the oral cavity. Patients with esophageal lesions tend to be asymptomatic but may complain of dysphagia, odynophagia, and hematemesis [41, 49, 50, 63, 119, 135, 145, 147]. A rare esophageal complication of pemphigus vulgaris is sloughing of the entire mucous membrane resulting in the formation of an esophageal mucosal cast, esophagitis dissecans superficialis [64, 121].

As with bullous pemphigoid, endoscopy can be used to evaluate the appearance of the esophageal mucosa and obtain biopsy specimens [18, 21, 45, 135]. Acantholytic blisters on direct immunofluorescence of esophageal biopsies confirm the diagnosis of esophageal pemphigus vulgaris [18, 21, 41, 102, 135].

High-dose systemic corticosteroids are used to initially treat and achieve disease

remission [16, 17, 18]. Steroid-sparing immunosuppressive medications are useful options for maintenance regimens [16, 18, 20].

Stevens-Johnson Syndrome

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe immune-mediated hypersensitivity reactions characterized by fever and mucocutaneous lesions [78, 81]. Cutaneous lesions can progress to epidermal necrosis and sloughing [78, 81]. Medications and infections, in particular *Mycoplasma pneumonia* and herpes viruses, are the leading precipitating factors for SJS and TEN in children [78, 81].

Clinically, esophageal involvement can manifest as bullous lesions and erosions of the mucosa. Mucosal scarring can lead to esophageal web and stricture formation [52, 59, 87, 90].

Treatment involves immediate discontinuation of potential triggering medication or identification and treatment of underlying infection. Further care is supportive and symptomatic (e.g., intravenous hydration, nutritional support, and pain management) [21, 78, 81].

Neuromuscular Disorders

Chiari Malformations

Chiari malformations are a structural defect of the brain characterized by caudal displacement of the cerebellar tonsils through the foramen magnum [113, 140]. Esophageal abnormalities reportedly occur in 5 % of patients with a Chiari malformation as a result of brainstem dysfunction [112, 113, 140]. Clinical manifestations include dysphagia, nasal regurgitation, tracheal aspiration, and symptoms of GER. Dysphagia may be the initial presenting symptom of brainstem dysfunction in patients with Chiari malformations [112, 113].

Diagnostic modalities to evaluate esophageal dysfunction include barium esophagrams and esophageal manometry [17]. Radiographic findings include delayed transit time through a narrowed cricopharyngeus and pharyngonasal regurgitation [112, 113]. Esophageal manometry is more sensitive and can identify UES dyscoordination or failure of the UES to completely relax [112, 113].

Treatment of esophageal dysfunction in patients with Chiari malformations involves treatment of the malformation to improve brainstem function, usually with craniocervical decompression [113].

Myotonic Muscular Dystrophy

Myotonic muscular dystrophy (OMIM 160900) is a rare form of muscular dystrophy. It is an autosomal dominant disorder with variable penetrance characterized by myotonia, muscle wasting, frontal baldness, cataracts, and cardiac heart block or arrhythmia. Disease presentation is usually during adulthood; however, childhood onset has been reported [140].

Pharyngoesophageal dysfunction occurs in the majority of patients; however, clinical symptoms are present in less than 50 % of patients [40, 79, 103]. Dysphagia is the most common complaint followed by symptoms of GER and regurgitation [96, 103].

Pharyngeal and esophageal dysmotility can be demonstrated utilizing barium esophagrams and esophageal manometry [29, 72]. Esophagram findings include barium stasis in the pharynx, prolonged esophageal transit time, and a dilated esophagus [29, 103]. Manometry reveals diminished UES tone and amplitude of peristaltic contractions in the striated and smooth muscle portions of the esophagus [29, 72, 79, 96, 103].

Myasthenia Gravis

Myasthenia gravis is an autoimmune neuromuscular disease caused by autoantibodies directed against the acetylcholine receptor (AChR) at the neuromuscular junction [29, 38]. It is characterized by striated muscle weakness and fatigability [29, 38]. Involvement of the striated muscle portion of the esophagus clinically manifests as

dysphagia [70]. Patients are generally able to chew and swallow without difficulty at the beginning of a meal; however, as the meal progresses, chewing and swallowing become more labored secondary oropharyngeal and esophageal muscle fatigue [83, 140].

Esophageal manometry demonstrates diminished peristaltic contractions, primarily in the upper esophagus, and prolonged peristaltic waves [60]. Esophageal weakness may only become evident after a few swallows. Both clinical and manometric features tend to improve with rest or treatment with anticholinesterase medication [60, 140].

Oesophageal Varices

64

P.J. McKiernan

Oesophageal varices are dilated submucosal veins usually found in the lower oesophagus which develop as a result of portal hypertension. Portal hypertension in turn is usually due to cirrhosis but can have a presinusoidal cause such as extrahepatic portal vein obstruction (EHPVO) or congenital hepatic fibrosis, the important distinction being that liver function is preserved.

Within the oesophagus there are four layers of veins, intraepithelial channels, a deeper superficial venous plexus, deep intrinsic veins and then the perforating veins through which blood drains into the perioesophagus and from there to the azygous veins. The arrangement is different in the palisade zone of the lower 4–5 cm of the oesophagus. Here vessels are arranged longitudinally in the superficial venous plexus and flow can be bidirectional [33].

If the hepatic venous pressure gradient (HVPG) is >10 mmHg, pressure is transmitted through the left gastric vein, and valves in the perforating veins become incompetent allowing retrograde flow into the deep intrinsic veins and their tributaries. These deep intrinsic veins dilate and assume a subepithelial position to become major variceal channels. In the palisade zone, in addition to the pressure from the perforating veins, there is also increased cephalad flow from the stomach [20].

Once established, varices usually increase in size unless the cause of portal hypertension can be corrected. Variceal bleeding occurs where the combination of large variceal diameter, decreased wall thickness and increased intraluminal pressure raise variceal wall tension beyond a tolerable threshold [20].

There have been no systematic prospective endoscopic studies of unselected groups of children with cirrhosis or portal vein thrombosis. Hence incidence studies have been derived from cross-sectional studies from large specialist centres. These show a high incidence of varices developing quickly in cirrhosis, with rates in children with biliary atresia ranging from 40 to 70 % [30, 45] usually before the age of 5 years. In cystic fibrosis-associated cirrhosis [9], nearly 90 % of those with cirrhosis developed oesophageal varices, on average 3 years after the first signs of liver disease. Varices are even more common in children with EHPVO [46].

The diagnosis of oesophageal varices still depends on upper GI endoscopy [40]. There have been attempts to develop clinical predictors of oesophageal varices [14], but none have yet been prospectively evaluated. Partly because of the lack of evidence for primary prophylaxis, there are no widely used guidelines for which children with portal hypertension should undergo diagnostic endoscopy, and hence there are wide variations in practice. In our centre we undertake

diagnostic endoscopy in all children who present with, or develop splenomegaly for the first time. Children who have oesophageal varices are then given individual plans for what to do if they should have a gastrointestinal bleeding.

At endoscopy, the size of varices and the presence of red colour signs should be recorded. A simple classification of varices into small and large is used in adult practice [7], but a variety of grading schemes are used in children. There is a need for prospective validation of these schemes and to determine whether there is acceptable interobserver consistency.

Endoscopic ultrasound is as effective as videoendoscopy for detecting oesophageal varices but has the added advantages that variceal wall thickness can be measured, and paraoesophageal varices and feeding perforating veins can be recognised. The use of miniprobe systems means the technique can be applied even to small children during videoendoscopy [26].

Risk of First Variceal Bleeding

The 2-year bleeding risk in adults with cirrhosis and at least moderate large varices is 25–30 %. Lifelong risk of variceal bleeding is close to 50 % [6]. An increased bleeding risk in childhood is associated with increased variceal size [2], red colour signs seen at endoscopy [2] and severity of liver disease [30, 45]. Combining data from a number of paediatric studies reveals an overall risk of 22 % for variceal bleeding in children with cirrhosis, and 38 % in those with cirrhosis known to have oesophageal varices, over a mean follow-up of 5 years [2, 9, 27, 30, 45]. Age at first bleeding is related to the cause of cirrhosis, occurring at a mean age of 3 years in biliary atresia [27, 30] and 11.5 in cystic fibrosis [9]. In the single paediatric study reporting serial endoscopic findings, where signs of portal hypertension progressed, one-third bled over a 3-year follow-up [2].

In portal venous obstruction, the bleeding rate is even higher than in cirrhosis. The lifelong risk of bleeding is 80 % with 50 % of bleeds occurring before age 5 [46]. Although there is an impression that bleeding rate falls with time, this is not consistent, and first bleeding may occur in adult life.

Pressure measurements have an established utility in adult practice. A threshold for HVPG of 10 mmHg is necessary for varices to develop and 12 mmHg for variceal bleeding to occur [15]. There is little experience with HVPG measurement in paediatric portal hypertension, and it requires general anaesthesia and technical expertise. Information from paediatric TIPS suggests that the threshold of 12 mmHg may also apply to children [18, 40].

Primary Prophylaxis

Primary prophylaxis is a standard of care for adults with at least moderate oesophageal varices. Two methods are established, β-blockade and endoscopic band ligation (EBL). Nonselective β-blockers have a combined effect; the β_1 effect causes a decrease in cardiac output, and β_2 stimulation has a splanchnic vasoconstrictive effect which results in a fall in variceal pressure and in collateral blood flow [20]. The relative cost-effectiveness, tolerability and effectiveness of these have been the subject of numerous studies. Current guidelines for adults state that both interventions are acceptable prophylactic therapy, with β-blockers generally preferred as first-line therapy, and EBL reserved for patients in whom β-blockers are contraindicated or poorly tolerated [7, 16].

There have been no randomised controlled trials of β-blockers for primary prophylaxis in children. There are three observational studies published which reported 75 children, not all of whom underwent pretreatment endoscopy [10, 31, 39]. Treatment was generally well tolerated but overall 20 % bled, with a 30 % bleeding rate in those with more advanced liver disease.

There has been one controlled trial of endoscopic prophylaxis in children which used sclerotherapy [17], which can no longer be recommended. There have been three observational studies of EBL in children reporting 50 children treated [4, 5, 36]. The treatment was safe and effective with only two children bleeding during follow-up. However, these studies were uncontrolled, so at

present primary prophylaxis cannot be recommended outside of a clinical trial or protocol. Pragmatically, postpubertal children may be treated according to the adult guidelines, but for younger children, there is an urgent need for definitive trials in this area.

Acute Variceal Bleeding

This is the most feared complication of portal hypertension and the commonest cause of severe gastrointestinal bleeding in children [40]. This usually presents acutely with haematemesis or melaena but may present more subtly with anaemia. There is often a history of respiratory tract infection or other minor illness and occasionally nonspecific abdominal pain.

In adult patients, the 6-week mortality following an acute bleeding has improved but is still 20–30 % [7]. The mortality in children with cirrhosis is lower but still significant with reported death rate of 5–19 % [11, 45, 47]. The mortality is very low in portal venous thrombosis but deaths can still occur in this group [46]. Success of treatment requires control of initial bleeding episode, preventing rebleeding and managing the underlying disease.

Children should be admitted to hospital, stable intravenous access established and samples taken for haemoglobin, coagulation profile, electrolytes, blood and urine culture and 70 ml/kg blood crossmatched. A nasogastric tube should be passed in almost all cases. The risk of variceal trauma is minimal, and this allows removal of residual gastric contents and blood, which untreated predispose to aspiration, encephalopathy and ongoing bleeding. In addition this allows the early detection of ongoing or renewed bleeding.

Blood and colloid should be transfused to achieve normal heart rate and blood pressure while maintaining a CVP of 5 mmHg and haemoglobin in the range of 7–9 g/dl. Overtransfusion should be avoided, and only severe coagulation disturbance and thrombocytopenia should be corrected.

Antibiotic prophylaxis has been shown to decrease mortality in adults, so an appropriate antibiotic such as ceftriaxone or ciprofloxacin should be prescribed [40].

Pharmacotherapy for Acute Variceal Bleeding

Evidence from adult practice suggests that pharmacotherapy should be started immediately, for 2–5 days and that this complements endoscopic treatment [1, 7]. Two drugs are suitable for paediatric use, octreotide or Glypressin. Vasopressin is now obsolete and somatostatin is difficult to source.

Octreotide is a synthetic octapeptide which has been shown to be superior to vasopressin with less side effects. This has emerged as the preferred vasoactive drug in paediatric practice, probably reflecting the ready availability of a suitable preparation, familiarity with the product for other indications and its ease of use and safety. Paediatric observational studies have shown it to be effective and safe with early control of active bleeding in most cases [11, 41]. However, it should not be relied on as sole therapy as early rebleeding is likely [24]. The most common dosage regimen appears to be 1 μg/kg by slow bolus followed by infusion at 1–3 μg/kg/h.

Terlipressin

This is a synthetic analogue of vasopressin which has an immediate intrinsic vasoconstrictive effect followed by a sustained portal haemodynamic effect as it is converted to vasopressin. This is the only drug that has been shown to reduce mortality when used in variceal bleeding as a sole therapy. Reported side effects are similar to vasopressin but less frequent and severe.

There are no studies on the use of terlipressin in paediatric practice. Personal experience has shown this drug is much better tolerated than vasopressin. There are no specific dose recommendations for paediatrics, and it has been used pro rata to the adult regimen of 2-mg IV followed by 1–2 mg every 4–6 h for 72 h.

Endoscopic Treatments

Therapeutic endoscopy should be carried out as soon as possible once the patient is haemodynamically stable, and under general anaesthesia using an endoscope with the largest operating channel that can be safely passed. The exact timing of endoscopy will depend on local facilities, and my own practice is to undertake this on the next available daytime list unless there is ongoing bleeding when it is carried out immediately.

Injection sclerotherapy has been used in paediatric practice for more than 50 years [12]. The principle is that bleeding is stopped either by inducing thrombosis in the varix, or by compressing the varix by the inflammatory reaction occurring when sclerosant is injected around the varix. In chronic use, this inflammatory response leads to fibrous obliteration of the variceal channels. A variety of sclerosants have been used with nothing to choose between them. The largest experience in paediatrics is with 5% ethanolamine oleate [23].

The injection is carried out via the operating channel of a flexible endoscope using single-use injectors with retractile needles. Endoscopes with working channels down to 2.2 mm may be used with modified equipment. If a bleeding varix is identified, this should be treated immediately. It is usually easy to recognise where bleeding had originated, but even if no stigmata of current or previous bleeding is found, treatment should usually be commenced, so long as no other obvious site for bleeding exists and the varices are large. Injections are started just above the gastroesophageal junction and may be intra- or paravariceal. All varices at this level should be treated, with 1–3 ml of sclerosant being used per injection, then repeated if necessary to all varices 3–5 cm caudally. No more than 10–15 ml of sclerosant should be used per session depending on patient size. Varices more than 5 cm from the gastroesophageal junction should not be treated unless actively bleeding.

Sclerotherapy is very effective, with control of acute bleeding in 90% of cases [23, 40]. Complications are more likely following emergency sclerotherapy and include bleeding from ulceration, mediastinitis, oesophageal perforation, chylothorax and pneumothorax. There is a reported procedural mortality of approximately 1% [19].

EBL was first reported in humans in 1989 as an adaptation of treatment established for haemorrhoids [44]. A hollow cylinder with prestretched rubber bands is attached to the front of an endoscope. The variceal column is directly sucked into the hollow cylinder, and a band is released around the base of the varix. Acute bleeding is stopped by strangulation of the varix at the bleeding site. Over the next few days, ischaemic necrosis of the mucosa and submucosa develops; the rings are sloughed leaving shallow mucosal ulceration. Epithelialisation occurs within 2–3 weeks, and the submucosal vascular layers are replaced by maturing scar tissue by 8 weeks.

An initial control endoscopy is carried out to recognise bleeding points and to document the distance to the gastroesophageal junction to help prevent inadvertent banding in the stomach. The multiband apparatus is loaded onto the endoscope, which should have an external diameter of at least 8.6 mm to ensure a secure fit, and then repassed as far as the gastroesophageal junction. The endoscope is placed against the most distal variceal column and suction applied. When the varix fills the cylinder, the tripwire is pulled by turning the wheel and the endoscope pulled back. Care must be taken, especially in small children, that the oesophageal wall is not aspirated into the cylinder. Subsequent bands are applied in a proximal direction to variceal columns in the lower 5–6 cm of the oesophagus. An oesophageal overtube is no longer necessary and 2–6 bands may be used per session. I tend to restrict this to four per session as using more than this is often uncomfortable for the patient. As more bands are fired, visibility progressively improves and some manufacturers insert a coloured band to remind the operator when a single band remains. Banding is much better tolerated than sclerotherapy. 10–15% of children complain of transient retrosternal pain, but oesophageal stricture has not been reported in the paediatric literature.

EBL is now the preferred technique for managing acute variceal bleeding in adults. The published paediatric literature suggests that EBL is very effective in children with active bleeding [4, 13, 25, 29, 34, 36]. A major advantage compared to sclerotherapy is that once the bleeding point is ligated, bleeding control with improved visibility is almost immediate. However, banding equipment has not been extensively modified for paediatric practice, and it will not be possible to pass the loaded apparatus in some small children; hence, both endoscopic modalities should continue to be available in the management of acute bleeding.

Following endotherapy, patients should fast for at least 2 h, and solid feeding withheld until liquids are tolerated. Sucralfate should be given for 5 days as this appears to decrease the risk of early rebleeding.

Detachable nylon miniloops, which are tightened around the base of the varix and detached, or a clipping apparatus (Olympus HX-3 L) where a metal clip is placed directly across the varix has been used in a small number of children [28]. Both techniques are carried out through the working channel and have the advantage that they can be carried out without removing the endoscope and can in theory be used with smaller endoscopes than can band.

Treatment Failures

Initial failures with combined pharmacological and endoscopic therapy are usually best managed by a second attempt at endotherapy, but the use of TIPS may be considered depending on local expertise and facilities.

Transjugular Intrahepatic Portosystemic Shunting (TIPS)

This is a radiologically created portosystemic shunt. Via the transjugular route, a tract is created between branches of the hepatic and portal veins. This is dilated and a self-expanding stent inserted along the tract. This has the clear advantage of much less morbidity than a surgical shunt and little compromise to future liver transplantation.

There are no randomised studies of TIPS in acute bleeding, but cumulative adult experience has shown this to be possible in >90 % of cases when used as rescue therapy for bleeding resistant to endoscopic and pharmacotherapy [3]. Limited but increasing experience in paediatrics has been similar, i.e. it is not a primary treatment but is a very useful rescue option [18, 40].

The most common complication of TIPS is shunt stenosis or thrombosis with subsequent rebleeding, but this complication has been reduced by the development of polytetrafluoroethylene-covered stents. Proactive surveillance with ultrasound and venography can maintain patency rates of >90 % at 1 year. As with any portosystemic shunt, encephalopathy is possible. However, this has been less of a concern in paediatric practice and has usually been easily managed.

Recombinant factor VIIa has no role in the routine management of variceal bleeding but has been safely used in intractable cases with acceptable safety [21].

Balloon tamponade is highly effective and has been shown to control bleeding in up to 90 % of patients, but there is a rebleeding rate of >50 % when the balloon is deflated [20]. The Sengstaken-Blakemore tube is usually used. This single unit consists of a gastric and an oesophageal balloon with oesophageal and gastric suction ports. The tube is passed and the gastric balloon inflated in the stomach. Moderate traction to impact the gastric balloon at the gastroesophageal junction is usually sufficient to control bleeding, but on occasion the oesophageal balloon must be inflated. The position of the gastric balloon should be confirmed radiologically or endoscopically. The major complications relate to inflation of a misplaced gastric balloon, oesophageal and gastric mucosal necrosis and ulceration and aspiration.

Balloon tamponade should only be used in an intubated and sedated child where there is failure to control active bleeding, as a bridge to definitive treatment or to facilitate transfer to a specialist centre [40].

Emergency Surgery

Liver transplantation will be the eventual definitive treatment for most children with cirrhosis and portal hypertension. However the decision regarding liver transplantation should be based on the severity of the liver disease rather than portal hypertension per se. Emergency liver transplantation is rarely necessary and if carried out soon after bleeding carries a higher mortality [42]. In general, patients who are candidates for transplantation should be managed conventionally with pharmacotherapy and endoscopic treatment, followed by planned elective transplantation. In view of the risks of sclerotherapy-induced ulceration following transplantation [48], EBL is the preferred option in those awaiting transplantation [35]. For those with better-compensated liver disease, emergency rescue surgical procedures such as a mesocaval shunt or oesophageal devascularisation are now very rarely necessary given the above armamentarium.

Following a variceal bleed in children, subsequent recurrent bleeding rates are as high as 80 % [23, 40]. Hence all children surviving a variceal bleed should receive secondary prophylaxis [40].

Techniques for Secondary Prophylaxis

(a) Endoscopic treatment
(b) Pharmacotherapy
(c) Shunts – TIPS
- Mesoportal bypass
- Portosystemic shunts

Endoscopic Treatment

Adult studies have established that EBL is the preferred endoscopic method for secondary prophylaxis. Compared to sclerotherapy, there is improved survival, less rebleeding, fewer complications and fewer treatment sessions needed for eradication of varices [7]. The cumulative evidence confirms that EBL is also the preferred method in children [40]. A single randomised trial has shown the superiority of EBL to sclerotherapy in children with EHPVO [49]. In addition, seven observational paediatric studies [4, 13, 25, 29, 34–36] of variceal banding in 96 subjects with mean follow-up of 27 months show varices were eradicated in 80 % with fewer treatment sessions (means 3.2 vs. 5.2), less bleeding and fewer complications than sclerotherapy.

EBL is usually carried out at monthly intervals until variceal ablation, followed by control endoscopies at 6–12 monthly intervals. Recurrent varices should be ligated if they are bigger than grade 1. EBL can safely be undertaken as a day case [25].

Pharmacotherapy

β-blockers have been shown to be as effective as EBL for secondary prophylaxis in adults. The effects of both treatments are additive and current adult guidelines recommend combination treatment [16]. The efficacy of β-blockade can be improved if treatment is titrated to the HVPG gradient. In those in whom it falls to <12, the risk of rebleeding is close to zero, and where the HVPG falls by >20 %, the rate is <10 %. Therefore the consensus in adult practice is that HVPG should be used to titrate β-blockade [15].

Propranolol has been shown to successfully lower portal pressure in children [32], but there is limited therapeutic experience in paediatrics with just three uncontrolled trials. Of 23 children treated, 11 (48 %) bled during a 3-year follow-up. In those with more advanced disease, the bleeding rate was 70 % [10, 31, 39]. In contrast to adults, there is no evidence that the addition of propranolol improves the efficacy of endoscopic treatment in children [10, 43].

Propranolol is usually started at 1 mg/kg/day with the dose initially increased every 2 days until there has been a 25 % decrease in the heart rate or until the heart rate falls to a predetermined minimum value. In the published studies, doses of 1–8 mg/kg/day have been used, and it has

apparently been well tolerated. There were no reports of children who did bleed failing to mount an appropriate tachycardia. In adult practice, approximately 15–20 % of patients will be intolerant of β-blockers, and it is likely this will be similar or greater in childhood. As a result, propranolol cannot be recommended for routine secondary prophylaxis in children.

New drugs such as carvedilol, a β-blocker with intrinsic α-blocking properties, and losartan may represent a step improvement over propranolol but have not yet been studied in children. Nitrovasodilators cannot be recommended in children.

TIPS

Studies of TIPS as secondary prophylaxis compared to endoscopic treatment in adult practice have consistently shown a lower bleeding rate with TIPS at the cost of more encephalopathy, but no difference in overall mortality. The current consensus is that endoscopic and drug treatments are preferred, with salvage by TIPS if these fail [15].

The place of TIPS in acute bleeding in paediatric practice is summarised above. The same considerations apply to use for secondary prophylaxis; it is best reserved for failed endoscopic treatment as a short-term bridge in candidates for liver transplantation [40]. Technical developments such as polytetrafluoroethylene-covered stents may however change this balance, and in individual cases, this may be an excellent option where expertise exists.

Mesoportal Shunt

This recently developed physiological shunt has been developed for the treatment of EHPVO [8]. The procedure depends on patency of the superior mesenteric vein (SMV) and the umbilical branch of the left portal vein. A natural vascular graft (usually from internal jugular vein) is placed between the SMV and the umbilical branch of the portal vein, hence restoring physiological portal blood flow.

The medium term results of this surgery are excellent with complete protection against bleeding. A positive effect on treatment of hypersplenism, correction of coagulopathy and restoration of liver volume is obvious within months. Additionally, there is improved growth, better fluid cognitive ability and reversal of encephalopathy related to portosystemic shunting. These benefits are maintained for at least 8 years, and increasingly this operation is seen as curative for EHPVO [37]. A recent consensus statement recommended that this is the treatment of choice for children with EHPVO [46]. All affected should be assessed for feasibility of mesoportal bypass, and where it is feasible, it should be considered in all cases, even prior to the development of clinical complications. Any portal hypertension-related complication in EHPVO is now an absolute indication for mesoportal bypass where feasible [46].

Portosystemic Shunts

Any of these will result in a decrease in portal pressure, but also to a greater or lesser extent diversion of blood from the liver, with the risk of encephalopathy, hepatic atrophy and deterioration, and hepatopulmonary syndrome [20].

There are no randomised controlled trials of portosystemic shunts for secondary prophylaxis in paediatric practice, but previous experience shows high complication rates if they are done in cirrhotic children [2, 22]. These are usually only indicated in those with presinusoidal portal hypertension, where the mesoportal bypass is not feasible and/or endoscopic treatment has failed or is not available. In current practice, this should amount to no more than 10–15 % of affected patients [23].

The largest experience is with side-to side splenorenal shunt and mesocaval shunts. In skilled hands, these procedures are extremely well tolerated with a very low incidence of encephalopathy, and >90 % prevention of recurrent bleeding can be achieved [22, 38]. However, the risk of encephalopathy is lifelong; hence, all other alternatives should be first considered before embarking on this course (Fig. 64.1).

Laparoscopic Heller-Dor Procedure for the Treatment of Esophageal Achalasia

65

Girolamo Mattioli, Alessio Pini Prato, Valentina Rossi, Stefano Avanzini, Giovanni Montobbio, and Vincenzo Jasonni

Introduction

Esophageal achalasia (EA) is a rare functional disorder of the esophagus characterized by abnormal motility of esophageal body (non-peristaltic waves) associated with incomplete, delayed, or absent relaxation of the lower esophageal sphincter (LES) [1]. The incidence is about 0.3–11/10^6/year with a prevalence of about 80/10^6 inhabitants. Only 5% of the patients suffering from this disease are younger than 15 years of age [2, 3].

Although EA is usually considered an acquired esophageal motility disorder, several studies suggested that genetic background may play a role, in children at least. Because the cause of achalasia remains unknown and there is no cure, treatment is aimed at relief of symptoms. The pathogenesis remains controversial; however the abnormal esophageal motility in EA seems to result from defects or imbalance between the excitatory and inhibitory neuromuscular transmitters [4–9].

Many different treatments have been proposed: pharmacological treatments (calcium channel blockers, such as nifedipine, sildenafil, or isosorbide dinitrate), pneumatic dilatations, removable self-expanding metal stents, and injection of botulinum toxin [10–15]. However these do not provide satisfactory long-term relief from symptoms of achalasia: the results are transitory, and repeated treatments are frequently required. The only way to definitively relieve symptoms is surgery. In 1914, Heller described an anterior/posterior myotomy for the treatment of "cardiospasm" [16]. Later on, Zaaijer et al. proposed an anterior myotomy alone for the same purpose. These techniques should be associated with a fundoplication, aimed at avoiding postoperative GERD and protecting esophageal mucosa. A partial anterior fundoplication according to Dor is the most effective in reducing the risk of stenosis or recurrence of achalasia and in preventing reflux. Laparoscopic modified Heller-Dor procedure is therefore the treatment of choice for EA.

Indication for Operation/Workup

Symptom onset of EA is variable. Almost all the patients present with fluid dysphagia ("paroxysmal dysphagia"), retention, and regurgitation of undigested food; these findings should not be confused with vomiting. Chest pain is described in up to 40 % of patients. Failure to thrive and halitosis are associated symptoms along with nocturnal cough or repeated pneumonia related to pulmonary inhalation [17].

Achalasia may be associated with Allgrove's syndrome, an autosomal recessive familial condition characterized by adrenocortical insufficiency, alacrima, and esophageal motor dysfunction (also called ALADIN syndrome) [18–29].

In any case of suspected EA, the patient should undergo X-ray barium meal, 24-h esophageal pH monitoring, esophageal manometry, and esophagogastroduodenoscopy. The X-ray barium meal is often diagnostic and usually shows a dilated esophagus (megaesophagus) associated with a stricture of the distal esophagus ("mouse tail" or "bird beak" sign). The contrast material progresses in the stomach after a considerable time. The 24-h esophageal pH monitoring excludes the presence of a gastroesophageal reflux disease (GERD), which can produce dysphagia in up to 37 % of the patients. The esophagogastroduodenoscopy should demonstrate the absence of any stricture or mucosal abnormality. Esophagitis may be seen after aspiration of the retained fluid but is generally secondary to fermentation of the stagnant fluid. Finally, the diagnosis is reached with esophageal manometry that demonstrates the absence of normal esophageal motility (non-peristaltic waves) and of post-deglutitive LES relaxations.

EA is a progressive disease that does not resolve spontaneously. Therefore surgery is required as soon as a sure diagnosis is achieved, to prevent complications (failure to thrive, aspiration, etc.).

Preoperative Preparation

Three days before surgery, the patients are fed only with fluids in order to reduce aliment retention. The day before surgery, the patients are kept in fasting state. Enemas are administrated on the day before surgery to reduce colonic distension.

Anesthetic Consideration

Once in theater, premedication is performed with midazolam (0.5–0.75 mg/kg for a maximum of 15 mg). Then a nasogastric tube is introduced when the patient is still awake in order to clean the dilated esophagus and stomach and to reduce the risk of aspiration during tracheal intubation. A clean esophagus is mandatory to minimize spill of contents in the event of inadvertent perforation. A balanced general anesthesia is performed using thiopentone (5–7 mg/kg) and propofol (2.5–4.5 mg/kg) as inductors, fentanyl (2–4 μg/kg) or remifentanil (0.2–0.4 mg/kg/min) as analgesic, and atracurium (0.5 mg/kg) as muscle relaxant. After tracheal intubation, all the patients undergo mechanical ventilation (Drager Primus) with a mixture of O_2/air ($FiO_2 = 0.4$) and sevoflurane 0.8–1 MAC.

Electrocardioscopy, noninvasive blood pressure monitoring [mmHg], pulse oximetry (partial oxygen saturation [%] and pulse rate), and capnography (end-tidal CO_2 [mmHg]) are used to monitor cardiocirculatory and respiratory status during surgery and carbon dioxide insufflation. Airways respiratory rate [cycles/min] (AWRR), peak inspiratory pressure [cm H_2O] (PIP), and tidal volume [ml] (TV) are registered during ventilatory support, as well. No vesical catheter is required.

Operative Technique

The patient is placed supine in the lithotomy position with a reverse Trendelenburg. Skin preparation with meticulous scrubbing of the umbilicus is needed, and the operative field should include the whole abdomen from the pubis to the sternum and laterally to the anterior axillary lines in case conversion to open approach is required.

The surgeon stands between patient's legs. The assistant holding the telescope is on the right,

and the second surgeon is on the left of the patient. The monitor is positioned on the left of the patient at the head of the table.

CO_2 insufflation is used to create pneumoperitoneum up to 12 mmHg. Similarly as in all laparoscopic hiatal procedures, five cannulas are inserted in a semicircular pattern: (a) left paraumbilical (5 mm) for the retraction of the stomach during dissection, (b) umbilical (12 mm) for the telescope, (c) left subcostal (5 mm), and (d) right subcostal as working ports, and (e) epigastric/subxiphoid (5 mm) for retraction of the liver. Recently, we introduced the Step® technology for the stab insertion of the trocars.

The anterior gastric wall is grabbed to retract the esophagus downward. The parietal peritoneum is opened, and the anterior and lateral sides of the esophagus are freed to proceed cranially in the mediastinum (Fig. 65.1). A single longitudinal anterior myotomy and partial myectomy of the circular esophageal muscle, namely, modified Heller procedure, is performed using monopolar coagulation (scissors or hook or LigaSure™) (Fig. 65.2). The length of the myotomy is established by intraoperative manometry or by resorting to specific landmarks. Our landmarks of proximal and distal ends of the dissection are the proximal dilated esophagus where it is crossed by the anterior vagal nerve that moves from the left esophageal side to the anterior wall and the distal transverse esophageal vessel at the esophagogastric junction. Complete myotomy is demonstrated by mucosal herniation (Fig. 65.3). Mucosal integrity is checked by insufflating air inside the esophagus through the nasogastric tube. Mucosal herniation is protected using an anterior 180° gastric fundoplication, namely, Dor fundoplication. The anterior face of the stomach is fixed to the two muscular edges of the myotomy, to maintain it wide open, and to the right portion of the left crura using nonabsorbable synthetic sutures (Figs. 65.4 and 65.5).

Clear fluids and large-spectrum short-term antibiotic prophylaxis (piperacillin) are administrated intravenously during the first 24 h postoperatively, until feeding is started. The patients are fed on postoperative day 1 after a contrast X-ray

esophageal contrast meal (hydrosoluble contrast medium) performed in order to detect leakage or incomplete myotomy.

Results

Our series of patients (since January 1994) sums 20 children. Mean age at operation was 10 years (range 5–14) and mean weight was 45 kg (25–72). Six patients were female and 14 were male. All the procedures were accomplished laparoscopically. Mean operative time was 125 min (range 90–180).

In all patients we did not experience mucosal perforation. Bleeding from an esophageal vessel occurred in one case and clip positioning was thus required. No case needed transfusion nor reoperation.

Nasogastric tube was removed soon after awakening in 13/20 patients, on postoperative day 1 in 7/20. No case showed leakage during postoperative X-ray esophageal contrast meal. All patients were fed by the mouth on postoperative day 1 with fluid meals and were sent home with full oral feeding on postoperative day 3.

All the patients were afterward checked to detect intra- or early postoperative complications and followed to identify recurrence of symptoms due to stricture or appearance gastroesophageal reflux.

The Visick symptom score [30] was used to evaluate postoperative outcome: (1) no symptoms, (2) better than before surgery, (3) no modifications, and (4) new symptoms or complications.

Mean follow-up was 50 months (range 6–102). Postoperative clinical score was Visick 1 in 16 cases and Visick 2 in 4. In one of these three children, symptoms reappeared 6 months after surgery and completely disappeared after one esophageal dilation. One patient was neurologically impaired and required parental care for feeding. The other case experienced dysphagia with good esophageal viability and no recurrence of stricture as checked by X-ray esophageal barium meal and endoscopy. No case developed gastroesophageal reflux on pH monitoring.

Conclusions

The modified Heller myotomy and Dor fundoplication through a laparoscopic approach are, in our opinion, the gold standard to treat esophageal achalasia in the pediatric population.

Complications were low in this group of patients and comparable to other published reports in the literature [31–39].

Pearls

1. We suggest to dissect only the anterior esophageal wall and mediastinum in order to reduce the risk of GER.
2. It is mandatory to perform a high myotomy in the mediastinum (up to the dilated esophagus or to the previously described landmark) and low in the stomach (down to the transverse vessels previously described). Landmarks are of utmost importance in order to reduce recurrence.
3. The myotomy should be carried out with a hook diathermy pulling the muscle fibers far from the mucosa in order to avoid dangerous mucosal lesions or burns.
4. The anterior fundoplication is performed to reduce GER occurrence and to avoid leakage in case of mucosal perforation. It should always be performed in association with a modified Heller procedure.
5. Immediately before realimentation each patient should undergo a contrast study in order to exclude recurrence, residual disease, perforation, and GER.

Pitfalls

- Pneumatic dilatations of the esophagus should be avoided as these carry a high risk of complication and make it harder to perform a subsequent Heller-Dor procedure.
- Reflux is frequently present, but a 360° wrap should never be performed because of high risk of dysphagia.
- A long-term follow- up is strongly suggested because of complications such as esophagitis, stricture, and reflux.

Esophageal Tumors in Childhood and Adolescence: Benign and Malignant

66

Till-Martin Theilen and Michael La Quaglia

Introduction

Of all tumors diagnosed during childhood and adolescence, less than 5 % occur in the gastrointestinal (GI) tract [1–3]. Of these GI neoplasms, only a very small percentage is comprised of esophageal tumors. In this chapter, we will review all published case reports of patients 21 years of age and younger with esophageal tumors, including both benign and malignant entities. Based on the number of reported cases, benign tumors are more common than malignant ones. Of 136 pediatric cases, 94 (70 %) describe benign tumors, and 42 (30 %) describe malignant tumors (Table 66.1). Leiomyoma/leiomyomatosis is the most common benign esophageal tumor, as well as the most common pediatric esophageal tumor overall, and comprises 39 % of all reported cases (Fig. 66.1). Squamous cell carcinoma (SCC) and adenocarcinoma (AC) are the most commonly reported malignant esophageal tumors (see Fig. 66.1).

The incidence data are only available for malignant esophageal tumors. Table 66.2 shows the consolidated incidence for pediatric esophageal cancers registered in some of the largest cancer registries in the world [3–6]. Overall, the incidence of esophageal cancer in infants and children is extremely low. In the United States, for example, only nine cases of esophageal cancer in patients under the age of 20 were registered in the Surveillance, Epidemiology, and End Results database between 1973 and 2007 [3]. Some registries provide the total number of esophageal tumors among all age groups and the total number of all pediatric cancers. In instances in which data are available, we calculated the relationship between the number of reported cases and the total number of esophageal tumors among all age groups or the total number of childhood malignancies. Worldwide, we found that 0.004–0.1 % of all esophageal cancers occur in patients under the age of 21. Similarly, of all pediatric cancers, 0.02–0.2 % are esophageal cancers (see Table 66.2). Interestingly, geographical regions with an increased incidence of adulthood esophageal cancer (e.g., some areas of India) do not likewise have an increased incidence of childhood esophageal cancer [7].

A comparison of the age of onset among children with esophageal cancer reveals that benign esophageal tumors have an earlier onset (median patient age at diagnosis of 11 years [range, 0.2–21 years]) than malignant esophageal

tumors (median patient age at diagnosis of 15 years [range, 4–21 years]) (see Table 66.1). Of patients aged 21 years and younger with malignant esophageal tumors, only four patients were younger than 10 years [8–11]. However, of all pediatric patients with benign esophageal tumors, 50 % were diagnosed before the age of 10. A comparison of the gender distribution among pediatric esophageal cancers reveals that benign tumors are almost evenly distributed among boys and girls (M:F = 1:1.5), whereas malignant tumors are more common in boys (M:F = 2.2:1) (see Table 66.1).

Although most pediatric esophageal tumors are benign and thus are associated with an excellent outcome, they may still adversely affect a child's health. An expanding benign esophageal lesion can lead to life-threatening conditions if it compresses the airway or hinders nutritional intake. With effective treatment, mortality from benign tumors only occurs as a result of operative complications or underdiagnosis and is found

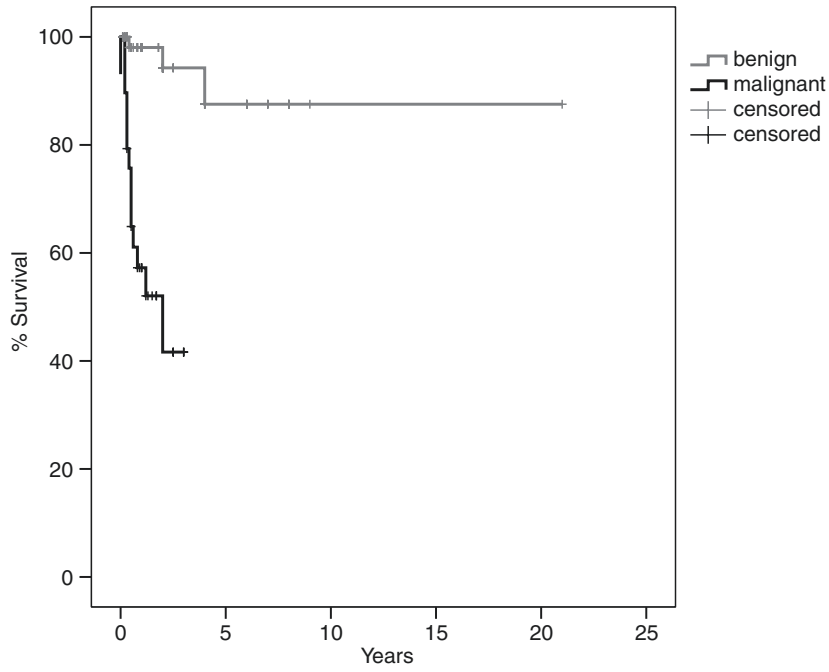

Fig. 66.2 Kaplan-Meier survival curves for pediatric patients aged 21 years and younger with benign ($N=70$) and malignant ($N=29$) esophageal tumors. Survival was significantly worse for patients with malignant tumors than for those with benign tumors ($P<0.0001$, log-rank test)

only historically [12]. On the other hand, the outcome of malignant esophageal tumors in children and adolescents is devastatingly poor. Of the 42 reported cases of malignant esophageal tumors, 36 mentioned follow-up status, and the median survival time was 2 years. Of the 94 reported cases of benign esophageal tumors, 70 mentioned follow-up data. The overall survival of pediatric patients with malignant tumors was significantly worse than that of those with benign tumors ($P<0.0001$, log-rank test). Figure 66.2 shows the Kaplan-Meier survival curves for both patient groups.

Clinical Presentation

A growing mass in the esophagus may lead to three symptom-causing conditions: obstruction of the esophageal lumen, compression of surrounding structures, and tumor ulceration with bleeding.

We reviewed all 136 case reports for presenting symptoms. As shown in Table 66.3, dysphagia is the most common presenting symptom for both benign and malignant esophageal tumors. However, with the exception of dysphagia, the clinical presentation of benign and malignant entities differs remarkably. In children with large and slow-growing benign tumors, respiratory symptoms (e.g., wheezing/dyspnea, recurrent pneumonia/bronchitis) due to airway compression and micro-aspirations are the most common presenting symptoms after dysphagia. In fact, some of the patients described in the literature with these symptoms were treated for asthma or recurrent pneumonia for years before additional evaluation revealed that an esophageal tumor was the underlying cause of their respiratory complaints [13–17]. On the other hand, in pediatric patients with malignant tumors, signs of physical deterioration are predominant in the clinical picture with weight loss, anemia, and dehydration being the most common presenting symptoms after dysphagia.

Unlike most malignant esophageal tumors, benign esophageal tumors do not immediately cause severe symptoms. In fact, many benign tumors are only found incidentally at autopsy. Benign tumors generally become symptomatic when they grow large enough to cause physical symptoms including dysphagia, respiratory

Table 66.3 Presenting symptoms of pediatric patients diagnosed with esophageal tumors

Benign (N=94)	N (%)	N (%)	Malignant (N=42)
Dysphagia	50 (53.2)	36 (85.7)	Dysphagia
Epigastric/retrosternal pain	26 (27.7)	23 (54.8)	Weight loss
Wheezing/dyspnea	25 (26.6)	15 (35.7)	Anemia
Recurrent pneumonia/bronchitis	22 (23.4)	9 (21.4)	Dehydration
Vomiting	22 (23.4)	8 (19.0)	Nausea
Weight loss	14 (14.9)	6 (14.3)	Vomiting
Coughing	12 (12.8)	4 (9.5)	Epigastric/retrosternal pain
Regurgitation	11 (11.7)	2 (4.8)	Recurrent pneumonia/bronchitis
Growth retardation	8 (8.5)	2 (4.8)	Hematemesis
Stridor	6 (6.4)	2 (4.8)	Wheezing/dyspnea
Hematemesis	5 (5.3)	1 (2.4)	Odynophagia
Anemia	5 (5.3)	1 (2.4)	Constipation
Constipation	4 (4.3)	1 (2.4)	Melena
Dysphonia/hoarseness	3 (3.2)	0 (0)	Regurgitation

Dehydration	0 (0)	0 (0)	Prominent jugular veins
Odynophagia	0 (0)	0 (0)	Coughing

compromise, or discomfort and pain. Patients are typically able to alleviate these symptoms, sometimes for years [18]. Of the 94 case reports of benign tumors, 44 reported the time to presentation after first symptoms. In these patients, the mean time between the first onset of symptoms and presentation was 3.5 years. Malignant tumors, however, become clinically apparent relatively quickly. Of the 42 case reports of malignant tumors, 24 reported the time to presentation after first onset of symptoms. These patients presented at an average of 3 months (±2.6 months) after the onset of symptoms.

When a pediatric patient presents with dysphagia, the differential diagnosis of esophageal tumors should include the following: achalasia (cardiospasm), esophageal webs, esophageal (duplication) cysts, esophageal stricture due to causes other than cancer, extra-esophageal lesions compressing the esophageal tube (such as mediastinal lymphomas), and esophageal impairment due to neurologic causes.

Diagnostic Studies

Contrast studies and endoscopy are usually the initial diagnostic interventions for suspected esophageal lesions. But an experienced and skilled diagnostician is needed as intramural tumors can easily be overlooked on these studies [19]. Although biopsies play an important role in the diagnosis-making process, they are frequently nondiagnostic in tumors covered by an intact mucosa, such as leiomyomas. Thus, biopsies of intact-appearing mucosa are not generally recommended by some investigators [18, 20].

We reviewed the 94 case reports of benign esophageal tumors for any false primary diagnosis. We found that 11 patients (11.7 %) were initially diagnosed with and treated for achalasia [18, 21–27] and that five patients (5.3 %) were initially diagnosed with and treated for asthma [13–17]. Benign tumors—most frequently leiomyoma/leiomyomatosis—were eventually found to be the underlying cause of these patients' symptoms. When distinguishing esophageal

leiomyoma/leiomyomatosis from achalasia, diagnosticians should consider the length of the constricted part on the contrast studies. Most often, the constricted part is much longer in patients with achalasia when compared to leiomyoma [28–30].

Additional diagnostic studies for esophageal tumors include endoscopic ultrasonography; computed tomography of the chest, abdomen, and pelvis; and positron emission tomography to delineate the extent of local and metastatic disease. These imaging modalities are also used to stage malignant esophageal tumors, which are classified according to the American Joint Committee on Cancer TNM staging system [31].

Etiology

The pathophysiology of esophageal tumors in pediatric patients is not completely understood. In general, the pathophysiology underlying esophageal tumors in adults is thought to be the same in children and adolescents. In fact, there is no known risk factor or genetic defect for any esophageal tumor in children.

The intimate relationship between the trachea, bronchi, and esophagus during embryologic development may lead to the formation of ectopic tracheal or bronchial tissue within the esophagus. This displaced tissue can be the origin of hamartomatous lesions within the esophageal lumen [32]. Also, the presence of ectopic gastric cells within the esophagus has long been thought to be the origin of AC [33].

An accumulation of familial traits has been observed in cases of leiomyomatosis associated with Alport syndrome (nephropathy, cataracts, hearing impairment) [34]. In these cases, a mutation in the type IV collagen gene is inherited. A familial trait has also been reported in cases of AC and SCC in adults but has not been reported in children with AC and SCC [35].

Esophageal tumors also arise in areas of chronic inflammation due to gastroesophageal reflux (GER) or caustic injury. Although the latency period between the onset of chronic inflammation and the development of Barrett's esophagus (BE) and subsequently AC during childhood seems to be too short, a few cases of synchronous BE and AC have been reported in children [36]. The same is true for chronic inflammation leading to dysplasia and SCC after caustic injury [37]. Importantly, chronic irritation may lead to the formation of not only malignant tumors but also benign tumors such as hyperplastic polyps.

Of special interest are cases of leiomyoma, esophageal AC, and esophageal SCC developing decades after the repair of esophageal atresia and tracheoesophageal fistula repair [38–43]. In patients who have undergone repair of esophageal atresia as an infant, the esophageal anatomy is altered. Impairment of the lower esophageal sphincter leads to GER-related problems such as heart burn, esophagitis, and even BE and cancer [44]. Lifelong follow-up is recommended for these patients as they transition from pediatric to adult gastroenterology care.

Treatment

The management of pediatric esophageal tumors is based on the same principles used in adults. For malignant tumors, complete resection with radical lymphadenectomy is the gold standard of therapy. Depending on the location of the primary tumor, lymph nodes need to be evaluated along typical drainage pathways. Tumors in the lower third of the esophagus and in the gastroesophageal junction have a high prevalence of positive lymph nodes around the celiac trunk and the lesser gastric curvature [45]. Tumors in the upper two-thirds of the esophagus primarily drain via lymphatics along the aorta and vena cava, along the esophagus itself, and in the supraclavicular region and neck. In adults, the primary esophageal tumor should be resected with proximal and distal margins of up to 7–10 cm [46]. However, the application of these margins in small children can be very challenging.

For malignant esophageal tumors, the tumor and lymph node resection can be achieved using either a transhiatal, transthoracic, or cervical approach or a combination. The transthoracic

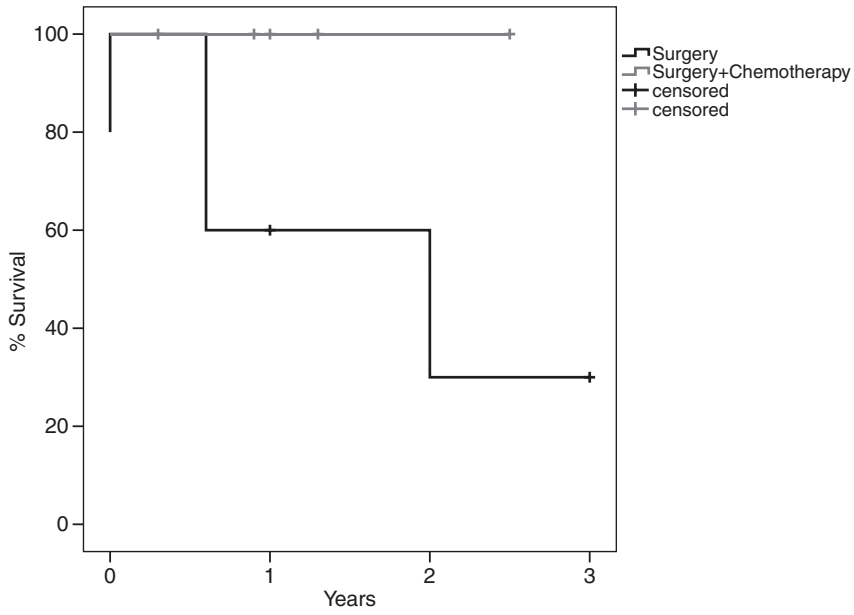

Fig. 66.3 Kaplan-Meier survival curves for pediatric patients aged 21 years and younger with esophageal adenocarcinoma treated with surgery plus chemotherapy versus those treated with surgery alone ($N=5$). There was no significant difference in survival between these two groups ($P=0.1573$, log-rank test)

approach (Ivor Lewis technique) allows greater exposure of the operative field and thus allows more extensive resection of the thoracic lymphatics. However, compared to the transhiatal technique, the transthoracic technique has been associated with increased operative morbidity in adults [47]. However, in terms of overall survival in adults, there are no significant differences between these two approaches [47]. The cervical approach is applied for tumors in the upper esophagus without needing a gastroesophageal anastomosis. Minimally invasive techniques for the resection of malignant tumors are being used with increasing frequency; however, long-term follow-up is still needed to adequately evaluate the outcomes [48].

Complete resection with radical lymphadenectomy is the primary treatment and the only chance for cure. In adults, there is emerging evidence that multimodality therapy in combination with operative resection results in superior survival rates over surgery alone [47]. In the pediatric population, however, it is almost impossible to assess the effectiveness of different treatment strategies because of the low number of cases. Of the pediatric patients with malignant esophageal tumors listed in Table 66.1, five patients with AC received a combination of operation and chemotherapy, and five patients underwent operation alone [36, 38, 49–55]. Both patient groups had comparable extent of disease with local lymph node metastases at presentation (two patients in the surgery plus chemotherapy group vs. three patients in the surgery alone group). There was a trend toward improved survival for the combination therapy group; however, this difference in survival did not reach statistical significance (Fig. 66.3). Studies with larger patient populations will be needed to generate more reliable data on the treatment outcomes of pediatric patients with malignant esophageal tumors.

For patients with unresectable disease, palliative treatment to relieve progressive dysphagia is the only treatment option. Stent placement is usually the procedure of choice. Other palliative treatment options for dysphagia include repeated endoscopic dilatations, intraluminal laser therapy, and single-dose external beam radiation therapy.

Benign esophageal tumors are treated less aggressively than their malignant counterparts. Nodular intramural tumors can usually be enucleated completely without resecting portions of the esophagus. Well-circumscribed intraluminal polypoid tumors can generally be resected endoscopically. However, when tumor ulceration has

occurred or when the tumor encloses the esophagus circumferentially, esophageal resection will be necessary.

After esophageal resection, the colon, jejunum, or stomach can be used to reestablish enteric continuity. Colonic interposition is preferred by many pediatric surgeons as an esophagogastric anastomosis can lead to severe reflux in the remaining esophagus later in life.

After esophagectomy and partial gastric reconstruction, gastric emptying may be impaired. Pyloroplasty or pyloromyotomy may improve gastric outlet obstruction in these patients. However, in adult esophageal cancer patients, these adjunct procedures have been shown to provide only short-term, but not long-term, relief of gastric outlet obstruction [56].

The most worrisome complication is insufficiency of the enteric-esophageal anastomosis. Infarction of the interposed organ due to chronic venous obstruction can also occur weeks to months after the operation. Other complications include esophageal stenosis, gastric reflux with peptic ulcerations in the esophageal stump, and comprised pulmonary function.

Benign Esophageal Tumors

Although benign esophageal tumors can arise from all parts of the wall of the esophagus, the vast majority are leiomyomas that arise from the muscle layers of the esophagus. Other benign esophageal tumors that have been described in the pediatric population are listed in Table 66.1.

Leiomyoma/Leiomyomatosis

Leiomyomatous lesions are the most common esophageal tumors in the children (see Table 66.1). They typically present either as a localized, well-circumscribed nodule (leiomyoma), a diffuse thickening of the entire esophageal muscle wall (leiomyomatosis), or a combination [57]. In 1989, Bourque and colleagues published one of the largest reviews of esophageal leiomyomas in children, which included a total of 22 case reports [18]. To date, 53 cases of childhood leiomyomatous lesions have been reported in the literature [22, 26, 34, 58–85]. A review of these 53 cases shows that the median patient age at diagnosis is 11 years (range, 1.6–20 years) and that these tumors are more common in girls than boys (M:F = 1:3.4).

Leiomyomatous lesions most frequently arise from the inner, circular layer of the muscularis propria. The muscularis mucosa and the longitudinal layer of the muscularis propria are rarely involved [86, 87]. In children and adolescents, these lesions usually present as diffuse leiomyomatosis, often with extension in a circumferential direction, which leads to progressive narrowing of the esophageal lumen [18, 88]. In contrast, in adults, these lesions typically present as a single leiomyoma with a non-circumferential growth pattern [46]. Importantly, the distal esophageal encasement caused by a leiomyoma can lead to misdiagnosis. As mentioned above, some pediatric patients with leiomyoma/leiomyomatosis were initially diagnosed with and treated for achalasia, because both conditions have similar clinical features.

Leiomyomas can grow to be quite large, weighing more than 1,000 g [24, 83]. In the 53 reported cases of childhood leiomyoma/leiomyomatosis, approximately 50 % of the lesions occurred in the distal third of the esophagus, and the remaining 50 % occurred throughout the entire esophagus. Extension beyond the gastroesophageal junction into the proximal stomach occurred in about half the cases.

Histologically, there is no difference between childhood and adult leiomyomas. Leiomyomas are positive for alpha-smooth muscle actin and desmin and are negative for GI stromal tumor (GIST) markers CD34 and CD117 (c-Kit) and neuronal tumor marker S-100 [89–91].

Familial etiologic factors are found in about 30 % of all reported cases of pediatric leiomyoma/leiomyomatosis [15, 22, 28, 61, 64, 69, 70, 72, 77, 79, 84]. The association between leiomyomatosis and Alport syndrome is due to simultaneous mutations in the type IV collagen genes *COL4A5* and *COL4A* [61, 72, 92, 93].

The coexistence of esophageal and vulvar leiomyomatous lesions, defined as esophagovulvar

syndrome, has been described in some patients [94, 95]. Also, in some patients with leiomyomatous lesions, additional foci of disease have been found in the small intestine or rectum, viscera, and tracheobronchial system [58, 96, 97]. Therefore, when evaluating a child who presents with leiomyoma/leiomyomatosis, clinicians should take a complete family history for Alport syndrome and perform a careful examination of the esophagus, lung, rectum, perineum, and genitalia to exclude generalized disease.

The management of leiomyoma/leiomyomatosis includes enucleation (for nodular tumors), subtotal or total esophagectomy (for large tumors or those with a diffuse growth pattern), and replacement procedures. Partial proximal gastrectomy is necessary when the stomach is involved. Myotomy, as performed for achalasia, has been shown to be ineffective for treatment of esophageal leiomyomas [18].

After complete resection, the prognosis of pediatric patients is excellent. In patients with leiomyomatous lesions associated with Alport syndrome, the severity of nephropathy determines the course of disease.

Hyperplastic Polyp

Twelve cases of esophageal hyperplastic polyps in pediatric patients have been reported [98–107]. A review of these 12 reported cases shows that the median patient age at diagnosis is 11 years (range, 9–17 years) and that these polyps are much more common in boys (M:F = 6:1). In six cases, a single polyp was located in the gastroesophageal junction; in five cases, the polyp was located in the distal third of the esophagus; and in one case, the location of the polyp was not specified.

Hyperplastic polyps most commonly consist of hyperplastic gastric foveolar-type mucosa with varying amounts of esophageal squamous epithelium. If stromal inflammation and granulation tissue predominates, hyperplastic polyps are designated as "inflammatory polyps."

The pathophysiology of hyperplastic polyps is poorly understood, but it is speculated that esophagitis caused by GER is the precursor for polyp formation. Seven of the 12 pediatric patients had GER and presented with retrosternal pain and histologic signs of esophagitis [100, 101, 103, 104, 106, 107].

Of the 12 cases of hyperplastic esophageal polyps, 3 were described in children with neurofibromatosis type 1 [100, 102]. A true association between these two conditions, however, has not been established [102].

Malignant transformation of a hyperplastic polyp has not been reported. However, areas of epithelial dysplasia have been seen next to hyperplastic polyps. It is probable that the same mechanism of chronic GER leads to the development of these simultaneous lesions [108].

Endoscopic polypectomy is the preferred treatment for hyperplastic polyps. However, eliminating GER might also be an effective therapy. For example, a pediatric patient with an esophageal inflammatory polyp and ulcerative colitis was treated with medication for reflux esophagitis, which resulted in the marked regression of the polyp [104]. In another child, the esophageal inflammatory polyp resolved 9 months following antireflux surgery [107].

Squamous Cell Papilloma

Six cases of esophageal squamous cell papilloma in pediatric patients have been described [109–114]. A review of these 6 reported cases shows that the median patient age at diagnosis is 3.5 years (range, 1.4–14 years) and that these papillomas are evenly distributed among boys and girls (M:F = 1:1). Unlike in adults, in whom squamous cell papillomas tend to be pedunculated, occur in single numbers, and are found mostly on the posterior wall of the lower esophagus [113], in children and adolescents, squamous cell papillomas tend to be sessile, to occur in multiple numbers, and to be found within the entire esophagus [114, 115].

Two of the six pediatric patients with esophageal squamous cell papilloma had simultaneous laryngeal papilloma; in these two patients, the larynx was the site of initial manifestation of disease [110, 114]. Therefore, endoscopic inspection of

the esophagus should be performed in pediatric patients diagnosed with laryngeal squamous cell papilloma and vice versa.

Etiologic factors for esophageal squamous cell papilloma are thought to be any irritation of the esophageal mucosa such as that caused by chronic acid reflux, irradiation, and ingestion of corrosive chemicals or foreign bodies [114]. Malignant transformation of a squamous cell papilloma has not yet been reported in children.

Resection of asymptomatic multiple squamous papillomata is generally not recommended, partly because recurrences are common, and because multiple resections increase the risk of developing esophageal stenosis. Also, endoscopic resection of esophageal squamous cell papilloma in children is frequently not possible because of the high number of lesions. Total spontaneous regression of papillomatosis of the entire esophagus has been described in a patient 2 years after removal of a laryngeal tumor [111].

Hemangioma and Lymphangioma

Hemangioma and lymphangioma are two types of vascular tumors commonly found in children. However, they usually do not occur in the esophagus. Three cases of esophageal hemangioma and two cases of mixed hemangioma/lymphangioma in pediatric patients have been reported [116–118]. In these cases, the tumors occurred during the first months of life (median patient age at diagnosis of 6 months [range, 3–19 months]), and they tended to occur in the proximal part of the esophagus. In two cases, the tumors grew larger than 10 cm. In one case, a bulky pedunculated hemolymphangioma of the esophagus grew so large that it refluxed into the oral cavity, leading to respiratory distress [116].

Spontaneous involution of hemangiomas and lymphangiomas in infants and young children is common. However, when esophageal hemangiomas and lymphangiomas become symptomatic, their removal is warranted. Treatment with steroids has not been effective [118].

Schwannoma and Neurofibroma

Schwannomas and neurofibromas are slow-growing spindle cell tumors that are positive for S-100 protein and neuron-specific enolase (NSE) because of their derivation from cells of the neural crest. Plexiform variants of these tumors arise from nerve bundles and tend to grow large and extend through tissue layers. They most commonly occur on the skin and very rarely involve the GI tract. Thus, esophageal manifestation of these tumors is very rare.

Only one case of esophageal plexiform schwannoma in a pediatric patient has been described [119]. In this case, a plexiform schwannoma in the esophagotracheal space and invading the esophagus was found in an 11-year-old girl with neurofibromatosis type 2 [119]. A frequent association between neurofibromatosis type 2 and plexiform schwannoma has been reported [120].

Three cases of esophageal neurofibroma in pediatric patients have been reported [121–123]. All three patients were adolescent females presenting with tumors in the distal and middle third of the esophagus. However, it is not clear whether all these tumors truly originated from the esophageal wall or primarily occurred in the posterior mediastinum and invaded the esophagus [123].

Unlike plexiform schwannomas, which are not associated with malignancy, plexiform neurofibromas carry a 10 % risk of malignant transformation [124]. For proper histologic evaluation, complete resection is required for both tumor types [124]. However, resection is often complicated because of the invasive nature of these tumors.

Hamartoma

The intimate relationship between the trachea and esophagus during embryonic development may explain the rare presence of cartilage and epithelia of the respiratory tract within the esophageal wall. Here, these sequestered cells can form

hamartomatous lesions with varying amounts of cartilage, respiratory epithelium, mucus glands, adipose, and fibrous tissue. Three cases of esophageal hamartoma in pediatric patients (aged 2, 3, and 6 years) have been described [32, 125, 126]. In two cases, the tumor was located in the proximal esophageal muscle wall; in the third case, the tumor was located in the distal esophagus as a pedunculated polyp. All three tumors had cartilaginous tissue and varying amounts of respiratory, gastric, fat, muscle, and fibrous tissue, as well as bronchial-like glandular tissue. In all three cases, resection was curative.

Aggressive Fibromatosis (Desmoid Tumor)

Two cases of aggressive fibromatosis (desmoid tumor) of the esophagus in pediatric patients have been found [25, 127]. In one patient, the tumor arose directly from the esophagus and upper stomach [25]. In the other case, the tumor originated in the prevertebral fascia and invaded the esophageal wall [127]. Aggressive fibromatosis of the abdomen usually occurs in the abdominal wall, mesentery, or retroperitoneum [127]. The differential diagnosis of aggressive fibromatosis includes GIST. One group recently described an esophageal tumor in a 15-year-old boy that had histologic features resembling those of GIST [128]. Histochemical analysis, however, failed to confirm this diagnosis, leading to the descriptive diagnosis of an undifferentiated mesenchymal tumor (see Table 66.1).

Management of locally aggressive desmoid tumors includes radical excision and optional adjuvant radiation therapy. Complete local excision is often limited because of the invasiveness of these tumors, especially if vital structures are involved. Since spontaneous regressions have also been reported [25, 127], it remains unclear if radical and often mutilating dissection is indicated in every case. These tumors have a high rate of recurrence, especially in cases with positive resection margins.

Lipoma

Manifestations of lipoma in the GI tract mainly occur in the stomach and the small and large intestines. Thus, esophageal manifestations are extremely rare, but they can be life threatening in the case of pedunculated tumors. Long pedicles can regurgitate into the pharynx, where they confer the risk of suffocation [129].

Only two cases of esophageal lipomas in pediatric patients have been reported in the world literature [17, 130]. One patient was treated for asthma for 2 years before being diagnosed with an esophageal lipoma at age 6. This patient had an intraluminal pedunculated tumor in the proximal esophagus, which was removed by open esophagotomy [17]. The other patient presented with an intramural lipoma in the proximal two-thirds of the esophagus at the age of 4. The tumor had displaced the trachea, resulting in respiratory compromise [130].

Endoscopic resection, when feasible, is the preferred treatment for pedunculated lipomas; otherwise, an open approach is needed.

Inflammatory Pseudotumor

The term "inflammatory pseudotumor" (IPT) is used to describe a spectrum of tumors associated with a previous infection or tissue injury. Before the term IPT was established, these tumors were referred to as "plasma cell granulomas," "post-inflammatory tumors," or "xanthomatous pseudotumors." Importantly, an association between IPTs and malignant neoplasms has been reported [131].

IPTs primarily affect young adults, and they occur mainly in the lungs and less commonly in the stomach and liver [132]. Only two cases of esophageal IPT in pediatric patients have been described [133, 134]. In the first case, an IPT occurred in a 15-year-old boy 9 years after he underwent treatment for Wilms' tumor. The IPT involved the gastroesophageal junction, parts of the stomach, and the liver [134]. In the second case, an IPT occurred in a 14-year-old girl who

presented with a tumor at the gastroesophageal junction that involved the stomach, pancreas tail, and splenic hilum [133].

Because esophageal IPTs can mimic malignant esophageal neoplasms, it is important to perform a thorough histologic evaluation to exclude malignancy [135]. Histologically, IPTs are characterized by an inflammatory infiltrate consisting of varying amounts of plasma cells, lymphocytes, and macrophages within a fibrous tumor.

The IPT that occurred in the 14-year-old girl was interpreted as being an "inflammatory myofibroblastic tumor" [133]. Among IPTs, inflammatory myofibroblastic tumors have received special attention because they have been shown to behave like malignant neoplasms in different anatomic sites. Chromosomal aberrations, namely, the activation of anaplastic lymphoma kinase and p53, have been found in some inflammatory myofibroblastic tumors [136].

Complete resection is the primary treatment for IPTs. Other treatment options, including corticosteroid therapy, anti-TNF-alpha antibody therapy, nonsteroidal anti-inflammatory drugs, and chemotherapy, are currently being investigated in clinical trials [133, 136].

Rhabdomyoma

Cardiac rhabdomyomas are classified as hamartomatous lesions, while extracardiac rhabdomyomas are classified as true neoplasms. Of all extracardiac rhabdomyomas, 93 % occur in the head and neck region—most frequently the larynx and pharynx—in adult male patients [137]. There are three subtypes of extracardiac rhabdomyomas: fetal, adult, and genital. Two cases of adult-type rhabdomyoma of the esophagus in young patients have been reported [16, 138]. In the first case, a rhabdomyoma occurred in an 8-year-old boy; [16] in the second case, a rhabdomyoma occurred in a 21-year-old woman [138]. These tumors were located in the proximal and middle third of the esophagus.

Resection is the treatment of choice for esophageal rhabdomyoma. Local recurrences have been reported and are mostly due to incomplete resection of a multicentric lobulated tumor [16].

Granular Cell Tumor

Granular cell tumor (Abrikossoff's tumor) most commonly presents in the skin. Only two cases of an esophageal granular cell tumor in pediatric patients have been described: one in a 14-year-old girl [139] and another in a 19-year-old girl [140].

The pathophysiology of granular cell tumors remains poorly understood. Both patients presented with progressively worsening dysphagia and GER symptoms. In both patients, the tumors occurred in the distal third of the esophagus. These tumors' ultrastructure and their positivity for NSE and S-100 protein support the hypothesis that they originate from Schwann cells or are derived, to some extent, from neural tissue [113, 139].

In adults, a 2–4 % malignant transformation rate has been reported for these tumors [141]. Therefore, excision seems warranted. However, it has also been suggested that these tumors should be excised only if they are growing rapidly and become symptomatic [139].

Malignant Esophageal Tumors

The vast majority of malignant esophageal tumors diagnosed in patients aged 21 and younger are SCC and AC. Other malignant esophageal tumors reported in the literature include synovial sarcoma, spindle cell sarcoma, melanoma, and lymphosarcoma (see Table 66.1). The lymphosarcoma listed is a historic case report from 1890 [11]. In retrospect, the patient may have had a non-Hodgkin lymphoma.

The development of malignant esophageal tumors is generally associated with lifelong exposure to carcinogenic stimuli, which might explain the rarity of these tumors in children. Nevertheless, it is important to remember that certain conditions such as repair of an esophageal atresia or caustic injury to the esophagus during

childhood may lead to cancer in early adulthood. In these cases, a close transition from pediatric to adult medical care is warranted.

Squamous Cell Carcinoma

To date, 20 cases of esophageal SCC in children have been reported [6, 7, 142–150]. A review of these 20 cases shows that the median patient age at diagnosis is 15 years (range, 8–21 years) and that esophageal SCC is almost evenly distributed among boys and girls (M:F = 1.2:1).

The development of SCC has been strongly associated with the consumption of certain foods and food ingredients (e.g., moldy foods, hot beverages, alcohol, cottonseed oil, lye, nitrosamines); *G. candidum* contamination; tobacco use; and low intake of riboflavin, retinol, zinc, and iron. Caustic injury to the esophagus leading to chronic inflammation is one of the strongest risk factors for its development. Although it generally takes decades for malignant changes to develop, three cases of esophageal SCC after caustic injury have been described in pediatric patients [37, 54, 145]. In these cases, esophageal SCC occurred 1, 10, and 12 years after a caustic injury in early childhood. In one case, the caustic injury occurred after lye ingestion. In the remaining two cases, it resulted from unknown caustic agents. Other case reports have mentioned a history of cigarette smoking at a young age, prior chemotherapy for osteosarcoma, a gastric trichobezoar, and esophageal human papilloma virus-16 infection as risk factors for SCC.

We examined the distribution pattern of SCC within the esophagus in these 20 children and found that SCC occurred equally throughout the entire length of the esophagus, without any predilection for a specific esophageal region. Most patients presented with local disease without evidence of metastases. When metastases were present, they were mainly found in the regional lymph nodes. Metastases to solid organs were found in only one patient.

Outcome was reported for 16 of the 20 patients. Ten patients were alive at a median follow-up time of 0.5 years (range, 0–1.7 years). Obviously, longer follow-up will be needed to generate more thorough survival data for these children.

The mainstay of therapy for esophageal SCC is complete resection with wide lymphadenectomy. These 20 patients offer insufficient data to adequately evaluate the effectiveness of different treatment regimens. Thus, it is unclear if adding chemotherapy or radiation therapy to operative resection prolongs survival in pediatric patients with esophageal SCC.

Adenocarcinoma

To date, 17 cases of esophageal AC in children have been reported [6, 9, 36, 38, 49–53, 55, 151, 152]. The median patient age at diagnosis is 16 years (range, 8–20 years). The youngest patient ever diagnosed with esophageal AC was 8 years old [9]. As in adults, the male gender is predominantly affected (M:F = 4.6:1) [153]. Interestingly, the dramatic increase in the incidence rate of esophageal AC in adults over the last few decades has not been observed in children and adolescents [154].

AC is closely linked to the sequence of GERD and the development of BE. Risk factors for esophageal AC in adults commonly include long duration of GERD symptoms, presence of BE, male gender, white race, age, history of smoking, and obesity [153]. Risk factors for esophageal AC in children are not clearly understood. In general, however, the same relationship of GERD and BE with the development of AC is thought to be true for children. Among the 17 cases of childhood esophageal AC, preexisting conditions included spinal palsy, history of esophageal atresia repair, hiatal hernia, obesity, and foreign body ingestion. All of these conditions are known risk factors for GERD and BE in children [155]. In 6 of the 17 cases, BE was actually observed next to the AC [36, 49, 51].

The time span, and thus the chance to develop BE and AC due to GERD, is seemingly short in children. However, it is postulated that GER in infancy can be carried on "silently," leading to problems in later childhood and adulthood [156, 157]. This observation is supported by recent findings

showing that preterm and small-for-gestational-age infants, in whom GERD is common, have a greater than 11-fold risk of developing esophageal AC in adulthood [158, 159].

In cases of familial BE, AC has an earlier onset and a higher rate of malignant transformation than in cases of nonfamilial BE [160]. However, a positive family history of BE has not yet been reported in children and adolescents with AC. It will be interesting to see if ongoing investigations will identify the genes involved in the development of BE and AC [161]. In summary, an early initiation of the GERD-BE-dysplasia sequence and a possible genetic predisposition are most likely the etiological steps for esophageal AC in children and adolescents.

Eleven of the 17 patients developed metastatic disease. Lymph node metastases occurred to the esophageal nodes, the aorta, and the stomach. Two patients had pulmonary metastases, and one had cerebral metastases [6, 152]. Of the 17 patients, 10 (59 %) died after a median follow-up time of 0.8 years (range, 0–3 years). Despite the generally poor outcomes reported for esophageal AC, there are some cases with survival for longer than 24 months [36, 52].

For children with esophageal AC, early diagnosis and aggressive therapy with complete surgical resection are critical for prolonging survival.

Sarcoma

Of all malignant pediatric tumors, 7 % are sarcomas; of these, 2 % occur in the GI tract [162, 163]. Synovial sarcomas rarely occur outside of joint capsules. When they do, they are thought to originate from undifferentiated mesenchymal cells. Three cases of synovial sarcoma of the esophagus in adolescent have been reported [164–166]. The patients presented at 14, 15, and 20 years of age with fairly large tumors in the proximal esophagus in close proximity to the hypopharynx.

Because synovial sarcomas are generally very aggressive, an aggressive treatment approach is warranted. Resection followed by a combination of chemotherapy and radiation therapy offers the only chance of cure, but only in the setting of localized disease [167]. In the three reported cases, the patients received chemotherapy and/or radiation therapy after resection and were disease-free at a median follow-up of 30 months after completion of treatment.

Melanoma

About 200 cases of primary malignant melanoma of the esophagus have been reported in adults [168], but only one case has been reported in a child [8]. In this single case, a 7-year-old boy presented with a lobulated melanoma in the mid-esophagus. Six months after wide resection, the patient lost weight, developed respiratory distress and pneumonia, and died. A highly aggressive malignant melanoma, which had surrounded and invaded the trachea, leading to airway obstruction, was found on autopsy [8].

Typically, melanoma of the esophagus is locally aggressive and disseminates early via the bloodstream and the lymphatics. Even with aggressive therapy, the prognosis of patients with melanoma of the esophagus is poor: the 5-year survival rate is less than 5 % in adults [168].

Conclusion

Esophageal tumors are exceedingly rare in childhood and adolescence. However, they should always be considered when a pediatric patient presents with dysphagia, respiratory compromise, retrosternal pain, failure to thrive, or a combination of these symptoms. Leiomyomatous lesions are the most commonly reported esophageal tumors in pediatric patients followed by SCC and AC. Early diagnosis, based on careful evaluation and diagnostic workup, is warranted for both benign and malignant esophageal tumors to reduce the operative morbidity and to improve outcome. While benign tumors are generally associated with an excellent prognosis, malignant tumors are associated with a devastatingly poor prognosis. Many clinical and laboratory investigations are under way to try

to identify the genetic and pathologic pathways involved in esophageal carcinogenesis, which may help improve the management of children with malignant esophageal tumors.

Epidermolysis Bullosa: Epidemiology, Diagnosis, Complications, and Treatment

67

Richard G. Azizkhan and Ahmed Mami

Introduction

Epidermolysis bullosa (EB) comprises a wide spectrum of rare genodermatoses of varying severity that are characterized by excessive skin fragility and mucocutaneous blistering in response to minor mechanical friction or trauma. The etiology of these conditions is attributed to mutations in one or more of ten different genes that affect structures that hold together the epidermal and dermal layers of the skin. According to a recently revised classification system developed with international consensus [12], there are four major EB types: EB simplex (EBS), junctional EB (JEB), dystrophic EB (DEB), and Kindler syndrome. Within these classifications, there are subtypes that also vary in both severity and genetic etiology (Table 67.1). Regardless of EB type, patients suffer with a continuous cycle of blistering, scarring, and wound healing that has a devastating impact on quality of life. The inability to take in sufficient calories to maintain an anabolic state in the presence of the increased metabolic demands of constant wound healing or the impact of disease on the esophagus and oropharynx typically leads to compromised nutritional status. Given that nutritional problems are more severe in patients with the recessive DEB subtype (RDEB) and JEB, these patients more commonly require nutrition-related surgical interventions. It is therefore essential for surgeons involved in their care to be knowledgeable as to these EB types in particular, the inherent nutritional issues that these patients face, and their special perioperative needs. To this end, our discussion will provide a succinct description of nutritional issues in RDEB and JEB, subsequently focusing on special needs of this patient population within the context of esophagogastric procedures.

Clinical Overview

Valuable clues as to EB type are often gained by experienced clinicians who become familiar with the various phenotypic expressions seen in EB, as well as the anatomic sites affected and extent and severity of disease.

Table 67.1 Ultrastructural findings and gene abnormalities among major types and selected subtypes of EB

EB type or subtype	Ultrastructural site of skin findings	Target gene (protein)
EB simplex (*EBS*)		
EBS localized	Basal layer	KRT5 (keratin 5)
EBS DM	Basal layer in subnuclear cytoplasm	
EBS-MD	Predominantly in basal layer, above level of HD attachment plaque	PLEC1 (plectin)
EBS-AR	Basal keratinocytes	KRT14 (keratin 14)
EBS, lethal acantholytic	Suprabasal cleavage and acantholysis	DSP (desmoplakin)
EBS, plakophilin-1 deficiency	Mid-epidermal cell-cell separation	PKP1 (plakophilin1)
EBS-PA	Lower basal layer, above level of HD plaque	PLEC1 (plectin)
Junctional EB (*JEB*)		
JEB-H	Lamina lucida	LAMA3, LAMB3, LAMC2 laminin 332
JEB-nH	Lamina lucida	LAMA3, LAMB3, LAMC2 laminin 332, COL17A1 (type XVIII collagen)
JEB-PA	Lamina lucida	ITGA6, ITGB4 (α6β4 integrin)
Dominant dystrophic EB (*DDEB*)		
DDEB, generalized	Sub-lamina densa	COL7A1 (type VII collagen)
DDEB-BDN	Sub-lamina densa	
Recessive dystrophic EB (*RDEB*)		
RDEB, severe generalized	Sub-lamina densa	COL7A1 (type VII collagen)
RDEB, generalized other	Sub-lamina densa	
RDEB-BDN	Sub-lamina densa	
Kindler syndrome	Multiple cleavage planes (intradermal, junctional or sub-lamina densa)	KIND1 (kindlin 1)

AF Anchoring fibril, *AR* autosomal recessive, *BDN* bullous dermolysis of the newborn, *DM* Dowling-Meara, *H* Herlitz, *HD* hemidesmosome, *MD* muscular dystrophy, *nH* non-Herlitz, *PA* pyloric atresia, *SBDP* subbasal dense plate

RDEB

The incidence of RDEB in the United States (US) is estimated at 2.04 per million, with a carrier frequency of 1 in 345 [26]. RDEB has been linked to mutations in the *COL7AI* gene, which resides on the short arm of chromosome 3 [31]. It is not uncommon for these mutations to occur de novo [32]. The *COL7AI* gene codes for type VII collagen, which is a major component of the anchoring fibrils responsible for epidermal-dermal adhesion beneath the basement membrane within the papillary dermis of skin and mucous membranes [9, 33]. This abnormality manifests in frequent blistering in areas of friction, which may result in extremity contractures that eventually lead to pseudosyndactyly in the hands and feet (Fig. 67.1). Repetitive injury often leads to aggressive squamous cell carcinomas in the third decade of life.

Fig. 67.1 Child with severe generalized RDEB. This patient has significant pseudosyndactyly, contractures, growth and nutritional failure

Because of the high nutritional demands of continuous inflammation and wound healing and difficulty with adequate intake due to oral and esophageal blistering and scarring, children with

RDEB generally have an array of nutritional problems [1, 5, 23]. In many patients, poor nutrition leads to anemia, failure to thrive, growth retardation, osteopenia, osteoporosis, and, rarely, dilated cardiomyopathy [13]. Nutritional deficits often involve a vitamin and trace metal deficiency that is not always correctable with enteral caloric supplementation [18]. Lip and oral mucosal involvement may lead to the development of progressive microstomia and subsequent ankyloglossia, rendering oral feeding problematic and painful. By 12 years of age, more than 50 % of RDEB patients suffer with both of these conditions [11]. Repeated blistering and scarring in the esophagus and oropharynx may lead to esophageal strictures [3, 4, 6, 17]. According to the National EB Registry, more than 90 % of patients eventually develop these strictures, and they are seen in patients as young as 18 months of age. Over time, esophageal strictures may lead to progressive dysphagia or odynophagia. If untreated, patients may even have difficulty swallowing their own saliva. Additionally, many patients suffer from constipation, resulting from painful defecation due to perianal skin involvement and fissures, dehydration from decreased oral intake, ongoing fluid loss through chronic wounds, and chronic ingestion of narcotic analgesics. In view of these numerous and complex issues, it is not surprising that up to 77 % of children with RDEB are at risk for significant malnutrition [5]. As such, every effort must be made to alleviate the array of distressing problems. Appropriate interventions can be accomplished only through the collaborative efforts of a multidisciplinary team of experienced professionals.

Although aggressive supportive therapy, including esophageal dilatations, allows most patients to maintain adequate nutritional status, approximately 25–30 % of patients require placement of a gastrostomy tube [29]. These interventions are discussed later in the chapter.

JEB

The estimated incidence of JEB in the United States is 2.04 per million, with a carrier frequency of 1 in 333 [26]. Mutations have been linked to four genes: *LAMB3* (70 % of all JEB), *COL17A1* (12 %), *LAMC2* (9 %), and *LAMA3* (9 %) [27].

Fig. 67.2 Small child with JEB Herlitz type. This child has a tracheostomy for airway involvement. The severe facial granulation tissue is a characteristic manifestation of this disorder

In several JEB subtypes (e.g., Herlitz), the physical manifestations of disease are extremely severe and may affect the respiratory tract, resulting in death during early childhood (Fig. 67.2). Despite tracheotomy placement, these patients may succumb to progressive airway obstruction. Some patients have bladder and kidney involvement and may require urological procedures. Pyloric atresia (PA) has also been identified (JEB-PA) and is often lethal in the neonatal period. Most patients with the non-Herlitz generalized subtype survive into adulthood. Although these patients may have nutritional issues, they are not as severe as those seen in patients with RDEB. In contrast to the high risk for malnutrition (77 %) in children with RDEB, research indicates that only 57 % of children with JEB are at risk [5]. Our own experience reflects this finding, as most of our patients who require surgical intervention for nutritional issues have RDEB.

Diagnostic Approaches

Laboratory approaches to the diagnosis of EB include transmission electron microscopy (EM) and immunofluorescence mapping (IFM). Both of these approaches allow determination of the

diagnostic level of skin cleavage. EM offers the advantage of permitting visualization and semi-quantitative assessment of specific structures (e.g., anchoring filaments and fibrils, keratin filaments, desmosomes, hemidesmosomes, and subbasal dense plates), which are known to be altered in number or appearance in certain EB subtypes (Table 67.1) [12].

IFM is the primary laboratory technique for confirming the diagnosis of EB. Many laboratories exist worldwide that properly perform this technique using a series of EB-relevant antibodies and well-established protocols. Moreover, IFM is relatively inexpensive and comparatively quick and easy to perform.

Mutational analysis provides a means of determining the mode of inheritance and the precise site(s) and type(s) of molecular mutation present in a patient. We now have the capability of using this technique for prenatal and preimplantation diagnosis [7, 10].

Assessment of Esophageal Strictures

Before undergoing dilatation, all EB patients should have a thorough medical examination and nutritional assessment. Patients presenting with dysphagia, nutritional deficiency, or poor weight gain should have a contrast esophagram performed to assess the status of their esophagus and the presence and number of strictures. The inclusion of the pharyngoesophageal junction in this study is crucial, as many patients with RDEB have a high cervical esophageal stricture that can be missed on a routine esophagram (Fig. 67.3). The proximal cervical esophagus is the most common location for strictures. Based on a recent analysis, this is seen in approximately 85 % of our RDEB patients; approximately 40 % have more than 1 stricture [3]. Dilatations are performed initially only when the stricture is radiologically confirmed. A barium esophagram delineates the number, level, and severity of the strictures, thereby providing a roadmap for the dilatation procedure. This study should incorporate frontal and lateral projections and must assess the entire esophagus from the oropharynx through to the gastroesophageal junction.

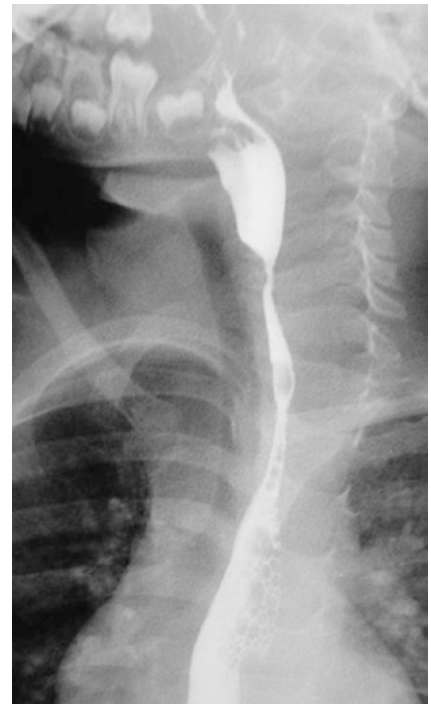

Fig. 67.3 Barium esophagram outlining proximal esophageal stricture at C4 in a patient with RDEB

Preoperative Evaluation

Optimally, EB patients and their families should be seen within 2 weeks of a scheduled surgical procedure. This permits data collection and evaluation to be carried out in an unhurried manner, avoiding the risk of last-minute preparation delays. A thorough overall assessment consists of a number of critical components, including airway, cardiac, and positioning evaluations, as well as appraisal of the readiness for anesthesia induction [15].

Airway Assessment

Airway assessment should focus on five areas of concern. First, both the vertical and horizontal aspects of the mouth opening may be limited.

This, together with an overbite, can make traditional laryngoscopy and intubation impossible to perform. Limiting mouth opening becomes more of an issue as EB patients approach adolescence, though it can occur earlier. The second area of focus is dentition. This can be poor, with multiple caries and overcrowding of the teeth [8, 34]. Third, skin fragility requires that utmost attention be paid to manipulation of the face, buccal mucosa, and gums during airway management and that preexisting lesions be noted. Fourth, the severity of ankyloglossia should be noted. This condition may be pronounced, such that the patient may have minimal to no tongue movement. Despite anatomic limitations and potential difficulties in intubating these patients, mask ventilation is often maintained without difficulty. The fifth area of concern is the possible presence of glottic stenosis, which may have occurred as a result of prior airway manipulations; this condition further compromises the ability to secure the airway. Patients with JEB (Herlitz generalized) are at higher risk for subglottic stenosis, as well as choanal and nasal stenosis, and excessive peritracheal and intranasal granulation tissue [21].

Cardiac Evaluation

Several studies demonstrate an increasing body of evidence for dilated cardiomyopathy in patients with RDEB [13, 25, 28]. Although the cause remains unclear, selenium or carnitine deficiencies have been implicated as a possible etiology. In view of this evidence, we advise that patients with RDEB who will be undergoing surgery and require anesthesia should have an echocardiogram within 12 months prior to surgery. If significant findings are present, it is prudent to repeat the exam closer to the scheduled date of surgery. Unfortunately, beyond standard measures for the treatment of dilated cardiomyopathy and improving nutritional status, there is no method of optimizing cardiac function. Nonetheless, this evaluation enables more accurate risk assessment and perioperative planning.

Positioning Evaluation

To ensure proper positioning, extensive or painful wounds or blisters should be noted. Because many EB patients have joint contractures as well skin lesions, improper positioning increases the risk of further skin damage.

Induction Readiness

Given that a smooth, atraumatic induction is optimal, the clinician should attempt to determine whether the patient is likely to be compliant with induction. Parental presence at induction is extremely helpful and should be encouraged. In patients who are extremely anxious, we routinely use oral midazolam to facilitate a smooth induction.

Esophagogastric Procedures

Esophageal Dilatation

Overview

Although intensive nutritional support is often sufficient to maintain the metabolic status quo, esophageal dilatations enhance the patient's ability to tolerate oral feeds and should thus be performed when necessary. Our clinical experience suggests that as many as 80 % of patients with RDEB have symptomatic strictures requiring esophageal dilatation by age 25. Historically, patients who underwent esophageal dilatations for strictures had some form of bougienage performed blindly with tapered mercury-filled rubber Maloney dilators or serial Tucker dilators pulled through a gastrostomy with the aid of a string guide. These techniques were associated with postoperative pain, extensive esophageal mucosal sloughing, and often, a prolonged period of recovery during which adequate oral intake could not be resumed.

In view of the poor outcomes, such techniques have been supplanted by endoscopically and fluoroscopically guided hydrostatic balloon dilatation techniques [2, 6, 17]. Owing to the fact that

some degree of mucosal shearing of the pharyngoesophageal region is inherent in endoscopically guided dilatation, this approach may result in a greater degree of mucosal blistering and sloughing than a nonendoscopic approach. To reduce the potential for iatrogenic sheer stress injury to the esophagus, we employ a nonendoscopic balloon dilatation technique. This has become our technique of choice for EB patients with symptomatic esophageal strictures. It permits a more specific anatomic identification of length and severity of the stricture(s) than does an endoscopic approach. Also, it allows for the use of much larger balloon sizes, achieving larger functional esophageal diameter. Most important in regard to quality of life, the nonendoscopic approach results in a longer interval between dilatations. Nevertheless, both dilatation techniques relieve distressing symptoms and effect dramatic changes in social behavior and the ability to enjoy food [4].

Cincinnati Esophageal Dilatation Technique

In the interventional radiology suite, using fluoroscopy, we initially place an 8-French umbilical artery catheter (Boston Scientific Corp., Natick, MA) transorally into the upper esophagus (Fig. 67.4a). We then pass a flexible soft-tip Benson 0.035-in guidewire (Cook Inc., Bloomington, IN) into the stomach through the catheter (Fig. 67.4b). Once the position of the guidewire is fluoroscopically verified, it remains in place throughout the entire procedure. The umbilical artery catheter is removed (Fig. 67.4c). The high-pressure hydrostatic balloon catheter is then placed over the guidewire into the distal esophagus (Fig. 67.4d). The balloon length and diameter depend on the age and size of the patient as well as the characteristics and number of strictures that are present. Balloon length typically varies from 6 to 8 cm; balloon diameter varies from 12 to 22 mm. We begin by inflating the balloon with a 50 % dilution of Optiray 240 water-soluble contrast (Mallinckrodt Inc., St. Louis, MO) centered over the most distal stricture (Fig. 67.4e). The initial portion of the injection is performed manually with a Bard Balloon Inflation System syringe (CR Bard Inc., Billerica, MA) with a built-in manometer. This is subsequently locked and the handle turned clockwise to apply a gradual increase in balloon pressure until stricture effacement has occurred (up to approximately 2 atmospheres) (Fig. 67.4f). The pressure applied must be kept less than balloon burst specifications at all times. Simultaneous fluoroscopy allows visualization of the stricture(s) and their gradual effacement as dilatation progresses. The center of the balloon must be placed at the midpoint of the stricture to prevent cephalic or caudal migration of the balloon, which could result in shearing forces on the esophageal mucosa. Aboral (caudal) migration of the balloon is prevented by applying gentle traction to the balloon catheter during balloon inflation. The balloon is left inflated for up to 30 s before deflation and repositioning to dilate other more proximal strictures. A small amount of contrast left within the balloon can facilitate the identification of additional strictures within the esophagus, as narrowing can clearly be seen on retracting a partially inflated balloon (Fig. 67.5a, b). It is important to perform this esophageal mapping maneuver up to and including the pharyngoesophageal junction in order to avoid missing high strictures commonly found in RDEB, which may not have been picked up on a routine contrast esophagram. We then replace the balloon catheter with the previously used umbilical artery catheter over the guidewire with the purpose of performing a limited contrast esophagram. This procedure can help confirm satisfactory patency of the esophageal lumen after dilatation and also rules out esophageal perforation. For this purpose, we use standard Optiray 240 injected through the umbilical artery catheter as it is withdrawn from distal to proximal during fluoroscopy. Any residual contrast is then aspirated from the esophagus to reduce the postoperative risk of contrast aspiration. In some patients with a difficult airway, masked ventilation can be used, and a retrograde esophageal dilatation can be achieved using as gastrostomy stoma. In this subgroup of patients, we perform the dilatation process from the proximal to the distal esophagus.

Postoperative Management

Once patients are safely recovered and awake, they resume a liquid diet. This is followed by a soft diet as tolerated. Patients who have undergone dilatation for the first time are usually monitored overnight in hospital and discharged home on the following day. Those who have previously undergone dilatation at our institution are discharged within 8 h. In an effort to delay recurrent stenoses, we routinely administer perioperative and postoperative steroid treatment. Patients receive 0.5 mg/kg of dexamethasone with a maximum dose of up to 20 mg intravenously at induction. This is followed by a 5-day tapered dose of liquid prednisolone that is started at 1–2 mg/kg. To minimize the effects of acid gastroesophageal reflux, we also prescribe a proton pump inhibitor. Patients who require repetitive dilatations remain on this regimen indefinitely.

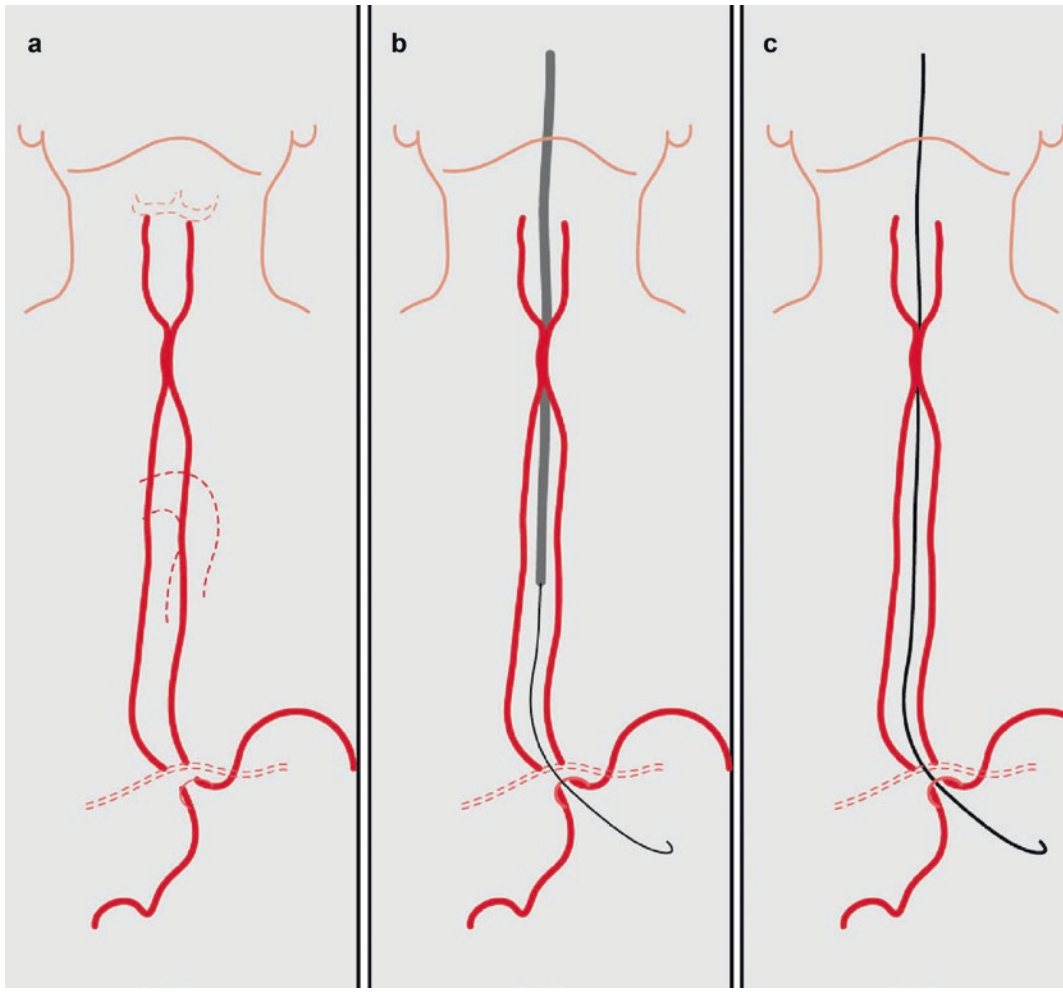

Fig. 67.4 The illustration depicts the sequential steps in performing the nonendoscopic hydrostatic balloon dilatation using fluoroscopic guidance. (**a**, **b**) An 8-Fr. umbilical catheter with a flexible soft guidewire is inserted through the oropharynx and positioned past the strictured esophagus. (**c**) The umbilical catheter is removed leaving the guidewire in place. (**d**) The hydrostatic balloon catheter is placed over the guidewire and positioned at the level of the stricture(s). (**e**, **f**) The balloon is insufflated with water-soluble contrast under fluoroscopy. Initially the stricture appears as a narrow waist. With gentle insufflation pressure (1–2 atmospheres), the stricture is effaced

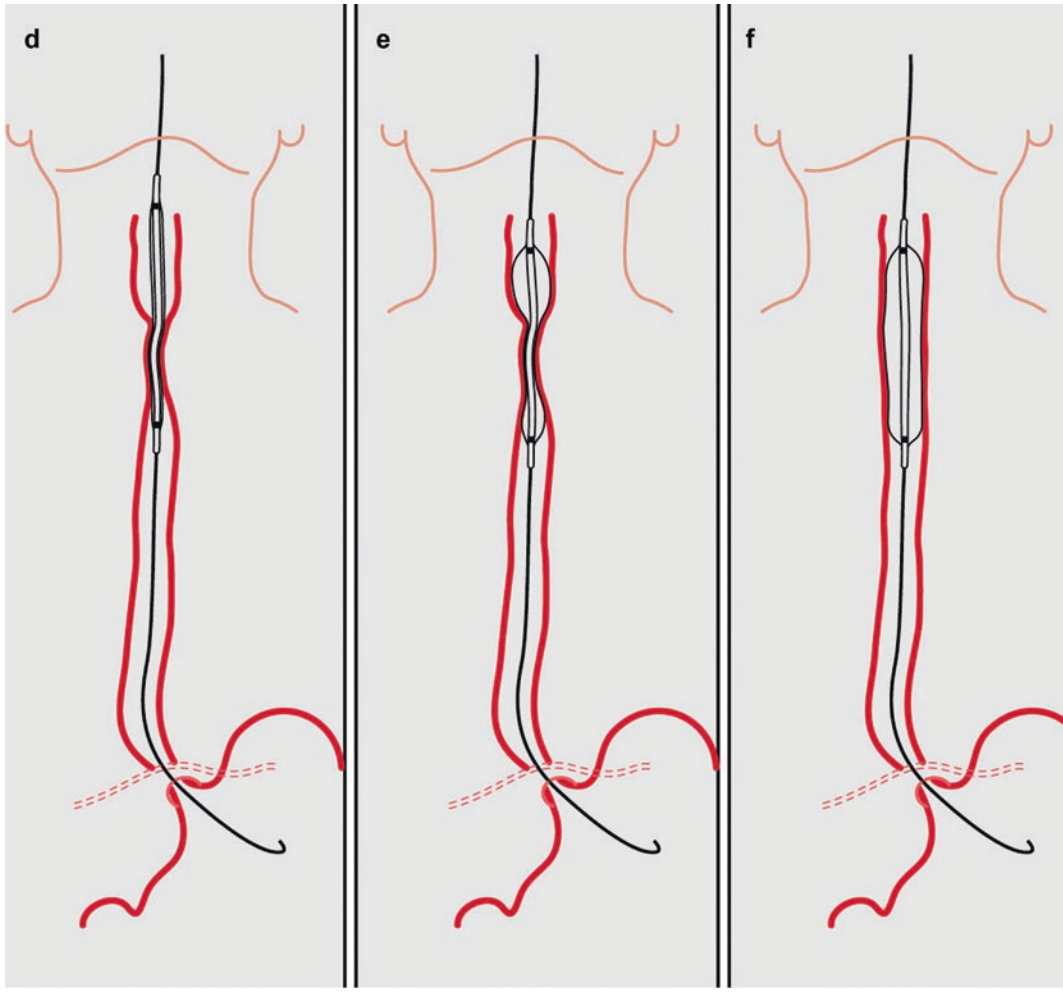

Fig. 67.4 (continued)

Our Outcomes

To date, we have performed 500 fluoroscopically guided hydrostatic balloon dilatations on more than 150 patients with RDEB over an 18-year period (1993–2010). The mean age of our patients at first procedure is 10 ± 8 years (range 1.5–40 years). Sixty percent of patients have had a solitary stricture, and 40 % have had two or more strictures; 85 % of these strictures have been in the proximal esophagus. Balloon diameter has varied from 12 to 22 mm, with a median diameter of 18 mm.

Most of our patients have experienced immediate relief of their symptoms and have been able to resume a normal diet within 24 h of the procedure. All have had significant weight gain 4–6 weeks after dilatation. The mean interval between dilatations has been 1 year, with a range of 1.5 months to 6 years. The median follow-up time has been 7 years (range 1–15 years). Using this technique, we have not encountered any dilatation-related esophageal perforations. Two patients who had dental procedures performed under the same anesthetic developed aspiration postoperatively and required antibiotics and intensive respiratory therapy; they both made a satisfactory recovery.

Radiation and Dilatation

The risks of repeated radiation exposure in EB patients subjected to frequent dilatations must be

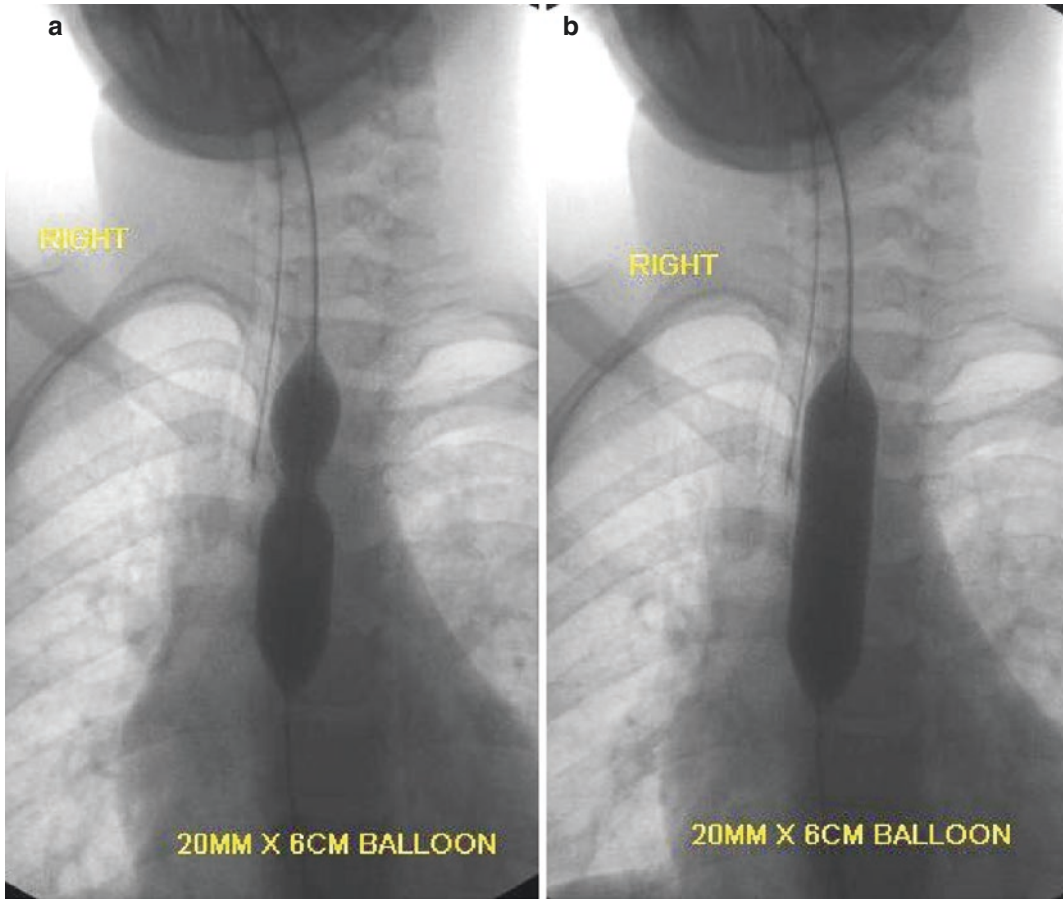

Fig. 67.5 Balloon dilatation of proximal esophageal stricture in a child with RDEB. (**a**) Balloon demonstrates stricture with a narrow waist. (**b**) Effacement of stricture with hydrostatic balloon catheter

balanced against the quality of life achieved from this intervention. Because of the increased risk of squamous cell skin carcinoma in EB patients [22], this is particularly important. It prompts us to adhere to strict radiation protection methods and to be vigilant for early signs of malignancy.

Gastrostomy Tube Placement

Overview

For some (25–30 %) patients, dilatations are not sufficient to counter the effects of nutritional compromise, and placement of a gastrostomy tube for enteral feeding is required [24, 29]. A number of approaches for gastrostomy tube placement have been used successfully. Either open or percutaneous gastrostomy can be performed, with the latter carried out using either an endoscopic or nonendoscopic technique. After gastrostomy tracts have healed and are well established, original tubes can be replaced with low-profile gastrotomy buttons.

When oral intake is insufficient, gastrostomy tube placement guarantees an enteral feeding route and helps to reduce constipation by ensuring adequate hydration. Nevertheless, it also has several disadvantages. It is not always well accepted in teenagers and adults, and many dislike the need for button change. Further, leakage and irritation can occur around the gastrostomy site, incontinence can occur with overnight feeding, and gastroesophageal reflux can worsen [24].

Spectrum of Techniques

The standard open approach with a Stamm gastrostomy is an excellent means of obtaining prompt, secure access to enteral feeding. We use this approach in almost all patients up to the age of approximately 18 months. In this procedure, we use a small upper midline incision, bringing the gastrostomy tube out through a separate paramedial opening in the abdominal wall. Given that the stomach is anchored to the abdominal wall, changing to the button gastrostomy tube can be accomplished within a few weeks.

The other techniques commonly used for gastrostomy insertion include percutaneous endoscopic gastrostomy (PEG) or laparoscopically assisted gastrostomy. Both of these procedures have potential drawbacks. Although PEG insertions are generally a safe and efficient means of obtaining gastric access, an endoscope can contribute to inadvertent esophageal trauma. Although not formally described in the literature, a theoretical drawback of laparoscopically assisted gastrostomy is that peritoneal insufflation with gas distends the abdomen, stretching the overlying skin. This may result in severe blistering and subsequent skin loss with associated pain and wound issues. In view of these considerations, we now employ the "push" technique of nonendoscopic percutaneous gastrostomy for patients older than 18 months of age.

Nonendoscopic Percutaneous Gastrostomy Placement ("Push" Technique)

Potential candidates for nonendoscopic gastrostomy placement must undergo a preoperative assessment with a contrast esophagram and upper gastrointestinal series to look for esophageal strictures and the size and orientation of the stomach. The presence of microgastria or a high-lying stomach makes them unsuitable for this approach, and alternative methods of gastrostomy placement must be used.

In performing this procedure, the edges of the liver and spleen are mapped out with ultrasound and marked on the patient's skin. The transverse and descending colon are outlined by the instillation of 100–150 mL of dilute water-soluble contrast via a rectal catheter under fluoroscopic control. An 8-French umbilical catheter is then passed through the oropharynx into the stomach, and 100–150 mL of air is insufflated radiographically to delineate the stomach. Before gastric insufflation, 0.1 mg of glucagon is administered intravenously to provoke pylorospasm, thereby reducing the amount of air passing into the duodenum during the procedure. The procedure is facilitated by the availability of anteroposterior and cross-table fluoroscopic guidance for gastrostomy tube placement (Fig. 67.6). Three or four needle-mounted T-fasteners are percutaneously passed into the air-filled stomach in a triangular configuration to pull the stomach up against the anterior abdominal wall. The stomach is then percutaneously cannulated with a needle through the midpoint of the T-fasteners. A small amount of water-soluble contrast is injected through the needle cannula to confirm its location within the stomach. A guidewire is then inserted through the needle cannula, and the needle is removed, leaving the guidewire in place. Over the guidewire, the tract is serially dilated to permit the placement of a 16- to 20-French peel-away sheath (depending on the size of the gastrostomy tube to be placed). A 12- to 16-French MIC® (Kimberly Clark-Ballard, Draper, UT) gastrostomy tube with external silicone flange is inserted through the sheath, and the balloon is inflated with sterile water. The T-fasteners are then tied down to anchor the gastrostomy tube flange to the abdominal wall. Each 3/0 nylon suture (mounted to the T-fastener) is passed through a layer of Mepilex® (Mölnlycke Healthcare, Göteburg, Sweden), a dental roll, and the holes in the flange, thus avoiding the placement of skin sutures and enabling anchorage of the entire gastrostomy system to the abdominal wall. A silk tie is then placed around a groove in the flange to prevent the tube and balloon from slipping inward [24, 29].

Postoperative Management

Gastrostomy feeds are begun the following morning, after the tube has been left overnight to drain into a Farrell bag reservoir (Corpak Medsystems Inc, Wheeling, IL). Once patients are established on an enteral feeding regimen (usually 48–72 h postoperatively), they are discharged. The T-fasteners are left in place for 10–12 weeks. For

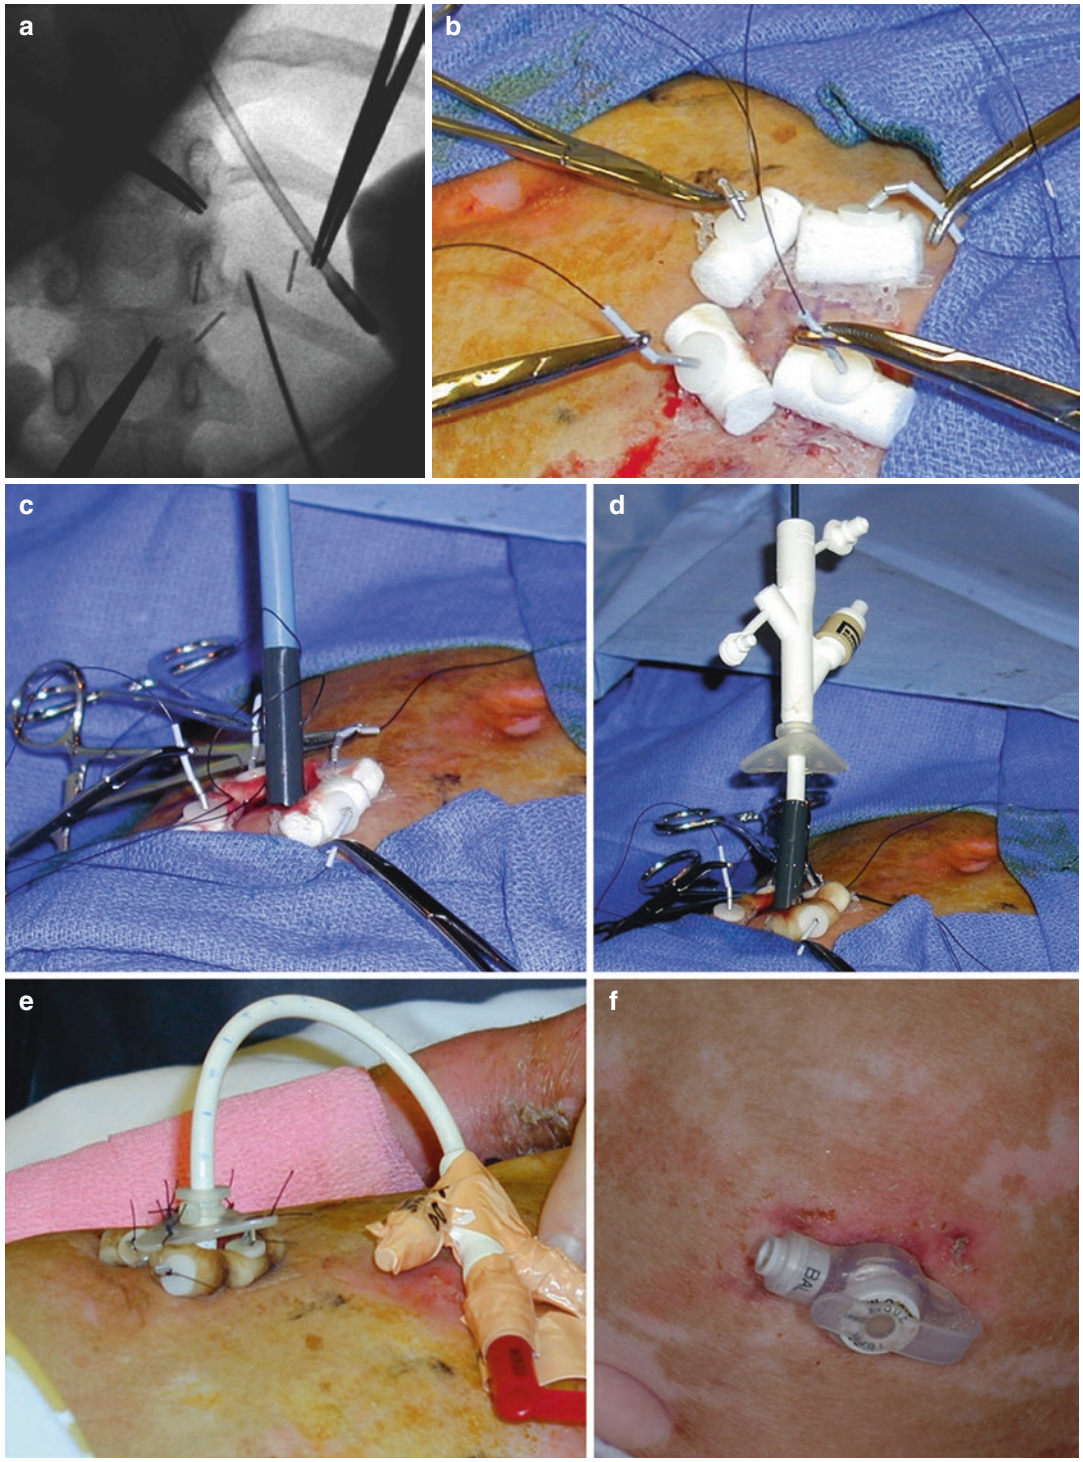

Fig. 67.6 Nonendoscopic percutaneous gastrostomy technique. (**a**, **b**) Percutaneous placement of T-fasteners to anchor stomach to the overlying abdominal wall. Needle will pass into the stomach to permit placement of a guide wire. (**c**) With gentle traction on the T-fasteners, the stomach is cannulated and the tract sequentially dilated to accommodate a large peel-away sheath. (**d**) The gastrostomy tube is placed through the sheath, and the balloon is inflated. (**e**) The catheter and stomach and abdominal wall are secured as a unit by tying the T-fasteners through the flange and securing the flange to the gastrostomy tube. (**f**) Gastrostomy tube site following removal of the initial tube and replacement with a low-profile button gastrostomy

removal, a slight amount of traction is placed on the T-fastener. Concurrently, the gastrostomy tube is replaced with a low-profile button gastrostomy. The T-fastener is then cut flush with the skin while maintaining traction. The gastrostomy stoma can be dressed with a small piece of cut Mepilex® placed between the button gastrostomy and the patient's skin.

Our Outcomes

We have performed nonendoscopic percutaneous gastrostomy tube placement in nine patients (age range 4–9 years) with RDEB. All of these patients had undergone multiple dilatations for esophageal strictures, and every effort had been made to optimize their nutritional status with maximal caloric intake. Despite these measures, they all had persistent growth failure.

All nine patients tolerated the procedure well; all commenced feeds on postoperative day 1; and all had successful gastrostomy button placement at 10–12 weeks postoperatively. Balloon migration obstructing the pylorus occurred in one patient. This complication was attributed to failure to tie the silk suture around the flange and was relieved by repositioning the gastrostomy tube. No other complications were encountered. Two of the nine patients have had subsequent retrograde esophageal dilatation performed through their gastrostomy without difficulty. To date (June 2010), the average follow-up in this group of patients has been 48 months (range 1–9 years). All patients have shown significant gains in weight and height. In addition, parents have noted higher energy and activity levels in their children, as well as less severe blistering and more rapid wound healing than seen before the procedure. As well, we have been able to administer medications more reliably.

Perioperative Care for Esophageal Interventions

The special needs of EB patients mandate comprehensive preoperative planning and assiduous perioperative care. To minimize skin trauma, we place patients on an eggcrate foam mattress before any surgical procedure. To lessen anxiety and decrease unnecessary movement, we generally administer oral midazolam preoperatively. In that skin lesions, low body mass index, and lack of subcutaneous fat predispose patients to the risk of heat loss, warming the operating room is crucial [15].

The surgical team must be cognizant of the fact that simply holding and sealing a facemask on the patient's face can cause serious skin damage under the mandible and around the mouth. Avoiding such complications requires lubricating masks, gloves, and instruments (including the laryngoscope blade) with Aquaphor ointment (Beiersdorf Inc, Wilton, CT) or a similar lubricant.

Because of repeated blistering and scarring, establishing peripheral venous access can be difficult. Our preference is thus to induce anesthesia by mask with inhalation anesthetics. If gaining peripheral intravenous (IV) access is difficult, we use ultrasound guidance and interventional radiology to facilitate IV placement. The skin must be protected from tourniquet and blood pressure cuff application by the placement of layers of gauze or Webril® (Tyco Healthcare, Mansfield, MA) on the skin initially. IV lines should be secured with an atraumatic soft silicone adhesive dressing such as Mepitac® (Mölnlycke Healthcare, Göteburg, Sweden) and gently wrapped with Webril® and Coban wrap (3M, St. Paul, MN). The eyes are lubricated and covered with saline-moistened gauze or taped closed with atraumatic Mepitac tape (Mölnlycke Healthcare, Göteburg, Sweden). The adhesive pulse oximeter probe that is commonly used in pediatric anesthesia is exchanged for a clip-type probe that can be placed on the ear lobe. Alternatively, the adhesive can be removed from the probe, and the probe can be secured in place by using the thin malleable metal strip commonly found in the nosepiece of a surgical facemask. The adhesive rim of electrocardiographic leads should be removed. The leads should be applied to a clear portion of skin on the chest and secured in position with Mepiform® or Mepitac®.

The importance of managing a potentially difficult airway in the setting of fragility of the skin and mucous membranes cannot be overemphasized [19, 20]. Oral airways should be used with caution, if at all, due to the risk of mouth and airway blistering. When possible, we perform endotracheal anesthesia. In patients with microstomia, the tongue is often scarred down to the floor of the mouth, and the teeth are often angled inward, making endotracheal intubation more difficult. All of these factors may necessitate an oral fiber-optic intubation. The endotracheal tube is secured with lubricated cotton tape tied to the tube and placed behind the patient's neck after a protective layer of Mepilex® or Mepilex Lite® has been placed on the skin to avoid traction or shearing forces of the tape on the skin.

Esophageal Replacement

For more than 35 years, esophageal replacements have been rarely performed for severe and recalcitrant esophageal strictures in patients with RDEB [16, 30]. The vast majority of these were colonic interpositions. In a recent analysis of the National Epidermolysis Bullosa Registry of 3,280 EB patients, only 16 patients had colonic interpositions [14]. All of these patients had a subtype of RDEB and accounted for less than 5 % of the RDEB patients in the registry. While reported complication rates and mortality for non-EB patients undergoing colonic interposition are a significant 30 % and 3 %, respectively, there is inadequate published data as to outcomes with this group of EB patients. However, Fine et al. report that EB patients who have had a successful interposition seem to do well and are satisfied with their ability to maintain adequate enteral intake [14].

Part XII

The Gastroesophageal Junction

Lower Esophageal Sphincter: Normal Structure and Function

68

Osvaldo Borrelli and Nikhil Thapar

Introduction

The esophagus acts as a conduit for the coordinated transport of food from the mouth to the stomach. Developmentally, it can be identified as a distinct structure from 4 weeks of gestation. At birth, it has a length of approximately 8 cm, which doubles in the first years of extrauterine life. Each of the three germ layers (endoderm, ectoderm, and mesoderm) is responsible for esophageal development, and their interactions are crucial for the development of the mucosa, muscular coats, and intrinsic nervous system.

Although the esophagus is capable of peristalsis during the first trimester of gestation, more complex patterns of esophageal motility are detected during the second trimester. By birth, motility of the esophagus functionally consists of three regions, corresponding to the upper esophageal sphincter (UES), body of the esophagus, and lower esophageal sphincter (LES). This chapter relates to the normal structure and function of the LES.

The Lower Esophageal Sphincter

Normal Anatomy and Function

The lower esophageal sphincter (LES) is a complex high-pressure zone localized at the esophagogastric junction, which regulates the flow of contents between the esophagus and the stomach (Fig. 68.1). Intrinsic smooth muscle fibers of the distal esophagus (LES) constitute the intrinsic active component of the sphincteric mechanism at the esophagogastric junction, whereas the skeletal muscle of the diaphragm represents the extrinsic active component [1]. Since the two components are anatomically superimposed and anchored to each other by the phrenoesophageal ligament that extends from the inferior diaphragmatic surface to the distal esophagus, the LES and crural diaphragm function as a well-coordinated and efficient functional unit. The muscles of the LES are thicker than those of the adjacent esophagus and are not completely arranged in a circular fashion. Distally, they are split into two segments: one straddles the greater curvature and is parallel to the sling fiber of the stomach, and the other consists of short clasps that straddle the lesser curvature and join the gastric sling fibers, which play a key role in the formation and modulation of the angle of His [1]. The LES is tonically contracted at rest to produce a roughly concentric occlusion. However, the occlusion is not perfectly uniform, showing a radial asymmetry

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_68

[2]. In adults, the LES is 2–4 cm long, whereas in children its length increases with age, ranging from few millimeters in newborns to adult values in adolescents [3, 4]. In adults, as in older children, the proximal 1.5–2 cm of the sphincter is above the squamocolumnar mucosal junction and completely encircled by the crural diaphragm, whereas the distal 2 cm is below the squamocolumnar mucosal junction [1]. Consequently, the proximal part of the sphincter lies in the esophageal hiatus and the distal 2 cm in the abdominal cavity. Sphincteric exposure to high intra-abdominal pressures is likely to contribute to the maintenance of EGJ competence. At 8 weeks of gestation, the abdominal portion of sphincter is wide and large; gradually, it shortens so that in newborns the intra-abdominal portion of the sphincter is very short or completely absent, predicting the increased possibility of developing gastroesophageal reflux [3]. Other mechanisms explaining the greater frequency of gastroesophageal reflux in infants include the less oblique angle of insertion of the esophagus into the stomach. However, the exact role of these predisposing factors in determining GER in infants is still largely unknown [5, 6].

Afferent sensory information from the LES to the brain runs in both spinal and vagal sensory afferents. Spinal afferents have their cell bodies in the dorsal root ganglia at T1–L3, whereas vagal afferents have cell bodies in the nodose ganglia [1, 7, 8]. The afferent stimuli travel to the sensory nucleus (NTS), which is closely connected with the dorsal root (DMN) of the vagus nerve [1, 7, 8]. The latter provides parallel inhibitory and excitatory motor innervation to the LES. The rostral neurons in the DMN preferentially give rise to the innervation of the excitatory vagal pathway, whereas neurons in the caudal regions give rise to the inhibitory vagal pathway [8]. Excitatory preganglionic neurons are cholinergic in nature and synapse on postganglionic nitrergic inhibitory neurons localized in the myenteric plexus [8]. Inhibitory preganglionic neurons are also cholinergic in nature and synapse onto postganglionic cholinergic excitatory neurons localized in the myenteric plexus [8]. Myenteric motor neurons to the LES are also innervated by postganglionic sympathetic neurons. However, the vagus nerve exerts the main regulatory action on the LES, whereas sympathetic neurons exert only a modulatory role [1, 7, 8].

One of the main functions of the LES is to create a high-pressure zone for preventing retrograde movement of gastric content into the esophagus. The LES is tonically contracted at rest (Fig. 68.1), exhibiting both radial and axial pressure asymmetries [9]. The LES resting tone is determined by three influences (Fig. 68.2): myogenic properties of sphincteric smooth muscle cells, which are independent of any neural influences and may be produced by ionic movement (i.e., calcium) through smooth muscle cell membranes; cholinergic excitatory activity; and nitrergic inhibitory activity [4, 10]. Excitatory cholinergic neurons and the tonic myogenic property of the LES stimulate contraction, whereas the inhibitory nitrergic pathway favors relaxation [10]. Thus, the net balance between these influences determines the final resting pressure of the LES.

LES pressure is influenced by several factors (Table 68.1). It is significantly variable during the interdigestive migrating motor complex (MMC) cycle. There is a pattern of LES contraction closely related to the phase of MMC in the stomach, showing higher LES pressure during MMC phase III than in phase I [11]. Postprandial LES pressure is rather constant at a level comparable with that measured during phase I of the MMC [11]. LES pressure also shows inspiratory augmentation due to contraction of the crural diaphragm encircling the sphincter [1]. LES pressure is also modified by intra-abdominal pressure, gastric distension, peptides, hormones, various foods, and many drugs [4, 10].

During swallowing and belching, the LES promptly relaxes in order to allow the passage of ingested food or air in appropriate directions (Fig. 68.3). At the time of swallowing, the LES relaxes promptly in response to the initial neural discharge from the swallowing center in order to minimize resistance to flow across the esophagogastric junction [1]. This relaxation starts within 2 s after the peristaltic contraction has begun in the

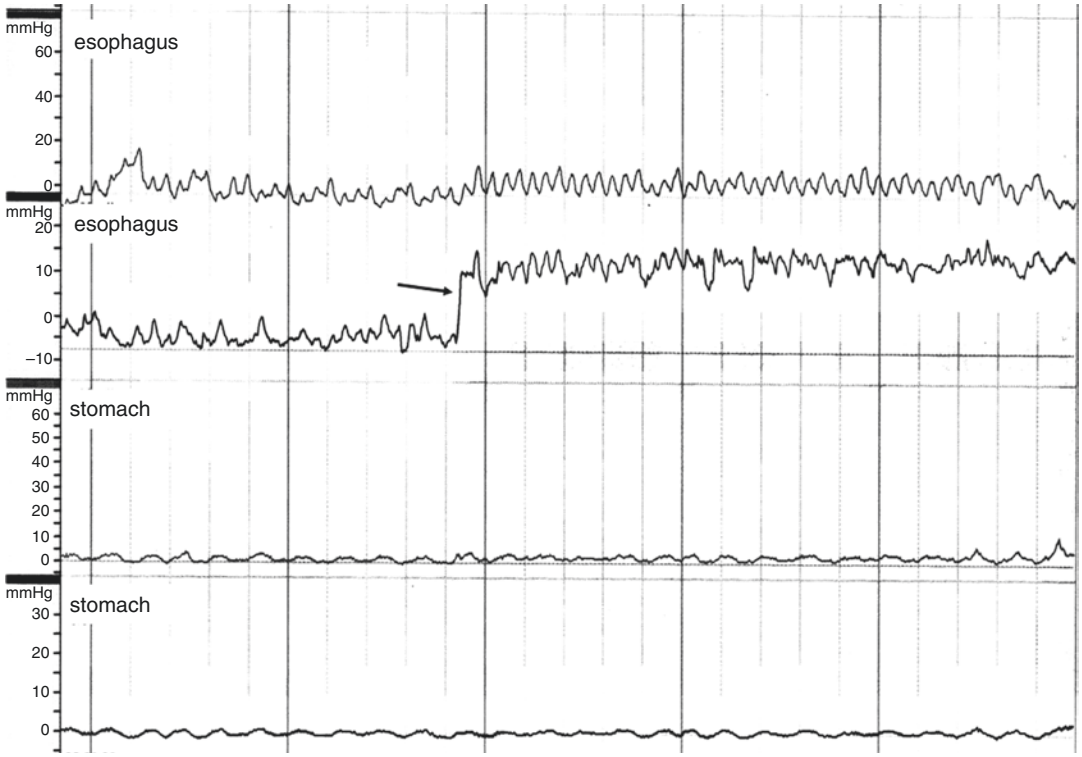

Fig. 68.1 Manometric tracing at the level of the distal esophagus and stomach. From *top* to *bottom*: distal esophagus (first channel), lower esophageal sphincter (second channel), stomach (third and fourth channels). At the level of the second channel, there is a sudden rise in the pressure profile (*arrow*) corresponding to the entrance of the recording side hole of a manometric catheter into the lower esophageal sphincter

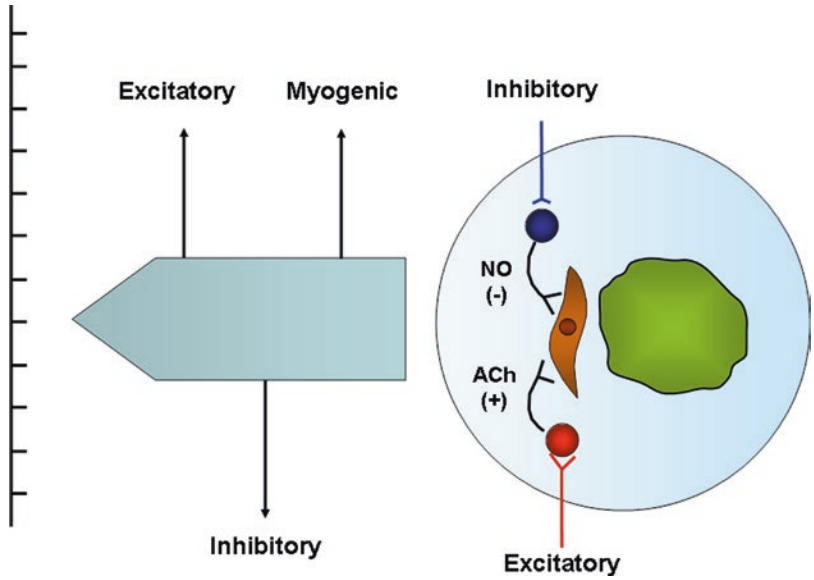

Fig. 68.2 Three mechanisms involved in the regulation of basal LES tone

Table 68.1 Factors affecting lower esophageal sphincter pressure

Factor	Increase LESP	Decrease LESP
Hormones	Gastrin, motilin, substance P, bombesin, galanin, pancreatic polypeptide, somatostatin	Secretin, CCK, glucagon, VIP, progesterone, calcitonin gene-related peptide (CGRP)
Neural agents	α-Adrenergic agonist, β-adrenergic antagonist, cholinergic agonist, serotonin	α-Adrenergic antagonist, β-adrenergic agonist, cholinergic antagonist, nitric oxide (NO)
Medications	Metoclopramide, domperidone, cisapride, histamine, prostaglandin F_{2a} erythromycin (motilin receptor agonist)	Nitrates, calcium channel blockers, theophylline, morphine, meperidine, diazepam, sildenafil, prostaglandin E_1, prostaglandin E_2
Food	Protein	Fat, chocolate, ethanol, peppermint

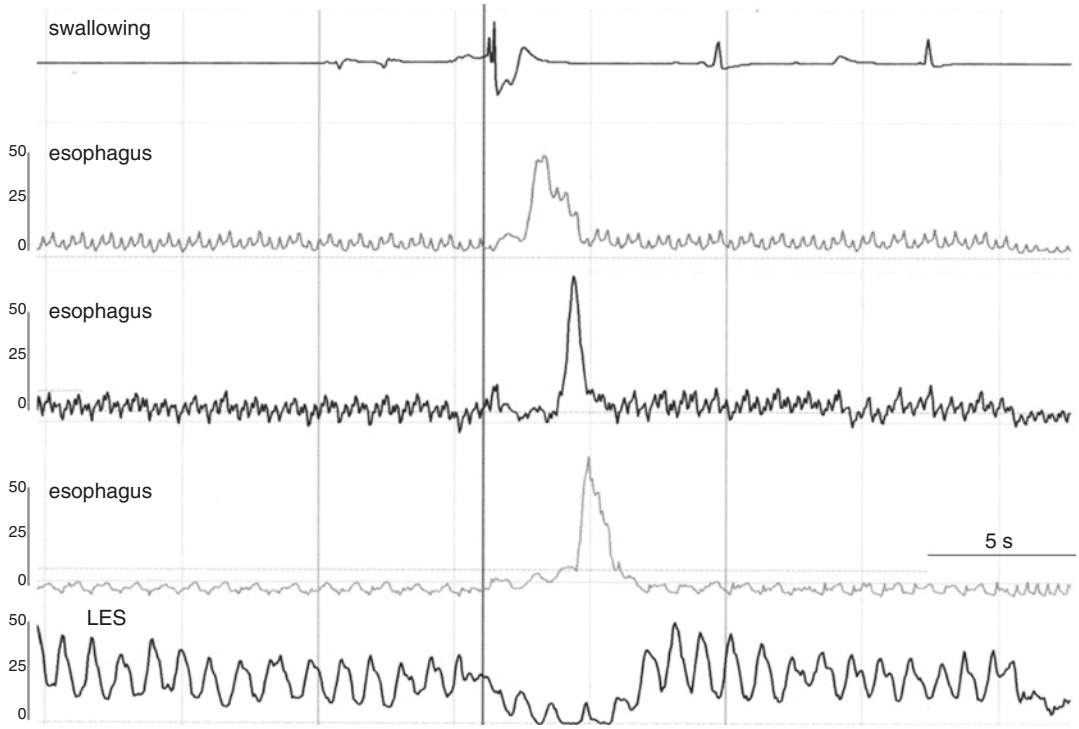

Fig. 68.3 Manometric recording of the esophageal peristalsis (second, third, and fourth channels) and relaxation of the lower esophageal sphincter (fifth channel). The first channel records the swallowing activity

proximal esophagus and lasts 5–10 s until the peristaltic wave reaches the distal esophagus. During relaxation, LES pressure falls to the level of gastric pressure. As the LES relaxes (an active process), it is passively opened by the bolus and propelled by the peristaltic wave. LES relaxation is followed by an after-contraction of the upper part of the sphincter, which likely represents the end of contraction wave as it reaches the distal esophagus [4]. Swallow-induced LES relaxation is part of primary peristalsis [1, 7, 8]. Central control is provided by preganglionic parasympathetic neurons originating in the nuclei of dorsal vagal complex, represented by the NTS, which receives sensory information from the pharynx and by the DMN, which contains preganglionic motor output to the LES [1, 7, 8]. Nitric oxide (NO) and acetylcholine are the principal neurotransmitters involved in the neural network at the DMN, even though γ-aminobutyric acid (GABA) is involved in the control of preganglionic neurons [12, 13]. The axons of preganglionic parasympathetic neurons

synapse with intramural inhibitory neurons. Convincing evidence supports the role of NO as the main postganglionic neurotransmitter mediating swallow-induced relaxation of the LES [13].

Transient relaxation of the LES refers to relaxation that is unrelated to either swallowing or secondary peristalsis. Transient LES relaxations (TLESRs) occur in healthy persons and represent the mechanism by which gas is vented from the stomach during belching [14]. Characteristically, they are associated with inhibition of the crural diaphragm [15]. TLESRs are of longer duration than swallow-induced relaxation of the LES, lasting between 10 and 45 s [16]. Manometric criteria for defining TLESR include: (1) the absence of a pharyngeal swallow for 4 s before and 2 s after the beginning of LES relaxation; (2) LES pressure falls of 1 mmHg/s; (3) $\leq$ 10 s to complete the relaxation of the LES; and (4) a nadir pressure during the relaxation $\leq$2 mmHg [16]. TLESRs are a neural reflex involving afferent and efferent pathways and a central pattern generator, corresponding to the nuclei of dorsal vagal complex [1, 8]. The afferent pathway is activated by stimulation of tension receptors in the proximal stomach, particularly the sub-cardial region, as well as by pharyngeal stimuli. Afferent neurons, through the vagus, travel to the NTS and the DMN via interneurons. The efferent pathway involves the same efferent neural pathways of swallow-induced LES relaxation. However, because the crural diaphragm is also inhibited during TLESRs, the phrenic nerve nucleus located in the spinal cord may also be involved [1]. TLESRs are more frequent in the seated position, with large meals, and in response to higher intragastric osmolarity. Although TLESRs are an essential component of belch reflex, they also represent the predominant mechanism underlying gastroesophageal reflux (GER) episodes in both normal and patients with GER disease (GERD). The proportion of reflux episodes attributable to TLESRs ranges between 100 % in children with nonerosive reflux disease (NERD) and healthy adults, compared to 60–80 % in children and adults with erosive esophagitis [17–20].

In children, LES pressure ranges between 10 and 40 mmHg [21, 22]. LES pressures of 5 mmHg above intragastric pressure are sufficient to maintain esophagogastric competence [1, 23]. Using a perfused side-hole pull-through technique, LES pressure was reported as very low in preterm infants, increasing from ~4 mmHg in premature infants younger than 29 weeks of age to 18 mmHg in term infants [24, 25]. By employing a micromanometric assembly with a sleeve device, LES pressure can be detected in preterm infants from 26 weeks of gestation [26]. In very premature infants, LES pressure ranges between 5 and 20 mmHg and promptly relaxes with swallowing, indicating full development of the central control of swallow-induced LES relaxation [27]. In addition, LES pressure in premature infants fluctuates substantially over time and significantly decreases after feeding. In both premature infants and term infants, TLESRs are the predominant mechanisms underlying GER episodes, indicating that the neural pathway responsible for transient inhibition of LES tone is already fully developed [26, 27]. Thus, LES motor patterns in premature infants are almost identical to those recorded in older children and adults.

Gastroesophageal Junction: The Mucosa – Anatomy and Cell Types

69

Marta C. Cohen

Concept of GEJ

The gastroesophageal junction (GEJ) is anatomically defined by the proximal limit of the gastric folds. Histologically, it is characterized by the presence of a squamocolumnar junctional epithelium. In normal conditions, the anatomic GEJ also corresponds to the histologic transition between the esophageal squamous mucosa and the gastric mucinous columnar epithelium [5].

The squamocolumnar junction (Z line) is visible endoscopically and affords a key marker of the GEJ. To the naked eye, the Z line presents as a serrated line where small projections of red gastric epithelium converge with the whitish esophageal squamous mucosa (Fig. 69.1) [7]. The inlets of gastric mucosa are approximately 5 mm long and 3 mm wide, conferring the mucosa of the GEJ an irregular appearance, also known as ora serrata. Occasionally, the squamocolumnar junction of the GEJ may be straight. This most frequently occurs in the presence of a lower mucosal ring (Schatzki's ring) [7].

The mucosal GEJ usually lies within the lower esophageal sphincter and is found within 2 cm of the proximal edge of the gastric folds [7]. The distal esophagus may appear lined by columnar cells, also known as cardiac-type mucosa [11]. The term cardia is then equally used to refer to that part of the gastric mucosa that lies around the lower esophageal sphincter and to the columnar mucosa that can be found at the distal esophagus.

Anatomy

The wall of the esophagus is described as constituted by four layers: mucosa, submucosa, muscularis propria, and serosa.

Cardiac Mucosa

There is great controversy regarding the nature and the origin of the cardiac-type mucosa at the GEJ. The view that the distal 2–3 cm of the esophagus is normally lined by columnar cardiac-type mucosa, extending between the esophageal squamous mucosa and the gastric acid-producing oxyntic mucosa, is denied by some investigators [4]. Chandrasoma et al. [4], in a retrospective and prospective autopsy study performed in pediatric and adult patients, demonstrated that columnar/cardiac mucosa was not identified in up to 70 % of the cases. These results are similar to an endoscopic study that reported the absence of cardiac mucosa in biopsies from the GEJ in 65 % of endoscopically normal patients [13]. These authors expressed the view that, even if present,

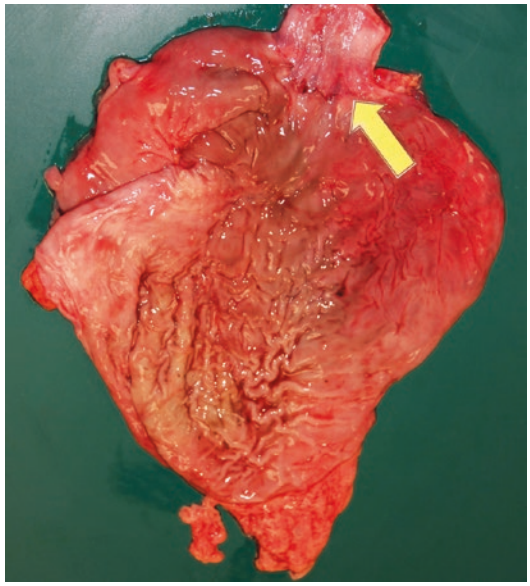

Fig. 69.1 Postmortem specimen from a 4-year-old child showing the irregular gastroesophageal junction (*arrow*) where the white esophageal mucosa joins the red gastric mucosa

cardiac mucosa and oxyntocardiac mucosa demonstrated considerable circumferential variation among individuals. They concluded that, when seen, the length of cardiac mucosa or oxyntocardiac mucosa in virtually all children is less than the 1–2 cm which is considered normal four decades ago [4, 11]. Moreover, the authors suggested that the presence of cardiac or oxyntocardiac mucosa represents early histological evidence of gastroesophageal reflux [4].

On the contrary, other investigators consider that cardiac mucosa is a normal structure at the GEJ and that it is defined by the presence of mucous cells without regard to the presence or absence of parietal cells (oxyntic mucosa) [14]. Cardiac mucosa was identified in all 33 autopsied children although with a usual length of less than 2 mm [14]. Another study conducted in fetal and pediatric postmortems concluded that cardiac mucosa contains both mucous and mixed glands, varies with age, is gastric (rather than esophageal) in origin, and does not develop before 13 weeks of gestational age [18]. More recently, a postmortem study performed in 253 unselected patients confirmed that cardiac mucosa was uniformly present adjacent to the squamous epithelium at the GEJ (either as pure cardiac mucosa or as oxyntocardiac mucosa), arguing against the hypothesis that cardiac mucosa is an acquired metaplastic lesion [16]. In our experience, columnar-lined cardiac-type mucosa is usually seen at the GEJ in fetuses (Fig. 69.2a) and children (Fig. 69.2b). Interestingly, the columnar cells of the cardiac-type mucosa present at the distal esophagus/GEJ region contain neutral mucins and can also contain acidic mucins [6, 16]. Both types of acidic mucins are more often present in the underlying glands (Fig. 69.2c).

As the cardiac mucosa narrows and changes with age [9, 10], it is likely that the older age of the patients studied by those who deny the existence of native cardiac mucosa in the upper stomach was a confounding factor [1–4, 8, 17]. Despite this debate, it has been suggested that it is still possible that a metaplastic expansion of the cardiac mucosa into the distal esophagus can occur as part of the stepwise transformation of the mucosa as a consequence of long-standing gastroesophageal reflux [6].

The Squamous Mucosa

The mucosa is composed of the lamina propria and the muscularis mucosae, both lined by epithelium. This is most usually non-keratinizing squamous epithelium (Fig. 69.3). As indicated above, in children, a short segment of the esophageal mucosa at the level of the GEJ can be lined by columnar (cardiac type) epithelium.

The non-keratinizing squamous epithelium is composed of three major cell layers: a deep basal cell layer, an intermediate or prickle cell layer, and a superficial functional cell layer.

The basal cell layer rests on the basement membrane and is the regenerative part of the mucosa. Basal cells are cuboidal and the layer is up to three cells deep or less than 15 % of the total mucosal thickness (Fig. 69.4). In comparison with the intermediate and superficial squamous cells of the mucosa, the basal cells appear smaller and darker. This is because their shape is cuboidal rather than polygonal, and they contain less

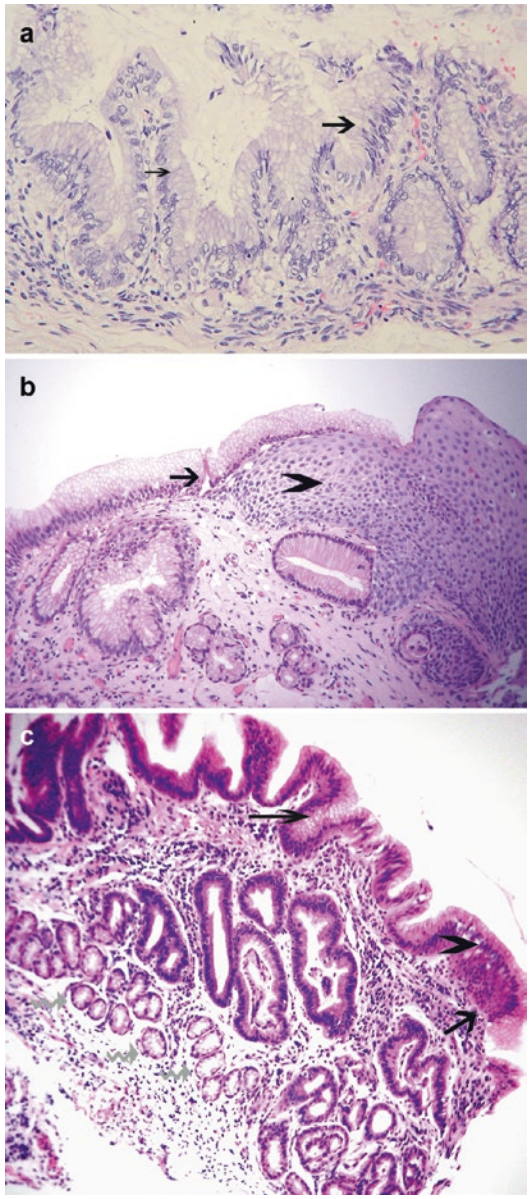

Fig. 69.2 Columnar cardiac-type mucosa is usually present at the gastroesophageal junction in fetuses (**a**, hematoxylin and eosin stain × 20) and children (**b**, hematoxylin and eosin × 20). Note in (**b**) how the squamous non-keratinizing epithelium (*arrow head*) is in direct contact with the columnar cardiac-type mucosa (*arrow*). Mucous-secreting glands are seen in the lamina propria (**c**, *curved arrow*) present below the columnar epithelium (*straight arrow*)

glycogen compared with the more superficial squamous cells. In the distal esophagus, and at the GEJ, it is not uncommon that the basal cell

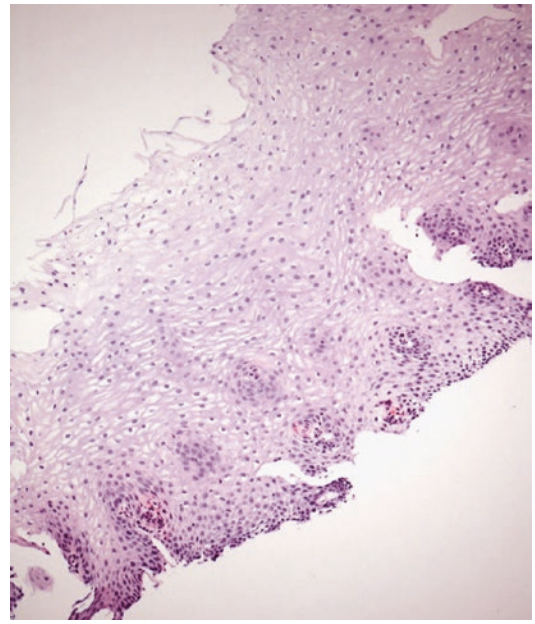

Fig. 69.3 Most of the esophageal mucosa is lined by non-keratinizing squamous epithelium (hematoxylin and eosin stain × 10)

layer is thickened and the papillae appear elongated and increase in number (Fig. 69.5). In cases of gastroesophageal reflux, the basal cell layer of the mucosa proliferates as a response to the increased turnover of the epithelium and becomes hyperplastic (it contains more than three cells in thickness) [7].

The intermediate or prickle cell layer is composed of several layers of polygonal cells with numerous intercellular bridges [12]. The superficial functional layer contains pale cells, rich in glycogen, gradually flattened, and with pyknotic nuclei. In addition, their long axis gradually becomes parallel to the basal membrane (Fig. 69.4).

T-cell lymphocytes are seen in an intraepithelial location. In normal patients, they are less than 6/high-power field [15]. Most of these lymphocytes have a cytotoxic immunoprofile (CD3+ and CD8+) [12] and are usually seen above the basal cell layer [7]. They "squeeze" between epithelial cells, making their nuclei to adopt an angulated shape, responsible for the name "squiggle" or "wiggly" cells, to which they are sometimes referred [12].

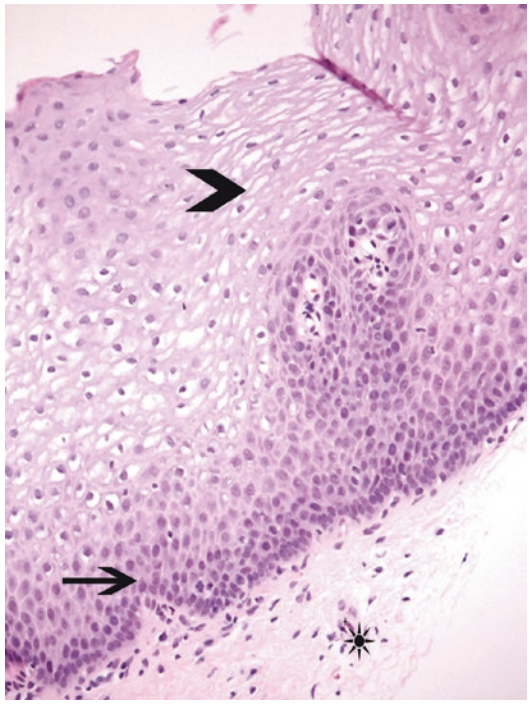

Fig. 69.4 The squamous non-keratinizing epithelium lining the esophageal mucosa is composed by a deep basal cell layer (*arrow*), an intermediate layer, and a superficial functional cell layers (*arrow head*). The epithelium lies above the lamina propria (*star*) (hematoxylin and eosin × 20)

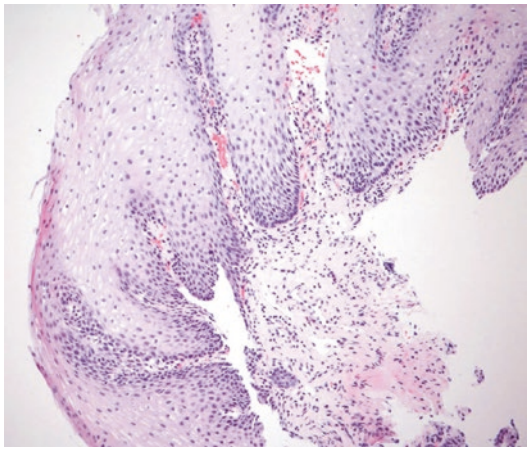

Fig. 69.5 At the distal esophagus, the basal cell layer is normally thickened, and the papillae appear elongated and increased in number (hematoxylin and eosin × 10)

Other cells present in the mucosa include endocrine cells, rare melanocytes, and Langerhans cells. The latter is part of the local immune system and acts as antigen-presenting cells. Occasionally mast cells and single eosinophils can be found in the epithelium of the normal GEJ [12].

The normal mucosa has innate mechanisms of resistance against reflux. Several factors contribute to the resistance of the epithelium against regurgitated gastric contents [12]: the epithelial integrity maintained by the processes of cell proliferation, differentiation and regeneration; the small amount of mucus that normally covers the luminal side of the mucosa; the acidic muco-substances present in the intercellular spaces of the intermediate and superficial layers of the non-keratinizing squamous mucosa; the cell junctions that provide protection against the penetration of toxic substances; the immune response provided by intraepithelial T lymphocytes and antigen-presenting Langerhans cells: and the presence of stromal papillae which contain capillary blood vessels that provide nutritional support among other benefits to the epithelial cells.

The Lamina Propria

This is comprised of loose connective tissue located between the muscularis mucosae and the epithelium (Fig. 69.4). It contains vessels and mucus-secreting glands. The local immune system is represented by a few T lymphocytes of CD4 (helper) and CD8 (cytotoxic) phenotype, alongside IgA-secreting plasma cells [7]. The connective tissue projects into the overlying epithelium as papillae. These contain delicate blood vessels that nourish the mucosa. In normal conditions, the papillae do not reach the upper third of the epithelium. However, in circumstances of gastroesophageal reflux, they become hyperplastic, reaching the most superficial part of the squamous mucosa. These features can be seen in normal patients at the very distal end of the esophagus.

The glands present in the lamina propria of the GEJ are mucous-secreting cardiac-type glands.

The Muscularis Mucosae

It is composed of longitudinal-oriented smooth muscle fibers and is characteristically thicker at the distal esophagus (GEJ) than in other segments of the esophagus.

The Submucosa

This is composed of connective tissue containing blood vessels, nerves, and mucus-secreting glands. These glands have a lobulated shape, produce acid mucins, and drain to the surface of the esophagus by squamous-lined ducts.

Epidemiology of Gastroesophageal Reflux Disease

70

Michael A. Manfredi

Introduction

In preparing to write a chapter on the epidemiology of infant and childhood gastroesophageal reflux (GER), it becomes quite apparent that many more questions arise than answers. In a large part, this is due to the lack of standard definitions, the variability in the tests used to diagnose GER, and the absence of large population-based and multicenter trials. Therefore, the true prevalence of GER in children is in fact unknown. In this chapter, we will discuss what is known about the epidemiology of pediatric GER as well as define the areas that need further research and investigation.

GER is one of the most common gastrointestinal disorders in adults. It has been reported that 10–20 % of adults in the Western population have weekly symptoms defined by at least weekly heartburn and/or acid regurgitation [1]. In Asia the prevalence is lower at less 5 %. The pediatric literature has lacked the multicenter trials necessary to capture the true prevalence of GER.

The Pediatric Health Information Survey (PHIS) database is a data collection system for 28 pediatric hospitals across the United States developed in order to assess the length of hospital stay and charges associated with different pediatric diseases. Gibbons et al. retrospectively reviewed the PHIS database for gastroesophageal reflux disease (GERD) from 1995 to 2000, which encompassed 1.8 million discharges. GERD represented approximately 4 % of all pediatric hospital admissions annually, and admissions for GERD have been increasing significantly during the past 5 years, the highest rate being in the 12- to 24-month age group, with a male predominance for all ages [2].

A cohort study in the United Kingdom was performed using data extracted from The Health Improvement Network (THIN), which is a primary care medical research database containing systematically recorded anonymous records for participating primary care practices [3]. There were approximately 2.3 million patients at the time of the study, which is approximately 4 % of the total UK population. In the study years of 2000–2005, a total of 1700 children and adolescents were recorded with a first diagnosis of GERD. The incidence of GERD was 0.84 per 1000 person-years. Further stratifying the incidence by age, we see that the incidence of GERD for 1-year-old children was 1.48 per 1000 person-years. Incidence then decreased until the age of 12 years, but increased after this age to a maximum at age 16–17 years of 2.26 per 1000 person-years for girls and 1.75 per 1000 person-years for boys. The annual prevalence of GER in 2003 was 1.05 % with an overall prevalence during the whole study period of 1.25 %. This and the previous study were both limited since they were both

retrospective and they relied on billing and/or diagnosis codes. These codes do not rely on standardized definition of GER so the accuracy of the diagnosis is questionable.

GER Definitions

The first attempt at defining and characterizing GER in infants was the Rome II criteria [4]. Regurgitation is the involuntary return of previously swallowed food or secretions into or out of the mouth. This article also gave criteria for infant regurgitation which include (1) regurgitation two or more times per day for 3 or more weeks. (2) There is no retching, hematemesis, aspiration, apnea, failure to thrive, or abnormal posturing. (3) The infant must be 1–12 months of age and otherwise healthy. (4) There is no evidence of metabolic, gastrointestinal, or central nervous system disease to explain the symptom (see Table 70.1). Rome II, however, did not define or give criteria for childhood GER.

Recently an international group of pediatric gastroenterologists using a modified Delphi technique came up with consensus statements on the definition of gastroesophageal reflux disease (GERD) in the pediatric population [5]. This was developed in a similar way to the Montreal definition of gastroesophageal reflux in adults. Through this process, regurgitation in pediatrics is defined as the passage of refluxed contents into the pharynx or mouth or from the mouth. GERD is defined as the reflux of gastric contents that causes troublesome symptoms and/or complications. The definition of GERD is complicated by unreliable reporting of symptoms in children less than 8 years of age. Regurgitation is a characteristic symptom of reflux in infants, but is neither necessary nor sufficient for a diagnosis of GERD, because it is not sensitive or specific. The Delphi technique was a rigorous process with the intended use of developing new clinical practice guidelines as well as standardizing future pediatric population-based studies of reflux symptoms.

Table 70.1 Rome II criteria for infant regurgitation

Diagnostic criteria
1. Regurgitation two or more times per day for 3 or more weeks
2. There is no retching, hematemesis, aspiration, apnea, failure to thrive, or abnormal posturing
3. The infant must be 1–12 months of age and otherwise healthy
4. There is no evidence of metabolic, gastrointestinal, or central nervous system disease to explain the symptom

Prevalence of GER in Infants

Much of the prevalence data for infant GER comes from a single study that surveyed 948 infants from 19 pediatric practices in the Midwestern United States [6]. Regurgitation of at least one episode a day was reported in half of 0–3 months old. This symptom decreased to 5 % at 10–12 months of age ($p < 0.001$). The peak reported regurgitation was 67 % at 4 months; the prevalence of symptoms decreased dramatically from 61 to 21 % between 6 and 7 months of age. Peak regurgitation reported as a "problem" by parents was most often seen at 6 months (23 %); this prevalence decreased to 14 % at 7 months of age. Since Nelson and colleagues' initial prevalence study, there have been several other studies looking at the prevalence of infant GER. Martin et al. looked at a large Australian infant cohort ($n = 1981$) and found of peak prevalence of GE reflux of 41 % between 3 and 4 months of age and thereafter declined to <5 % between 13 and 14 months of age [7]. Campanozzi et al. prospectively followed an Italian cohort of 2642 patients aged 0–12 months [8]. Unlike the previous two studies, this study used a standard agreed upon definition of GER. They used the Rome II definition for GER and found that 313 infants (12 %) had GER. This study also followed these children over 2 years and found that GER resolved in 27 % by 6 months and 61 % at 1 year of age.

Prevalence studies looking at GER in different ethnic populations have also been performed. Miyazawa et al. looked at a cohort of 921 Japanese infants and found that 47.1 % had one or more regurgitation or vomiting episode per day at 1 month [9]. This proportion decreased to

28.8 % at 4 months old and 6.4 % at 7 months old. There was no significant difference in the prevalence of regurgitation or vomiting between breast-fed infants and formula-fed or mixed-feeding infants. Osatakul et al. looked at a cohort of 145 Thai infants in a 1-year study. The prevalence of reflux regurgitation peaked at 2 months at 86.9 % and significantly decreased to 69.7 % at 4 months, 45.5 % at 6 months, and 22.8 % at 8 months [10]. At 1 year of age, only 7.6 % of infants had reflux regurgitation, and again there was no significant difference in prevalence of reflux regurgitation between breast-fed and bottle-fed infants. We therefore see that GER in infancy is common and a majority of symptoms resolve within the first year of life; however, there are variations in reported prevalence that may be related to ethnicities or due to the definition of GER used in the study.

Prevalence of GER in Childhood

Nelson et al. in another cross-sectional survey of Midwest pediatric practices examined the prevalence of GER symptoms in children [11]. The parents of 566 children aged 3–9 were surveyed and reported symptoms of heartburn (1.8 %), epigastric pain (7.2 %), and regurgitation (2.3 %). In addition 615 children with an age range of 10–17 were surveyed. The prevalence of heartburn, epigastric pain, and regurgitation was 5.2 %, 5.0 %, and 8.2 %, respectively.

Prevalence of GER Complication in Children

The prevalence of GER complications in children is also not well described. El-Serag et al. retrospectively reviewed 402 children who underwent upper endoscopy with the diagnosis of GER. In this study one third of these patients had endoscopic evidence of erosive esophagitis [12]. Another complication of GER is Barrett's esophagus. In adult population studies, it appears that Barrett's is uncommon in the general population with an incidence of 1.3–1.6 % [13]. The prevalence of Barrett's esophagus in children is not well characterized. In the El-Serag study, they suspected Barrett's in 2.7 % of patients; however, there was no histological evidence in those same patients [12]. The Pediatric Health Information System database suggested that the prevalence of Barrett's rose from less than 2 % in 1997 to 3.8 % in the first 6 months of 2000; however, since this is based on coding data, the accuracy of this data is questionable [14].

Prevalence of GER in Special Pediatric Populations

Prematurity

GER is a common finding in premature infants. It has been reported that that GER occurs on average three to five times per hour in premature babies [15]. There have been single-center studies showing more that 85 % or premature infants have GER proven by pH monitoring [2]. This common clinical diagnosis has been associated with longer NICU stays and higher hospital costs [16, 17]. When the promotility medication cisapride was on the market, a study showed that 19 % of premature infants admitted to teaching hospitals in the United States received this medication [18]. A retrospective study of extremely low birth infants from the National Institute of Child Health and Human Development (NICHD) network centers showed that 25 % of infants were discharged home on medications for GER [19].

Like in infant and childhood reflux, there is considerable variability between NICU units for diagnosing and managing GER. Dhillon et al. demonstrated that the diagnosis of GER was extremely heterogeneous in 77 neonatal intensive care units in the United Kingdom [20]. In this study, GER was diagnosed based solely on clinical grounds in 42 % of units; despite the availability of pH monitoring in 93 % of units, it was only used in 32 % of suspected GER patients. Another study by neonatologists, gastroenterologists, and pulmonologists surveyed on the symptoms, treatment, and diagnosis of GER in premature infants. This study revealed a near-complete disagreement between specialists [21].

Neurologically Impaired

The prevalence of GER has been well reported in neurologically impaired children. There is a wide reported incidence range from 15 to 75 % which could be attributed to small patient numbers studied and variations in GER testing [22]. In the THIN cohort study done in the United Kingdom, children with neurodevelopment disabilities, such as cerebral palsy, motor neuron disorders, and other neurological impairments, had a greater than threefold increase in the risk of a GER diagnosis. Of the 107 children with neurological impairment with a GER diagnosis, 26 % received the diagnosis of esophagitis [3].

The proposed mechanisms for this include prolonged supine positioning, scoliosis, hiatus hernia, and CNS dysfunction leading to poor lower esophageal sphincter function. Bohmer et al. looked at 69 neurologically impaired children with symptoms of GER (vomiting, regurgitation, food refusal, hematemesis, and behavioral problems) and who underwent endoscopy. Fifty-two children were found to have esophagitis on endoscopy. In this same study, there was marked improvement of persistent vomiting, regurgitation, food refusal, iron deficiency anemia, and signs of depression at the end of treatment [23]. The high prevalence of GER in the neurologically impaired population warrants close monitoring of GER symptoms and treatment with acid-blocking medicine [23].

Asthma

It has been hypothesized that asthma symptoms are caused by the reflux of stomach contents reaching the respiratory tract or via stimulation of the esophagobronchial reflex. Alternatively, symptoms such as cough and wheezing may cause reflux through an increase in intra-abdominal pressure. The relationship between GER and asthma in children is another area that has deficiencies. These range from small sample sizes, lack of standardized definitions for reflux and asthma, as well as different definitions used for abnormal test values. In two systematic literature reviews, the estimates on the prevalence of GER in children with asthma varied between 19.3 and 65 % and 19.3 and 80 %, giving a pooled sample-size-weighted average prevalence of 23.4 % in one study and 22.8 % in the other [24, 25]. The variation in the results is likely secondary to the methodology used to identify GER. The studies using an esophageal pH probe reported relatively high prevalence estimates (33–65 %), whereas the studies that used a questionnaire to assess GER symptoms reported the lowest prevalence estimates (19.3 and 19.7 %) [25].

The relationship between asthma and GER in adult studies is clearer. A systematic review of the adult literature reported a significant association between GERD and asthma in adults; however, a temporal relationship could not be established [26]. In the published systematic reviews in pediatrics, the data suggest a possible association, but further well-constructed studies are needed.

Natural History of GER or Do Children with Reflux Grow Up to Be Adults with Reflux?

Like the prevalence of GER in children, little is known definitively on the natural history of GER. There is debate in the literature regarding whether infants and children outgrow reflux or they are a high-risk population for becoming adults with GER. Nelson et al. who prospectively looked at her original cohort of infants and surveyed them 1 year later. Based on GER questionnaires, Nelson reported that infants with GER symptoms at 6 and 12 months of age outgrew it within 1 year [27]. Campanozzi et al.'s prospective GER study on an Italian infant cohort showed that all 210 subjects were followed longitudinally over a 2-year period and reported a complete resolution of GER symptoms by the end of the 24-month period [8]. Both of these studies support the idea that infants will outgrow reflux.

There is also growing literature that supports the idea that GER in childhood is a more chronic disease. El-Serag et al. followed up young adults 10 years post their diagnosis of GERD. A total of

113 cases completed the questionnaires, and at least weekly heartburn or regurgitation was reported in 52 (46 %) participants, 94 % of whom were taking proton pump inhibitors, H2RA, or antacids. This study suggested that GER can persist from childhood to young adulthood [28]. Another study surveyed 400 adults, 225 of whom were classified as refluxers, 154 non-refluxers, and 21 claimed to not know their reflux status, and the majority (63 %) of refluxers recalled at least one childhood GER symptom, compared to 35 % of the non-refluxers ($p<0.001$) [14]. Although this study has recall bias, it suggests that GER is a chronic disease. Martin et al. in a cohort study of Australian infants made the observation that children with over 90 days of GER during the first 2 years of life were more likely to have GER symptoms at 9 years of age. Children with frequent infant spilling, compared with those with no spilling, had a relative risk of 2.3 (95 % confidence interval: 1.3–4.0) of one or more GER symptoms at 9 years of age: a relative risk of 4.6 (95 % CI: 1.5–13.8) for heartburn, 2.7 (95 % CI: 1.4–5.5) for vomiting, and 4.7 (95 % CI: 1.6–14.0) for acid regurgitation [7].

Two important studies emphasize the important need to better understand the natural history of GER. The first was Lieberman et al. who reported the prevalence of Barrett's esophagus being strongly associated with duration of GER symptoms [29]. This was an observational, prospective, community-based study that demonstrated an odds ratio of 6.4 in patients with symptoms for more than 10 years ($p<0.001$). The second study was by Lagergren et al. who first demonstrated a strong and probably causal relation between GER and esophageal adenocarcinoma. This study was a case-controlled population-based study done in Sweden [30]. The risk of esophageal adenocarcinoma also increased with an increasing duration of symptoms. The adjusted odds ratio for esophageal adenocarcinoma was 43.5 (95 % confidence interval, 18.3–103.5) among persons with both long-standing symptoms and severe symptoms when compared with asymptomatic persons [30]. These two studies stress the need for well-designed, population-based epidemiologic studies to accurately assess pediatric GER and identify children at risk for chronic GER.

Future Directions

In order to further research in the epidemiology of pediatric GER, validated and standardized age-appropriate definitions are needed to critically and reliably assess data. This process has already started with the Montreal definitions for pediatric GER [5]. There is a need for uniformly accepted, reproducible, and validated symptom-scoring instrument, quality of life index, as well as a pediatric GERD severity indexes to assess disease throughout the study. These tools should be made for both parents and children. Multicenter longitudinal and cross-sectional studies with pediatric and family cohorts are needed to study incidence, prevalence, and natural history of GER. Only then will investigators be able to determine risk factors for the development of chronic GER, GERD, Barrett's esophagus, and esophageal adenocarcinoma.

The Genetics of GER and GERD

71

Isabel Filges and Raoul I. Furlano

Introduction

We have learned much more about the molecular genetics of diseases in the last few years than in the previous decades. This includes both a new appreciation for the role of rare genetics variation and the identification of the first contributory common variants by genome-wide association. These data show that although the population attributable risk of common variation may be moderate to large, the genotype risk of common variants at the individual level is small. In contrast a large number of diverse rare mutations of large effect have been identified, but none appear to be specific to GERD. All of these findings point to extreme genetics heterogeneity suggesting complex gene-gene or gene-environment interactions in GERD etiology. Available knowledge, reviewed below, also suggests that phenotypic presentation is the result of complex interactions and diverse pathogenetic mechanisms.

Background

Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus with or without regurgitation or vomiting and is a normal physiologic process occurring several times per day in infants, children, and adults [35, 50, 59]. In contrast, alterations in several protective mechanisms including hiatal hernia allow physiologic reflux to become gastroesophageal reflux disease (GERD) [34].

The diagnosis of GERD is mainly clinical when the reflux of gastric contents causes troublesome symptoms and/or complications [52]. However, the spectrum of clinical symptoms is large and variable, differing between infants, children, and adults. Clinical diagnosis is challenging as in infants and toddlers, there is no symptom or symptom complex that is diagnostic of GERD or predicts response to therapy. Esophageal pH impedance monitoring [49], manometric studies, endoscopy and biopsy, and barium contrast radiography can help in the diagnosis of GERD or its underlying causes as well as in the differentiation to other pathologies. In elderly children or adults, heartburn is often the leading clinical presentation.

The risk of Barrett's metaplasia is considered as a complication of chronic GERD. This premalignant lesion of the esophageal mucosa is correlated with the development of adenocarcinoma of the esophagus, which has increased in incidence over the past 20 years faster than any other form of cancer.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_71

Despite clinical heterogeneity, proper diagnosis should be a clinical goal and is not only essential to the management of patients with GERD but is a prerequisite for inclusion of patients in studies aiming at the identification of its genetic origin. Given the variety of presenting symptoms and the lack of a noninvasive gold standard, the inaccurate diagnosis of GER and GERD can present a major pitfall in genetic studies.

However, significant familial clusterings of reflux symptoms, hiatal hernia, erosive esophagitis, Barrett esophagus, and esophageal adenocarcinoma suggest some heritability of GERD and its complications. Differences between adult and pediatric GERD may lead to caution in extrapolating data from one to another. However, as a genetic basis has been considered in the literature for both ends of the age spectrum recently, it is worth reflecting on the literature as a whole. Nonetheless it may be distinct genetic predispositions identified for different presentations, including presentations in different age groups.

Besides GERD as an isolated disease, several other pediatric patient populations appear to be at higher risk for GERD than healthy infants, children, or adolescents. These include individuals with neurologic impairment, obesity, esophageal atresia, chronic lung diseases, those with a history of premature birth, and a number of genetic syndromes that we will specifically discuss in this chapter.

Twin Studies

Individuals within families share a similar environment and may experience similar diseases based on environmental influences only. When studying the genetic contribution to disease, confounding by environmental factors can be minimized by looking at twins and very young children. Twin studies have been proved to be a powerful methodology for studying the influence of nature (genes) and nurture (environment) on a particular phenotype. As monozygotic twins share virtually identical genetic material, phenotypes which have a genetic basis will be more highly correlated between twins that are monozygotic when compared with dizygotic twins.

Two large twin studies of familial GERD used 3,000 adult twin pairs from the Minnesota Twin Registry [59] and 8,401 adult twin pairs from the Swedish Twin Registry [11]. The former study found 19 % concordance for monozygotic versus 4 % for dizygotic pairs. The latter study compared concordance for reflux defined by heartburn or acid regurgitation occurring at least weekly in twins aged 55 or older, 15.3 % having reflux. They found 31 % concordance for monozygotic and approximately 13 % for dizygotic pairs. The limited concordance in both studies in the monozygotic pairs (19 % and 31 %, respectively) suggests markedly decreased penetrance or complex non-Mendelian factors as well as environmental influences participating in the origin of disease. Similarly, Mohammed et al. [38] performed a comparison of 4,480 twin pairs in the UK of the heritability of GERD. Again, GERD was defined as symptoms of heartburn or acid regurgitation at least once a week. A total of 1,960 twin pairs were evaluable, with a prevalence of GERD of 18 %. Case wise, concordance rates were significantly higher for monozygotic than dizygotic twins (42 % versus 26 %; $P < 0.001$). Their heritability estimate was that 43 % of the variance in liability to GERD is due to additive genetic factors.

Gene Identification

Approaches of gene identification in GERD are challenging as there are multiple phenotypes and the fundamental processes of disease origin are poorly understood and probably diverse. Successful identification of candidate genes is generally dependent on well-defined phenotypes, shared biological processes, or pathway interactions.

Linkage Studies

The number of linkage studies concerning GER and GERD is limited, and studies have shown

inconsistent results with regard to the identification of candidate loci. The Center for Genomic Sciences; Allegheny Singer Research Institute; the Pediatric/Adolescent Gastroesophageal Reflux Association (PAGER), founded in 1995 by children and parents who suffer from chronic severe GER; and the patient-supporting Fourth Love Foundation, specifically supporting GERD-related research efforts, collaborated on a genome-wide linkage study aiming to identify candidate loci for GER/GERD. By restriction of the phenotype to severe pediatric GER 20 families with multigenerational history of GERD were identified. Five families with 26 affected members had been identified through PAGER suggesting autosomal dominant inheritance with high penetrance and were selected for the study. A genetic locus on 13q14 was mapped cosegregating with the phenotype in families with multiple affected members [30]. Using polymorphic microsatellite markers, a gene for GERD was mapped to a 13 centimorgan (cM) region on chromosome 13q with a maximum multifamily multipoint LOD score of 7.15. Within the chromosomal region 13q14, the gene *HTR2A*, encoding for the 5-hydroxytryptamine receptor 2A, was an attractive candidate gene given the role of serotonin throughout the gastrointestinal tract. However, sequencing of the *HTR2A* gene and its promoter on affected and unaffected family members revealed benign polymorphisms but no mutations segregating with the disease phenotype. Additional linkage analysis narrowed the region to a 9cMorgan interval which did not include *HTR2A* [29]. Later the same group screened affected patients for exonic mutations of all genes within the linkage locus without concluding to causative mutations [28]. Linkage of GERD to 13q14 was inferred in a linkage study of five additional well-characterized families [41]. Differences in the findings of these two major linkage studies were proposed to lie in the age and phenotypic disparity between the subjects of the studies [40]. Whereas in the latter one the phenotype was defined as typical infantile GERD with esophagitis, Hu et al. excluded children whose GERD was limited to infancy [30]. Phenotypic variability, genetic heterogeneity of GERD itself, or both were discussed to explain the different study outcomes [40].

Asling et al. [3] performed whole genome linkage analysis in 36 families by identifying children diagnosed with GERD by an abnormal finding from endoscopic examination, a 24 h esophageal ph test, or having been subject for fundoplication and a positive family history. A region on chromosome 2, containing collagen type III alpha 1 (*COL3A1*), was identified (LOD = 3.3) in families with dominant transmission of GERD, stratified for hiatal hernia. *COL3A1* showed significant association with GERD in an independent pediatric trio cohort (p(corr) = 0.003). The association was male specific (p(corr) = 0.018). The *COL3A1* association was replicated in an independent adult case-control cohort (p(corr) = 0.022). Moreover, male-specific association to hiatal hernia (p(corr) = 0.019) was found for a single nucleotide polymorphism (SNP) not associated to GERD. Collagen type III protein was more abundant in esophageal biopsies from male patients ($p = 0.03$). The authors concluded that *COL3A1* is a disease-associated gene in both pediatric and adult GERD and is associated with hiatal hernia in adult males. As the GERD- and hiatal-hernia-associated alleles were different, the authors proposed that two separate mechanisms were leading to disease. However, the data potentially could point to a connective tissue component in the etiology of GERD. A number of *COL3A1* mutations are described to cause autosomal dominantly inherited Ehlers-Danlos syndrome type IV, a connective tissue disease characterized by the joint and dermal manifestations as in other forms of the syndrome but also by proneness to spontaneous rupture of bowel and large arteries. The observation of frequent GER/GERD in patients affected by Ehlers-Danlos syndrome is not reported in the medical literature.

Association Studies

Genome-wide association studies (GWAS) between common sequence variation and phenotypic variation were recently performed for a

large number of human phenotypes. Altogether over 200 GWAS studies each including several thousand patients have now been published accounting for the statistical association and subsequent validation between a considerable number of genomic regions defined by SNP variation and common complex traits. Due to the discovery of the common variation in human population, the development of technologies for large-scale genotyping and biostatistical methods and the collection of a very large number of well-phenotyped sample GWAS were successful in identifying low-risk alleles, but the current clinical utility of these findings remains very limited [10]. This implies that even if the SNP genotype for all the SNPs that impact the trait is known, the ability to predict the phenotype is poor. SNPs chosen in the studies are common variants based on the HapMap studies and not causal factors, so if the variance in traits is explained by rare SNPs, the correlation between the SNP markers that were used and these rare SNPs could be quite low. Even if methods of genome-wide association studies based on full sequence will be improved in the near future, the prediction of an individual's disease risk given only his or her genome sequence may never attain useful accuracy apart from Mendelian disorders, especially if environmental factors or complex gene-environmental interactions mainly contribute to the disorder. However, even if the associated SNP does not accurately predict common traits, a newly defined locus might highlight molecular pathways involved in pathophysiological processes [20, 27, 55].

There are no large GWAS performed for GER or GERD probably due to the fact that very large patient cohorts with a stringent phenotype are needed to determine a risk allele.

However, de Vries et al. [18] suggest that enhanced perception of reflux events occurs in GERD as a consequence of increased sensory signal transduction that is partly genetically determined. They present data from a medium-sized case-control study and test the association with a common polymorphism of the gene *GNß3* that encodes the ß3 subunit of the G-protein, key to secondary messenger function and thus signaling in the gut.

In total, 363 GERD patients, defined as having esophageal pH <4> or = 6 % of time and/or symptom index > or = 50 % or symptom association probability > or = 95 %, participated and were studies against 373 healthy controls free of gastrointestinal symptoms. Genotyping was performed by molecular beacon assay. The C825T genotype was more prevalent in GERD patients relative to healthy controls (adjusted odds ratio (OR) =1.43, 95 % CI 1.04–1.98). GERD patients sensitive to physiological amounts of reflux displayed a higher OR (1.59) as did GERD patients with a positive symptom association score (1.50). The strongest association was detected in patients without concomitant functional dyspepsia and/or irritable bowel symptoms (OR = 1.66). They concluded that GERD is associated with *GNß3* polymorphism C825T and may mediate an increased response to neurotransmitters. The authors suggested that enhanced perception of reflux events occurs in GERD as a consequence of the increased sensory signal transduction. However, patient sample size is very small although the characterization seems to be robust.

GERD-Correlated Phenotypes

In 1995, Carre published the first reports of familial clustering of hiatus hernia (HH) that he called "partial thoracic stomach." The use of x-ray as a definitive diagnostic tool for HH and GERD makes the studies difficult to interpret today due to different diagnostic standards. In a large group of children, he identified 31 families with multiple affected members [13]. He also described a three-generation family with eight individuals presenting with HH [14]. In an evaluation of 406 younger siblings of 465 probands with HH, Carre et al. identified GERD symptoms and suggestive symptoms in 15 %. HH was detected in 3 % of siblings tested by fluoroscopic examination arguing against familial inheritance. Several other anecdotic reports of familial HH clustering have been published [23, 52]. Later on, studies on familial manifestations of GERD have focused on Barrett's esophagus (BE). The tendency to develop Barrett's esophagus is itself

thought to be a heritable trait. As summarized by Romero and Locke [46], the reported familial clusterings comprise 88 individuals, of whom 28 % had BE and 42 % had esophagitis or heartburn. Further three families with six individuals having either BE or esophageal adenocarcinoma were described [44]. As these findings were suggesting a familial tendency in BE, the Mayo Clinic conducted a prospective study to evaluate the prevalence of reflux symptoms in the relatives of 122 probands with either reflux esophagitis, BE, or esophageal adenocarcinoma [45]. Currently the clinical implications of genetic studies are restricted to acknowledging that familial clustering with an inherited predisposition to developing BE does exist [54]. In addition to genetic influences including male gender, contributing factors such as obesity, smoking, and gender were identified. A potential role of the microbiome is also discussed [51].

Related Syndromes

The increased frequency and severity of GERD among infants and children with neurological impairment and developmental disorders is well documented ("syndromic GERD"). It is assumed that underlying pathological changes in the nervous system of patients with developmental disorders probably affect physiological and neurological features leading to associated anomalies of the gastrointestinal tract (GIT). Developmental defects within the enteric nervous system are also likely to be the cause of significant functional disorders. The GIT develops from the embryonic gut, an endodermally derived epithelium which is surrounded by cells of mesodermal origin. Cell signaling between these two layers appears to control the patterning and organogenesis and plays a critical role in coordinating GIT development. The enteric nervous system develops from the colonization of neural crest cells which migrate down the developing GIT [22, 24]. Vagal neural cells are thought to give rise to the majority of these neuroblasts. The normal development of the enteric neural system is complex, involving cascades of signaling molecules that determine proliferation, migration, differentiation, and survival of these enteric neuroblasts. Developmental defects within the enteric nervous system appear to be related either to defects in vagal cell migration or the development of the intermyenteric and submucosal plexuses.

Chromosome Anomalies

For many years, cytogenetic identification of rare chromosomal anomalies serves for the identification of disease-related regions and genes by correlating genotypes to phenotypes in patients with similar chromosomal aberrations.

The most frequent chromosomal anomaly is trisomy 21 causing Down's syndrome (DS) with approximately 1 in 800 live births worldwide. Up to 77 % of DS children have associated gastrointestinal abnormalities, which are either of structural or functional nature. The affection of the enteric nervous system in DS might not only concern the anatomy but also nerve function. This suggests that developmental disorders of the enteric nervous system are probably involved in the functional gastrointestinal disturbances encountered in patients with DS. However, the interaction between the central and enteric nervous system and gastrointestinal involvement is still poorly understood. Mechanisms and pathways in brain development during embryogenesis are probably interlinked with enteric development, but the precise underlying mechanisms have to be elucidated. Functional motor disturbances of the esophagus and colon may be congenital or acquired and are relatively frequent. These include esophageal dysmotility syndromes (e.g., achalasia, gastroesophageal reflux, dysphagia) as well as chronic constipation and Hirschsprung's disease (HSCR) (2–15 %) occurring in association with DS. The pathogenetic role of threefold dosage of chromosome 21 and its possible genome interactions in the etiology of developmental and functional anomalies remains undetermined.

GER is one of the most frequently encountered esophageal symptoms in DS and is, in addition, probably underreported because of its

general frequency. An increase in the number of associated complications has been reported in the study by Hillemeier et al. [26], who showed a 43 % occurrence of serious complications arising from GER in DS patients. Central nervous system disease and gastrointestinal disease necessitating surgery have been independently associated with a poorer developmental outcome [56].

As cytogenetically visible anomalies in standard conventional karyotyping encompass a large number of genes, clear involvement of a particular genomic region does not typically reveal individual molecules which may be contributory. Advances in technology by the development of fluorescence in situ hybridization in the 1980s and the recent introduction of array-comparative genomic hybridization in the clinical investigations of children with developmental disorders allowed to define structural anomalies at the submicroscopic level. The identification of these disorders has not only increased the number of patients with a now-defined origin of their developmental disease but has also contributed to more detailed observation of the natural course of disease within the groups of patients with the same chromosomal anomalies. There are a number of well-characterized microdeletion syndromes which appear to be associated more frequently with GER/GERD. Examples are the microdeletion syndrome 22q11 [19], 1p36 deletion [9], Wolf-Hirschhorn syndrome [6–8], 22q13.3 deletion syndrome [36], 16p13.3 deletions leading to the severer form of Rubinstein-Taybi syndrome [4, 5, 25, 48], and Williams-Beuren syndrome [12, 32, 33] as well as anecdotally reported rare structural chromosome anomalies [16]. All of the described syndromes lead to neurodevelopmental impairment supporting the assumption that a developmental pathogenetic process in the enteric system may contribute to the origin of GER/GERD. As symptoms are not confined to children with a particular chromosomal anomaly, but also can be observed in a variety of microdeletion syndromes throughout the genome, genetic heterogeneity and possible complex underlying pathogenetic mechanisms in GER/GERD seem likely. The application of array-comparative genomic hybridization in clinical routine diagnosis of patients with developmental disorders will further contribute to the identification of additional patients as well as new distinct microdeletion syndromes.

Monogenic Disorders

To date, more than 4,500 single genes are known to cause a disease by Mendelian inheritance. A number of developmental syndromes as well as monogenic neurological disorders present with esophageal reflux as an adjunct symptom (Table 71.1).

Cornelia de Lange syndrome (CdLS) has been particularly studied for GER probably because symptoms in affected patients seem to be particularly severe. The Cornelia de Lange syndrome is caused by mutations in the *NIPBL* gene, which encodes a component of the cohesin complex, in about half of the clinically diagnosed patients [39]. An X-linked form of the disorder (CdLS2) can be caused by mutations in the *SMC1L1* gene, and a mild variant of Cornelia de Lange syndrome (CdLS3) has been related to mutations in the *SMC3* gene. Both genes encode different components of the cohesin complex. CdLS is recognized on the basis of characteristic facies (low anterior hairline, synophrys, anteverted nares, maxillary pragmatism, long philtrum, "carp" mouth) in association with prenatal and postnatal growth retardation, intellectual disability, and, in many cases, upper limb anomalies [57]. Gastroesophageal dysfunction in patients with CdLS was emphasized in medical literature, and gastroesophageal reflux with reflux esophagitis, aspiration pneumonia, and esophageal stenosis has been described [15, 35, 47]. Sommer et al. [53] examined 17 CdLS patients, ranging in age from 9 months to 19 years, and found that 13 had evidence of gastroesophageal reflux causing paroxysmal dystonic posture including torticollis and opisthotonus. A number of children with typical CdLS and congenital diaphragmatic hernia were reported [17, 21, 31]. In a series of 43 patients with CdLS, the incidence of GER and the correlation between its presence and severity and the clinical phenotype were evaluated [37]. Pathologic GER was evident in 28 (65 %) of the

43 patients. The incidence was not significantly different in patients with classic (93.3 %) versus mild (82.3 %) phenotype, whereas a strong correlation was present between the degree of esophageal damage and the clinical phenotype. Hyperactivity was the most frequent sign associated with GER, present in 23 (85 %) of the 28 patients.

There is a variety of other monogenic developmental disorders which present with symptoms of GER/GERD such as Rett syndrome, Ras-pathway-associated syndromes such as Noonan-Cardiofaciocutaneous and Costello syndrome, Kleefstra syndrome, and Cohen syndrome.

Interestingly the group of neuropathies, such as Charcot-Marie-Tooth CMT1A and 2B [1], and hereditary sensory and autonomic neuropathies are mentioned in association with GER, as well as spastic paraplegia [42]. Descriptions of patients with connective tissue diseases, especially fibrillinopathies, such as Marfan syndrome [43] and congenital contractural arachnodactyly [57] presenting with GER, remain rather rare and anecdotic.

Occurrence of GER/GERD in monogenic disorders seems to be widespread; however it seems to be mentioned in particular in neurodevelopmental and neurologic phenotypes. Whether this underlines a contribution of disturbance in enteric neurological mechanisms remains to be verified.

Closing Remarks

GER/GERD is a heterogeneous and probably complex disease with evidence for genetic but also environmental contribution to its origin first suggested on the basis of twin studies. The straightforward identification of genes or susceptibility genes seems to be particularly challenging as the clinical presentation and definition is highly variable and thus the borders between physiologic GER and definite GERD might be blurred. GER/GERD is a generally common finding, and its prevalence especially when associated with severe disabling disorders may be even underreported and the specific GER/GERD phenotype only marginally mentioned. The pathogenesis of GERD in regard to cellular mechanisms remains sparsely elucidated, but there are lessons learned from chromosomal and monogenic diseases suggesting a major contribution of disturbance in the enteric nervous system to the pathogenesis. Despite the efforts made in the identification of low-risk alleles, further elucidation of disease mechanisms through Mendelian traits might be the strategy to adopt [2].

Pathophysiology of Gastro-oesophageal Reflux Disease

72

Silvia Salvatore and Geoffrey Davidson

Introduction

Gastro-oesophageal reflux is an extremely common paediatric problem, and its pathogenesis is complex and multifactorial involving anatomic, hormonal, environmental, and genetic factors (Fig. 72.1). The difference between physiological reflux (GER) and gastro-oesophageal reflux disease (GERD) is often blurred by the anxiety engendered in parents, particularly first-time parents, by symptoms such as vomiting and irritability in young infants.

Epidemiological data show that spilling or regurgitation in infancy is very common and decreases spontaneously and almost completely by 1 year of age [1, 2]. It is generally accepted that infants with regurgitation are thought to have an excellent long-term prognosis. It is classically stated that infant regurgitation is physiological and rarely requires medical intervention needing only explanation and reassurance.

However, somewhere between 5 % and 9 % of infants have ongoing and troublesome GERD [3, 4]. If these GERD symptoms continue after the age of 3 or older [5], they are more likely to persist into adulthood.

Reflux oesophagitis is reported to occur in 2–62 % of children with symptoms of GERD and Barrett's oesophagus (BE) in 0.1–3 %, and refractory GERD requiring surgery is seen in 6–13 % [6]. More than 50 years ago, in the absence of reflux treatment, oesophageal strictures were reported in about 5 % of children with reflux symptoms [7]. Nowadays, oesophageal stenosis and ulceration in children have become extremely rare.

Children with neurological impairment, cystic fibrosis, and repaired oesophageal atresia are known to be children at risk for severe reflux and subsequent complications.

Research into the physiology and pathophysiology of GER has advanced markedly over the last decade with the development and use of new technologies such as micro-manometry, noninvasive breath testing, and multichannel intraluminal impedance (MII) [8]. These techniques have demonstrated that reflux episodes occur most often during transient lower oesophageal sphincter relaxations (TLESRs) unaccompanied by swallowing,

Fig. 72.1 Factors involved in the pathogenesis of GERD. *CNS* central nervous system, *LES* lower oesophageal sphincter, *PGE* prostaglandin E, *VIP* vasoactive intestinal peptide. Inappropriate relaxation is typed in blood as it represents the most important pathophysiological mechanism in GER

which permit gastric contents to flow into the oesophagus [9, 10]. However, in patients with severe reflux oesophagitis, many GER episodes occur unrelated to TLESRs [11]. A minor proportion of reflux episodes occur when the LES pressure fails to increase during a sudden increase in intra-abdominal pressure or when LES's resting pressure is chronically reduced [10].

In the past decade, GER and/or GERD has become a major part of paediatric gastroenterological practice. This chapter will discuss more recent advances in our knowledge with regard to the pathophysiology of GERD.

Definitions

Gastro-oesophageal Reflux and Gastro-oesophageal Reflux Disease

GER is the passage of gastric contents into the oesophagus [12] and is a normal physiologic process occurring several times per day in healthy infants, children, and adults. Most reflux episodes are asymptomatic, brief, and limited to the distal oesophagus.

'Physiological GER' is defined as GER without associated symptoms, during the first months of life, with regurgitation being the most visible symptom occasionally accompanied by vomiting. This usually resolves spontaneously within the first year of life [2].

In contrast, GERD is present when the reflux of gastric contents causes troublesome symptoms and/or complications [13].

Primary and Secondary GERD

Primary GERD results from a primary motility disorder and dysfunction of the LES. Primary peristalsis is the most common motor event after reflux and accounts for up to 90 % of initial and subsequent motor activity [14].

Secondary GERD is caused by diseases within or outside the gastrointestinal tract (i.e. cow's milk allergy, idiopathic pyloric hypertrophy, metabolic or respiratory disorders, infections, and intracranial hypertension).

The symptoms of primary and secondary reflux are similar, but a distinction is conceptually helpful in determining the therapeutic approach. Secondary GER is not further discussed in this chapter.

Mucosal Resistance

The oesophageal mucosa contains established protective mechanisms operating within the pre-epithelial, epithelial, and post-epithelial compartments.

The stratified squamous epithelium protects against rough food material that is swallowed, but its integrity is compromised by recurrent, chronic exposure to refluxate of strong acid or alkali [10]. Oesophageal glands are irregularly distributed, are small, contain only mucous cells, and lubricate the swallowed bolus during its passage. Bicarbonate secretion capacity of the human oesophagus is small and of little clinical relevance for mucosal defence [15].

Oesophageal mucosal dilated intercellular spaces (DISs) are frequently observed in patients with non-erosive reflux disease (NERD) and patients with oesophagitis. The specificity of DIS is questionable, as it is present in up to 30 % of asymptomatic healthy subjects and in patients with other oesophageal disorders. DIS occurs in parallel with a drop in potential difference, diminished transepithelial resistance, and increased oesophageal mucosal permeability. These alterations arise with exposure to acid and pepsin during GER, but the exact pathway of damage to the intercellular junctions remains unclear and seems to be multifactorial. Other noxious contents of the refluxate, such as bile acids, are harmful, and DIS can also be induced by acute psychological stress. DIS can disappear after treatment with proton-pump inhibitors (PPIs); however, this is not the case in all NERD patients [16]. Oesophageal mucosal DIS may be important for symptom perception in NERD. Patients with NERD might have DIS even in the proximal oesophagus [17]. In 14 healthy adults, oesophageal perfusion with acid or weakly acid solutions, with or without bile acids, provoked DIS in the 'exposed' and in the more proximal 'nonexposed' oesophageal mucosa. However, in spite of the presence of perfusion-induced DIS, most healthy subjects do not perceive heartburn [17].

Since refluxed acid and pepsin always act from the luminal side of the mucosa, protective factors, like the epidermal growth factor operating as a part of the pre-epithelial defence, are essential in the maintenance of the integrity of the oesophageal mucosa. The resistance of the mucosa to the noxious effect of the refluxed material (acid, pepsin, chymotrypsin and trypsin, bile, etc.) is different from person to person and seems genetically determined. Prostaglandin E2 and nitric oxide (NO) are said to be protective (in

low concentrations) and detrimental (in high concentrations) for oesophageal mucosal integrity. The release of prostaglandin differs for the subtypes and in the function of the composition of the refluxed material [17].

Nitric oxide is the inhibitory neurotransmitter in the oesophageal muscle, is responsible for the latency gradient of oesophageal peristalsis, and is involved in LES relaxation [18]. However, the mechanism of peristalsis in the oesophagus is complex and involves both central and peripheral mechanisms.

Composition of Refluxate

In adults, the severity of oesophageal injury has long been attributed to oesophageal acid exposure [19], and healing of reflux oesophagitis has been directly correlated with the maintenance of the intragastric pH above 4.0 [20]. However, more recent reports failed to show a correlation between the results of a classic pH-metry and oesophageal histology [20]. The relation between reflux symptoms, endoscopic or histologic findings and exposure of the oesophagus to acid is complex [21]. In paediatric patients, the concordance between the results of pH-metry and oesophageal histology has been debated, denied or sustained [22].

The advent of MII-pH has demonstrated that nonacid (now defined as weakly acidic when oesophageal pH is between 4 and 7) reflux is as common as acid reflux (pH<4) and significantly more frequent than acid reflux in the first months of life and postprandial time because of gastric buffering related to frequent meals or milk.

Nonacid, mixed gastric, and duodenal reflux and impaired oesophageal clearance have been suggested to play a role in determining oesophageal mucosal injury. In a small paediatric study group, MII-pH results failed to identify parameters correlating with the presence of histologic oesophagitis. The duration and number of acid, weakly acid and alkaline, and gas reflux episodes were comparable in children with and without oesophagitis [22].

Reflux of pepsin and trypsin may exert an aggressive effect on the oesophageal epithelial cells and mucosa due to their proteolytic actions (maximum at pH 2–3 for pepsin, but with action up to pH 5.5, and at pH 5–8 for trypsin) [10]. The exact role of bile reflux or duodeno-gastric reflux is as yet poorly understood. Conjugated or deconjugated bile salts exert a predominant noxious effect which is pH dependent [23].

The myogenic tone of the LES is modulated by a variety of neurohormonal influences.

The following increase LES pressure: muscarinic M2 and M3 receptor agonists, α-adrenergic agonists, gastrin, motilin, substance P, prostaglandin F2α, gastric contractions, alkalinisation and proteins in the lumen [18].

The following decrease LES pressure: oesophageal balloon dilatation, the presence of fat in the duodenum, progesterone, prostaglandin E, β-adrenergic agonists, atropine, cholecystokinin, glucagons, vasoactive intestinal peptide (VIP), nitric oxide (NO) dopamine, secretin, oestrogen, nicotine, alcohol, mint, caffeine and chocolate [18]. VIP, NO, and cholecystokinin induce TLESRs, and L-arginine, the endogenous source of NO, prolongs TLESRs although NO levels were equal in biopsies of normal and inflamed oesophageal mucosa [18].

Upper and Lower Oesophageal Sphincter (LES)

The upper oesophageal sphincter (UES) and LES are not anatomically distinct muscles, but differ from that of the oesophageal body by their thickened muscle layer and high-pressure zone. Studies in children have demonstrated UES pressures comparable with those in adults (40–50 mmHg) and UES relaxation in response to swallowing. The pressure of the UES differs in relation to the kind of material present in the oesophagus: it disappears when there is air as in belching, whereas it increases when there is ingested material or acid refluxes [10]. In addition, basal UES pressure is highly dependent on the state of arousal and behaviour, varying from 18 mmHg during rest to 56 mmHg when crying

[24]. These findings are also similar to that noted in preterm infants >33 weeks postmenstrual age where the motor mechanisms regulating the UES are well developed [25]. UES pressure also increase with discomfort and straining [24, 26].

The LES consists of a segment of specialised muscle that is contiguous with and just exterior to the smooth muscle of the oesophagus and the stomach and is a functional barrier representing a zone with an intraluminal pressure greater than that of the stomach and oesophagus. In adults, this high-pressure zone has a length of 3–6 cm and a pressure of about 20 mmHg (range, 10–40 mmHg). An absolute pressure of less than 6 mmHg is required for GER [27].

In infants the length of the LES is only a few millimetres, but despite this, studies have shown that mean resting LES pressure at the onset of relaxation in preterm infants is not dissimilar to that in adults with a mean LES pressure around 20 mmHg [28, 29].

The LES relaxes 2.5 s after the initiation of a swallow, well before the arrival of the bolus, and remains open for 10–12 s, until the bolus has passed [10]. There is also a postprandial decrease in LES pressure in both normal and GERD patients. The LES is characterised by tonic muscle innervated by inhibitory and excitatory neurons. The LES maintains tonic closure due to its myogenic property [28]. Relaxation of the LES without oesophageal peristalsis may occur during belching, vomiting and TLESRs. Increased abdominal pressure is, in the main, associated with increased sphincter pressure, but gastric distension is accompanied by a fall in LES pressure or by TLESRs that can last for 10 up to 17 s [30]. It is believed that these responses are mediated via vagal reflexes and are inhibited by GABA-β agonists such as baclofen. The larger the meal, the more TLESRs, and equally, the greater the gastric secretory volume and the higher the intragastric osmolarity, the more TLESRs [9, 10]. Stimulation of mechanoreceptors in the gastric fundus, or stretching of the gastric fundus, initiates vago-sympathetic-mediated reflexes resulting in these TLESRs. TLESRs are also more frequent in the seated position than in supine position.

Using a micro-manometric assembly incorporating a micro-pH electrode recorded oesophageal motility and pH in 36 preterm and term infants showing that TLESRs were the predominant mechanism of GER, triggering 50–100 % of GER episodes (median, 91.5 %) [31]. Gastric distension (by feeding) also stimulated TLESRs. Abdomino-thoracic straining significantly increased the occurrence of GER in association with TLESRs. In infants with GERD, the number of TLESRs overall was similar to normals, but the proportion of TLESRs accompanied by acid GER was significantly higher than in normals (16.5 % vs. 5.7 %, respectively; $p < 0.001$) [32].

Oesophageal Clearance

Oesophageal clearance is influenced by at least three factors: oesophageal peristaltic waves, gravity, and saliva. Oesophageal clearance mechanisms are well developed by at least 31 weeks of postmenstrual age [32]. It is also important to note that the more proximal the reflux reaches, the more likely a swallow will occur leading to not only bolus clearance but also assistance in airway protection [33].

Oesophageal clearance of acid reflux consists of an initial volume clearance followed by neutralisation of the acidified mucosa by swallowed saliva (chemical clearance). The pH of saliva varies from neutral to alkaline and contributes to the neutralisation of the refluxed acid. Moreover, the bolus effect of swallowed saliva will increase primary oesophageal peristalsis and help oesophageal clearance from the refluxed material [10]. Saliva flow increases concurrently with the onset of heartburn, a phenomenon called ‘water brash’. Oesophago-salivary reflexes become mainly effective in prolonged episodes of GER [8]. Impaired oesophageal clearance of acid and decreased salivary function have been reported in patients with reflux oesophagitis, especially in those with neurological compromise [10]. The important reduction of saliva secretion and swallowing rate during quiet sleep may contribute to delayed oesophageal clearance of nocturnal reflux episodes.

Secondary peristalsis is caused by GER and starts at the highest level; the refluxed material reaches in the oesophagus. It contributes to oesophageal clearance of remnants of the refluxed material that were not cleared by a primary peristaltic wave. The larger the volume of refluxed material, the higher the amplitude of the secondary waves. Secondary peristalsis can be produced experimentally by inflation and deflation of an oesophageal balloon [10]. Hot substances increase speed and amplitude of peristaltic contractions; cold swallows have the opposite effect. Pain, at least in adults, delays oesophageal clearance [10].

Impedance-pH data has demonstrated that acid (chemical) clearance is significantly longer than bolus clearance at all ages. Combined MII-pH and oesophageal manometry (MII-EM) has recently demonstrated that patients with erosive oesophagitis exhibit a significantly lower percentage of complete bolus transit and a longer mean bolus clearance time (MBCT) compared to healthy controls and non-erosive reflux disease (NERD) patients [34].

Proximal Extent of GER

The clinical relevance of the proximal extension of a reflux episode in generating symptoms needs further research. In infants and children, a stronger association between symptoms and proximal reflux than with non-proximal reflux was sustained by some authors [35, 36], but not confirmed by others [37]. Proximal extension of reflux is frequent but is not necessarily a cause of symptoms. As expected, the proportion of proximal reflux is higher for 'vomiting' as a symptom than for all the other symptoms.

Effect of Body Position on GER and Gastric Emptying

The recent combination of manometry with impedance has provided the ability to explore the effect of body position and its relationship to GER to the rate of gastric emptying (GE) [33].

In an initial study of ten healthy preterm infants, TLESRs were the predominant mechanism of reflux, triggering 83 % of GER. Of the 92 TLESRs recorded, 17 % were not associated with reflux. Infants studied in the right lateral position had significantly more GER ($p<0.01$), a higher proportion of liquid GER ($p<0.05$), and faster GE ($p<0.005$) when compared with infants studied in the left lateral position [38].

A 'crossover position study' was carried out in another cohort of ten healthy preterm infants, and postprandial evaluation confirmed more liquid GER in the right than in the left lateral position (median, 9.5 [range, 6.0–22.0] vs. 2.0 [range, 0.0–5.0] episodes/h; $p=0.002$). Gastric emptying was faster in the right than in the left lateral position (37.0 ± 21.1 vs. 61.2 ± 24.8 min; $p=0.006$) [38].

Similar findings were reported by Corvaglia et al. in 22 preterm infants with regurgitation and postprandial desaturations. The number of acid- and nonacid reflux episodes was significantly smaller when the subjects were in the prone and left-side position in comparison to those in the supine and right-side positions [39]. The left-side position showed the lowest oesophageal acid exposure (0.8 %) in the early postprandial period, whereas the prone position showed the highest oesophageal acid exposure (acid exposure, 5.1 %) in the late postprandial period [44].

A further study using combined MII-pH with epigastric impedance for 3 h was carried out in 30 newborns referred for apparent life-threatening events and signs of GERD [40]. An inverse correlation was evident for reflux frequency and gastric emptying velocity ($R^2=0.94$; $p<0.001$) and between acid refluxes and the gastric filling state ($R^2=0.95$; $p<0.001$), whereas a positive correlation was found between the reflux level and the gastric filling state ($R^2=0.52$; $p<0.05$) [45].

Eight healthy preterm infants studied using an oesophageal impedance-manometry catheter incorporating an intragastric infusion port showed that more TLESRs were triggered in the right lateral position compared with left lateral position (4.0 [3.0–6.0] vs. 2.5 [1.0–3.0]; $p=0.027$). First TLESRs occurred at a significantly lower infused volume and percentage of feed in the right compared with left lateral

position (10.6±9.4 vs. 21.0±4.9 mL; $p=0.006$) (17.6±15.5% vs. 35.4±8.02%; $p=0.005$). TLESRs and GER were triggered at volumes unlikely to induce gastric distension [41].

Delayed GE has been reported in 10–15% of adult and in 28–50% of paediatric GERD [42, 43]. Delayed GE can be secondary to a number of conditions including infections (*Rotavirus*, *Helicobacter pylori*), food allergy, prematurity, drugs (opioids, anticholinergics), previous surgery, eosinophilic gastroenteropathy, metabolic (hypokalemia, acidosis), endocrine (diabetes mellitus, hypothyroidism), muscular (visceral myopathy, myotonic dystrophy) and neuronal (cerebral palsy, vagotomy, pseudo-obstruction) disorders [43].

Diagnosis relies on clinical observation, confirmed by gastric emptying scan, antroduodenal manometry, ultrasound (after a test meal), electrogastrography, 13C-octanoic acid breath test, and impedance epigastrography. As overlap between healthy and affected subjects exists, the interpretation of these tests is often challenging.

Gastric emptying studies in 36 infants using the 13C-octanoic acid breath test showed similar results in GERD patients and normals [31]. For all infants, mean half GE time was 33 min, and breastfed infants had faster rates. Infants receiving feeds at two, three, or four hourly intervals had different GE times, with longer intervals between feeds being associated with significantly slower GE most likely due to differences in feed volumes administered (smaller in the more frequently fed infants). Delayed GE in infants and children does not seem to correlate with symptoms due to GERD or in fact be a contributor to it [38].

Effect of Frequency and Duration of GER

The frequency and duration of reflux episodes may determine the response of oesophageal nociceptors. Repeated noxious stimuli or one very strong stimulus can sensitise both afferent types of fibres (C-unmyelinated and A-delta) to respond to typical non-noxious stimuli as very painful. Thus, a small oesophageal distension as occurs in belching, minimal regurgitation, or even the passage of a swallowed food bolus may be experienced as very painful. The sensation of pain is transported to the brain via calcitonin gene-related peptide (CGRP) and substance P which determines smooth muscle contractions, vasodilatation and increased mucosal permeability. Substance P is also released when there is tissue damage, as in oesophagitis, inducing a vicious cycle: the more tissue damage, the more substance P and the greater the noxious effect of the refluxed material [10]. Substance P also causes histamine release from the mast cells in the alveoli and thus contributes to bronchospasm and GER-related respiratory symptoms.

Hiatus Hernia and GERD

Hiatus hernia refers to herniation of gastric cardia in the most common type I or sliding hiatal hernia through the oesophageal hiatus of the diaphragm. The prevalence of hiatal hernia in infants and children is unknown. Most adults with hiatal hernias are asymptomatic. However, there is a high prevalence of hiatal hernia in adults with reflux symptoms and oesophagitis. The likelihood of developing reflux disease is directly related to the size of the herniation. Hiatal hernia is more frequent within an affected family, and severe hiatal hernia may be an autosomal dominant inherited disorder [44]. Hiatal hernia is more frequent in different conditions that all have severe GER in common, such as neurological impairment, chronic lung disease (especially cystic fibrosis), oesophageal atresia, etc., and in Barrett's oesophagus [45]. In patients with a hiatal hernia, the LES is dislocated into the thorax, and the (local) negative pressure (exacerbated during inspiration) facilitates gastric reflux (due to the abdominal positive pressure).

Genetic Influence

The genetic influence on GER is supported by increased GER symptoms in relatives of GER disease patients [46] and by higher concordance

for GER in monozygotic than dizygotic twins [47]. Moreover, a locus on chromosome 13q, between microsatellite D13S171 and D13S263, has been linked with severe GER disease in five multiple affected families [48], but not confirmed in another five families, possibly due to genetic heterogeneity of GERD and different clinical presentations of patients recruited [49]. Familial inheritance of hiatal hernia does also occur with a likely autosomal dominant mode of inheritance [44]. More recently a GERD susceptibility gene (collagen type III alpha 1) has been discovered and shown to be a male risk factor for hiatus hernia [50]. It is not known how important genetic factors are in explaining the differences in presentation and the natural course of GER.

Extraoesophageal Manifestations of GERD

Respiratory

Nearly every single respiratory manifestation (subglottic stenosis, stridor, recurrent croup, laryngomalacia, apnea, asthma, bronchitis, pneumonia, chronic sinusitis and recurrent otitis media) has been reported in relation to GERD [12, 51]. GERD is reported in 40–75 % of children with chronic respiratory symptoms, especially when the symptoms are nocturnal and unresponsive to classic treatment [12].

A history-based diagnosis of GER was made by Chouhou, a French physician, in 18 % of a population of unselected infants younger than 10 months of age. Interestingly, he reported a higher incidence of infants with more than three episodes of rhinopharyngitis (18 % versus 16 %), more than three episodes of otitis media (11 % versus 5 %), and more than two episodes of bronchitis (3.6 % versus 2.8 %), during the first year of life [52].

In a large paediatric case-control study, GERD has been associated with an increased risk for sinusitis, laryngitis, asthma, pneumonia and bronchiectasis [53]. A systematic review on the association between GERD and asthma in children found 20 articles that described 5,706 patients, where the prevalence of GERD in asthma was highly variable (19.3–80.0 %) with a pooled average of 22.8 % with GERD symptoms, 62.9 % of 789 patients with abnormal oesophageal pH and 34.8 % of 89 patients with oesophagitis. Only five studies included controls and enrolled 1,314 patients with asthma and 2,434 controls without asthma. The average prevalence of GERD was 22.0 % in asthma cases and 4.8 % in controls (pooled odds ratio: 5.6 [95 % confidence interval: 4.3–6.9]) [54].

GER may be causing respiratory symptoms through a direct relation by (micro-)aspiration or by neurogenic reflex. The reverse may also be happening: respiratory difficulties cause greater respiratory breathing efforts and thus more pronounced negative intrathoracic pressures, provoking GER [9]

The relationship between respiratory manifestation and GERD remains controversial mostly because of the difficulty demonstrating the association between symptoms and reflux and the improvement with reflux treatment.

Apnea and Bradycardia

Frequent apnea and bradycardia, particularly with feeding, are widely accepted to be a common clinical correlate of reflux disease [10]. It is hypothesised that GER may be a direct or indirect trigger for apneic episodes via the mechanisms related to poor coordination of swallowing with breathing and neural reflex mechanisms initiated by chemical stimulation of the larynx/pharynx or oesophageal distension. Alternatively the likelihood of GER occurring may be exacerbated by a transient increase in the gastro-oesophageal pressure gradient resulting from airway obstruction [9]. The evaluation of the temporal association between reflux and apnea requires prolonged simultaneous monitoring of both reflux and respiratory events [9]. Conflicting findings of either little or no association or an association between apnea and GER, recorded by either pH probe of MII, have been reported [55, 56].

Otitis Media

Tasker et al. [57] were the first to describe the presence of gastric juice in the middle ear of children with otitis media by finding pepsin in middle ear effusions. Eighty three percent of 54 effusions contained pepsin/pepsinogen at concentrations of up to 1,000-fold greater than those in serum. A later study from He et al. [58] evaluated a larger cohort of 152 children and showed only 14 % had pepsin in middle ear fluid, and that the incidence was significantly higher in the older age groups.

This concludes the summary of the pathophysiology of GER and GERD in children.

73 The Oesophageal Mucosa: To Barrett's and Beyond – The Genesis of Oesophageal Injury and Cellular Mutations

N. Haider, A. Day, and Spencer W. Beasley

Introduction

Gastro-oesophageal reflux (GER) is a normal physiological phenomenon in infants and young children, occurring as a consequence of immaturity, a transient relaxation of the lower oesophageal sphincter and the relative short length of intra-abdominal oesophagus. Gastro-oesophageal reflux disease (GERD) can be defined as reflux leading to symptoms and/or complications and may be seen in infants or older children. Reflux of gastric contents in GERD is frequent during the day but is more common after feeds and when recumbent. Normal mechanisms tend to clear the refluxate in the oesophagus quickly, thus avoiding any mucosal damage or injury. In some conditions such as oesophageal atresia, there may be delayed oesophageal clearance, prolonging the time the refluxate is in contact with the oesophageal mucosa.

Chronic or frequent reflux may result in changes to the lower oesophagus including local inflammation, erosions or ulcerations. During the healing process, the damaged areas are usually re-reepithelialized by normal squamous epithelium. This healed area may, however, undergo a metaplastic change and be replaced by columnar epithelium, which can be gastric, fundic or of intestinal type [1]. The development of intestinal type columnar epithelium with goblet cells is termed Barrett's oesophagus (BE). The American society for gastrointestinal endoscopy (ASGE) defines Barrett's oesophagus as "specialized intestinal metaplasia of the distal esophagus irrespective of the length of segment involved" [2]. BE can lead to dysplastic changes and a subset of individuals subsequently develop adenocarcinoma. Overall, columnar lining of the oesophagus confers a 30–40-fold increase in the incidence of carcinoma. Although the precise pathogenesis of BE is not completely understood, recent data illustrates the importance of chronic acid or bile reflux with cycles of injury, inflammation and repair leading to genotoxicity.

Endoscopic Appearance of Barrett's Oesophagus

BE is able to be seen endoscopically less than 50% of the time and, otherwise, is determined only during histological examination of mucosal biopsies. When it is evident macroscopically, the typical appearance is of a circumferential irregular, "salmon pink" area with irregular edges at or above the gastro-oesophageal junction (Fig. 73.1).

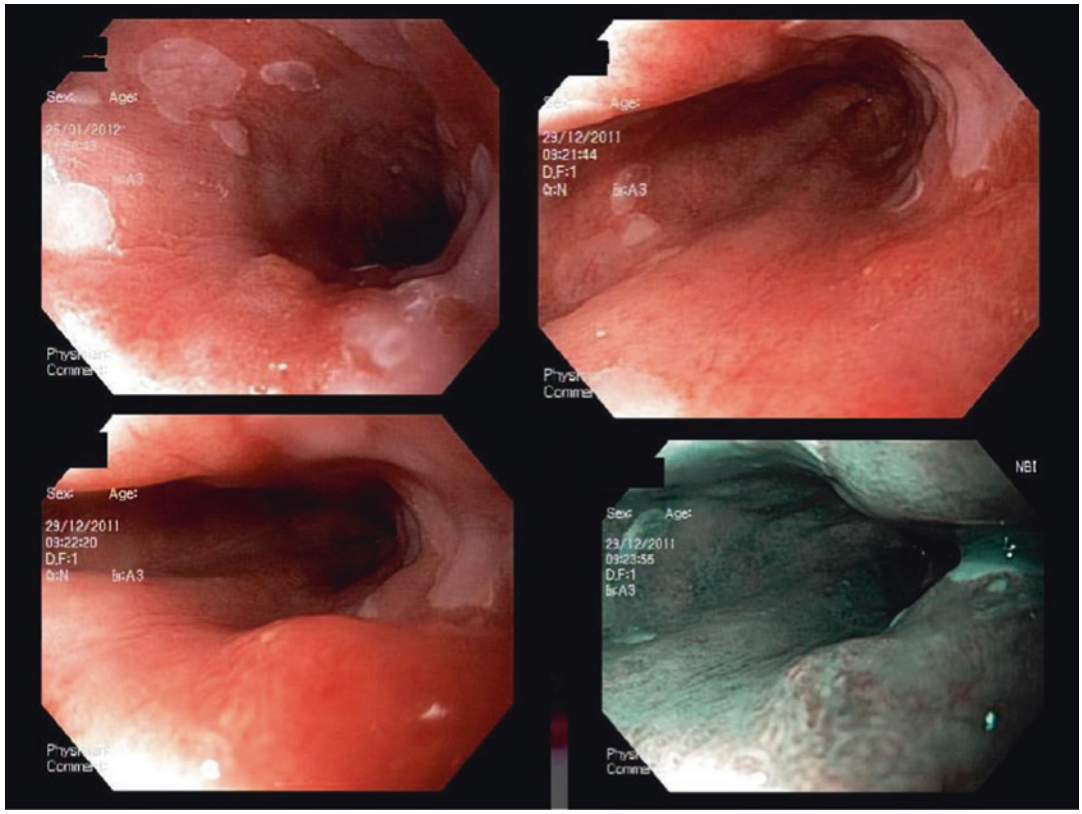

Fig. 73.1 Long-segment Barrett's oesophagus, nodule at 5 o'clock under white light and narrow-band imaging (*bottom right picture*)

Other features are of irregular or raised areas, plaques or ulcerations. Areas of metaplastic BE may be present in conjunction with dysplastic changes (low grade or high grade) or even carcinoma. Plaques, areas of increased vascularity, depressions or ulcerations in the mucosa and slight villiform elevations of the mucosa can represent dysplasia, but none of these are pathognomonic. About 50% of cancers detected at screening endoscopies are early-stage cancers (Table 73.1).

Table 73.1 Features of dysplasia and malignancy on endoscopy [3]

No	Endoscopic feature	Significance
1	Columnar epithelium	30–40× increased incidence of carcinoma
2	Plaques	May indicate dysplasia
3	Areas of increased vascularity	May indicate dysplasia
4	Depressed or elevated areas	May indicate dysplasia
5	Villiform elevations	May indicate dysplasia
6	Circumscribed, polypoid or protruded lesions	May represent malignancy

Endoscopic Appearance of Early Malignancy

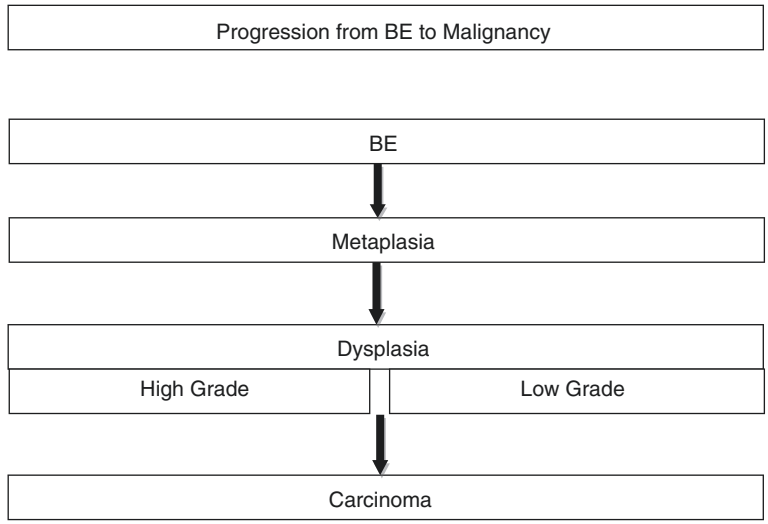
Early superficial malignancy is cancer confined to the mucosa and submucosa without lymph node metastasis. The endoscopic appearance can be divided into three types as described in Table 73.2.

As would be expected, type 2 is the most difficult to diagnose by virtue of its very subtle features, and confirmation relies on histological examination.

Table 73.2 Macroscopic appearance consistent with early superficial malignancy [3]

Type	Macroscopic appearance
Type 1	High (elevated more than 3 mm)
	Low (elevated less than 3 mm)
Type 2	Superficial flat type
Type 3	Depressed or excavated

Progression from Normal Mucosa to Malignancy



As a result of GER and chronic inflammation, the lower oesophageal mucosa may undergo carcinomatous change. The presumed sequence of events is the development of low-grade dysplasia (LGD), which progresses to high-grade dysplasia (HGD) that ultimately culminates in oesophageal adenocarcinoma. This progression from normal→metaplasia→cancer is characterized by overexpression of growth factors and inducible nitric oxide synthase and cyclooxygenase-2 [4]. There is recruitment of cells from G0 to G1, loss of control at G1/S phase transition and accumulation of cells in G2 [5]. Cyclin D1 is also overexpressed in Barrett's metaplasia, dysplasia and cancer [6]. Patients with BE with overexpression of cyclin D1 are more likely to develop adenocarcinoma compared to those without [7, 8]. Overexpression of telomerase has also been shown in BE as well as in other dysplastic and malignant lesions. This suggests that telomerase is upregulated in early neoplastic progression of BE. Various studies have reported genetic and epigenetic abnormalities in oesophageal carcinoma. Different genes may be important at different stages of tumour progression. Epigenetic changes, however, are thought to precede genetic changes. Nonsteroidal anti-inflammatory drugs (NSAIDs) appear to have a cytoprotective effect for the development of oesophageal adenocarcinoma. Long-term use of acid suppression can decrease cellular proliferation and can potentially stabilize the fragile sites [9, 10].

Risks of Malignancy and Prediction in Barrett's Oesophagus

BE has a 10% potential of turning into a malignant adenocarcinoma. Five-year survival of oesophageal adenocarcinoma is only about 10% unless detected at an early stage [11]. Mutations of p53 are common in oesophageal cancers [12]. These mutations increase with progression along the metaplasia→dysplasia→carcinoma sequence. The loss of heterozygosity (LOH) at p53 locus has been identified in 94% of cancer related to BE, and p53 mutations are seen in 88% cases of oesophageal adenocarcinoma [13]. LOH at 5q (APC locus) has also been found in p53 in 75% of Barrett's cancers. P53 mutation and allelic loss are an early event and can be identified in the stage of high-grade dysplasia before aneuploidy develops [14]. Zhuang et al. [15, 16] found LOH at APC locus in 50% of oesophageal adenocarcinomas with identical patterns of allelic loss in adjacent HGD in all cases. They also explained allelic loss in 40% of adjacent non-dysplastic areas in BE confirming that APC loss is an early event. While LOH at APC locus is

common in oesophageal adenocarcinoma, APC mutations are quite rare. Tumour-suppressor genes including CDKN2A/p16, VHL, Rb and DCC have also been shown to undergo LOH in over 50% cases of adenocarcinoma. Barrett et al. [17] showed LOH at CDKN2A/p16 locus in 75% cases. LOH was seen in both cancer and dysplasia and preceded aneuploidy. This suggested that LOH is an early event in cancer progression.

Putative Pathogenic Mechanism of Damage in Barrett's Oesophagus

BE is an acquired premalignant condition secondary to the effects of chronic reflux [18, 19]. Persistent exposure to acid and bile salts results in genetic alterations which progress with time from dysplasia to oesophageal adenocarcinoma [20]. Exposure to acid and bile salts changes oesophageal mucosa and can promote regeneration with columnar rather than squamous epithelium [21]. While a number of risk factors have been linked to the development of oesophageal carcinoma in adults, the most significant factor appears to be GERD. Obesity, hiatus hernia, diet high in fat and cholesterol and low in antioxidants and fibre and smoking are all thought to contribute to the development of oesophageal cancer but have a less pronounced effect [22–25]. It is unclear, at the molecular level, exactly how GERD leads to carcinoma.

Possible mechanisms include:

1. Prolonged acid and bile reflux causes mucosal injury either directly or via an inflammatory process [26–32].
2. The reduced antioxidant capacity of Barrett's oesophagus plays a role in tissue injury and genetic damage [33, 34].
3. Oxygen free-radical damage may be contributory as shown in animal models [35].

Secondary Healing and Damage by Acid and Bile Salts

Acid and bile salt exposure results in a range of biological effects to the oesophageal epithelium. Jolly et al. [29] have demonstrated specific damage patterns including DNA strand breaks in oesophageal cell lines, FLO 1 and HET 1, when exposed to acid and bile salt in vitro. The acid-induced damage to epithelial cells appears to be time dependent. In addition, acid exposure of epithelial cells stimulates activation of MAP kinase and cyclooxygenase-2 expression, as well as modifying proliferation and differentiation rates [31, 36–40]. DNA damage results directly from the acid component of the refluxate. Acid suppression results in further damage by bile salts which are rendered inactive at a lower pH.

FLO 1 cells derived from oesophageal adenocarcinoma have been shown to withstand longer acid exposure. These cells can withstand more noxious stimuli in part because they are derived from adenocarcinoma and possess more cytoprotective properties. In contrast, HET 1 cells derived from normal squamous epithelium show an enhanced sensitivity to damage in an acid milieu [29]. Consistent with this, patients with BE have a higher incidence of bile reflux compared to those with oesophagitis alone or control groups [41–43].

Cellular damage from bile acids includes stimulation of cell proliferation and tumour invasiveness, inhibition of apoptosis and modification of the promoter genes involved in DNA synthesis, DNA repair and oxidative stress. Some of these effects may be mediated through a bile acid-specific nuclear receptor, FXR via protein kinase C activation [44]. In addition, ex vivo exposure of BE tissue to bile salts has been shown to upgrade cyclooxygenase-2 expression and modify cell proliferation rates [31, 39]. Genetic alterations can lead to increased malignant potential [45]. It is possible that alkaline GERD causes DNA damage which results in changes at the molecular level. The promoting effects of bile salts are:

1. Increased rates of proliferation
2. Reduced differentiation
3. Elevated cyclooxygenase-2 expression [36, 38, 39]

Other possible mechanisms include topoisomerase II-mediated DNA damage as shown by Xiao et al. [20] in a mouse model or damage through reactive O2 species (ROS).

Injury and Mutations at a Cellular Level

DNA damage affects fragile sites of a chromosome. These are areas of rearrangement or loss that are observed in many malignancies. Lisa et al. [11] have reported copy number loss/loss of heterozygosity (LOH) at 56 fragile sites in patients with early BE. They found LOH in high frequency at several sites: FRA3B (81 %), FRA9A/C (71.4 %), FRA5E (52.4 %) and FRA4D (52.4 %). They also found LOH in lower frequency at other loci: FRA1K (42.9 %), FRAXC (42.9 %), FRA12B (33.3 %) and FRA16D (33.3 %). These data suggest that deletion and genomic instability at certain fragile sites could act as a biomarker for genetic damage in (BE) and also be a potential biomarker of cancer risk. Unlike in many other cancers, the LOH and copy loss observed in BE are narrow and well conserved in a subset of fragile sites, most commonly FRA3B. While wide-ranging deletions at FRA3B over a broad range, 300 KB to over 2 MB, have been reported in other cancers, deletions in the subregion (60.2–60.6 MB corresponding to FHIT exons 4–5) have only been reported by Lisa et al. The high frequency and uniformity of alterations in BE may reflect a common aetiology of genotoxic stress. In BE, this is thought to be oxidative damage as a result of direct effect and via the effects of O2 free radicals. Fragile site damage is induced by replication stress in vitro [46, 47], meaning that fragile sites may be the first regions of a genome to have mutations in vivo when exposed to a carcinogen.

Are the Mucosal Changes Reversible?

Can an antireflux procedure (ARP) result in regression of BE and reverse the dysplasia? Regression after an ARP is not proven, and there are only occasional reports of reversal of BE epithelial changes following surgical correction of reflux [48–52]. Most studies, have failed to demonstrate reversible changes following an ARP [53–57] perhaps indicating that there might be an ongoing risk of dysplasia and malignancy. Williamson et al. [58–61] reported three cases of malignancy after an ARP, while Stein and colleagues identified two further cases. Mc Donald et al. [62] demonstrated that after a failed antireflux procedure, the progression to cancer occurred during the first 3 years. The fact that all three of their cases occurred in the early follow-up period raises the possibility that changes were already present before surgery but were not detected. If so, it could be argued that there was no progression in this group of 113 patients. There is no strong evidence to suggest that ARP will reverse the changes or BE will necessarily progress to malignancy. The Mc Donald study [62] did not show any cancers in the late follow-up period, and McCallum's study [59] showed a definitive decrease in the incidence of dysplasia following an ARP. These observations would suggest that ARPs might play some role in preventing the development of new cancers.

How long does it take for these changes to develop? Low- or high-grade dysplasia which occurs in almost 20 % of patients with BE is currently the most reliable marker for progression to oesophageal carcinoma [63–66], but the process is clearly and not always predictable [64, 67]. Some have suggested that HGD can be present for several years without progression to carcinoma and may even be reversible [66, 68–70]. Altorki et al. [71] demonstrated that carcinoma was already present in 30 % cases of patients undergoing surgery for HGD.

How Long Does It Take to Progress from Barrett's Oesophagus to Malignancy?

An elegant study by Thiesen et al. [72] gives us some insight into the time frames relating to progression from the time of diagnosis of BE to when a carcinoma develops. They showed that progression from metaplasia to LGD develops in a median of 24 months, HGD 33 months and cancer 36 months, but it is not clear how long these patients had BE prior to their initial assessment. Schnell et al. [70] found a mean surveillance period of 7.3 years before cancer was detected. However, their study group included patients

with advanced cancer as well as early cancer. Early cancer was detected in their cohort of patients at about 4 years. Hameeteman et al. in a prospective study showed that it took between 1.5 and 4 years for patients to progress from LGD to cancer. This also showed HGD may be present for as long as 3.5 years before progression to cancer occurs [64]. One patient in Thiesen's study who developed cancer after a Nissen fundoplication had a time lag of 2 years before cancer was diagnosed. Though most patients with BE never develop cancer, there is a small subset that does. Despite considerable research we are still uncertain as to which patients will follow the metaplasia, dysplasia and carcinoma sequence.

Surveillance in Barrett's Oesophagus

Improvements in surveillance tools, e.g. endoscopy, augmented by ultrasonography, other imaging modalities and molecular markers may enable surveillance to become less invasive and give greater reliability in detecting disease progression.

Given the possibility that the risk of adenocarcinoma might persist even after ARP, endoscopic surveillance is still recommended. Since upper gastrointestinal endoscopy in children requires specialist facilities with provision for appropriate endoscopes, general anaesthetic and day-case arrangements, a sensitive biomarker for this condition would be particularly useful. The measurement of deletion and LOH at fragile sites may prove to be a biomarker of cancer risk in patients with BE and could play a role as an indicator of success of chemopreventive strategies in BE.

In the meantime, controversy exists regarding efficacy of screening and surveillance [73]. Some US studies have shown survival benefits in patients with BE who undergo endoscopy at least 1 year prior to diagnosis of cancer [74, 75]. Early diagnosis is thought to improve prognosis by detecting early-stage tumours and higher respectability. North American economic models suggest that screening of high-risk individuals is cost-effective as opposed to no screening [76–78]. However, one retrospective case-controlled study showed that surveillance endoscopy did not reduce the risk of death from oesophageal cancer in patients with BE [79]. They reviewed records of 36 patients who had a diagnosis of BE >6 months before diagnosis of oesophageal adenocarcinoma and subsequently died of cancer or treatment. These were matched with a control group of 134 patients who subsequently developed BE but did not die of cancer or treatment. Both these groups of patients had a similar proportion 3 cm or more Barrett's segments. The BE group had a higher prevalence of HGD at initial examination, but otherwise the two groups were similar. The age or other criteria for which surveillance should be commenced in children are yet to be determined.

A barium swallow has a limited role to play in surveillance. It may show some indirect features concomitant with BE but is not diagnostic. For example, an upper gastrointestinal contrast study can identify dysphagia as a consequence of oesophageal stricture secondary to reflux and scarring and after oesophageal atresia repair. It will also show poor oesophageal contraction and delayed oesophageal emptying.

Surveillance Recommendations

Columnar lining of the oesophagus confers a 30–40-fold increase in the incidence of carcinoma. About 50 % of cancers detected at screening endoscopies are early-stage cancers [3]. Recommendations for surveillance of BE apply to adult patients. The paucity of guidelines in children is partly because a significant proportion of children with Barrett's oesophagus does not have symptomatic reflux. In a Swedish study, 44 % patients from a random sample lacked symptoms of troublesome reflux and heartburn [80]. The natural history of asymptomatic reflux is unclear. The risk group in adults comprises of those over 40 years of age, with long-standing reflux and those with heartburn [81–83]. No such risk group for BE has been identified in children. Therefore, no definite surveillance guidelines in children have been developed. The recommenda-

tion for screening in adults, however, is yearly screening for patients with frequent reflux (several episodes per week) or chronic long-standing reflux (>5 years). If screening oesophagogastroduodenoscopy (EGD) shows no abnormality, there is no need for further screening endoscopies. When Barrett's oesophagus is identified, ongoing screening is indicated. When the endoscopic appearance is suggestive of BE or when the diagnosis is confirmed histologically, repeat endoscopy should be undertaken within 6–12 months with multiple biopsies obtained from all four quadrants at multiple levels above the gastro-oesophageal junction (GEJ).

Any macroscopic lesion is biopsied specifically in addition to the multiple other biopsies taken. A commonly practised approach is to obtain four-quadrant biopsies at 2 cm intervals [66]. The biopsy specimen should be examined by an experienced paediatric gastroenterology pathologist and classified as carcinoma, high-grade dysplasia (HGD), low-grade dysplasia (LGD), indefinite for dysplasia or no dysplasia. If there is evidence of dysplasia on the initial biopsy, a repeat biopsy should be taken within a year. If the repeat biopsy is not dysplastic, the risk of progression to malignancy is believed to be low. Further surveillance biopsies in these cases can be done after 3 years or by AGA consensus, 5 years, as patients with HGD have a 30 % chance of progressing to oesophageal carcinoma [84].

Most experts would take HGD as a threshold for intensive surveillance or more aggressive treatment: definitive surgical treatment, mucosal ablation or close surveillance. Comorbidities in adults influence the mode of treatment. Since children tend not to have comorbid factors, close surveillance is more readily undertaken. If mucosal ablation is undertaken, the follow-up should include biopsies of the entire area of prior Barrett's mucosa at intervals appropriate for the prior grade of dysplasia until three consecutive biopsies are normal. Various surveillance protocols in patients with HGD have been proposed (Table 73.3).

The role of surveillance for LGD is less certain as the risk of LGD progressing to carcinoma is less well defined. The recommendation of the American Society for Gastrointestinal Endoscopy (ASGE) is a repeat endoscopy at 6 months with multiple biopsies. If LGD is confirmed, it would seem reasonable to undertake yearly surveillance endoscopy with biopsies for the duration that dysplasia persists. Oesophagitis can mask changes in the oesophageal mucosa. In a study by Hanna et al. [86], about 12 % patients with erosive oesophagitis were found to have BE after treatment of their condition. Hence, a repeat biopsy should be performed after 8 weeks of acid

Table 73.3 Surveillance protocol in dysplasia [85]

No Dysplasia	**Low grade dysplasia**	**High grade dysplasia**	Every three months for one year with 4 quardrant biopsies 1 cm apart
Every 2-3 years	Repeat endoscopy and biopsy at 1 year. If no HGD at that time, then endoscopy and biopsies every 2-3 years	If no progression to dysplasia or cancer on 2 consecutive endoscopies	6 monthly for 1-2 years

suppression therapy if the first biopsy revealed indeterminate dysplastic changes and/or acute inflammation secondary to GERD. Endoscopic brush cytology has also been proposed as a diagnostic tool [87]. The application of this technique has been limited, but with the development of more sensitive fluorescent in situ hybridization techniques, its clinical utility may improve [88]. Capsule endoscopy is a new, noninvasive technique that may eventually replace routine endoscopy. Although initial studies described high sensitivity, subsequent studies have been less enthusiastic [89, 90]. The special setup, equipment, cost implications and technical difficulties in introducing the capsule in children have limited the application of this technique in paediatrics.

New Diagnostic Techniques

Narrow-band imaging and autofluorescence imaging have been used to detect dysplastic areas. In narrow-band imaging the illuminating light is filtered into blue and green colours which have a differential absorption in blood vessels of the mucosa and the subepithelial layer allowing better to visualization of the mucosa with a high-resolution endoscope [91–93]. In one study the specificity of narrow-band imaging was found to be 98.7 % [94]. The autofluorescence technique uses blue light to detect fluorescence from oesophageal lining. Areas of dysplasia do not have the normal fluorescence and appear dark red. One study using autofluorescence identified dysplasia in 100 % cases, but there was a 40 % false-positive rate [95]. Chromoendoscopy, still used in some places, relies on the observation that methylene blue binds to areas of intestinal metaplasia but not to areas of high-grade dysplasia or cancer. Prospective studies have not found chromoendoscopy to be superior to four-quadrant biopsies in the detection of dysplasia [96–98]. All these methods gain in utility with larger areas of dysplasia. Different imaging techniques are used to establish changes in smaller areas. Optical coherence tomography uses light to create interference patterns to detect intestinal metaplasia [99]. Laser confocal microscopy can magnify the mucosa and actually image the cellular structures. In a study of 63 patients, this technique showed an accuracy of 94 % in detecting neoplasia [100]. Spectroscopic instruments to assess the optical properties of light have been combined to allow improved visualization and characterization of the mucosa. All these imaging techniques and systems are potentially attractive but at this stage are not feasible for routine clinical investigations at this time (Table 73.4).

Search for a Reliable Biomarker

The availability of a sensitive and specific biomarker would assist in the surveillance and screening of BE. Various nuclear DNA content abnormalities like aneuploidy, tetraploidy and loss of heterozygosity of genes like p16 and p53 have some value in predicting cancer risk in patients with BE. Flow cytometry on fresh frozen specimens is used to demonstrate aneuploidy and tetraploidy. There is virtually no risk of cancer development in the absence of aneuploidy and tetraploidy on flow cytometry [101], whereas the presence of either of these increases the risk of cancer. Unfortunately, these techniques have limitations due to the number and size of biopsies required. Similarly, the loss of heterozygosity of

Table 73.4 Role and reliability of various imaging techniques [84]

Technique	Useful in detecting	Reliability	Drawback
Narrow-band imaging	Dysplasia	Up to 98 %	
Autofluorescence	Dysplasia	100 %	40 % false positive
Chromoendoscopy	Metaplasia	Uncertain (not superior to four-quadrant biopsies)	
Laser confocal microscopy	Neoplasia	94 %	

p16 and p53 is indicative of 16-fold increased risk of cancer [102], but these techniques have only been used in specially processed tissues, and hence clinical validation is required before they can be used in standard practice. Multiple biomarkers including markers of cell immortalization, loss of apoptotic control, angiogenesis, cell proliferation and cell cycle abnormalities have been proposed, but none have been validated in clinical studies.

Ongoing search for new markers has resulted in the discovery of sialyl Lewis^a, LewisX, *Aspergillus oryzae* Lectin (AOL) and Wheat-Germ Agglutinins. These can be studied in formalin-fixed tissues. Cyclin A is a marker of cell proliferation and correlates with the degree of dysplasia. It can be assessed using immunohistochemistry techniques. DNA content abnormalities [103] have been known to be important in disease progression and can be measured by flow and image cytometry [104]. The role of p53 in the development of OAC is well known and inactivation of this gene plays a vital part in development of OAC.

Changes in glycan expression occur in the development of OAC. Most genes which influence glycan pathways do so via Lewis antigens (Le) which are also known to be altered in many other malignancies [105–107].

Bird-Lieberman et al. [108] have previously shown that expression of Le antigens, sialyl Lewis^a and LewisX correlates with the degree of dysplasia in BE. They have, in a different study, also confirmed decreased binding of lectins (specific glycan-binding proteins) like Wheat-Germ Agglutinin (WGA) and *Aspergillus oryzae* Lectin (AOL) in progression of BE to EA. sLe^a and LeX are new markers which may help to predict the behaviour of BE in the future.

A more recent study by Bird-Lieberman et al. [109] suggests an 11-fold increase odds of progression to HGD or cancer if LGD already existed in BE. They have proposed a three-biomarker panel which includes DNA ploidy, sLe^a and AOL abnormalities, to ascertain the likelihood of disease progression. In their study of 89 patients who developed cancer between 1993 and 2005, cyclin A, p53 and WGA abnormalities did not show a significant trend towards disease progression. The outcome of HGD and OAC was similar based on the above markers, with the exception of p53 expression which was predictive of progression from BE to OAC. They have proposed a clinical algorithm; if ≤1 biomarker (of AOL, aneuploidy or LGD) is abnormal, a surveillance protocol should be followed. However, in the presence of ≥2 abnormal biomarkers or recognition of HGD, endoscopic ablation should be offered or recommended. This algorithm is based on limited evidence, but may serve as a guide until there is more thorough validation by further prospective studies.

Clinical application of these biomarkers and their role in detecting evolution from a premalignant condition to malignancy will play a very important role in satisfactory surveillance. While underinvestigation of the high-risk patients can result in failure to recognize disease at an early stage, over-investigation has definite cost and resource implications.

Treatment Options

Photodynamic therapy has been shown to reduce cancer risk in BE. In a prospective study, photodynamic therapy using sodium porfimer and photoradiating balloons decreased the risk of cancer by 50%. It also eliminated HGD in 78% of patients [110]. Photodynamic therapy with 5-aminolevulinic acid has been successful in eliminating HGD and early carcinoma but may cause hypotension, and there has been one report of a patient death [111]. Thermal ablation using laser produces deep tissue injury. Argon or multipolar coagulation devices produce similar results. Multipolar coagulation has been used to treat LGD and non-dysplastic BE with success rates of up to 90% after multiple applications. Argon plasma coagulation at high power output has been used to treat HGD and small cancers [112, 113].

Oesophageal adenocarcinoma can be treated by surgical or endoscopic ablation. Endoscopic ablation decreases the risk of cancer within Barrett's mucosa and is always done in combination with acid suppression treatment. This procedure involves endoscopic identification of

dysplastic areas which are then resected. Endoscopic surveillance can miss 43 % of early cancers by the time a diagnosis of cancer is made by which time it may have already metastasized [114]. However, the risk of metastatic cancer when the initial lesion is intramucosal carcinoma may be as low as 4 %, especially if there is no mucosal involvement [115]. Surgery for oesophageal adenocarcinoma can be carried out using the traditional transhiatal approach or using minimally invasive laparoscopic or thoracoscopic techniques. Minimally invasive techniques have a complication rate of up to 32 % similar to the conventional transhiatal approach [116]. Vagal-sparing oesophagectomy with colonic replacement has been described but is not popular in the adult population. A recent retrospective study comparing the long-term mortality of 200 patients with HGD treated with photodynamic therapy and mucosal resection compared with surgical resection found similar mortality between the two groups at a 5-year follow-up [117]. While the results of two forms of treatment are similar, the decision of the mode of treatment may be made according to the expertise and facilities available.

GERD	Gastroesophageal reflux disease
NASPGHAN	North American Society of Pediatric Gastroenterology, Hepatology and Nutrition

A careful history and physical examination remain the basis of sound medical practice. The symptoms and signs leading to a differential diagnosis that includes gastroesophageal reflux disease (GERD) vary with age. History needs to be specific to reveal known symptom associations. Physical examination should include feeding or behavioral observation when complaints indicate problems in those areas.

History

In the case of infants and young children, history is taken from the parents or caregivers. Attention should be paid to the child's description of the problem as soon as she or he can express her- or himself. Toddlers are able to indicate pain and provide a limited description. From the age of 5 or 6 years old, the history should definitely be taken from both the caregivers and the child. Neurologically disabled children remain largely dependent on their caretakers for a history, by proxy. In such cases, it can be important to talk with the different caregivers involved as at least a part of the day is often spent in an institution. Careful history taking is time consuming and is better done initially since it will be the basis for the differential diagnosis and plan. It also allows the physician to meet the patient and the family and to gather a sense of the social and familial setting.

A general history includes information about gestation, birth, perinatal events, prior medical conditions, medication, allergies, developmental milestones, and growth. A percentile chart for weight, length, and head circumference should *always* be part of the patient's chart.

Based on the recently published global evidence-based consensus on the definition of GERD in the pediatric population [1], history should aim at discovering esophageal and extraesophageal symptoms. Symptoms suggestive of GERD and reported

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_74

by the parents in young children (up to 8 years) or in neurologically compromised patients include excessive regurgitation, feeding refusal, choking, gagging, coughing, sleep disturbance, and abdominal pain. Although excessive crying is often attributed to GERD and treated accordingly, there is no evidence to support the link between excessive crying in the infant and GERD. Studies in infants treated with proton pump inhibitors fail to demonstrate an effect on crying despite effectively treating acid reflux [2, 3]. Older children are able to report symptom associations that are typical for GERD such as heartburn and epigastric pain. According to the consensus [1], extraesophageal symptoms such as dental erosion and dystonia suggestive of Sandifer's syndrome are definitely associated with GERD. The association of respiratory symptoms, bradycardia, and apnea are considered possibly associated with GERD.

The changing pattern of symptoms with age is represented in Table 74.1. In the youngest age group, regurgitation and vomiting are more prevalent. In adults, epigastric pain and heartburn are typical symptoms. In an attempt to facilitate a symptom-based diagnosis of GERD, specific questionnaires have been developed and validated [4, 5]. However, their sensitivity and specificity is too low to reliably make a diagnosis of GERD, suspect complications, or predict response to therapy [6].

Finally, as always, a thorough system history should never be omitted since symptoms suggesting GERD are nonspecific and the differential diagnosis is broad. The physician should exclude symptoms caused by allergic, infectious, neurological, urinary tract, respiratory, cardiac, or psychosomatic conditions. Warning signals in a vomiting infant or child should lead to immediate appropriate action to exclude diagnoses other than GERD, especially increased intracranial pressure. Bilious or hemorrhagic vomiting, forceful or sudden vomiting, altered consciousness, lethargy, seizures, and severe failure to thrive are warning signals. These situations are more of the exception than the rule. The physician should remain alert for exceptions but be well aware that uncomplicated GERD is a common condition.

Another frequent condition is food allergy, specifically cow's milk allergy (CMA) in infants.

Table 74.1 Symptoms of GERD according to age categories

Symptoms	Infants	Children	Adults
Gastro			
Vomiting	++	++	+
Regurgitation	++++	+	+
Excessive crying	+++	+	–
Food refusal	++	+	+
Failure to thrive	++	+	–
Abnormal posturing	++	+	–
ALTE	+	–	–

Chest pain	?	+	++
Dysphagia	?	+	++
Dental erosions	?	+	+
Hoarseness	?	+	+
Vocal problems	–	+	+
Stenosis	–	+	+

CMA and GERD both cause regurgitation and vomiting. These conditions may coexist or mimic each other. Symptoms should be reevaluated after adherence to an exclusion diet.

The most recently published guidelines by a joint committee of experts from NASPGHAN and ESPGHAN conclude that in infants and toddlers, there is no symptom or symptom complex that is diagnostic of GERD nor one which predicts response to therapy. However, in older children and adolescents, as in adult patients, history and physical examination may be sufficient to diagnose GERD, if the symptoms are typical [6].

Family History

The physician should know about chronic and congenital conditions in the family. History of gastrointestinal surgery should be specified.

Hiatal hernia or other congenital abnormalities can be inherited [7]. In some cases, GERD is familial [8]. A history of atopy in first-degree relatives is considered a high risk for CMA in infants and guides diagnosis and therapy.

Physical Examination

A careful physical examination by system is mandatory for each patient. Vital signs including blood pressure, weight, height, and head circumference should be charted. Developmental stage and neuromotor skills should be noted. Dysmorphic features may be the clue to a genetic disorder. Eczema suggests allergy. GERD does not cause any specific clinical sign. Accompanying signs may be dystrophy, dental or ENT abnormalities, wheezing or bronchial spasms, dystonia, and abnormal posturing in the case of Sandifer syndrome. The history (symptoms) and findings by physical examination (signs) contribute to the differential diagnosis.

Feeding observation is an extension of the physical examination. A skilled feeding therapist is frequently involved for this type of observation. Oral reflexes, signs of oral aversion, and swallowing can be assessed using specific scales such as the NOMAS [9].

In conclusion, although many tests are available for the diagnosis of GERRD and related complications, the care of an infant or child with possible GERD should always start with a good history and complete physical examination. Symptoms and signs of GERD are nonspecific. In other words, history and physical examination will generally give a pointer towards, but not be completely sufficient to make a diagnosis of, GERD, except in adolescents with heartburn. The physician should always be alert and have a differential diagnosis in mind. It is based on the critical first step of assessing signs and symptoms that further tests would be necessary – generally history will suffice. Each infant or child is unique and should be assessed and cared for as such. The risk is real that a patient enters a protocol based on a far too limited history and no physical examination.

GER: The Place of pH Testing

75

Yvan Vandenplas

Introduction

Gastroesophageal reflux (GER) is the involuntary passage of gastric contents into the esophagus. GER is a physiological event several times a day in every individual, particularly after meals. Most reflux episodes are asymptomatic, brief, and limited to the distal esophagus.

The knowledge that esophageal pH measurement may be of clinical importance started with the observation that a drop in esophageal pH below 4.0. may cause heartburn [1, 2, 3]. This historical observation points out one of the major pitfalls of pH monitoring: the cutoff of "pH 4.0" was defined to separate reflux causing "heartburn" from reflux causing "no heartburn." The first clinical tests were performed in the early 1960s by Miller [4, 5, 6]. The commercialization of esophageal pH monitoring devices in the 1980s changed the work-up of GER substantially. It took many years to discover advantages but also pitfalls of pH monitoring.

The Hardware

Purchase costs, system abilities, costs in use, number of measurements, and durability of the material are factors to consider before purchasing equipment. Of importance for pediatric use is a time indication on the display of the recording device (i.e., the number of data recorded, the real time and duration of the investigation) and the protection of event marker(s) to avoid erroneous use by the child. A system should refuse to work if it has not been calibrated properly. One of the advantages of pH monitoring is the possibility of obtaining an ambulatory recording, even in young children. The device should be as small and light as possible.

The utility of wireless technology to measure GER has been validated in several studies, with improvements over catheter-based pH monitoring in tolerability, accuracy, and sensitivity. The major advantage of the wireless capsule is the possibility to allow prolonged pH recording in more physiologic conditions. The capsule sloughs off the wall of the esophagus in 7–10 days and passes out of the body naturally. However, data in children are still limited. Recently, a new technique (Restec®) has been developed. It is a new antimony-based technologically using short pharyngeal electrodes and is indicated in patients with extraesophageal symptoms such as chronic coughing.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_75

pH sensors or "electrodes" exist in several forms, of which the two most popular are glass and antimony. Ion-sensitive field effect pH electrodes (ISFET) are modified field effect transistors (they are frequently used in impedance catheters). Clinical studies require a pH sensor that is both affordable and reliable. Electrodes should have an internal reference, avoiding all the technical problems due to the external reference electrode.

Reproducibility

Data obtained with a glass electrode correlate poorly with data obtained using an antimony electrode. In other words, normal ranges obtained with glass electrodes cannot be used for recordings with antimony electrodes. Whatever the type of electrode chosen, each center should preferentially use one device and one type, or a limited number of different electrodes. Data on reproducibility of pH monitoring vary from fair to poor. However, data on the reproducibility of all investigations for GER are poor, probably at least in part due to the day-to-day variability.

Location of the Electrode

The exact esophageal location of the pH electrode is of critical importance regarding the number and duration of acid reflux episodes recorded. The closer the electrode is located to the lower esophageal sphincter (LES), the more acid reflux episodes will be detected.

The Cutoff of pH 4.0

Esophageal pH monitoring is often considered as an investigation technique studying esophageal motility, which it obviously does not. In fact, esophageal pH metry does even not measure GER. The technique simply measures changes in esophageal pH, not GER. pH 4.0 may be an appropriate cutoff for heartburn, but it has not been validated in patients with respiratory symptoms caused by GER. Over time, many attempts have been proposed in literature to use other cutoff values than pH 4.0. Every cutoff value has the disadvantage that a value just above is considered normal and a value just below is considered abnormal. Therefore, the "oscillatory index," which is an index measuring the risk for erroneous interpretation, has been developed. Although the reflux index (the % of time with a pH <4.0) was not, the "area below pH 4.0" (taking into account the acidity of the reflux episode) has been shown to be related to esophagitis.

Indications

The main indications for esophageal pH monitoring are (1) clinical and laboratory research; (2) clinical procedure to diagnose acid reflux, especially in children presenting with atypical GER manifestations; and (3) the evaluation of the efficacy of anti-reflux medication [7].

Esophageal pH monitoring measures per definition acid reflux. Impedance measures acid, weakly acid, and weakly alkaline reflux. Although impedance measures many more reflux episodes than pH monitoring, the question remains if it is clinically important to measure "more" reflux. The technique of impedance is much more expensive (cost of devices and electrodes), and time-consuming for interpretation, than pH monitoring.

Esophageal pH monitoring will detect the number and duration of acid reflux episodes. Today, the role of weakly acid or nonacid reflux is still not clearly demonstrated. Weakly acid reflux has been shown to be related in time to symptoms. However, a causal relation has not been demonstrated, and there are no therapeutic trials to confirm this hypothesis. Thus, the question remains if it is clinically relevant to demonstrate that weakly acid reflux is more frequent than acid reflux or if the "association in time" is as well demonstrated for acid reflux. Moreover, especially in young infants, up to

25 % of the episodes with presence of acid in the esophagus are only detected with pH monitoring and not with impedance because there is no apparent bolus movement. In other words, since impedance recording includes pH monitoring, impedance will detect more reflux than pH monitoring. The question is: is it clinically relevant to detect more reflux episodes?

The limited therapeutic options are another reason to prefer pH monitoring to impedance in daily clinically routine. Therapeutic efficacy has only been demonstrated for dietary and positional treatment and for acid-blocking medication. It can be questioned if it is relevant to measure reflux that is obviously acid or if the therapeutic options are limited to reducing gastric acid.

Because today only acid reflux has been shown to cause symptoms (heartburn), and because medical therapeutic options are limited to reducing acid reflux but not reflux per se, a diagnostic tool measuring "acid reflux" should still be considered as the "reference diagnostic tool."

pH and Impedance Measurements in Infants and Children

76

Yvan Vandenplas

Why Monitor the pH and/or Impedance in the Esophagus?

Gastroesophageal reflux (GER) is the involuntary passage of gastric contents into the esophagus. GER is a physiological event occurring in every individual several times during the day, particularly after meals. Most reflux episodes are asymptomatic, brief, and limited to the distal esophagus. GER may be a primary gastrointestinal motility disorder but may be secondary to other conditions, such as cow's milk protein allergy. According to recent literature, cow's milk protein allergy is a frequent cause of GER during infancy [1, 2]. This review will discuss both the advantages and disadvantages of pH and impedance techniques to measure GER.

The idea that pH measurement in the esophagus may be of clinical importance started with the observation that acid perfusion-induced heartburn coincides with a fall of intraesophageal pH below 4.0 [3]. This simple historical observation points out one of the major pitfalls of pH monitoring: the cutoff of "pH 4.0" was defined to separate reflux causing heartburn from reflux causing no heartburn. However, "heartburn" is only one of the indications for pH monitoring. In other words, pH 4.0 may be an appropriate cutoff for heartburn, but it has not been validated in patients with respiratory symptoms caused by GER. Esophageal pH monitoring is often considered as an investigation technique studying esophageal motility, which it obviously does not. In fact, esophageal pH metry does not even measure GER. The technique simply measures changes in esophageal pH, not GER. The commercialization of esophageal pH monitoring devices in the 1980s changed the workup of GER substantially. It took many years to discover advantages but also pitfalls of pH monitoring.

The first clinical tests were performed in the early 1960s by Miller [4]. Electronic technology has profoundly changed the practice of medicine, principally through its ability to monitor, record, and analyze large volumes of data. The introduction of computers has provided physicians with powerful tools to identify elusive and intermittent disorders, such as GER disease (GERD). As a consequence of this technical evolution, measurement of the impedance in the esophagus has become possible.

The basic principle of impedance recording is identical to pH monitoring: registration of esophageal events with a probe placed transnasally and connected to a recorder. Impedance allows the detection of the frequency, the esophageal height, and duration of reflux episodes, independent of the pH of the refluxate. The term "intraluminal impedance monitoring" is preferred because of

the concurrent measurement of impedance from multiple intraluminal recording segments. The method allows detection of GOR based on changes in electrical resistance to electrical current flow between two electrodes, when a liquid and/or gas bolus moves between them (Table 76.1: GER as measured by intraluminal impedance monitoring). Impedance detects GER if there is a sequential orally progressing drop in impedance to less than 50 % of baseline values starting distally (3 cm above the lower esophageal sphincter) and propagating retrogradely to at least the next two more proximal measuring segments. According to the corresponding pH change, impedance-detected reflux can be classified as acid if the pH falls below 4 for at least 4 s or, if pH was already below 4, as a decrease of at least 1 pH unit sustained for more than 4 s. Weakly acidic reflux is defined as a pH drop of at least 1 pH unit sustained for more than 4 s with basal pH remaining between 7 and 4. Reflux is considered to be weakly alkaline when there is impedance evidence of reflux but the pH does not drop below 7 [5, 6]. According to literature, the number of weakly acid reflux episodes differs substantially (Table 76.2). In many studies, weakly alkaline and weakly acidic reflux are grouped together as "nonacid reflux." Intraluminal air (which has a very low electrical conductivity) provokes a rapid and pronounced rise in impedance [5].

The main indications for esophageal pH monitoring are (1) clinical and laboratory research; (2) clinical procedure to diagnose acid reflux, especially in children presenting with atypical GER manifestations (Table 76.3: symptoms according to age); and (3) the evaluation of the efficacy of treatment of GERD on the frequency and duration on the presence of acid in the esophagus [7, 8]. Intraluminal impedance (measuring flux of ions) will measure more events than measurements of drops in esophageal pH, since not all reflux is acid.

Table 76.1 Definition of types of gastroesophageal reflux (GER) detected by intraluminal impedance

Liquid GER: drop in impedance to less than 50 % of baseline values
Acid GER: pH falls below 4 for at least 4 s or, if pH was already below 4, decreases by at least 1 pH unit sustained for more than 4 s
Nonacid reflux: weakly acidic and weakly alkaline GOR
Weakly acidic reflux: pH drop of at least 1 pH unit sustained for more than 4 s with basal pH remaining between 7 and 4
Weakly alkaline: pH does not drop below 7
Gas reflux: rapid and pronounced rise in impedance

Hardware and Software: Pediatric Needs

The Device

Purchase costs, system abilities, costs in use, number of measurements, and durability of the material are factors to consider before purchasing equipment. Impedance equipment is considerably more expensive than pH metry devices. Of importance for pediatric use is a time indication on the display of the recording device (i.e., the number of data recorded, the real time and duration of the investigation) and the protection of event marker(s) to avoid erroneous use by the child [8]. A system should refuse to work if it has not been calibrated properly.

There is no difference between a device for pH or impedance recording: it is a "box" that stores data in memory; at the end of the recording, the device needs to be connected to a computer to read out the stored data. One of the advantages of pH and impedance monitoring is the possibility of obtaining an ambulatory recording, even in young children. The device should be as small and light as possible. For pH metry, devices no larger than a credit card, although of course a little thicker, are now commercially available.

The utility of wireless technology for GER diagnosis has been validated in several studies, with improvements over catheter-based pH monitoring in tolerability, accuracy, and sensitivity, as well as the ability to record periods both off and on therapy with proton pump inhibitors in a single study [9]. The major advantage of the wireless capsule is the possibility to allow prolonged pH recording in more physiologic conditions. The capsule sloughs off the wall of

the esophagus in 7–10 days and passes out of the body naturally. However, data in children are currently limited [10].

The pH and Impedance Electrode

pH sensors or “electrodes” exist in several forms, of which the two most popular are glass and antimony. Ion-sensitive field effect pH electrodes are modified field effect transistors. Clinical studies require a pH sensor that is both affordable and reliable. Glass electrodes with an internal reference are “the best” but are expensive and have a rather large diameter (3.0–4.5 mm) [11, 12]. Although the passage of such an electrode through the nostrils of a baby is, most of the time, technically possible, it does not mean that it is well tolerated and that it is the best option.

Owing to their smaller diameter, antimony (2.1 mm) or glass microelectrodes (1.2 mm) are preferable in infants. Antimony electrodes also exist with a diameter of about 1.5 mm for use in premature babies; these electrodes are too flexible for use in older babies. Glass electrodes have only one pH sensor. Antimony electrodes with multiple pH sensors may help to detect alkaline reflux episodes, although measurement of esophageal pH is not recommended to detect alkaline reflux [13]. Antimony electrodes with two sensors can also be helpful to evaluate the therapeutic efficacy of acid-reducing medication: the esophageal sensor measures the incidence of acid reflux, while the gastric sensor measures efficacy of the medication. Antimony is only poorly resistant to gastric acid, but the fact that acid should be reduced or minimalized in these patients reduces the impact of this shortcoming. Thus, “Bilitec” (a technique measuring the presence of bile in the refluxed material) and non-pH-dependent techniques such as impedance offer much more benefits to measure nonacid reflux compared with using pH electrodes with multiple electrodes.

Glass microelectrodes and, historically, also antimony electrodes need an external cutaneous reference electrode, which may cause erroneous measurement resulting from transmucosal potential differences. If the environmental temperature is high or the patient sweats a lot, the conductivity of the contact gel will change, resulting in a less accurate conduction of the electric potential. Antimony electrodes with a diameter of about 2.0 mm containing an internal reference electrode have been developed, providing adequate results. This electrode is accurate, thin, flexible, and easy to place in the esophagus and has become standard. Data obtained with a glass electrode correlate poorly with data obtained using an antimony electrode [14]. In other words, normal ranges obtained with glass electrodes cannot be used for recordings with antimony electrodes. Whatever the type of electrode chosen, each center should preferentially use one device and one type or a limited number of different electrodes.

Prior to each study, an in vitro two-point calibration must be carried out. The electrode and reference are placed in two buffer solutions (usually pH 1.0 and 7.0; for antimony pH 4.0 and 7.0) at either room or body temperature until stabilization is reached. This calibration should be repeated on return of the patient to rule out electrode failure and to check for slow pH drift. A drift of less than 0.5 pH over the 24-h period is acceptable. Calibration needs to be corrected according to both room and body temperatures.

Both the device and the electrodes for impedance testing are considerably more expensive than those used for pH metry. The impedance electrode also has one or two antimony sensors to

measure pH and rings (generally 6) to measure impedance. In older patients, the pH electrode at the tip of the catheter measures gastric pH, whereas the other pH antimony sensor measures esophageal pH.

Location of the Electrode

The exact esophageal location of the pH electrode is of critical importance regarding the number and duration of acid reflux episodes recorded. The closer the electrode is located to the lower esophageal sphincter (LES), the more acid reflux episodes will be detected [15, 16]. In adults, the electrode is, by consensus, positioned 5 cm above the proximal border of the LES. Also in adults, determination of the position of the LES by means of a standard stationary esophageal manometry study is generally regarded as the optimum method for pH probe localization [12]. In children, several other methods have been proposed to determine the location of the electrode: fluoroscopy, calculation of the esophageal length according to Strobel's formula (distance from the nose to the cardia = 5 + 0.252 [length in cm]), and endoscopy. Ideally, as in adults, the electrode should be sited in reference to the manometrically determined LES. However, this has several inconveniences: (1) manometry in infants and children is time consuming, rather invasive, or at least unpleasant and (2) this method has the inconvenience that the electrode is located at a fixed distance to the LES, whereas the length of the esophagus increases from less than 10 cm in a newborn to over 25 cm in an adult. Moreover, manometry cannot be performed in all centers. Therefore, the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition Working Group recommended the use of fluoroscopy to locate the electrode [8]. The radiation involved is minimal, and the method can be applied in each center. As the tip of the electrode moves with and during respiration, the tip should be positioned in such a way that it overlies the third vertebral body above the diaphragm throughout the respiration cycle. Dislocation by a curled electrode is also prevented with fluoroscopy. If the pH device is exposed to X-rays, the data and calibration may be erased.

For impedance it is also relevant to know the location of the impedance sensors, since the esophageal height of reflux episodes is considered one of the advantages of impedance.

Impedance: The Technique

Experience with pH monitoring has shown the pitfalls of an arbitrary cutoff limit such as pH 4.0. A similar comment can be made for impedance: the automated analysis considers only a drop of impedance of 50 % or more as a reflux episode. However, it is likely that a drop of 49 % also can be attributed to reflux. Although impedance interpretation necessitates a manual analysis, the relevant question remains what level of decrease in impedance is needed to be considered as a reflux episode? A drop in impedance is not related to the volume of the refluxate. The multiple impedance rings allow the height of the reflux episode to be identified. If pH monitoring is performed with a probe with multiple pH sensors, it is also possible to determine the height of the refluxate. The major difference between both techniques is restricted to the detection of nonacid reflux. As a consequence, another fundamental questions arises: what is the clinical relevance of nonacid or weakly acid and alkaline reflux?

Patient Preparation

Other than fasting, no special patient preparation is required for pH monitoring. The patient should fast for at least 3–5 h before the study, depending on the age, to avoid nausea and vomiting. If the child is able to communicate, it is important to reassure the child at the beginning of the study and explain what will happen. The child should understand that the passage of the catheter through nostrils and pharynx is uncomfortable,

but after the first few swallows, it will feel better. To facilitate insertion, a spray containing silicone can be placed on the electrode (but not on the pH sensor!), and/or the mucosa of the nostrils can be sprayed with a topical anesthetic. Sedation should not be used because the sedative interferes with swallowing and influences LES pressure.

Histamine$_2$ (H^2) blockers and proton pump inhibitors should be stopped at least 3 or 7 days, respectively, before a diagnostic pH monitoring (except when the investigation is performed to evaluate the acid-blocking effect of the drug). Antacids are permitted up to 6 h prior to the start of the recording. Prokinetics should be stopped at least 48 h before the pH monitoring [15]. Whether acid-suppressing medications decrease reflux events or only change the pH of the reflux events has been insufficiently validated with impedance. This issue is one of the priority areas for research with impedance.

It is best not to start a pH metry study the same day that an upper gastrointestinal tract endoscopy is performed because the sedation, fasting, and inflated air may be confounders. It is best to start pH metry at least 3 h after a barium swallow or radionuclide gastric or esophageal studies.

Patient-Related Influencing Factors: Recording Conditions

Feeding, position, and physical activity are examples of patient-related factors influencing reflux events. Patient-related factors that possibly influence the results of reflux investigations remain a controversial topic [8, 15]. The answer to the fundamental question regarding whether patient-related factors should be minimized and standardized is difficult and necessarily ambiguous. If the reflux investigation is performed as part of a diagnostic workup in a patient, it is interesting to undertake the study during normal daily life. On the other hand, if the reflux investigation is performed as part of a clinical research project, recording conditions should be standardized. Standardization of recording conditions inevitably causes a loss of patient-specific information.

Duration of the Recording

The duration of the recording should be as close as possible to 24 h and at least 18 h, including a day and a night period both for pH and impedance measurements [8, 36, 37]. If pH monitoring is performed for diagnostic purpose, there is no indication for short-duration pH tests (e.g., Tuttle and Bernstein tests, 3-h postprandial recording). The first reports on the clinical use of pH monitoring concerned esophageal tests of short duration. Tuttle and Grossman developed the "standard acid reflux test" [38]. This test was modified by Skinner and Booth [39] and Kantrowitz and colleagues, [40] demonstrating that pH tests can contribute to define abnormal GER. The Tuttle test was reported to have a sensitivity of 70 % [41]. However, after great initial enthusiasm for this test, criticism was overwhelming. The test is unphysiologic in requiring intragastric instillation of acid and various artificial maneuvers to raise intragastric pressure. In the early 1980s, it was reported that the false-positive rate might be as high as 20 % and false-negative rates as high as 40 % [42–44]. Bernstein and Baker demonstrated, in 1958, that heartburn could be provoked by infusing diluted hydrochloric acid into the esophagus in susceptible individuals [45]. This test was reported to be 100 % positive in heartburn patients [46]. A modified Bernstein test was used to illustrate the relationship between GER and apnea and stridor and between nonspecific chest pain and GER [47, 48]. Provocative testing can be used in particular conditions to demonstrate the relationship between GER and specific symptoms such as bradycardia in relation to the presence of acid in the distal esophagus. However, provocative testing has the inconvenience that the investigation conditions are unphysiologic, which likely explains discrepancies reported in the literature. For instance, Ramet and colleagues showed prolongation of the R-R interval on ECGs in infants during provocative testing with instillation of acid in the esophagus [49], whereas other investigators could not reproduce these findings in 24-h

recordings under more physiologic conditions [50, 51].

There is now substantial evidence that both in controls and in the majority of infants and children with classic symptoms of GERD, esophageal acid exposure is highest during the day, probably because of provocation of GER by food ingestion and physical activity. Controls have more reflux upright than supine and more reflux awake than asleep [52]. The relationship between esophagitis and nocturnal acid reflux is far from clear [53–55]. Limited experience with impedance confirms knowledge for pH monitoring: more reflux during the day (during activity) than at night (during sleep), more acid reflux during fasting, and more nonacid reflux during feeding.

The reproducibility of impedance-pH recording on two consecutive days is rather poor, especially for nonacid reflux [51]. The variability between the number of acid and nonacid reflux episodes with a second recording performed 2 days after a first recording have a high variation: 0.2–5.3 and 0.04–8.6 times the value obtained at day 1, respectively [56]. However, reproducibility of pH monitoring on two consecutive days is reported to have high correlation coefficients, ranging from 0.88 to 0.98 [57]. Applying a similar study design, Nielsen and coworkers reported an overall reproducibility of 70 % for impedance [58]. The reflux index at day 2 was 0.2–3.3 times the initially obtained value at day 1 [58].

Intraluminal impedance monitoring data can be read manually or analyzed automatically using commercially available software. Over 95 % of reflux events detected by automatic impedance-pH analysis were confirmed by two independent investigators, although they added about 33 % acid, weakly acid, and nonacid reflux episodes [59]. The agreement between investigators for reflux episodes detected by manual reading of 24-h impedance-pH tracing was only about 50 % [59]. Interobserver variability was reported much better in impedance recordings obtained in neonates during a period of 6 h [60]. The discrepancy between automatic analysis and manual reading is influenced by the preset definitions of the automatic reading: the software indicates as acid reflux only in those episodes in which the impedance falls below 50 % of baseline in two consecutive channels simultaneously with a drop in pH below 4. This means that the reflux (or "drop in impedance") should reach at least 5–7 cm above the pH channel to be detected as "acidic impedance reflux." Most pediatric centers choose to register all reflux episodes detected with the pH channels independently from the impedance reflux events. More data are needed regarding the comparison between automatic and manual reading. It is clear that more reflux episodes are detected with manual reading; however, it has not been shown that more reflux detected equates to better diagnosis. Moreover, manual reading induces human bias in the interpretation of the results. In general, "pH reflux" does last longer than "impedance reflux," or in other words, acid exposure lasts longer than bolus exposure. This observation is likely to be related to a difference in clearance time between acid and bolus exposure.

Feeding

Feeding during pH monitoring is an area of controversy. On the one hand, it seems logical to forbid the intake of acidic foods and drinks. However, many popular foods and beverages have a pH of <5.0 (e.g., cola drinks, fruit juice, tea, soup), resulting in a quite restricted diet. A too restricted diet might alter the patient's normal dietary habits in such a way that the investigation is no longer performed in physiologic conditions. Electrodes are temperature sensitive; therefore, very hot and ice cold beverages and foods (e.g., coffee, tea, ice cream) should be avoided [8]. Chewing gum or hard candy should be withheld because these increase saliva production and thereby induce swallowing and esophageal peristalsis, tending to normalize test results. This is also true for impedance recording: during periods of increased saliva production and swallowing, less reflux will occur. In older children, alcohol intake and smoking should be recorded on the diary.

In infants, it has been suggested to replace one or several feedings during pH monitoring with apple juice [55]. This solves the problem of gastric anacidity after a milk feeding. Apple juice has a pH of about 4.0, has a very rapid gastric emptying, and is not part of normal infant feeding. Although the ingestion of acid, such as a cola drink, might simulate a reflux episode, the duration of ingestion is limited to a few minutes and most of the time irrelevant in relation to 24-h data. It is also possible to eliminate these false reflux episodes with the help of a diary. Impedance (in combination with pH) recording allows much better determination of the bolus movement: from proximal to distal, as happens after a swallow, or from distal to proximal, as happens during GER.

The influence of a particular food on the frequency of acid GER episodes detected by pH monitoring might be opposite to its influence on the incidence of reflux episodes: for instance, a high fat meal provokes GER because of delayed gastric emptying [61]. Since the duration of postprandial gastric anacidity after a fatty meal is prolonged, a meal with a high fat content will result in delayed gastric emptying, and thus, less acid reflux episodes will be detected by pH monitoring [61, 62]. Postprandial GER after feedings varying in fat content is an interesting research topic for impedance. Some drugs that influence gastric emptying have a comparable effect on pH monitoring data: prokinetic drugs enhance gastric emptying, shorten the period of postprandial gastric anacidity, and prolong the periods during which acid GER can be detected. Combined impedance and pH recording may enhance understanding of the effects of various constituents of food on GER.

The impact of postprandial nonacid reflux decreases with age, since the number of feedings decreases, and with it the total duration of postprandial periods and the overall buffering effect of milk [22]. It seems logical that nonacid reflux events decrease with time elapsed from the last meal [20]. While symptom correlation (within a 5-min window) is similar between acid and nonacid reflux (25.2 % vs 24.6 %), reflux events reaching the proximal esophagus are more frequently associated with epigastric pain and burping [22].

Position

Different patterns of GER (upright, supine, combined) have been reported in adults and older children [63]. Orenstein and colleagues demonstrated that the prone sleeping position is the preferred position for infants as far as GER is concerned because crying time is decreased if compared with the supine position [64–66]. There is evidence that the prone anti-Trendelenburg 30° sleeping position reduces GER in normal subjects and patients, although the position is difficult to apply and maintain correctly (infants have to be tied up in their bed). Meanwhile, the literature on sudden infant death syndrome (SIDS) shows that infant mortality decreases if infants are put to sleep in supine position [67, 68]. The position of the infant should be recorded on the diary during reflux monitoring. The impact of position has been analyzed through combined manometry and impedance in ten healthy preterm infants (35–37 weeks of postmenstrual age): 89 reflux episodes were recorded (74 % were liquid, 14 % air, and 12 % with mixed contents) [24]. In the right lateral position, the total number of reflux episodes (as well the total as the liquid episodes) was significantly higher than in the left lateral position despite a faster gastric emptying in the right position. This finding suggests that the major pathophysiological mechanisms causing reflux episodes are inappropriate transient relaxations of the lower esophageal sphincter [24, 25].

In addition to position, the effects of formula feeding and alginate on height, frequency, and type of reflux have also been studied. Impedance confirms the efficacy of an anti-regurgitation formula on the frequency and severity of regurgitation with a trend for a more pronounced effect on nonacid reflux [26]. Although there was a trend for reflux to be less proximal, the difference was

not significant [26]. In other words, with the antiregurgitation formula tested, there was no statistically significant difference in the duration and number of acid and nonacid GER and in the height of the reflux episodes [28]. Impedance shows that alginates do not decrease the number of postprandial episodes of GER, but may marginally decrease the height of the refluxate [28].

Data Analysis

Interpretation and Parameters

Interpretation starts with a visual appreciation of the tracing, which is subjective and difficult to standardize. Nevertheless, it is of the outmost importance to look at the tracing. A progressive constant reduction in esophageal pH at the end of a feeding, which continues up to the next feed, may be suggestive for cow's milk protein allergy [69]. Parameters that are classically analyzed for pH monitoring are the total number of reflux episodes, the number of reflux episodes lasting more than 5 min, the duration of the longest reflux episode, and the reflux index (the percentage of time of the entire duration of the investigation during which the pH is less than 4.0). From all classic parameters, the acid exposure time or reflux index is the most relevant. The correlation between all four parameters is good, and they are closely related to the reflux index [70]. Results should also be automatically calculated for periods of interest, such as sleep, wakefulness, feeding, postprandial fasting, and body position. A time relation between atypical manifestations (e.g., cough, bradycardia, desaturation) and changes in pH (not necessarily a drop in pH below 4.0) should be searched for. The duration of reflux during sleep has been suggested to be a good selection criterion for reflux related to apnea in infancy (the "ZMD score") [71]. For unclear reasons, this parameter has been insufficiently validated. However, it should be noted that the response time of an antimony electrode (the time needed to reach 95 % of the exact pH) is at least 5 s. The "area below pH 4.0" is a parameter considering the acidity of reflux episodes [72], which has been shown to correlate better with the presence of reflux esophagitis than with the reflux index in children [73].

Various complex reflux scoring systems (Johnson-DeMeester composite score, Jolley, Branicki, Kaye, Boix-Ochoa scoring systems) have been developed. The majority of the parameters were developed for assessing reflux esophagitis in adults. Jolley and colleagues proposed a score for children [74]. However, there is abundant literature, both in adults and children, that not one parameter of pH monitoring (except the "area under pH 4.0") and no single symptom has a high specificity for esophagitis. Endoscopy and histology remain the gold standard to diagnose esophagitis. In marked contrast to these complex scoring systems is the simple recommendation by some investigators that the reflux index or total acid exposure time should be regarded as the most important, if not the only, variable in clinical practice [70, 72]. Scores based on symptom indices are not applicable in infants and young children.

A major interfering factor in the interpretation of pH monitoring data is the "yes" or "no" interpretation provided by a computer software: a pH of 4.01 is regarded as normal, whereas a pH of 3.99 will be considered as acid reflux. Minimal changes in esophageal pH around pH 4.0 can be at the origin of different software interpretations, although without difference in clinical meaning. The oscillatory index, a parameter measuring the time pH oscillates around pH 4.0, was developed to evaluate this risk for erroneous computer interpretation [75].

A similar comment can be made regarding impedance: a drop in impedance of 50 % is postulated to be a GER episode. However, it is very unlikely that a drop in impedance of 49, 50, or 51 % has a different meaning. Although impedance allows or more often requires a manual analysis, the relevant question that remains is why is the decrease in impedance needed to be considered as a reflux episode? The drop in impedance is not related to the volume of the refluxate. If pH monitoring were to

be performed with a probe with multiple pH sensors, it would be possible to determine also the height of the refluxate. The major difference between pH and impedance-pH monitoring is restricted to the detection of weakly acid reflux.

Normal Ranges

As for any measurement, normal ranges are mandatory. However, because there is a continuum between physiologic GER and pathologic GERD, normal ranges should be regarded as a guideline for interpretation. Reproducibility has been shown for various parameters. Intrasubject reproducibility supports the diagnostic use of continuous pH monitoring. In general, a reflux index above 7 % is considered as abnormal, a reflux index below 3 % as normal, and a reflux index between 3 % and 7 % as indeterminate. However, normal ranges were developed to separate patients at risk for esophagitis from those not at risk, which is not the major indication of the procedure. Normal ranges proposed by one group can be used by another group only if the investigations are performed and interpreted in a comparable way. This means that materials and methodology should be identical. For some individuals and in some clinical situations, it may be more important to relate "events" (e.g., coughing, wheezing, apnea) to recorded events rather than to know if the data are within the normal range. There are no normal ranges currently available for impedance.

Significantly fewer acid reflux episodes are detected using pH monitoring combined with impedance when compared to pH monitoring alone [76]. Estimates of esophageal acid exposure using pH monitoring alone were twofold higher than estimates derived using pH and impedance techniques. Of the total acid reflux episodes detected by pH monitoring alone, almost three-fourth could not be confirmed by combined pH and impedance [18]. Detection of significant numbers of "pH-only" episodes raises concerns regarding possible overestimations of acid exposure that may occur when estimates are based solely on esophageal pH monitoring.

Weakly Acid Reflux

Weakly acid reflux was previously called nonacid reflux. Up to now, there has been general consensus that investigations measuring reflux during the postprandial period (ultrasound, radiology, scintigraphy) are of limited value in the diagnosis of GER disease because of the high prevalence of GER in the postprandial period. The pH of reflux during a postprandial period is mostly above pH 4 (thus regarded as nonacid based on pH monitoring criteria). However, based on experienced obtained with impedance, there is general consensus that it is preferable to consider this type of reflux as "weakly acid" reflux.

If a nasogastric tube passes the cardia, impedance shows an increase in postprandial reflux (from 72 to 122 episodes) in preterm infants [18]. Del Buono confirmed these findings in neurologically impaired children: more than half of the reflux events are nonacidic and would therefore go undetected by conventional pH metry [19]. The number of reflux episodes, both acid and nonacid, and the median height of reflux events were increased in the subgroup that was fed through a nasogastric tube, compared to the orally fed subgroup [63]. However, the difference in GER events may well be explained by the difference in neurologic impairment between groups. In a small group of seven healthy preterm newborns receiving nasogastric milk feeding, the mean prevalence of nonacid reflux (29 episodes/24 h) was more than two times the prevalence of acid reflux (12 episodes/24 h), and about 80 % of these reflux episodes reach the proximal esophagus [20]. The same group reported in a larger series of 21 healthy premature neonates a much higher incidence of approximately 70 reflux events in 24 h; of the reflux episodes, 25 % were acid, 73 % weakly acidic, and 2 % weakly alkaline [21]. In preterm infants, weakly acidic reflux is more prevalent than acid reflux, particularly during the feeding periods [21]. In contrast, similar to healthy adults, weakly alkaline reflux

was uncommon. Most reflux events are pure liquid during both fasting and during postprandial periods; gas reflux is very rare. The majority of reflux events in asymptomatic preterms reaches the proximal esophagus or pharynx. The acid exposure related to reflux events and detected by impedance is significantly lower than the total acid exposure during 24 h [72]. Increased acid exposure could be attributable to pH-only reflux events or, less frequently, to slow drifts of pH from baselines at approximately 5 to values <4. These changes are not accompanied by a typical impedance pattern of reflux but by slow drifts in impedance in one or two channels. These findings confirm the need for the use of impedance together with pH metry for diagnosis of all GER events [21]. Conversely, Condino and coworkers report in a group of 34 infants, aged between 2 and 11 months, that the distribution or acid and nonacid reflux is almost equal: 47 % of the reflux episodes were acid and 53 % nonacid [22].

Chronic respiratory symptoms such as chronic bronchitis, wheezing, chronic cough, and infant apnea have been related to GER. A strong relationship between acid and nonacid GER and respiratory abnormalities was suggested by Wenzl et al.: in a group of 22 children presenting with repetitive regurgitation and chronic respiratory symptoms, impedance recorded 364 reflux events, of which only 11.4 % were acid [29]. Three hundred and twelve (85 %) of these reflux episodes, of which 12 % were acid, were associated with irregular breathing [73]. In a minority of these episodes (n:19), oxygen desaturations of more than 10 % occurred (3/19 or 19 % of such episodes were acid). Analysis of the polysomnographic recording showed 165 episodes of apnea, of which 30 % were associated with a reflux episode; again, the majority (78 %) of reflux episodes were detected with impedance only [29]. However, an association between pathologic central, obstructive, or mixed apnea and GER has not been convincingly demonstrated but has also not yet been well studied. Clear cutoff values discriminating normal from pathological children still need to be determined. The number of reflux events per hour (two to three events per hour) is slightly lower in normal healthy preterm infants than in premature neonates with cardiorespiratory events (four per hour) [21]. When compared with pH monitoring, impedance is a technique that will allow a more accurate determination whether apnea of short duration is a physiologic phenomenon occurring frequently in relation to an episode of GER [77]. In a group of 22 infants, 364 episodes of GER were detected with impedance [30, 31]. Visual validation records confirmed 165 apneas. Of these events, 49 (30 %) were associated with GER and 38 (77.6 %) were exclusively recorded by impedance [30, 31]. A decrease of oxygen saturation >10 % was observed in 19 reflux events recorded with impedance, of which only 3 (15.8 %) episodes were acid (pH <4.0) [30, 31]. Nineteen preterm infants (gestational age 30 weeks) presenting with apnea were studied at a mean age of 26 days (13–93 days): 2039 episodes of apnea (median: 67; range: 10–346), 188 oxygen desaturations (median 6; range 0–25), 44 bradycardias (median 0; range 0–24), and 524 episodes of GER (median 25; range 8–62) were detected [32]. The frequency of apnea in a 20-s period before and after an episode of GER was not different than the frequency of apnea not related to a reflux episode (0.19/min [0.00–0.85] versus 0.25/min [0.00–1.15]) [32]. The analysis and conclusions were identical for oxygen desaturations and bradycardias [32]. Mousa analyzed the temporal relationship between apnea and GER in a group of 25 infants presenting with an apparent life-threatening event (ALTE) or pathologic apnea [33]. A time interval as long as 5 min between apnea and reflux was considered acceptable to demonstrate a “temporal link” between the two phenomena [33]. In total, 527 apnea episodes were recorded but only 80 (15.2 %) were temporally linked to a reflux episode. Of these 80 episodes, 37 (7.0 % of the total episodes of apneas) were related to acid reflux and 43 (8.2 %) to nonacid reflux. Thus, even when considering a time interval as long as 5 min, one can conclude that a relationship between reflux and apnea is uncommon [33]. The majority of the reflux events reach the proximal esophagus or the

pharynx, both in asymptomatic preterm babies and in neonates with cardiorespiratory symptoms [21]. This lack of discernable differences between asymptomatic and diseased infants contravenes the hypothesis for macro- or microaspiration, but does not exclude hypersensitivity to reflux as a cause for respiratory symptoms.

Chronic respiratory manifestations, such as coughing and wheezing, are reported to occur in older children with reflux. Rosen and coworkers reported their experience in 28 children (mean age: 6.5±5.6 years) with chronic respiratory disease under treatment with antacid medications [34]. A total of 1822 episodes of reflux were measured with MII-pH; 45% of them were nonacid. Multivariate analysis showed a stronger association between respiratory symptoms and nonacid reflux episodes than with acid reflux episodes [34]. Also the height of the refluxate in the esophagus was related to respiratory symptoms: the higher the reflux, the stronger the association [34]. The association score between symptoms and episodes of reflux detected with impedance and pH monitoring was 35.7±28.5 and 14.6±18.9 (p=0.002), respectively [34]. However, it is not too surprising that pH monitoring detects less reflux during antacid treatment. In a series of 25 children (age 6 months to 15 years) with unexplained chronic cough, wheeze, or sputum production, data support a relation between acid GER and chronic pulmonary symptoms, but do not support a role of nonacid reflux in children with respiratory symptoms not on antacid medication [35]. Condino et al. studied 24 children with recurrent asthma and concluded that both acid and nonacid reflux occur with equal frequency in children with asthma and that most symptoms occur in the absence of a reflux event [23]. In a selected group of 22 adults, a relation between chronic cough and GER was studied by combined manometry and MII-pH [5]. Using a time frame of 2 min and symptom association probability, 69.4% of coughing episodes were considered independent of a reflux episode. When a "reflux-cough" sequence occurred, the reflux in 65% of cases was acid, in 29% weakly acid, and in 6% weakly alkaline [5]. Contradictions in the literature on the role of acid and nonacid GER in children with chronic respiratory symptoms may, in part, be explained to the fact that these studies have not considered whether reflux is primary (motility disorder) or secondary (to infection, allergy, respiratory efforts, etc.) in nature.

The use of pH alone for the detection of acid reflux is very sensitive but lacks specificity compared with MII-pH. pH alone may overdiagnose abnormal acid reflux. Also, the use of pH for the detection of weakly acid reflux has poor sensitivity [78].

pH Monitoring and Other Investigations

Many different techniques to evaluate GER exist, focusing on different aspects, such as postprandial reflux (scintiscan, barium swallow, ultrasonography), histologic abnormalities (endoscopy), continuous measurements that are pH dependent (pH monitoring) or not (Bilitec, impedance), and pathophysiology by measuring the relaxations of the LES (manometry). Recent evidence in adults reveals the clinical utility of Bilitec monitoring showing a possible role for duodenogastroesophageal reflux in a subset of patients who continue to report reflux symptoms in the setting of normalized esophageal acid exposure on high-dose proton pump inhibitor [9]. However, bile reflux can also be detected by impedance. Bilirubin is as toxic to the esophageal mucosa as acid, but the number of patients with esophagitis and only pathologic alkaline or nonacid reflux and normal acid reflux is small [79, 80].

In specific situations other techniques might be of interest such as lipid-laden macrophages, pepsin, and lactose in bronchial secretions. Abnormal pH monitoring does not accurately predict the risk for esophagitis [81, 82]. In a group of reflux patients with esophagitis, the sensitivity of pH metry is 88% and of scintigraphy is 36% [83]. In a group of patients with abnormal scintigraphy, the sensitivity of pH monitoring is 82%, endoscopy 64%, and manometry of the LES 33% [83]. Nonacid reflux may be inoffensive (simple postprandial) reflux at a neutral pH, but may also contain bile, which is toxic for the esophageal mucosa [84]. There is limited experience with esophageal bile monitoring in children.

The overall correlation between scintiscanning and pH monitoring is acceptable ($r = .78$) [85]. However, during simultaneous pH recording and scintiscanning, only 6 of 123 reflux episodes were recorded simultaneously [86]. There is no correlation between the number of reflux episodes detected using scintigraphy and pH monitoring [87]. Barium studies seem to have a much lower sensitivity to detect reflux episodes if pH monitoring is regarded as the gold standard [85]. According to many authors, there is a high frequency of both false-positive and false-negative results with barium studies that relates to the short investigation time on the one hand and the intensity of reflux-provoking maneuvers on the other hand. Fifteen-minute postprandial period color Doppler ultrasonography was compared with 24-h pH monitoring, showing agreement in 81.5 % [88]. However, if pH monitoring was considered the gold standard, the specificity of the color Doppler ultrasonography was as low as 11 %, and there was no correlation between the incidence of reflux episodes measured with both techniques [88]. A far higher number of reflux episodes is detected with impedance in comparison with pH monitoring because only 14.9 % of all reflux episodes are acid [89]. However, only 57 % of acid reflux episodes are detected with impedance [89].

Conclusion

The miniaturization of devices and electrodes has made pH monitoring a procedure that is easy to perform, even in the youngest children. Patient-related factors, such as feeding and physical activity, influence the results of pH monitoring. Impedance needs further evaluation in children before it can be recommended in clinical practice. Hardware- and software-related factors, as well as patient-related factors and recording conditions, determine the results of both pH and impedance recordings. In clinical practice, pH monitoring is of interest in a subset of patients in whom GERD is suspected but who present without clear regurgitation or emesis and to measure the efficacy of treatment such as acid suppression and/or prokinetics. Impedance has theoretical benefits over pH monitoring, but the technique still needs clinical validation.

Impedance is a costly and time-consuming technique, which allows for the detection of all reflux events. The diagnostic sensitivity of MII may correspond to that of the pH probe in untreated patients, but is superior to the pH probe in patients treated with antiacid medications [90]. Episodes detected only by pH monitoring are numerous in children; therefore, pH monitoring should be included in pH-MII analyses [91].

Day-to-day variability of the number of nonacid reflux episodes is considerable (1), and the detection of nonacid reflux episodes has a high interobserver variability (3). Although impedance clearly records more GER events than pH monitoring, the advantage and the relevance of recording more episodes of GER in daily clinical practice needs to be demonstrated. Thus, impedance still needs to be considered as a clinical research tool. The clinical relevance of the detection of weakly acid and nonacid reflux is also still a matter of research, because current data are inconclusive and specific treatment is not available. Symptom-correlation analysis, especially for extraesophageal symptoms, is likely to be more convincing with impedance than with pH monitoring.

Since pH monitoring is part of an impedance recording, it is likely that impedance will become more frequently performed in routine practice [92, 93]. From the data presented in the chapter, it emerges that it is currently difficult to draw conclusions on the precise advantages of the application of MII-pH in children to detect GER events. The heterogenicity of the studies (in terms of populations recruited and technical criteria such as time and symptoms association) and the lack of normative data and of outcome measures do not support this at present. More homogeneous inclusion criteria and analysis associated with a complete baseline and prospective clinical features are mandatory. Impedance is a new, promising technical development offering unexplored possibilities to investigate GER [92, 93]. Although many papers suggest a degree of usefulness, the technique is

still in a phase where the added value to other techniques in the routine workup of patients needs to be evaluated and demonstrated without scientific rigor.

Assessment of GE Reflux: Esophageal Motility Studies

77

Samuel Nurko

Esophageal manometry is the gold standard for the diagnosis of primary motor disorders of the esophagus [1–3]. It is most frequently performed in children with dysphagia who have no evidence of anatomic obstruction, and the clinical use of esophageal manometry is in defining the contractile characteristics of the esophagus [1, 2]. Previous chapters review concepts on basic esophageal physiology and pathophysiology of esophageal dysfunction, as well as the technical aspects of performing esophageal motility studies. It is beyond the scope of the present chapter to discuss the pathophysiology of gastroesophageal reflux disease (GERD) in otherwise healthy children or children with malformations. Therefore, the present chapter will focus on reviewing the role that esophageal motility studies have in the evaluation and treatment of patients with suspected gastroesophageal reflux.

Indications

Esophageal manometry has no role in the diagnosis of GER [1, 4] and is not indicated in the routine evaluation of patients with GER [1–3]. The exact role that the measurement of esophageal motility in the preoperative evaluation of children with GERD is not clear [1, 5]. The only clear role it has is when there is uncertainty about the correct diagnosis and a primary motility problem such as achalasia is suspected [6]. Esophageal manometry is also used to localize the LES before placement of a pH probe in patients with abnormal anatomy (e.g., hiatal hernia) [2] and may be useful in the evaluation of the intractable patient with severe esophagitis, as a low LES pressure of <10 mmHg has been associated with a poor response to medical therapy [7].

The use of esophageal manometry in patients with GERD before fundoplication has not been useful to predict postoperative outcome, so it does not need to be performed routinely before surgery (see below). There are no studies that have addressed the utility of esophageal manometry in the preoperative evaluation of children with diseases that may be associated with severe underlying motility disorders like scleroderma or esophageal atresia in which the surgery may create or aggravate a functional obstruction [1].

Even though esophageal manometry is not routinely indicated in the evaluation of patients with GER, it has been employed to try to better

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_77

understand the pathophysiology of the disease, or as a way to predict which patients may benefit from anti-reflux surgery, or who may develop postoperative complications like dysphagia.

Esophageal Motor Abnormalities in Patients with GERD

As mentioned in previous chapters, it is thought that TLESRs (transient lower esophageal sphincter relaxations) are the main mechanism underlying reflux events [8] and that the number of TLSERs associated with acid reflux is significantly higher in those with GERD. Low or absent LES tone is a rare occurrence [4, 8], and most pediatric studies have failed to demonstrate a low LES tone in otherwise healthy patients with GERD with or without esophagitis [4, 9–12]. On the other hand, the prevalence of low LES pressure is much greater in patients with underlying congenital malformation like esophageal atresia [3, 13].

There is limited information regarding esophageal motor function in patients with GERD, particularly children. In adults with GERD, the most important motility abnormality in the esophageal body is referred to as "ineffective esophageal motility" (IEM). IEM is characterized by nontransmitted contractions and simultaneous contractions of reduced contraction amplitude (<30 mmHg) in the distal esophagus [4, 14, 15]. This ineffective esophageal motility has been associated with abnormal acid clearance [16]. In a recent study, Somani et al. [17] reported in adults a negative correlation between esophageal acid exposure and LES pressure, as well as between the amplitude of distal esophageal contractions and more severe esophagitis. These abnormalities are mainly found in adults with severe GERD and have been shown to impair esophageal clearance and contribute to the development of esophagitis [18]. Multiple studies in adults have documented that the subtle esophageal motility abnormalities that are found do not improve after successful therapy [19]. There is still an ongoing controversy as to whether impaired esophageal body motility in severe reflux disease is a primary disorder contributing to the pathogenesis of GERD or whether it is a consequence of long-standing reflux or esophageal inflammation [9, 20]. Therefore, it is unclear whether abnormal esophageal body contractions are the cause or consequence of peptic esophagitis. The information in children is limited. One study by Cucchiara et al. demonstrated nonspecific motor defects (simultaneous, broad-based, double-peak waves) in children with severe esophagitis and showed the dysfunction normalized with successful treatment [11]. Chitkara et al. in our laboratory showed there was no difference in the results of stationary manometry when comparing GERD patients with controls or by the degree of esophagitis [9]. Recently, Hoffman et al. [4] also showed that esophageal motor function in otherwise healthy children with GERD was normal. In a study using prolonged esophageal manometry, we also showed that even though baseline manometry was normal in all patients with GERD, there was a significant decrease in the total number of contractions per minute, before, during, and after a reflux episode, independently of the presence or not of esophagitis [9], suggesting the abnormalities may be secondary to an underlying motor disorder and not as a consequence of the inflammation.

On the other hand, children with underlying congenital malformations (like esophageal atresia) or severe systemic illness (like scleroderma) may have severe underlying esophageal dysmotility that predisposes them to severe GERD. Children with esophageal atresia have severely impaired dysmotility. This has been reported in up to 75–100 % of cases [21, 22]. The alterations described have been a low LES pressure and a lack of peristalsis, with esophageal contractions that tend to be simultaneous and weak although at times of normal amplitude especially in the lower esophagus [3, 13]. The peristaltic function of 22 adolescents and adults after esophageal atresia repair was also described with the use of ambulatory 24-h pH manometry [23]. All had diminished contractile activity, disorganized propulsive activity, and abnormal and ineffective peristalsis. This indicates a poor capacity for acid clearance and may explain the

frequent dysphagia and GER-related problems experienced by these patients. Given that not all patients with esophageal atresia develop GERD, manometry studies have been used to try to predict which are the patients at risk. In some studies, specific manometric abnormalities like a lack of distal esophageal contractions have been associated with the presence of GERD [24].

Esophageal abnormalities are present in one half to three quarters of patients with scleroderma, a much higher frequency than in patients with other collagen vascular disorders [25, 26]. The characteristic esophageal manometric findings are (1) incompetent lower esophageal sphincter, (2) low-amplitude esophageal contractions in the smooth portion of the esophagus, and (3) later alterations in the striated muscle section [25, 26]. The incompetent LES fails to provide an effective barrier against the gastric acid, and the abnormal peristalsis provides an inadequate acid clearance, predisposing the patients to severe complications from GER [25, 26]. By studying the relationship between the severity and extent of esophageal acid exposure and manometric abnormalities in patients with systemic sclerosis, it was concluded that the severity and extent of GER are closely related to the integrity of distal peristalsis. In a study of children with scleroderma, Flick and others [25] studied seven children with PSS and two with LS. The most frequent symptoms in patients with PSS were regurgitations, heartburn, and dysphagia. They showed that in 72 % of the patients with PSS (mean age 15; range 10–18), there was a decreased LES pressure, tertiary waves, or feeble contractions. They found a strong correlation between the presence of Raynaud's phenomenon and esophageal symptoms but no correlation with disease duration. There was a correlation between dysphagia and the presence of esophageal motor abnormalities.

Therefore, from all these observations, it can be concluded that the presence of severe esophageal dysmotility, mostly abnormal LES pressure and abnormal distal esophageal contractions, predisposes patients to have more severe GERD. In reality, we are dealing with two distinct populations: the otherwise healthy patient in which there may be some nonspecific motility disorders that may or may not improve after successful therapy, but on the other, patients with severe underlying esophageal motor disorders, in which the primary motor problem predisposes them to severe GERD and its complications and in which surgery may create a functional obstruction.

Role of Esophageal Manometry in the Preoperative Evaluation of Patients with Intractable GERD

The controversy if the esophageal motor abnormalities in GERD are primary or secondary to inflammation in otherwise healthy patients is not only academic but has practical consequences as dysphagia is one of the main complications after fundoplication, and it has been suggested that underlying motility abnormalities of the esophagus may be responsible. Therefore, trying to better understand the genesis of postoperative dysphagia is one of the main indications that have been used in the past for the performance of esophageal motility in patients with GERD.

In general, once a decision to perform a fundoplication has been made, esophageal manometry has not been shown to predict clinical outcome [6]. The role that preoperative esophageal peristalsis plays in the development of dysphagia after fundoplication has been controversial [27]. The dysphagia may be related to either a wrap that is too tight around an esophagus with good peristaltic function or secondary to a functional obstruction created by the inability of some damaged esophagus to produce enough force to propel the food into the stomach.

The role that preoperative esophageal peristalsis plays in the development of dysphagia has been controversial [27, 28]. It was initially suggested that care should be exercised when a fundoplication is performed in patients with abnormal esophageal peristalsis [27, 28]. Since then, the relationship between preoperative esophageal motor abnormalities and postoperative dysphagia has been questioned [27, 29, 30]. In a study after laparoscopic Nissen in 81 adults

that had baseline esophageal motility, there showed no difference in the prevalence of dysphagia up to a year after the operation (12.5 % vs. 15 %), when comparing the 48 patients with normal motility, with the 33 with abnormal esophageal function [27]. They suggested that there was poor correlation between the preoperative manometry and outcome and that abnormal esophageal peristalsis is not a contraindication to perform the operation [27]. Another recent prospective randomized clinical trial of 200 patients randomized either to Nissen (360°) or Toupet fundoplication (270°) studied esophageal motility before and after the surgery. They found that preoperative esophageal dysmotility reflected more severe disease, but it did not affect postoperative clinical outcome. In 85 %, the motility remained unchanged, as it was not corrected by the fundoplication (independent of the surgical procedure performed). In 20, it improved, while in 9 it worsened. They concluded that preoperative esophageal dysmotility requires no tailoring of the surgical management [30]. A recent study showed no difference in postoperative dysphagia after a Nissen laparoscopic fundoplication when they compared 28 patients that met manometric criteria for abnormal esophageal motility (<30 mmHg mean contractile pressure or <80 % peristalsis) and 63 patients with normal esophageal function, indicating that the presence of esophageal motor abnormalities does not seem to increase the risk for postoperative problems [31] and does not need the performance of a partial fundoplication. There are also some recent studies that in fact suggest that fundoplication improves ineffective peristalsis in patients with GERD [31]. These studies have not included patients with severe underlying conditions like scleroderma or other severe motility disorders.

No similar studies to determine the incidence of dysphagia after fundoplication taking in account preoperative manometric findings have been performed in children, but current information suggests there is no need to routinely perform an esophageal manometry before surgery in otherwise healthy children [2, 3], given that most patients have normal esophageal motility.

The considerations in those patients with conditions that are associated with underlying severe motility abnormalities are different, as those are the patients that may have worse outcomes after surgery. A preoperative manometry may be useful in those children with scleroderma or esophageal atresia, as a fundoplication may cause a functional obstruction because of the lack of peristalsis [25, 32]. Patients with scleroderma provide a model in which there is underlying primary severe esophageal dysmotility that leads to intractable GERD that often requires surgical intervention. Most studies in scleroderma patients document postoperative dysphagia in between 31 and 71 % after fundoplication [25, 26, 33], but there are no prospective studies that have tried to correlate the preoperative manometric findings with outcome. There are some studies that have shown that the absence of distal esophageal peristalsis in patients with esophageal atresia may be correlated to the presence of severe GERD and that in those circumstances modified fundoplications may be needed to avoid the creation of a functional obstruction [24, 32]. However, there are no prospective studies that have shown that the performance of a manometry indeed changes the surgical management or the outcome in those patients.

Another indication for esophageal manometry in GERD patients is in the evaluation of those with a failed fundoplication, as it is very important to be sure there is no underlying primary disorder before a new surgery is performed. Low et al. [34] reported in a series of patients that underwent secondary operations for failed Nissen procedures that six patients presenting with severe postoperative dysphagia had evidence of primary esophageal motility disorders (four collagen vascular diseases and two with achalasia) that were not diagnosed before surgery, indicating the importance of assessing esophageal motility before the initial operation or reoperation if a primary motility disorder is suspected [28].

Advances in Esophageal Manometry and Their Potential Use in the Evaluation of Patients with GERD

It has been suggested that one of the main reasons that the use of esophageal manometry in the preoperative evaluation of patients with GERD

has not been found to be useful is that it may not accurately reflect true esophageal transit. In fact, the advent of multichannel intraluminal impedance combined with manometry has allowed the simultaneous evaluation of esophageal contractions and bolus transit (Fig. 77.1) [1, 35–37]. The technique has been validated with the simultaneous use of manometry, videoesophagram, and impedance, and the authors concluded that impedance monitoring is a valid transit test [35]. During the test, either liquid swallows (usually saline) or viscous swallows are studied, and the transit through the esophagus is measured by analyzing the changes in impedance. It has been shown that for both liquid and viscous boluses, the likelihood of impaired bolus clearance is related to the number of segments with hypotensive pressure waves [38]. Because the transit of viscous material may be more sensitive than liquid boluses in assessing mild transit abnormalities, both bolus types have been used. Different studies have shown that normal bolus transit in healthy individuals occurs at least in 80 % of liquid and 70 % of viscous swallows when solid-state catheters are used [39] or in 70 % of liquid and 60 % of viscous, when perfused catheters are utilized [40]. No similar information is available for healthy children, but preliminary information in children has shown that the technique is feasible [1, 41]. Studies in adults have shown that the manometric evidence of ineffective peristalsis may underestimate the true bolus clearance and that the combined impedance with manometry may be a more sensitive technique to assess esophageal function and to evaluate patients with dysphagia [38, 39]. The combined use of manometry and impedance has shown that approximately 97 % of normal peristaltic swallows have normal bolus transit but also that almost half of manometrically ineffective peristalsis had normal liquid transit [39]. In children, preliminary information has shown that effective bolus clearance by impedance is present in 75 % of swallows that had ineffective peristalsis [41]. In a report of 350 patients, it was found that all patients with achalasia and scleroderma had abnormal bolus transit time but that 51 % of those with ineffective esophageal motility and 55 % of those with diffuse esophageal spasm had normal bolus transit. Furthermore, almost all with normal esophageal manometry, nutcracker esophagus, poorly relaxing LES, hypertensive LES, and hypotensive LES had normal bolus transit [37]. This indicates that the addition of impedance and the study of bolus transit may provide a more accurate diagnosis of esophageal dysfunction as compared to esophageal manometry alone [37]. Recent studies demonstrate that combined impedance manometry provides important additional information about esophageal motility as compared to conventional manometry: (1) monitoring of bolus transport patterns, (2) calculation of bolus transit parameters, (3) evaluation of bolus clearance, (4) monitoring of swallow-associated events such as air movement and reflux, and (5) investigation of the relationships between bolus transit and LES relaxation [42]. It can therefore be concluded that combined esophageal manometry with impedance is a new technique that allows the simultaneous study of both manometry and transit and therefore provides a validated tool to study esophageal transit and its relation to motility patterns without radiation exposure [35, 36]. Future studies will demonstrate if the addition of the impedance to the manometry will prove to be more sensitive to detect which are the patients that will develop dysphagia after fundoplication.

Another advance in the study of esophageal physiology has been the use of high-resolution manometry (HRM) (Fig. 77.2) [1, 43]. The basic concept being that by vastly increasing the number of recording sites and decreasing the spacing between them, one can completely define the intraluminal pressure environment without spatial gaps between recording sites and, consequently, with minimal movement-related artifacts [43, 44]. The vastly increased quantity of data associated with HRM studies creates new challenges with respect to data display and data analysis. Hence, algorithms have been devised to smoothly interpolate HRM data, making it appear as a space-time continuum that can be displayed as isobaric contour plots. The advantages of isobaric contour plots are multiple, but the most evident is that it provides a seamless, dynamic representation of peristalsis at every axial position within and across the esophagus

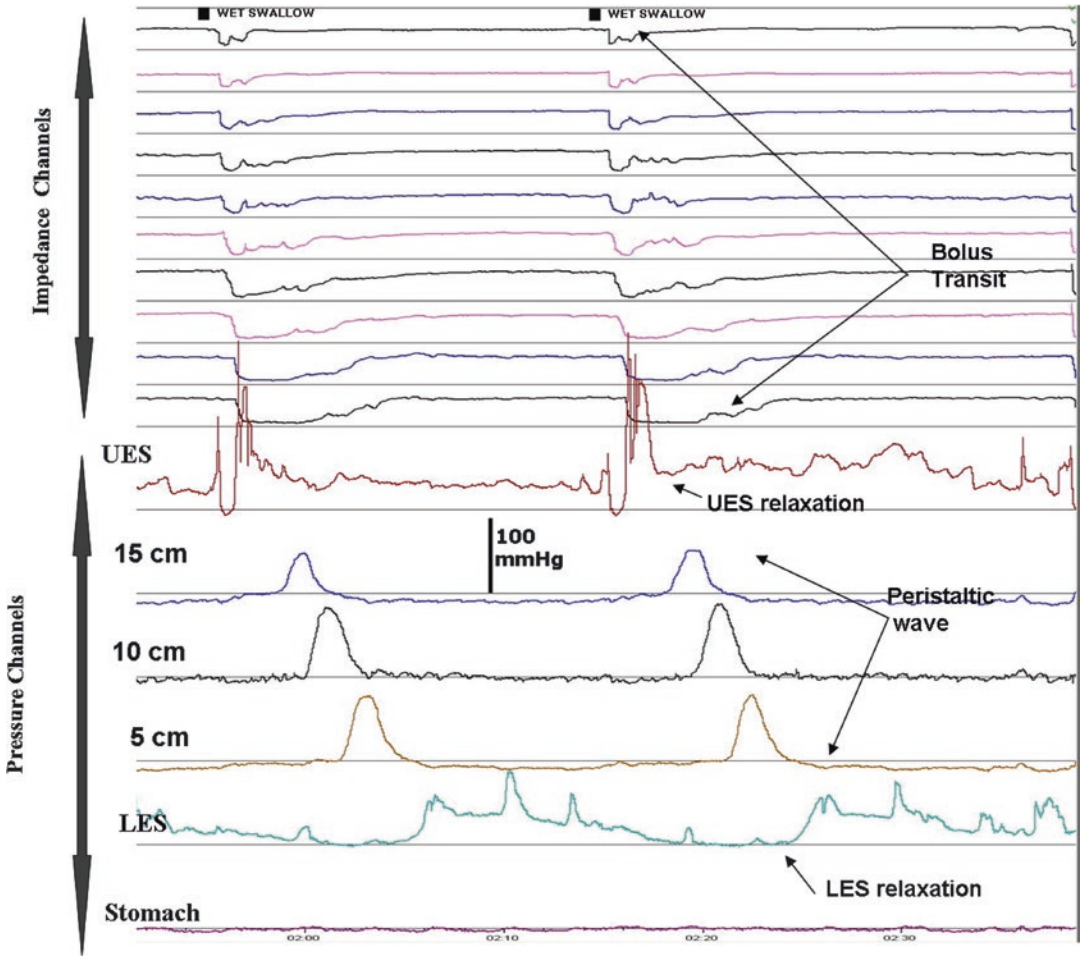

Fig. 77.1 Normal esophageal manometry. This represents a combined manometry and impedance study. The upper ten channels represent impedance measurements, while the lower six channels represent pressure measurements. A normal response to wet swallows can be observed. There are UES and LES relaxations, followed by normal esophageal peristalsis. The impedance channels show a normal progression of a saline bolus. *UES* upper esophageal sphincter, *LES* lower esophageal sphincter (Adapted with permission from Rodriguez and Nurko [1])

[43, 44]. Recent studies have shown that HRM predicts the presence of abnormal bolus transport more accurately than conventional manometry and identified clinically important motor dysfunction not detected by manometry and radiography [45–47]. It has been suggested that HRM predicts bolus movement more accurately than conventional manometry [47]. The recent addition of impedance to the HRM will also provide further insight into esophageal function [1] (Fig. 77.2). The use of HRM has recently been shown to better characterize peristaltic dysfunction in patients with GERD, particularly those with erosive esophagitis [16]. They showed that the esophageal motor response after solid swallows was even more impaired, suggesting that now it is possible to perform studies with swallowed material that increases the workload of the esophagus; HRM may become a more sensitive tool in the evaluation of patients with GERD [16]. The exact role that HRM, or HRM with impedance, will play in the evaluation of preoperative patients before reflux surgery still needs to be defined, and there is still no available information about its use for this purpose in children either.

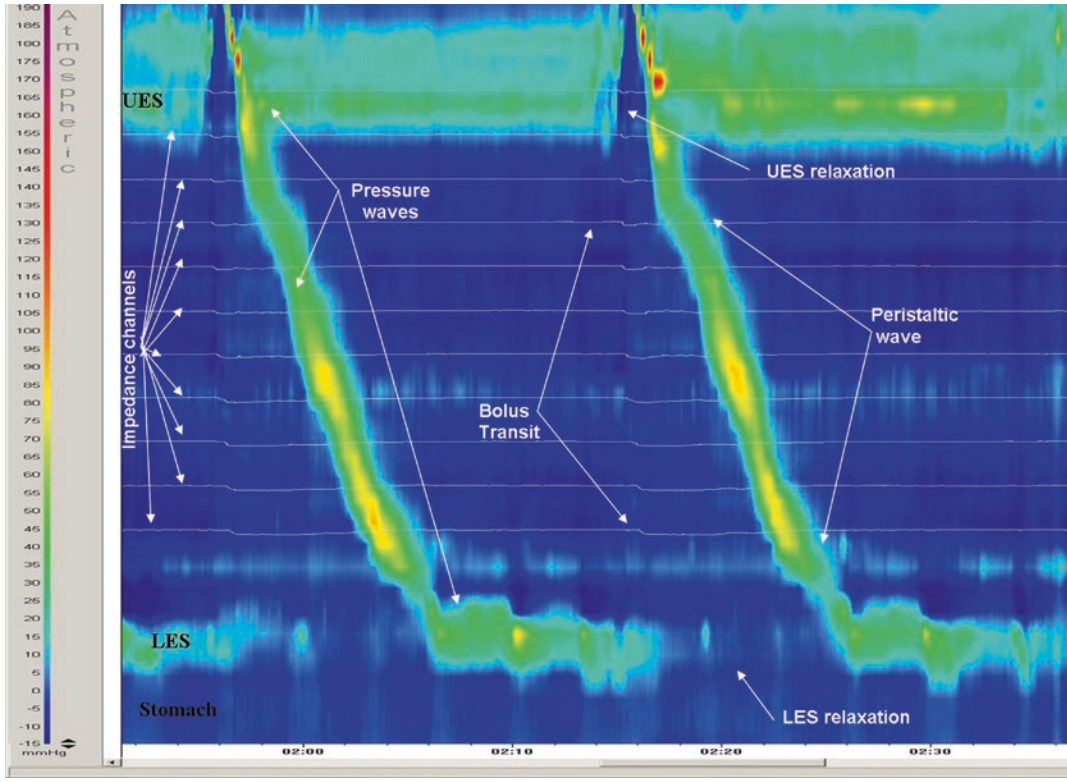

Fig. 77.2 Normal high-resolution manometry. Contour plot obtained with the use of high-resolution manometry and impedance in a healthy child. The colors represent different pressure intensity, as can be seen in the scale. A normal response to wet swallows can be observed. There are UES and LES relaxations, followed by normal esophageal peristalsis. The impedance channels in white show a normal progression of a saline bolus (bolus transit) (Adapted with permission from Rodriguez and Nurko [1])

Conclusions

At present, there is no evidence to show the benefit for the routine preoperative assessment of peristaltic function in otherwise normal children with GERD that will undergo fundoplication. However, esophageal manometry may have a role when there is severe preoperative dysphagia or atypical symptoms or when severe underlying dysmotility is known to occur. In children, the latter problem is commonly found in patients with scleroderma or esophageal atresia [32, 48], in which a fundoplication may create a functional obstruction in a dysmotile esophagus. New advances in esophageal motility testing may give new insight into those GERD patients that may develop complications after surgery.

Esophageal Intraluminal Impedance

78

Tobias G. Wenzl

Electrical impedance is defined as the relation of voltage (U) to current (I). It is measured in Ohm (Ω) and is, similar to resistance, inversely proportional to electrical conductivity. The multiple intraluminal impedance (MII) technology is based on the measurement of impedance in an organ lumen and the change of impedance during the passage of a bolus through this lumen. To measure impedance, cylindrical electrodes are placed on a hollow catheter. For signal transduction and registration, these electrodes are connected via thin wires inside the catheter with impedance-voltage converters and a display/recording unit outside the body. Impedance is measured bipolarly between two electrodes on a catheter. These two electrodes form an impedance channel, representing a defined area of the luminal organ. The total length of all channels is defined by the number of and distance between the electrodes [6].

Impedance changes characteristically depend on the content of the bolus. The electrical conductivity of air is close to zero, whereas the electrical conductivity of a liquid bolus is high, even compared to the conductivity of the muscular organ wall. All components (air, bolus, organ wall, body) together form a volume conductor around the catheter and the impedance electrodes (Fig. 78.1).

By high-frequency registration (50–100 Hz registration rate) in the esophagus, it is possible to distinguish between the resting phase, the bolus passage, and the muscular contraction in every single impedance channel. During the resting phase, due to the close proximity of the relaxed muscles (low conductivity) to the measurement electrodes, the impedance baseline is recorded. The increase of impedance just before the bolus passage, e.g., during a swallow, represents air that is propelled in front of the bolus. This is followed by a decrease of impedance after entry of the bolus into the measuring segment. The consecutive increase of impedance represents bolus exit and the contracted muscle wall after bolus passage through the measuring segment. Finally, muscles relax and impedance values return to baseline [3].

By placing multiple impedance channels consecutively on a single catheter inside a luminal organ, e.g., the esophagus, it is possible to determine the direction, height, and velocity of the bolus movement [6].

All impedance channels are recorded digitally and displayed simultaneously. Stationary or portable recording systems are available. Impedance measurements are analyzed using dedicated software and manually-visually to detect the typical changes during the passage of a bolus. If these changes appear in the most proximal impedance channels first and then in

Impedance (Z) is measured bipolarly between adjacent electrodes (= impedance channel, Z_n). Defined electrode distance (x) and number of channels (n)

the more distal impedance channels, this is interpreted as antegrade bolus movement, e.g., a swallow. If these changes appear in the most distal impedance channels first and then in the more proximal impedance channels, this is interpreted as retrograde bolus movement, e.g., a gastroesophageal reflux (GER) (Fig. 78.2). As the software allows the use of different time scales on the screen, longer episodes can be displayed completely, but also a more detailed analysis can be performed using a magnified view.

In a pilot study, the conductivity and impedance of various tissues, liquids, and foodstuff were measured in vitro using an eight-channel impedance catheter. A measuring current of <6 μA was used, as this is well below the stimulation threshold of human nerves and muscles and therefore does not interfere with the impedance registration of gastrointestinal motility. The theoretical principle of the technology was confirmed with these experiments, and the typical phases of a bolus passage were verified [6].

In vivo studies in the esophagus and duodenum of healthy volunteers confirmed the bolus phases found in vitro and the general potential of the method. Typical impedance patterns during swallows and muscular contractions were recorded and analyzed [3].

In studies on healthy adults, fluoroscopy, manometry, and MII of the esophagus were performed simultaneously. These studies delivered information regarding normal motility during the antegrade passage (swallow) of solid meals and liquids. The potential of recording GER and its clearance was demonstrated, the temporal relation of pressure changes in the esophagus, and the different impedance phases were analyzed (Fig. 78.3). The passage of air and a bolus results in relevant changes of impedance, but only little pressure increase. Maximum pressure is only experienced when the bolus exits the measuring segment.

From the defined electrode distance and the time difference between appearances of the typical impedance pattern in the neighboring impedance channels, the bolus velocity and length could be calculated for every organ segment. With this technology, it is possible to analyze changes of bolus velocity and length during the passage through the esophagus. A difference between the bolus velocity and the contraction wave velocity became apparent.

In a first clinical trial, adults with reflux esophagitis and healthy controls were examined with MII and manometry. MII patterns of the upper and lower esophagus were compared after test meals. A significant reduction of bolus velocity in

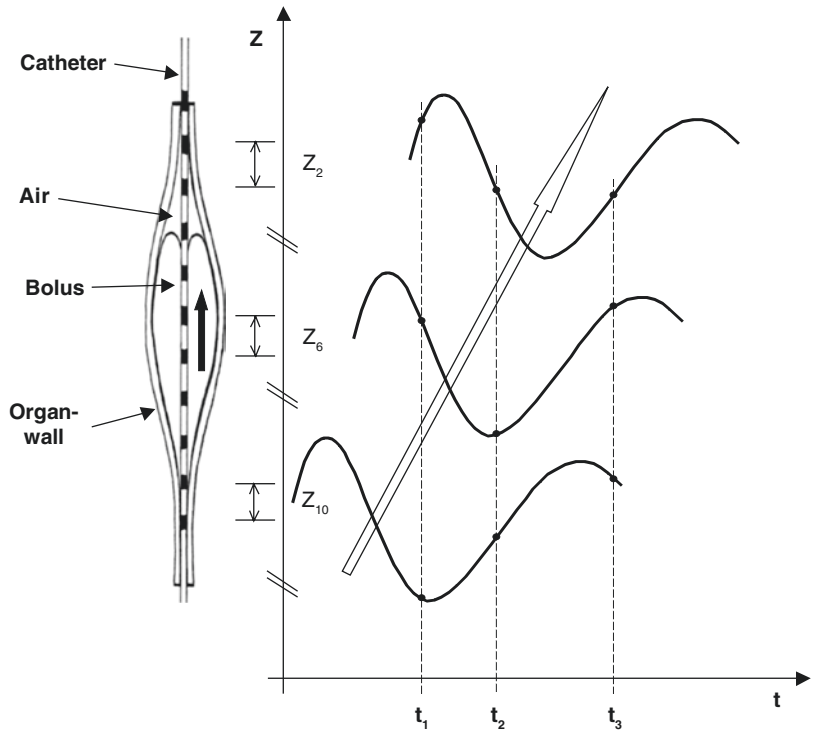

Fig. 78.2 Typical impedance changes during bolus passage through multiple measuring segments. Cross section through a luminal organ. *Thick arrow*: direction of bolus movement. Impedance (Z) over time (t). Impedance values of channel 2 (Z_2), 6 (Z_6), and 10 (Z_{10}) at the time of bolus passage. Typical sequential impedance changes (*thin arrow*) during bolus passage, first appearing in Z_{10}, then in Z_6, and ultimately in Z_2. t_1: bolus passage through Z_{10}, bolus entry in Z_6, and air entry in Z_2. t_2: bolus exit from Z_{10}, bolus passage through Z_6, and bolus entry in Z_2. t_3: return to baseline in Z_{10}, contracted muscular wall in Z_6, and bolus exit from Z_2

the aboral direction was recorded in all study individuals. Velocity was hereby inversely proportional to the viscosity of the test meal. Patients with reflux esophagitis showed a significant delay of bolus passage in the distal esophagus as compared to healthy controls; impedance values stayed well above baseline and only slowly returned to baseline after the second swallow. As no corresponding changes were documented with manometry, these were most likely non-occluding contractions.

In the next trials, MII was combined with pH-metry to study adults with reflux esophagitis. Impedance data was analyzed for the typical pattern of retrograde bolus movement; additionally, the pH of the GER episode could be defined. Shortly after the development of impedance and pH registration on a single catheter, the technology was applied in infants [7]. Impedance channels covered the lumen from the hypopharynx to the most distal esophagus [11].

The most proximal impedance channel displaying a drop of impedance resembling bolus presence was defined as height reached by the reflux. Most GER in infants reached the most proximal channel and occurred early postprandially.

The beginning of a bolus reflux was defined as a drop of impedance of at least 50 % of the impedance baseline prior to the reflux episode. It was shown that even very small bolus volumes were detectable by intraluminal impedance [4].

Volume clearance was defined as the time interval from bolus entry until bolus exit, i.e., the return of impedance values to at least 50 % of the impedance baseline prior to the GER. This was derived from in vitro studies and known to correspond to a clearance of more than 90 % of the bolus from the measuring segment [6]. Acid

Impedance (*Z*) and pressure (*P*) over time (*t*). Increase of impedance and slight increase of pressure in phase 2. Maximum pressure increase (phase 4) during segmental muscular contraction. (*A*) Entry of bolus head and return of impedance to baseline; (*B*) maximum bolus conductivity and lowest impedance; (*C*) maximum luminal occlusion

clearance was defined as the time interval from the drop of pH below threshold (usually pH 4) until its return to values above pH 4. Due to the chemical definitions, GER with pH <4 was defined as being acid GER, with pH 4–7 as weakly acidic GER, and with pH >7 as being nonacid or alkaline GER. In almost all GER, volume clearance was shorter than acid clearance and achieved after a single swallow.

All studies in infants clearly demonstrated that the major amount of GER episodes were weakly acidic, with pH monitoring alone showing a very low sensitivity for GER detection in all pH ranges.

This was found to be the new definition of gastroesophageal reflux in children [1, 5]. Color-coding of impedance changes improved visual analysis of the tracings significantly (Fig. 78.4). To date, multiple combined impedance-pH measurements have been performed in clinical routine in children of all age groups worldwide [9, 10]. International standards have been created for the procedure. The establishment of normal values and the validation of the automated analysis software in pediatric patients are in the focus of current collaborative efforts. The most recently published international

guideline on gastroesophageal reflux in children describes combined multiple esophageal impedance-pH recording as being superior to pH monitoring alone for evaluation of GER-related symptom association [2, 8].

Endoscopy with Biopsy for Esophagitis

79

Mike Thomson

Endoscopy of the whole upper GI tract (esophagus, stomach, and duodenum) with multiple biopsies is the investigation of choice in the evaluation of infants and children with symptoms suggestive of esophagitis [1, 2]. From the technical and technique aspects, useful texts to refer to are available for pediatric-specific endoscopy nowadays [3, 4]. Endoscopy should be performed only by experienced and qualified pediatric endoscopists trained in endoscopy in infants and children, with appropriate back up from pediatric anesthesiologists, and most importantly pediatric GI histopathologists. Technology now allows us to perform esophagogastroduodenoscopy (EGD) in even the smallest infants using 5.5 mm diameter instruments [5, 6]. EGD and biopsy, however, are useful only if it will lead to alteration in diagnosis, treatment, or prognosis, and useful position papers for the individual and conjoint North American and European Pediatric Gastroenterology Societies have been published on reflux and esophagitis, including the place of endoscopy in management of these conditions [2, 7–11]. Short general anesthetic is preferable to IV sedation for the procedure for reasons of safety, ease, and success of a complete and comprehensive study [12], although, with an anesthesiologist present, short-acting agents such as propofol can be used.

Macroscopic appearances of the esophagus revealing, for instance, erythema, erosions, or ulceration will guide biopsy acquisition from the areas and lesions most likely to yield highest diagnostic return. A normal endoscopy or an absence of macroscopic lesions does not exclude the presence of histologic esophagitis [13], and with our increased understanding of the variety of etiologies for esophagitis, biopsies have an enhanced role in altering management. The counterargument to this was previously advanced to defend endoscopy without esophageal biopsy in cases in which no macroscopic lesions existed [1, 14, 15], and these authors also suggested that the increase in the cost of endoscopy, when combined with biopsy, may mitigate against the latter in some countries. This is generally held to be an outdated philosophy. No conjecture exists when performing biopsies for detection or surveillance of Barrett's esophagus in which four-quadrant biopsies between 1 and 5 cm from the GEJ can be most helpful – the so-called Seattle protocol, using jumbo biopsy forceps [16].

Recent global consensus guidelines define reflux esophagitis as the presence of endoscopically visible breaks in the esophageal mucosa at or immediately above the GE junction [17–19]. Evidence from adult studies indicates that visible breaks in the esophageal mucosa are the endoscopic sign of greatest interobserver reliability

M. Thomson
Centre for Paediatric Gastroenterology, Sheffield Children's Hospital NHS Foundation Trust, Sheffield S10 2TH, UK

DOI 10.1007/978-3-642-11202-7_79

[20–22]. Operator experience is an important component of interobserver reliability [23, 24]. Mucosal erythema and an irregular Z-line are not reliable signs of reflux esophagitis [21, 22]. Grading the severity of esophagitis, using a recognized endoscopic classification system is useful for evaluation of the severity of esophagitis and response to treatment. The Hetzel-Dent classification [20] has been used in several pediatric studies [11, 25, 26], while the Los Angeles classification [19] is generally used for adults but is suitable also for children. The presence of endoscopically normal esophageal mucosa does not exclude a diagnosis of nonerosive reflux disease or esophagitis of other etiologies [27–29].

Classifications and scoring systems are employed in an attempt to semi-quantify the appearances suggestive of esophagitis, which helps to remove interobserver error. The most widely used of these are the modified Savary-Miller criteria (Table 79.1) [20]. The classification of Hetzel and colleagues has also been employed (Table 79.2). However, a criticism of the latter is that distinction between grades 0 and 1 is relatively subjective [11]. These classification systems have uses other than introducing objectivity, namely, that the pretreatment grade of esophagitis is of value in predicting the pattern and severity of acid reflux and healing rates [30], and improvement to grade 0 or 1 would be the usual aim, in either classification, of treatment.

Table 79.1 Proposed endoscopic classification of esophagitis

Grade	Features
Normal mucosa	
1	Nonconfluent erosions appearing as red patches or striae just above the Z line[a]
	Erythema or loss of vascular pattern
2	Longitudinal noncircumferent erosions with a hemorrhagic tendency of the mucosa
2a	1 plus bleeding to light touch (friability)
2b	1 plus spontaneous bleeding
3	Circumferent tendency; no strictures
4a	Ulcerations with stricture or metaplasia
4b	Stricture without erosions or ulcerations

Adapted from Savary and Miller
[a]Z line defined as junction between columnar gastric fungal mucosa and stratified esophageal mucosa

The specific macroscopic appearances of conditions other than GER esophagitis are noted in the relevant sections on pathogenesis above. Hassell suggests that erosions usually found on the tops of esophageal folds are specific for reflux disease, often with a rim of erythema around the white erosions [14]. However, these may mimic, for instance, Crohn's disease. Gupta and colleagues suggest that vertical lines in the distal esophageal mucosa are a true endoscopic manifestation of reflux esophagitis in children (Fig. 79.1) [31]. In severe ulcerated esophagitis, objective proof of recovery following treatment is important, and repeat endoscopy between 3 and 12 weeks later is generally recommended.

Table 79.2 Endoscopic classification of esophagitis

Grade	Features
No mucosal abnormalities	
1	Erythema, hyperemia, mucosal friability
2	Superficial erosions affecting <10 % of the distal 5 cm of esophageal squamous mucosa
3	Superficial erosions or ulceration of 10–50 % of the mucosal surface of the distal 5 cm of esophageal squamous mucosa
4	Deep peptic ulceration anywhere in the esophagus or confluent erosion of >50 % of the mucosal surface of the distal 5 cm of the esophageal squamous mucosa

Adapted from Hetzel et al.

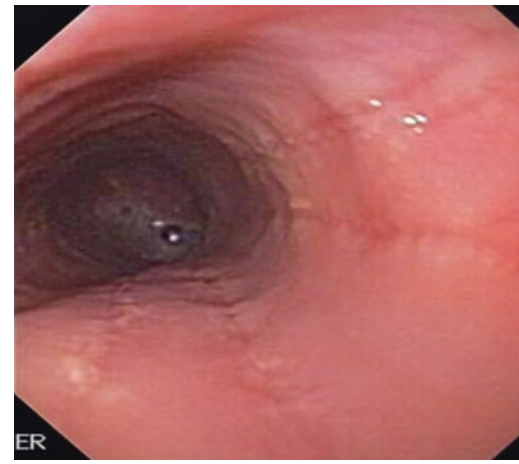

Fig. 79.1 Eosinophilic esophagitis: not the longitudinal furrowing and the white papules with a degree of circular indentations known as 'trachealisation' of the esophagus

Generally, it is held that although the majority of esophagitis is due to reflux, the esophageal appearances themselves do not reliably differentiate between reflux and other causative pathologies. This is perfectly demonstrated in the diagnosis and management of esophagitis in children with cancer, in whom esophagitis is a common occurrence but whose etiology is not predicted accurately by clinical observations (e.g., oral candidiasis does not predict for candidal esophagitis) or by macroscopic endoscopic appearances [32] – hence, the requirement for confirmatory biopsy and histology.

EE and GERD have very similar symptoms and signs and can be best distinguished by endoscopy with biopsy. A key difference endoscopically is that EE is not generally an erosive disease, but has its own typical endoscopic features such as speckled exudates, trachealization of the esophagus, or linear furrowing. In up to 30 % of cases, however, the esophageal mucosal appearance is normal [27]. When eosinophilic esophagitis is considered as part of the differential diagnosis, it is advisable to take esophageal biopsies from the proximal and distal esophagus [27]. Mucosal eosinophilia may be present in the esophageal mucosa in asymptomatic infants <1 year of age [33], and in symptomatic infants, eosinophilic infiltrate may be due to milk protein allergy [34].

There is insufficient evidence to support the use of histology to diagnose or exclude GERD. The primary role for esophageal histology is to rule out other conditions in the differential diagnosis, such as eosinophilic esophagitis, Crohn's disease, Barrett's esophagus, infections, and others. This conclusion concurs with that of a global pediatric consensus group [17]. When symptoms suggestive of GERD are present in adolescents or adults in the absence of erosive esophagitis, the clinical entity is known as nonerosive reflux disease (NERD). In NERD, there is no evidence that esophageal histology makes a difference to clinical care decisions, i.e., patient treatment is guided by symptoms, whether or not reactive histologic changes are present on biopsy.

At endoscopy, accurate documentation of esophagogastric landmarks is necessary for the diagnosis of hiatal hernia and endoscopically suspected esophageal metaplasia (ESEM) [35–40]. This is of particular importance in children with severe esophagitis, in whom landmarks may be obscured by bleeding or exudate, or when landmarks are displaced by anatomic abnormalities or hiatal hernia [35, 36, 41]. In these circumstances, a course of high-dose PPI for at least 12 weeks is advised, followed by a repeat endoscopy, in order to remove the exudative camouflage and better visualize landmarks [36, 42].

Histology

A diagrammatic representation of an esophageal cross-section is shown in Fig. 79.2. Nowadays, biopsies are endoscopic, but suction biopsies have been assayed in the past and probably yield

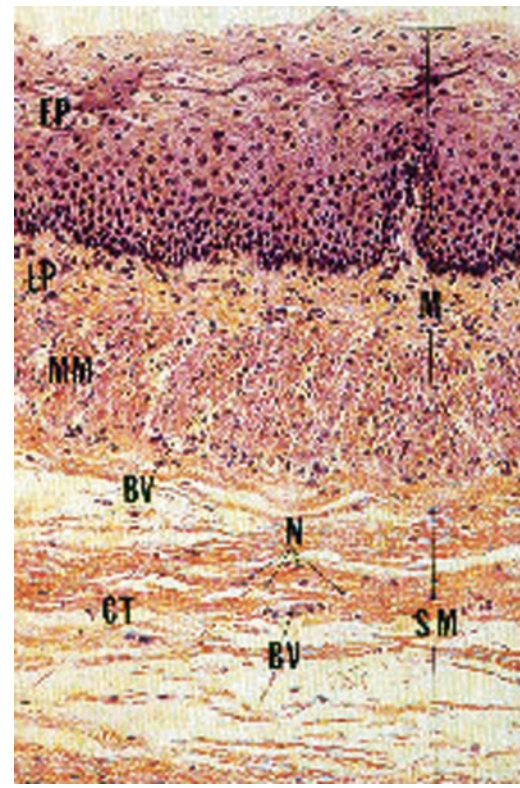

Fig. 79.2 Histological cross-section of the esophagus. *SM*: smooth muscle; *MM*: muscularis mucosa; *EP*: epithelium; *M*: mucosa; *LP*: lamina propria; *N*: nerve; *BV*: blood vessel; *CT*: connective tissue

Table 79.3 Grading criteria for histologic appearance of esophagus

Grade	Histologic criteria	Clinical diagnosis
0	Normal	Normal
1a	Basal zone hyperplasia	Reflux
1b	Elongated stromal papillae	Reflux
1c	Vascular ingrowth	Reflux
2	Polymorphs in the epithelium ± lamina propria	Esophagitis
3	Polymorphs with epithelial defect	Esophagitis
4	Ulceration	Esophagitis
5	Aberrant columnar epithelium	Esophagitis

Adapted from Knuff et al. and Leape

a deeper, more satisfactory biopsy [43]. When suction biopsies were added to conventional grasp biopsy technique in a study by Hyams and colleagues, the histologic diagnosis of esophagitis was increased from 60 % to 83 % of cases, although if one takes more biopsies, one would expect a greater diagnostic yield given the patchy nature of childhood esophagitis; hence, this cannot be used to suggest that suction biopsies are superior in pediatric practice [44]. Friesen and colleagues showed no statistically significant difference in predictive value for esophagitis in infants between the two techniques [29]. Correctly oriented endoscopic biopsies (e.g., immediate orientation on filter paper or nylon mesh in 10 % formalin) are, however, perfectly adequate, and so-called "crocodile" biopsy forceps, which allow the operator to biopsy perpendicular to the esophageal lumen, may be preferable. Large-cup ("jumbo") biopsy forceps are increasingly used and are mandatory for the surveillance of Barrett's esophagus using the so-called Seattle protocol (quadrantic biopsies every 1 cm above the GEJ involving the distal 5 cm of the esophagus) because they yield deeper biopsies [16]. The site of biopsy should be above the distal 15 % of the esophagus to avoid confusion with normal variance [44]. Biopsies should include epithelium, lamina propria, and muscularis mucosae and be oriented in a perpendicular plane to maximize diagnostic yield, such as evaluating properly the thickness of the basal zone, vascular ingrowth, and the elongation of the stromal papillae. For definitive diagnosis, the presence of two of three of these features is preferable, which will not be possible with poorly oriented

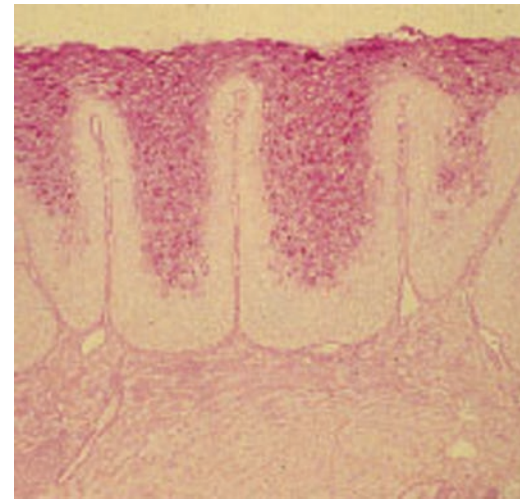

Fig. 79.3 GOR changes with papillary height change and the papillary to epithelium ratio approximately 90 % where normal is <33 % approx

tissue [1, 2]. Vertical macroscopic lines may be useful in determining histological esophagitis [26]. The classic histologic findings of GER esophagitis are displayed in Table 79.3 (Fig. 79.3). Elongation of stromal papillae is a useful indicator of reflux, and basal zone hyperplasia is defined when the papillae are more than 25 % of the entire thickness of the epithelium, and if more than 50 %, then the papillae are considered to be elongated [45].

The diagnostic yield of endoscopy is generally greater if multiple samples of good size and orientation are obtained from biopsy sites that are identified relative to major esophageal landmarks [35, 36, 41]. Several variables have an impact on the validity of histology as a diagnostic tool for reflux esophagitis [29, 46]. These

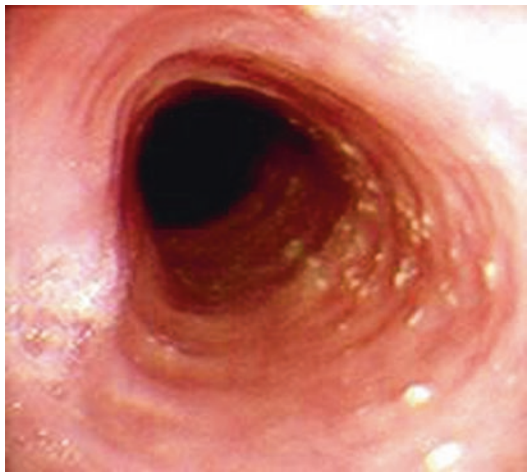

Fig. 79.4 Features of eosinophilic esophagitis although the white plaques may be mistaken for esophageal candida

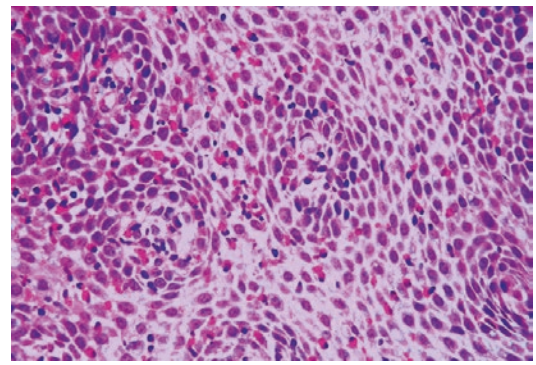

Fig. 79.5 Eosinophilic infiltration of the esophagus in eosinophilic esophagitis

include sampling error due to the patchy distribution of inflammatory changes and a lack in standardization of biopsy location, tissue processing, and interpretation of morphometric parameters. Histology may be normal or abnormal in nonerosive reflux disease (NERD) because GERD is an inherently patchy disease [29, 47]. Histologic findings of eosinophilia, elongation of papillae (rete pegs), basal hyperplasia, and dilated intercellular spaces (spongiosis) are neither sensitive nor specific for reflux esophagitis. They are nonspecific reactive changes that may be found in esophagitis of other causes, or in healthy volunteers [28, 29, 46, 48–54]. Recent studies have shown considerable overlap between the histology of reflux esophagitis and eosinophilic esophagitis [27, 28, 34, 55]. Many histologic parameters are influenced by drugs used to treat esophagitis or other disorders.

Esophageal mucosal eosinophilia has been described in both suspected cow's milk-associated reflux esophagitis [15, 56] and reflux esophagitis [57], as well as in other conditions, such as eosinophilic esophagitis (Figs. 79.4 and 79.5) [58]. The clinical significance of eosinophils and their role in the pathogenesis of mucosal injury are poorly understood and are the subject of recent debate [14, 15, 59]. Some have suggested an active role for eosinophils in the inflammatory process of esophagitis and have supported this with the observation of resolution of symptoms and eosinophils in the esophagus on dietary exclusion of cow's milk [60, 61] or with oral steroids [58, 61], both suggesting a pathoetiologic role for eosinophils. The mucosal density of the eosinophils may be important, as noted above, in distinguishing between allergic esophagitis and EE. In addition to eosinophils, intraepithelial T lymphocytes, known as CINC or squiggle cells, have also been implicated as markers of reflux esophagitis (Fig. 79.6) [62, 63]. However, the degree of intraluminal esophageal acid exposure did not correlate well with the CINC count in one study in children, and the authors use this fact to question the day-to-day reliability of pH metry in defining the extent of reflux in children [45]. In adults, such cells are of memory phenotype and display activation markers [63], although little is known of their pediatric equivalents. The finding of mucosal mast cells may also help to differentiate GER from CMP-associated esophagitis, but there is considerable overlap with the presence of eosinophils [64]. Neutrophils also indicate a degree of inflammation [65], and actual numbers of eosinophils and/or neutrophils per most-involved HPF have been used to indicate the severity of esophagitis [45]. Minimal histologic criteria are simultaneous occurrence of elongated papillae and basal zone hyperplasia. Moderate esophagitis is diagnosed if there is ingrowth of vessels in the papillae, and 1–19

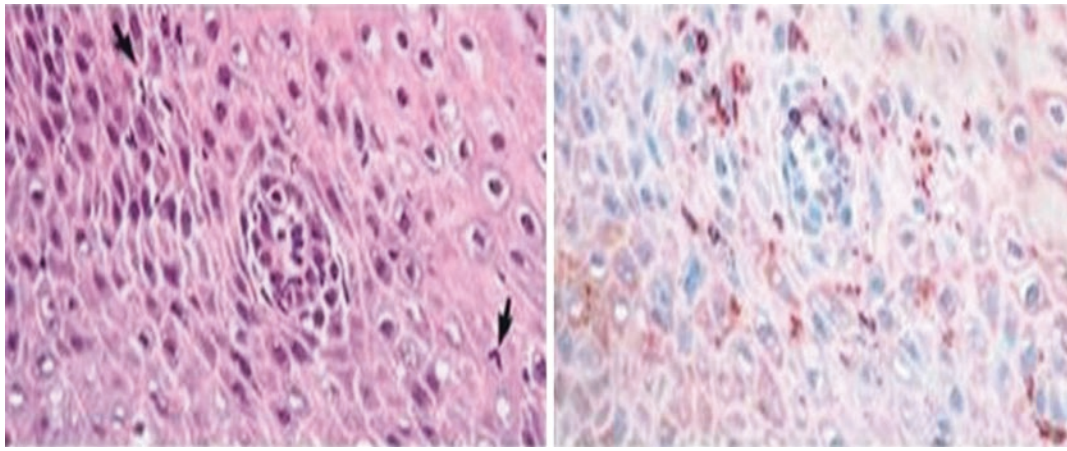

Fig. 79.6 Intraepithelial T lymphocytes in GORD biopsies and these are also known as squiggle cells

eosinophils/neutrophils are seen in the most-involved HPF. Severe esophagitis is diagnosed if more than 20 eosinophils/neutrophils are seen in the most-involved HPF. These criteria must now be taken in the context of eosinophilic esophagitis. However, the criteria established by European Society of Paediatric Gastroenterology Hepatology and Nutrition and displayed are probably the most robust to date [2].

The important point to realize is that correlation between macroscopic and histologic features is generally poor, partly because the esophagitis may be a patchy lesion but also because histologic esophagitis may exist when the esophagus is macroscopically normal [13]. This is not now merely academic because it does have the potential to direct therapy appropriately, for example, in the case of CMP allergy-associated esophagitis when a cow's milk exclusion diet is associated with a better outcome than use of antacid therapy alone, and it is suggested that up to 40% of cases of esophagitis may have CMP GI allergy as an etiologic factor [60, 61, 66].

Furthermore, with the advent of more complex diagnostic techniques such as immunohistochemistry and electron microscopy, the esophagus, which is apparently normal both macroscopically and histologically, may still yield diagnostic information. Standard endoscopic biopsy and histology do not reliably distinguish between, for instance, primary reflux esophagitis and the clinical entity of cow's milk-associated reflux esophagitis. Some differentiation from primary reflux has been suggested on the basis of esophageal pH testing pattern and α-lactoglobulin antibody response, although the former has not been substantiated by more than one center [61, 67].

Barrett's esophagus and premalignant or malignant esophageal pathology are dealt with in another chapter. Cytologic esophageal brushings may be helpful in such situations, as they are in candidal esophagitis [68].

Immunohistochemistry

A variety of immunohistochemical markers have been used to examine the esophageal mucosa. An increase in Ki-67, a proliferation marker, has been shown in the longer papillae seen in GER, suggesting increased cell turnover (Fig. 79.7). Basal focal distribution of CD4 lymphocytes showing expression of the activation markers CD25 and HLA-DR, together with upregulated epithelial HLA-DR expression, has also been reported [66]. Eotaxin is a recently described eosinophil-specific chemokine [69], and, despite the mild histologic abnormality in CMP-associated esophagitis, an increased expression of eotaxin colocalized with activated T lymphocytes to the basal and papillary epithelium has been shown, distinguishing this from primary reflux esophagitis (see Fig. 79.8) [66]. Inhibitory neurotransmitter production is integral to LES relaxation, and the nonadrenergic,

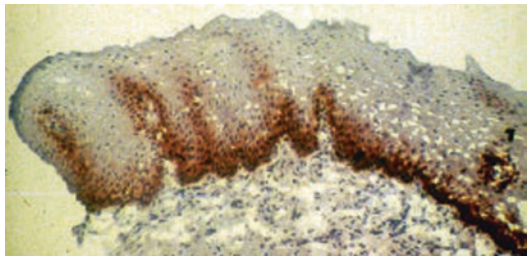

Fig. 79.7 The brown stain indicates Ki67 which is a marker of cell turnover and is upregulated here indicating that in reflux the cells are damaged in the epithelium and require more rapid replacement

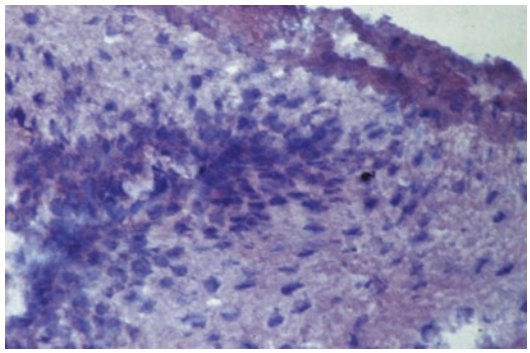

Fig. 79.8 Increased expression of eotaxin colocalized with activated T lymphocytes to the basal and papillary epithelium typical of allergic type esophageal changes often seen in conjunction with reflux

noncholinergic neurotransmitter NO has received recent attention in human studies [70, 71]. Increased esophageal expression of iNOS has also been noted [72, 73], although in another study, it was not upregulated in the inflamed pediatric esophagus [74]. Because NO is a powerful smooth muscle relaxant, it is interesting to speculate whether inflammation-induced iNOS may play a role in LES relaxation, leading to more reflux and hence worse inflammation, and so on. An exciting development is that of confocal endo-microscopy in which real-time images of the cell ultrastructure can be obtained at endoscopy, which is dealt with below.

Hence, techniques such as immunohistochemistry will allow better comprehension of the pathophysiology of esophageal pathology in the near future and already allow a diagnostic distinction to be drawn between etiologies.

Electron Microscopy

Electron microscopy has demonstrated the ultrastructural changes associated with esophagitis, adding to our comprehension of the lesion. Stratified squamous non-keratinizing epithelium line the mucosa, and the surface is composed of large flat cells displaying a regular pattern of parallel microridges 200 nm in thickness. Three layers are visible by transmission electron microscopy: (1) the basal layer, composed of polygonal cells with a high nucleus-to-cytoplasm ratio; (2) the intermediate layer, composed of large prickle cells; and (3) the superficial layer, composed of flattened cells. Three grades of ultrastructural changes in esophagitis in children have been identified: grade I, irregular microridges and reduced intercellular junctions; grade II, of the superficial epithelium only, microvilli instead of microridges that, when present, are distorted, and extruding cells with degeneration and interruptions of the cell membrane; lymphocytes and monocytes occupy the large intercellular spaces in the intermediate layer, and the basal layer is thickened; and grade III, microerosive cytopathy, loss of superficial layer microridges with crater-like erosions and abundant cell debris. Degenerating cells are seen in all three layers. Reduced numbers of desmosomes and large intercellular spaces containing lympho-monocytes are seen. Ultrastructural damage to nuclei, nucleoli, Golgi complex, and endoplasmic reticulum is seen. Activation of eosinophils by electron microscopic criteria has helped in the distinction of GER and CMP-associated esophagitis [64]. Hence, a more compelling case can be made for biopsy than previously.

Upper GI endoscopy allows direct visual examination of the esophageal mucosa; mucosal biopsies enable evaluation of the microscopic anatomy [10]. Macroscopic lesions associated with GERD include esophagitis, erosions, exudate, ulcers, strictures, hiatal hernia, areas of possible esophageal metaplasia, and polyps. While endoscopy can detect strictures, subtle degrees of narrowing may be better shown on barium contrast study, during which the esophagus can

be distended with various techniques, such as a radiopaque pill, barium-soaked bread, or marshmallows. Malrotation and achalasia cannot be diagnosed by endoscopy. These and other anatomic and motility disorders of the esophagus are better evaluated by barium radiology or motility studies.

Endo-ultrasound

There is little or no role for endo-ultrasound in the evaluation of reflux esophagitis, although Fox et al. have used this technique to identify that eosinophilic esophagitis is a transmural condition [75].

Confocal Endo-microscopy

The endoscopic procedure using the confocal endomicroscope (EC3870CILK; Pentax, Tokyo, Japan) has been well described [76]. Following duodenal intubation, 0.05–0.1 ml/kg of 10 % fluorescein sodium is administered intravenously and flushed adequately with normal saline. On withdrawing the scope to the lower end of the esophagus, acriflavine 0.05 % is sprayed on the surface of the esophageal mucosa using a spray catheter. CLE image acquisition is performed by placing the tip of the endoscope in direct contact with the surface of the esophageal mucosa (Fig. 79.9). Using gentle suction to stabilize the mucosa, image acquisition and focal plane z-axis scanning depth is then actuated using two discrete hand-piece control buttons (Fig. 79.10). The imaging depth below the tissue surface can be dynamically controlled by the operator. With each deeper plane, the focal plane of the confocal microscope moves by 4 μm and consequently the image obtained is approximately 4 μm deeper than the previous one. Consecutive confocal images are then obtained from the esophagus sequentially at different planes from the surface to the maximum permissible depth (Fig. 79.11). The S-P distance in μm is calculated by counting the number of images obtained from the surface until the first capillary loop is first detected and multiplying by a factor of 4.

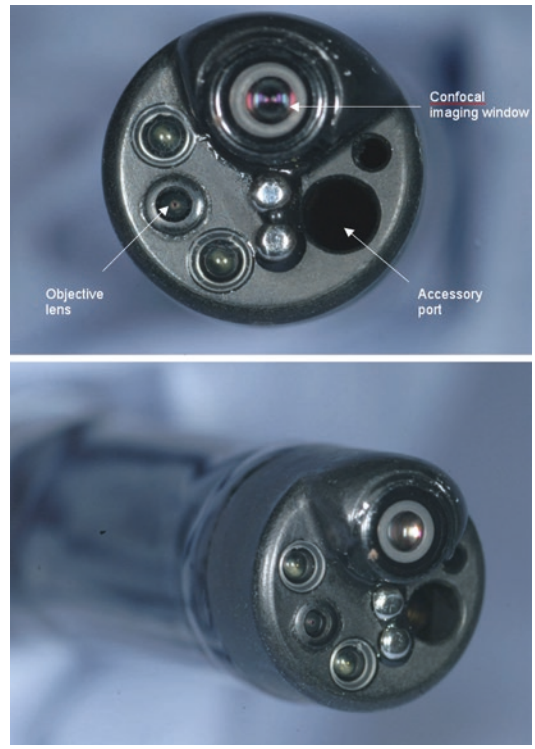

Fig. 79.9 The tip of a confocal endo-microscope

Fig. 79.10 The endoscope handle with all features demonstrated

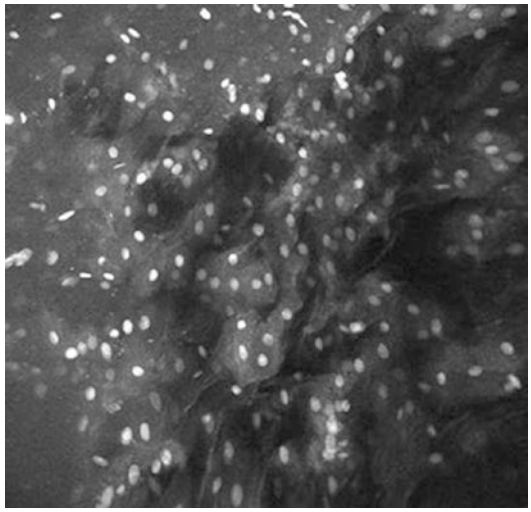

Fig. 79.11 The esophageal mucosal surface visualized with confocal endo-microscopy 'en-face' – nuclei are the white dots and the stratified epithelial cells can be clearly seen

One small pilot study indicates that the epithelial surface to papillary tip distance (which would be less in reflux if papillae were elongated in reflux), when measured with respect to the denominator of patient height, was indeed smaller in reflux suffering patients than in controls. Furthermore EE patients had a longest epithelium-papilla tip distance as has been shown on endo-ultrasound [77].

The major advantage of the confocal method is the capacity to make a real-time in vivo diagnosis of reflux-related esophageal change associated with esophagitis. One limitation is the reliance on one particular feature (papillary elongation) in arriving at a diagnosis, and may decrease the number of biopsies needed, and as a corollary allow targeting of biopsies for histology. While this method may not be the most accurate and definitive method to diagnose esophagitis, it may add to the diagnostic armamentarium of reflux-related esophagitis, and further studies on GERD and other pathologies such as eosinophilic esophagitis are needed.

This Chapter has not dealt with Barrett's esophagus which can be reviewed elsewhere.

In summary, endoscopy need not be utilized in the diagnosis of reflux-related esophagitis, but where it comes into its own realm is in the differentiation against other pathologies especially eosinophilic esophagitis – indeed this may, in years to come, provide the major justification for endoscopy and biopsy in children presenting with reflux-like symptoms and especially in those with dysphagia. There remains little or no reason to subject infants to endoscopic assessment to determine reflux-related esophagitis or reflux-related changes on histology alone, unless assessment of disease control on treatment in combination with pH or combined pH-impedance monitoring is contemplated. More sophisticated technologies may allow smart targeting of biopsies with attendant decrease in biopsy numbers and associated financial saving.

Barium Contrast Radiography and Scintigraphy

80

Rossella Turco, Dario Ummarino, and Annamaria Staiano

Introduction

Several tests have been advocated to evaluate patients with suspected gastroesophageal reflux disease (GERD), including endoscopy, manometry, barium contrast radiography, scintigraphy, 24-h pH monitoring, and combined pH-metry and multichannel intraluminal impedance [51]. Barium contrast radiography was proposed in the investigation of GER in order to document the retrograde flow of gastric content. This technique has been proposed to be useful for the evaluation of motility and for morphologic abnormalities of the esophagus. Scintigraphy utilizes milk or liquid-labeled ^{99m} technetium feeds to evaluate gastric emptying and possible microaspiration. This nuclear scan evaluates only postprandial reflux and is not able to correlate refluxes with gastric pH. A lack of standardized technique and the absence of age-specific values reduce the accuracy of this test. According to the last NASPGHAN and ESPGHAN guidelines on GERD, both techniques are not useful in the routine diagnosis of GERD. The main reasons are:

– The small duration of the exam may show only an isolated episode of reflux which cannot be considered significant [54].
– The sensitivity and the specificity of barium contrast radiography and scintigraphy are 29 % and 15 %, and 21 % and 83 %, respectively. These values are definitely very low compared with pH-metry sensitivity (86 %) and specificity (100 %) [25, 50, 54].

Barium Contrast Radiography

Barium contrast radiography, or gastrointestinal series (GI series), is a noninvasive technique used for the evaluation of upper gastrointestinal disorders. This technique is usually executed as a multiphase examination that includes various steps such as the timed barium swallow, the oropharyngeal phase, the motility phase, the distended or single-contrast phase, and then an attempt at reflux identification. The upper GI series can be performed in different views:

1. Double-contrast view using a high-density barium suspension.
2. Single-contrast view using low-density barium suspension.
3. Mucosal relief view using higher or low density of barium suspension [29, 30].

These different techniques are associated with different positions, allowing the radiologist the ability to detect specific abnormalities or disease processes. With barium contrast radiography, it is only possible to evaluate malformations in the GI tract. Historically it has been used to

try to demonstrate the presence of ulcers, strictures, or other abnormalities of the mucosa. At the same time, it can monitor a retrograde flow of the barium from the stomach to the esophagus that could indicate a reflux of gastric content (Fig. 80.1). Bilious vomiting, protracted vomiting, feeding difficulty or dysphagia, poor weight gain or weight loss, and assessment of the status of previous fundoplication are the major indications of barium contrast radiography in children. The upper GI series is also utilized for assessing swallowing disorders and oropharyngeal aspiration in children and is usually termed a "videofluoroscopy" in these situations [4].

Use of the Upper GI Series in Diagnosis of GERD

The effectiveness and importance of reflux identification during barium studies have been questioned by many authors [35]. An upper GI series can identify a single reflux event (Figs. 80.2 and 80.3), but conflicting data exist about the possible correlation between the size and height of reflux detected by barium contrast radiography and the presence of GER/GERD. Christiansen et al. found a positive correlation between the level of reflux on barium studies and the proximal extent of reflux esophagitis on microscopic examination of endoscopic biopsy specimens from the esophagus [11]. Moreover, Pan et al. comparing the findings on 24-h pH-metry, with those of barium contrast radiography of 28 patients, observed that patients with massive reflux episodes on barium contrast radiography had pathologic acid reflux on pH monitoring [37]. On the other hand, it has been recently established that no correlation exists between the height of reflux and esophageal/extraesophageal symptoms, prognosis, or the natural history of GERD [6]. Indeed, reviewing various data reported in the literature, we noted a broad agreement not to consider barium contrast radiography as a useful tool in the diagnosis of GERD because of its low sensitivity and specificity. In a review of ten previously published studies, Ott found that only 204 (35 %) of 587 patients with proven reflux had a GERD detected on GI series, showing a lower sensitivity of this technique compared to 24-h pH-metry [35]. In the literature, several studies, concerning the attempt to demonstrate higher barium contrast radiography sensitivity and specificity, are reported. Thompson

Fig. 80.1 A retrograde flow of barium in pharynx due to an incoordination of swallowing evaluate trough barium contrast radiography (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

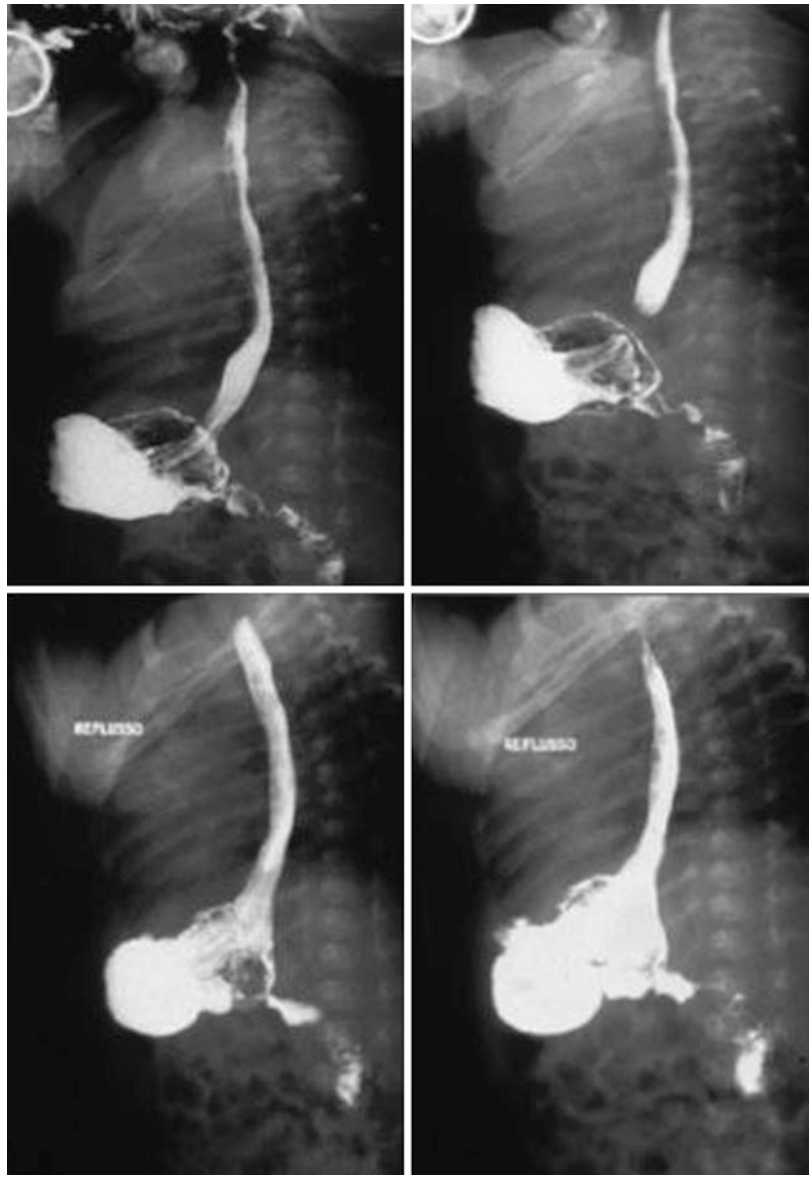

Fig. 80.2 Gastro-esophageal reflux (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

et al. [46] studied 117 patients with clinical findings suggestive of reflux by using GI series and pH-metry. Seventy (59 %) had a positive pH-metry while 47 (41 %) had a negative one. They found, according to previous data, that using provocative maneuvers, including abdominal compression, the Valsalva maneuver, positional changes, leg lifting, coughing, and water siphon test, induced an enhancement of sensitivity (44–92 %), with decrease in specificity (0–75 %) [6, 17, 46]. In addition, it has been observed that the upper GI series is not indicated for infants less than 1 year of age because it has a specificity of 50 % and a sensitivity of 29 % when compared with 24-h pH-metry [1].

Several reasons could explain the limits of an upper GI series in detecting GER. One being that many infants have non-pathological, or physiological, reflux, producing false-positive results. Moreover the short duration of the upper GI series is the cause of false-negative results. Importantly the relatively high level of radiation

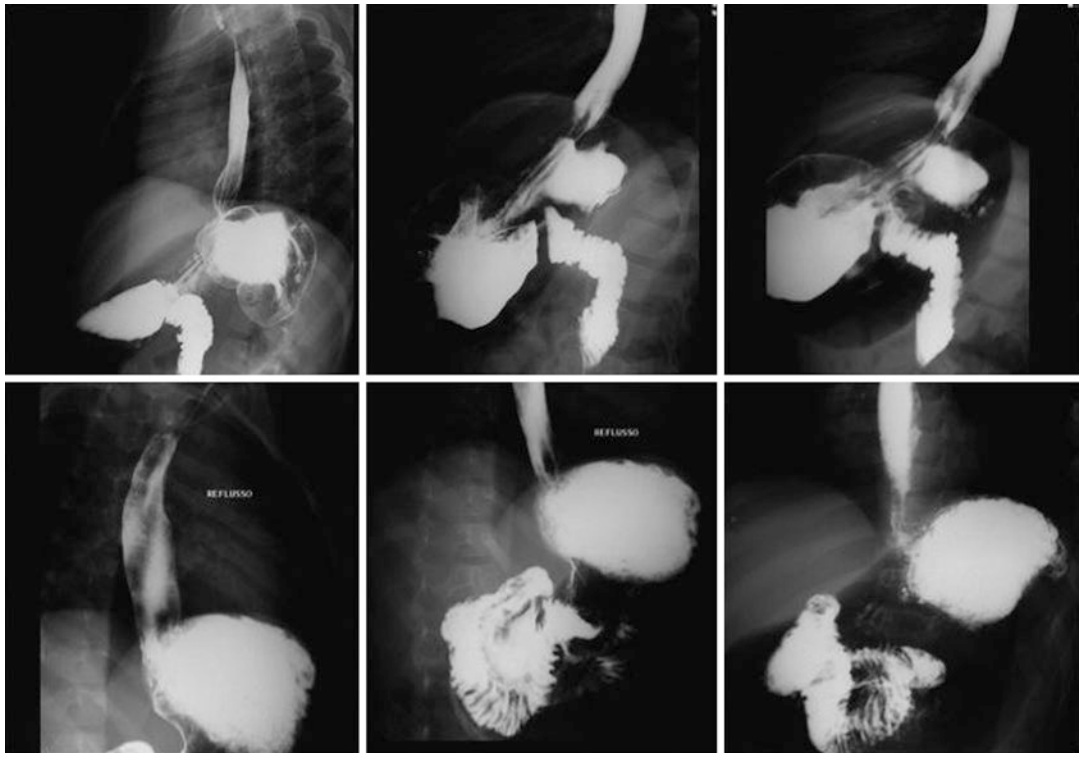

Fig. 80.3 Gastroesophageal reflux (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

received by the child during a barium contrast examination is another important limitation for the use of this technique which should be considered in the diagnostic approach of a child with GERD suspicion [53]. For all the abovementioned reasons, GI series is not of value for the routine diagnosis of GERD, but its possible indications in GER are confined to the evaluation of upper GI anatomical abnormalities such as esophageal strictures, hiatal herniae, achalasia, tracheoesophageal fistulae, intestinal malrotations, or pyloric stenoses, which may be considered in the differential diagnosis of infants and children with symptoms suggestive of GERD.

The upper GI series is reported by some to have a sensitivity of 90 % in the detection of reflux esophagitis. The early manifestations of reflux esophagitis are said to be represented by a fine nodular or granular appearance with poorly defined radiolucencies that fade peripherally for the edema and inflammation of mucosa [10, 31] (Fig. 80.4). In patients with severe reflux, barium contrast radiography may, it is said, show the evidence of small ulcers, erosions, or strictures of the esophagus, but this remains highly dubious and generally thought to be without substance or reliability [43]. The classic signs of Barrett's esophagus instead are found only in 5–10 % of all patients, and this modality remains extremely suspect in this essentially histological diagnosis [13, 21, 22]. Achalasia is characterized by the incomplete relaxation of the lower oesophageal sphincter (LES) and the absence of esophageal peristalsis which causes a functional obstruction of the distal esophagus. Using barium contrast radiography, the esophagus appears dilated with a tapered beak-like narrowing near the gastroesophageal junction [28, 29, 36, 44] (Fig. 80.5).

Hiatal herniae consist of the herniation of parts of the abdominal contents through the oesophageal hiatus of the diaphragm. The relationship between esophagitis and hiatal hernia

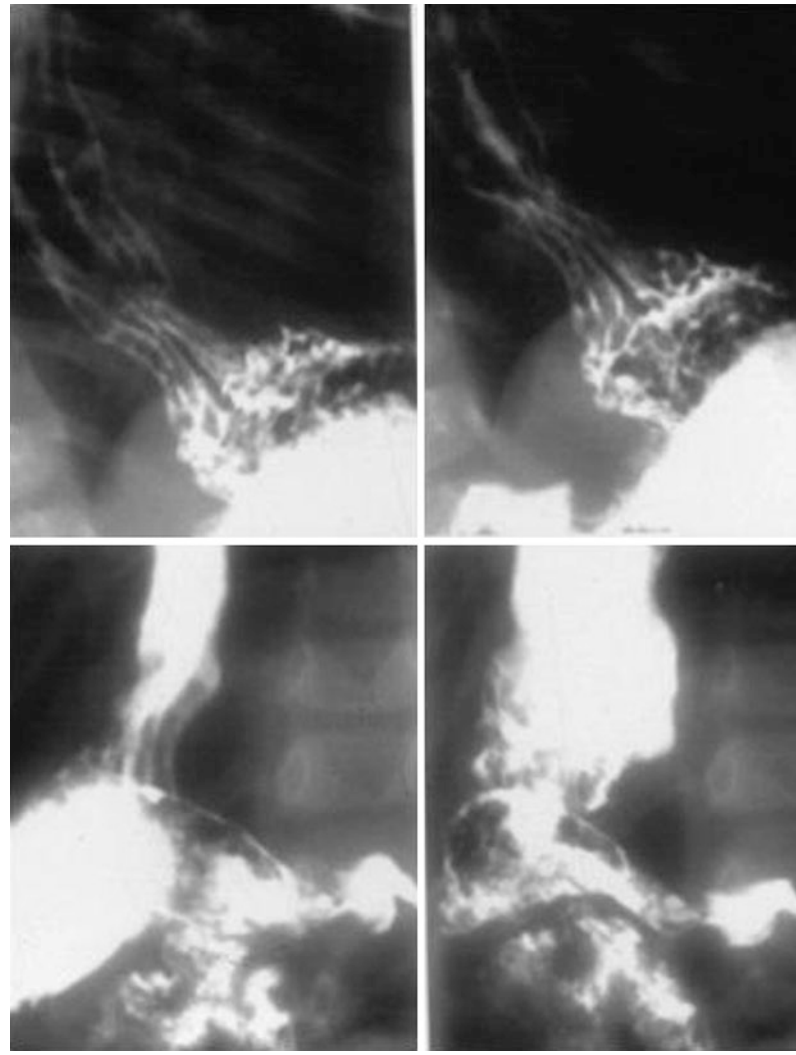

Fig. 80.4 Early esophagitis. It is possible to note the edema of the mucosa with an increasing of the esophageal folds (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

has been established for many years both in children and in adults. It is known that in the presence of a hiatal hernia, all of the antireflux barriers at the LES (including crural support, intra-abdominal segment, and angle of His) are compromised [7, 9, 33, 50], and transient LES relaxations also occur with greater frequency [33], increasing the possible onset of GERD. On the contrary the presence of erosive esophagitis by itself may promote esophageal shortening and consequent hiatal herniation, although this remains conjectural [33]. Both the presence and size of the hiatal hernia are important factors determining the GERD severity [8, 25]. As of now an upper GI series remains the most sensitive technique in the diagnosis of a hiatal hernia and its size.

Intestinal malrotation can occur as an acute abdomen or as a recurrent episode of abdominal pain and/or vomit. An intermittent volvulus or a duodenum compression due to Ladd's band or to adhesions of the ileum or colon can explain this symptomatology. GI radiography, especially barium contrast radiography, is useful for the diagnosis of this malformation. It remains the most sensitive and specific technique for the diagnosis of malrotation, and the presence of bile-stained vomiting is categorically not needed for the suspicion of this diagnosis – in other words any child with intermittent abdominal pain/vomiting should

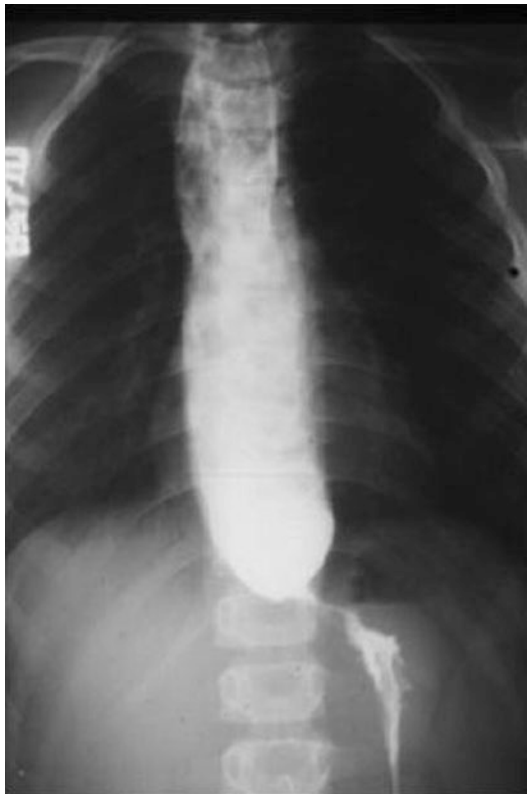

Fig. 80.5 An image of esophageal achalasia (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

have this diagnosis borne in mind by their doctor. Anything less than a high index of suspicion for this potentially devastating condition with volvulus and small bowel necrosis leading to short bowel syndrome and a life dependent on parenteral nutrition is inadvisable.

Esophageal strictures can be congenital or acquired. They can be caused by or associated with GERD, esophagitis, dysfunctional LES, disordered motility, hiatal hernia, surgical anastomosis, infections, and caustic ingestion (Fig. 80.6). GI series is the gold standard to diagnosis of the majority of esophageal strictures.

Classically, infants with hypertrophic pyloric stenosis have non-bilious vomiting or regurgitation which sometimes can be interpreted as consequences of GERD. In these cases an upper GI series may show an elongated pyloric canal, a prominence of the pyloric muscle in the gastric antrum (the so-called *shoulder sign*), and parallel barium streaks in the narrowed canal which determine the so-called *double track sign*. Nowadays ultrasound is considered the gold standard for pyloric stenosis diagnosis.

Scintigraphy

First Kazem in 1972 tried to develop a new technique, scintigraphy, for the evaluation of GI function [27], and since that time it has been applied to a variety of pathophysiologic conditions. Esophageal scintigraphy, which was introduced in 1976 [16] as a diagnostic tool to try to evaluate GER, seemed to be a potentially accurate and noninvasive technique to diagnose and quantify reflux. However, the lack of a standardized technique for the performance and the interpretation of this test and the absence of age-specific values are the main reasons to explain why the importance of scintigraphy in the diagnosis of GER has decreased. Nevertheless, several studies have been conducted to estimate the role of scintigraphy for the evaluation of upper GI function, especially the ability to detect gastroesophageal reflux, both in pediatric and adult populations. Scintigraphic evaluation of children with suspected GERD is performed with several approaches using caloric liquid or solid meals labeled with ^{99m} technetium (Tc), appropriate to the patient's age. A gamma camera equipped with an adequate collimator placed in front of the recumbent patient is needed to obtain a dynamic study of the esophagogastric region and lungs. Standard protocols and guidelines on GERD scintigraphy require a 60-min dynamic acquisition during which reflux episodes with their duration, extension, and aspiration are recorded. Since transient reflux can rapidly dissolve, a rapid imaging (10–20 s/images) is needed. At the end of dynamic acquisition, 5-min static images of the anterior and posterior lung fields are acquired. Reyhan et al., comparing the posterior dynamic imaging with the anterior imaging in the evaluation of children with GERD, showed that posterior imaging was superior to anterior imaging, being more comfortable and with less motion

Fig. 80.6 A stricture of the distal esophagus due to an advance esophagitis (Photographs made available by Department of Radiology, University of Naples Federico II, courtesy of Hana Dolenzalova, M.D.)

artifacts, especially for infants and anxious children [41]. Finally gastroesophageal reflux can be described using different indices, which usually consider the volume of each episode, the frequency of the episodes, and the rate of reflux clearance from the esophagus.

Scintigraphy in Diagnosis of Upper Gastrointestinal Diseases

Although gastroesophageal scintigraphy is a practical and noninvasive technique with low levels of radiation exposure for children compared to barium, its significance in diagnosing GER, it is limited by the failure of scintigraphy to achieve a sensitivity similar to that of other tests, particularly esophageal pH monitoring. Sensitivity and specificity of a 1-h scintigraphy for the diagnosis of GERD are 15–59 % and 83–100 %, respectively, when compared with 24-h pH-metry [2, 3, 14, 42, 47]. Seibert et al. [42] first reported a sensitivity and a specificity of 79 % and 93 %, respectively, when comparing gastroesophageal scintigraphy to 24-h pH-metry, analyzing 49 infants and children with suspected GER. Tolia et al. [47] comparing esophageal pH-metry with gastroesophageal scintigraphy observed that the incidence of GER was 69.5 % by pH-metry and 66.0 % by gastroesophageal scintigraphy in symptomatic infants of less than 1 year of age. Vandenplas et al. also performed simultaneous pH monitoring and scintigraphy in children and found that among 123 separate reflux episodes detected, only six were recorded by both techniques [3]. Gastroesophageal scintigraphy evaluates only postprandial reflux and it is not able to correlate refluxes with gastric pH. This offers certain advantages over pH monitoring because gastric acidity may be neutralized by food, especially milk, in the immediate postprandial period, making pH studies unreliable [49]. Scintigraphy may be particularly useful in patients with GERD suspicion, but with negative result at pH monitoring. Gastroesophageal reflux can be acid, nonacid,

or weakly acid. GERD-associated respiratory problems seem to be related to nonacid refluxes which can be missed by intraesophageal pH monitoring. Studies using multichannel intraluminal impedance/pH-metry have shown that sensitivity of pH monitoring for the detection of retrograde bolus reflux is only 8%, and up to 90% of refluxes may be missed since they are neutral or slightly alkaline [34, 54]. It is known that in infants, only 16% of all reflux episodes associated with breathing abnormalities and oxygen desaturation were detected by pH monitoring [57], and only 22% of apnea-associated reflux episodes were acid and thus detected by pH monitoring [56]. According to the previous study, Thomas et al. [55] studied 126 children aged 6 months to 6 years and found that 70% of them had no gastrointestinal symptoms suggestive of GERD despite scintigraphic evidence of reflux. Karaman et al. using radionuclide scintigraphy showed a 21.1% incidence of GERD in 74 children with recurrent wheezing [45]. These data confirmed a possible use of gastroesophageal scintigraphy for the diagnosis of GERD in patients with atypical GERD symptoms in which gastric pH could be within the physiologic range. A recent study [26] assessed the validity of GERD scintigraphy in children older than 7 years demonstrating that of 75 patients who presented with chronic cough, 65 (86%) had GERD on scintigraphy. Nevertheless gastroesophageal scintigraphy has a relatively low sensitivity to analyze microaspiration [5, 15, 19] so that a negative test does not exclude the possibility of infrequently occurring aspiration [19]. Evidence of pulmonary aspiration may be detected during a 1-h scintigraphic study or on images obtained up to 24 h after administration of the radionuclide [16]. One study of children with refractory respiratory symptoms found that half had scintigraphic evidence of pulmonary aspiration [19]. However, aspiration of both gastric contents and saliva also occurs in healthy adults during deep sleep [17, 40]. Scintigraphy can provide information about gastric emptying. It is known that delayed gastric emptying may predispose to GERD in adults [32] and in children [20, 24]. Gastric emptying studies have shown prolonged half-emptying times in children with GERD. Gastric emptying scintigraphy has become a complementary part of routine gastroesophageal reflux scintigraphy, and even if tests of gastric emptying are not a part of the routine examination of patients with suspected GERD, they may be important when symptoms suggest gastric retention or when gastrostomy placement is needed [12, 23, 38, 52]. Respect to barium studies, scintigraphy is unable to delineate anatomic features, such as hiatus hernia, frequently associated to GERD, but its radiation exposure is considerably less than with barium studies. In addition, it has the advantage of allowing long periods of observation to detect refluxes. In a study on 35 children with a suspicion of GERD, comparing barium studies and scintigraphy with endoscopic findings, authors found that scintigraphy was more accurate to estimate reflux episodes than barium studies [18]. However, there was no significant relationship between scintigraphic study and endoscopic findings. In conclusion these data confirm the notion that even if scintigraphy can explore some important aspects of GERD, it is not recommended in the routine diagnosis and management of this disease in infants and children [39, 48].

Conclusions

According to the last evidence-based NASPGHAN and ESPGHAN guidelines on the diagnosis of GERD, we recommend:

1. The upper GI series is not useful for the diagnosis of GERD, but is useful for the diagnosis of anatomic abnormalities (Quality of Evidence B).
2. Scintigraphy could have a role in the diagnosis of aspiration in patients with chronic refractory respiratory symptoms, but the technique is not recommended in patients with other potentially gastroesophageal reflux-related symptoms (Quality of Evidence B).

Assessment of GERD: Ultrasound

81

Ahmed Sarkhy

Ultrasound (US) or sonography has been utilized for many years in different fields of diagnostic imaging, including GERD diagnosis mainly due to pragmatic reasons: low cost, wide availability, and relative noninvasiveness [1–4].

US study allows for direct, real-time visualization of the gastroesophageal junction (GEJ) and of the retrograde movement of reflux events. In addition, it can detect anatomical defects such as hiatus hernia and indirectly measure the lower esophageal sphincter (LES) length. Color Doppler ultrasound was also added to the standard US study which has been reported to increase its sensitivity in detecting GER events [5–8]. Furthermore, recent studies started to use endoscopic US in the measurement of the esophageal wall thickness to assess esophageal inflammation secondary to GERD; however, this is still an evolving technique [9, 10]. Using specific criteria, Tomita et al. conducted a study to correlate the abdominal US findings with endoscopy findings in adult patients with erosive GERD ($n=37$) and nonerosive GERD ($n=24$) compared to a control group without GERD ($n=32$). All of the participants had upper gastrointestinal endoscopy. The US operator was not aware of the endoscopy findings. GERD was diagnosed when two or more of these items were positive: (i) lower esophageal thickness (> or = 5 mm), (ii) abnormal architecture of the esophageal wall, and (iii) the presence of reflux. The thickness in erosive GERD was reported to be significantly greater than that in nonerosive reflux disease (NERD) patients and controls. Sensitivity, specificity, and accuracy of abdominal US diagnosis for erosive GERD and NERD (control participants worked as a reference group) were 84.6%, 25%, 91.1% and 91.1%, 89.4%, and 63.8%, respectively [11].

Though US is a cheap and noninvasive diagnostic tool, it does have several limitations in GERD diagnosis. These include its inability to depict the intrathoracic esophagus which limits the study to a short segment of the distal esophagus; another limitation is that it provides only a snap shot picture of the fluid movement across a short period of time. However, the major limitation is that it does not provide any information about the nature of the refluxate (acidic or not) and it does not correlate well with the reflux index of acid reflux as measured by pH monitoring [8, 12]. Jang et al. conducted a study where contrast color Doppler US (CDUS) and 24-h esophageal pH monitoring were performed in 54 children (2 months to 10 years). The authors demonstrated that CDUS had a high sensitivity (95.5%) for diagnosing the presence of GER but a very low specificity (11.0%), with a positive predictive value of 84.3% and a negative

predictive value of 33.3 %. However, they did not find a statistically significant correlation between the frequencies of GER detected on CDUS and the reflux index detected on pH monitoring. In addition, there was no correlation between the reflux grades on CDUS and that measured by pH monitoring [8].

The conclusion from different studies that demonstrated the utility of US in GERD diagnosis is that US is difficult to transfer to reliable clinical application because of several methodological issues among some of these studies. Namely, some studies did not compare US findings to a gold standard test such as the pH metry/impedance study – in fact some of these studies compare it to barium swallow which is neither sensitive nor specific for GER/GERD diagnosis. In some of these studies, the GER/GERD diagnosis had variable denominators for diagnosis which were therefore not comparable [13]. Others tried to measure an age-standardized abdominal esophagus length in children without taking into consideration the effect of the weight/height of the children, which could be a potential confounding factor on these measurements and probably therefore would affect its clinical application [14]. Recording of longitudinal muscle contraction using catheter-based, intraluminal ultrasound imaging technique represents another technological advance – this is dealt with elsewhere.

In summary, though US is a noninvasive and readily available diagnostic tool, its role in GER/GERD diagnosis is very limited. Providing information about the presence/absence of GER events and/or the volume/proximal extension of the reflux episodes is insufficient without having the information about the reflux index provided – typically by a pH/impedance monitoring study. The current combined North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) clinical practice guidelines do not recommend using US for the routine diagnosis of GERD [15]. It should be remembered that endo-ultrasound may be of benefit in defining other pathologies of the esophagus such as eosinophilic esophagitis and structural abnormalities such as diverticuli or strictures – these various pathologies as related to US will be dealt with in the relevant chapters.

Ear, Lung, and Esophageal Fluid Evaluation in GER Diagnosis

82

David J. Rawat

Introduction

The upper aerodigestive tract, which consists of the nose, mouth, pharynx, larynx, and the esophagus, allows for the passage of air and food. In children, extraesophageal ENT manifestations of GER may affect the ears, paranasal sinuses, lungs, and oral cavity. These structures form one of the most complex neuromuscular systems of the body providing the structural and dynamic components for swallowing, respiration, and speech. Historically, the extraesophageal or supra-esophageal manifestations of GERD had received more attention from our ENT and respiratory colleagues. However, better understanding and appreciation of pathophysiological processes and concordant clinical importance of the esophagus especially in relation to these supra-esophageal manifestations have resulted in a revival of interest. Fortunately, techniques to study esophageal motor patterns have improved tremendously over the years. From the side-hole sensor to Dent sleeve sensor to the current electronic sleeve sensors, life has been made much simpler for clinicians and researchers alike. State-of-the-art catheters equipped with 36 solid-state transducers that are circumferentially sensitive and span the entire length of the pharynx, esophagus, and proximal stomach have replaced infusion manometry recording techniques. Topographical visualization of pressure waves recorded by closely spaced sensors and high-resolution manometry (HRM) with seamless color pressure plots using computer algorithms with linear interpolation of pressure between closely spaced transducers along the length of the esophagus represent a significant advance. Recording of longitudinal muscle contraction using catheter-based, intraluminal ultrasound imaging technique represents another technological advance. The ontogeny and motor disorders of the upper GI tract will be discussed in other chapters, but are ultimately integral to direction of flow and therefore relevant in the context of fluid evaluation.

The evaluation of fluids in the detection of disorders affecting the esophagus, larynx, lungs, and ears has been the focus of many researchers, clinicians, and scientists alike, largely because of the noninvasive nature of potential diagnostic tests, which is particularly attractive in pediatrics. This chapter will focus mainly on the evaluation of fluid involving the otolaryngeal and respiratory tracts and only briefly explore the esophagus which will be covered more extensively in some of the other chapters.

Evaluation of fluids of the aerodigestive tract requires recognition of the motor patterns of the foregut which ultimately influence the direction of flow of bolus passage. The three components required to produce mature esophageal motor

function that are necessary are an integrated enteric and autonomic neural system, the inherent rhythmicity of smooth muscle, and the initial propagation of the peristaltic wave by the coordination of striated muscle.

Localized mechanical, or chemical, stimulation of the smooth muscle, or stretch of the muscularis externa, will elicit contraction above, and relaxation below, the point of stimulation. A stretch-sensitive neuron with connections in the myenteric plexus and chemosensitive or mechanosensitive neuron with connections in the submucosal plexus may both be stimulated, and this may result in ascending excitation (mediated by acetylcholine and substance P) and descending inhibition (mediated by vasoactive intestinal polypeptide and nitric oxide) of contraction of the smooth muscle of the muscularis externa. Stimuli to the mucosa evoke release of serotonin (5-HT) from enterochromaffin cells in the mucosa. Sensory neurons are simulated by 5-HT. The myenteric stretch receptors however respond directly to stretch. These sensory neurons then release intermediary substances, mainly calcitonin gene-related peptide, which acts on the neurons within the myenteric and submucosal plexuses thus controlling motility of that portion of the GI tract.

The neurohormonal influences on esophageal motility and lower esophageal sphincter (LES) pressure/function include:

Substance P (increases LES pressure and motility)
Vasoactive intestinal peptide (VIP) (inhibits esophageal tone)
Inducible nitric oxide synthase (iNOS) (may decrease resting tone and allow LES relaxation)

iNOS can be altered by inflammation. Inhibitory neurotransmitter production is integral to LES relaxation, and the non-adrenergic noncholinergic neurotransmitter nitric oxide (NO) has received attention in animal [1] and human studies [2, 3]. Vasoactive intestinal polypeptide (VIP) is another candidate undergoing investigation, and the importance of the ontogeny of neuropeptides in the human fetus and infant is becoming increasingly apparent [4]. The complex interaction of the neuroenteric-hormonal axis has particularly been the focus of recent work in such conditions as allergic and eosinophilic esophagitis (EE) suggesting a role for other inflammatory-induced mediators in the pathogenesis of the associated LES dysfunction (e.g., interleukin 5, eotaxin, eosinophil-derived neurotoxin) [5, 6]. It should be mentioned that the central nervous system may play a part in overall esophageal motility, as evidenced by the disorder to normal esophageal peristalsis which occurs in neonates with peripartum cerebral insults leading to cerebral palsy.

The process of swallowing consists of four phases for liquids and solids alike:

Oral preparatory
Oral
Pharyngeal
Esophageal

Functional real-time swallowing is best studied using videofluoroscopy. The pharyngeal phase consists of several closely coordinated functional elements that make up the complex motor event referred to as the swallow response. Pharyngeal swallows are initiated in an ordered, sequential pattern in response to stimulation by food or sensory stimulation to the medullary swallowing center (i.e., nucleus tractus solitarius and ventromedial reticular formation) via cranial nerves V, IX, and X [7]. In the older child or adult, the upper pharynx and the soft palate close against the posterior pharynx as the food bolus is propelled by the tongue into the pharynx, sealing the nasal cavity. Closure of the larynx protects against airway penetration of the bolus. Simultaneously there is complete and automatic closure of the glottis, and the epiglottis is brought down over the glottis hence deflecting the bolus laterally and posteriorly toward the upper esophageal sphincter (UES). The upper esophageal sphincter opens, and peristaltic contractions of the pharyngeal constrictor muscles drive the bolus through the pharynx, past the displaced, closed larynx into the esophagus. With high-speed videofluoroscopy four sequential events associated with laryngeal closure have been noted:

Adduction of the true vocal cords associated with the horizontal approximation of the arytenoid cartilages, vertical approximation of the arytenoids to the base of the epiglottis, laryngeal elevation, and epiglottic descent.

The other major function of the laryngopharyngeal space is in eliciting a protective cough reflex precipitated by a number of vagally mediated receptors (chemo-, thermoreceptor, etc.) which detect the presence of potentially damaging noxious stimuli and cause laryngeal closure and a cough. This is becoming increasingly important to gastroenterologists as a phenomenon with the recent appreciation of the pathological importance of laryngopharyngeal reflux from the stomach (LPR) in symptoms such as recurrent cough, hoarseness, and dysphonia. An elevated resting pressure of the cricopharyngeal muscle is necessary to prevent pharyngeal penetration of the retrograde esophageal bolus. A normal pharyngeal swallow includes complete bolus transport through the pharynx and to the cricopharyngeus or upper esophageal sphincter (UES). The bolus must pass as the airway is protected from aspiration of swallowed material. Posterior transport through the pharynx is achieved by posterior tongue thrust, effective pharyngeal peristalsis, and upper esophageal sphincter opening [8, 9].

Nasopharyngeal reflux (NPR) can be considered a problem in both oral and pharyngeal phases of swallowing as it occurs at the transition between the two phases. The single most common oral phase occurrence of NPR occurs with a structural deficit, as a cleft palate. More than often NPR occurs when the palate or posterior pharyngeal wall do not oppose completely or in a timely manner relative to the transport of the bolus. In normal newborn infants, both premature and term, small amounts of NPR are considered normal [10]. However, NPR is a problem if it occurs repetitively or in amounts large enough to compromise nasal breathing. In rare instances a nasopharyngeal mass can interfere with palatal elevation, resulting in NPR. NPR may also be evident as a functional deficit when incoordination in pharyngeal phase timing occurs with neurologic deficits. Lack of velopharyngeal (VP) closure or incoordination of VP function at the onset of the pharyngeal phase results in material getting into nasal passages. Normally, the VP closure is brief just as the bolus passes the velopharyngeal port. When the pharyngeal swallow initiation is delayed and the barium pools in pharyngeal recesses, it is not uncommon for some of the bolus to get into the nasopharynx just prior to or during trigger of the swallow. NPR can also occur later in the pharyngeal phase when the velopharyngeal port has reopened if material cannot readily pass through the pharynx into the esophagus. NPR is more common with liquid than with other textures. In addition, NPR may be more common in infants who are fed in a semi-reclined position rather than an upright position.

An esophageal phase promptly follows each separate pharyngeal phase of the swallow when there is definite time delay between swallows. However, an immediate and complete inhibition of the esophageal phase is noted when a second pharyngeal swallow occurs while the bolus remains in the striated muscle segment of the esophagus. If the bolus from the first swallow is in the smooth muscle segment when the second swallow occurs, the initial bolus will progress for several seconds before dissipating. In contrast, the original swallow can alter the amplitude and velocity of subsequent swallows for as long as 10 s, depending on the bolus size [11]. A series of rapid swallows results in an inactive esophageal body and LES relaxation. The final swallow in the series will be followed by a solitary normal peristaltic wave that clears the esophagus of infants and adults [12].

As the correlation between extraesophageal reflux (EER) and airway and ear, nose, and throat (ENT) disease is gradually gaining recognition, so too is the need for new normative and diagnostic standards for EER relative to GER. We have also now come to accept that the sensitivity of airway and ENT tissues to gastric refluxate demands more stringent diagnostic criteria relative to GER. Moreover, the diagnosis of EER currently relies on the tools designed for the diagnosis GER. Such tools lack the sensitivity and reproducibility to detect the less frequent and mildly acidic reflux associated with EER disease.

This chapter will present a comprehensive review of the currently available diagnostic biomarkers that are utilized in the evaluation of ear, lung, and esophageal fluids concentrating mostly on the extraesophageal manifestations of GERD.

Ear Manifestations of Extraesophageal Reflux

Extraesophageal reflux disease (EERD) has long been implicated in the pathophysiology of otitis media (OM) in children. Ear manifestations, especially otitis media with effusion (OME), are nearly always exclusive to neonatal and infantile periods. This is because eustachian tube dysfunction is more frequent in children than adults. GER is now included among the risk factors for tube dysfunction due to large numbers of episodes of reflux in babies with respect to adults and due to prolonged lying in the supine position. The pathogenic mechanism would appear to be linked to contact of the rhinopharyngeal region with reflux material, and repeated exposure of the ciliate respiratory epithelium to pH 4 or less blocks the ciliary movement and subsequent mucus clearance. Hydrochloric acid and pepsin cause local inflammation, edema, and ulceration of the respiratory mucosa leading to loss of tube ventilatory function.

As with ear manifestations, those affecting the nose and sinuses are also frequent in children and are due to chronic inflammatory processes in the nasal and paranasal cavities. Considering the multifactorial etiology of rhinosinusitis, GER can be regarded as a cause of chronic pediatric rhinosinusitis [13]. The pathogenic mechanism by which acid reflux may affect the nose and sinuses is unclear. One possibility is its direct action on the nasal respiratory mucosa as occurs in the hypopharyngo-laryngeal district [14]. Excluding the hypothesis that reflux could reach the paranasal sinuses directly through the ostia, it may reach the rhinopharynx and posterior part of the nasal cavities where the only ostium communicating with the sphenoidal sinus is located. In this way, acid reflux could lead to nasal mucosal inflammation, edema, and obstruction of the osteo-meatal complex [15]. Another mechanism is hyperreactivity of the autonomic nervous system induced by reflux and leading to nasal edema and ostial obstruction [16]. The studies did not satisfactorily demonstrate these correlations. Although previously postulated, the relationship between GER and enlarged adenoids seems less likely. The question is whether reflux promotes an inflammatory process of adenoid tissue or whether the adenoids facilitate reflux by modifying intrathoracic inspiratory and expiratory pressures, thus favoring retrograde movement of gastric content in the esophagus.

Laryngeal Manifestations of Extraesophageal Reflux

Cherry and Margulies [17] were the first to recognize that GER could cause posterior laryngeal inflammation, contact ulceration, and granulation that improved with anti-reflux therapy.

The main set of laryngeal symptoms of GER in children is as a result of laryngotracheal stenosis, supraglottic stenosis, and laryngomalacia. Laryngotracheal stenosis, which develops at the posterior commissure and the subglottic area and can cause typical relapsing paroxysmal laryngospasm, is mostly nocturnal and typical of children. Supraglottic stenosis is typical of the neonatal period and due to reflux in a large proportion of cases, and in most cases there is vestibular involvement. Laryngomalacia also typically presents in the neonatal period and is due to GER in 50 % of cases. This condition is characterized by prolapse of the supraglottic tissue into the glottal space. Symptoms are classically worse during crying and when in prone compared to supine position.

Kaufman [18] produced evidence of a significant link between reflux and laryngeal stenosis: 72 % of children had anomalous pH, monitored over 24 h. GER was presumed to trigger episodes of apnea by acid stimulation of laryngeal, pharyngeal, and esophageal chemoreceptors, causing laryngospasm. However, since these episodes did not show a clear temporal relation with GER, a clear cause-effect relationship could not be

demonstrated [19]. Although the incidence of GER in children with subglottal stenosis is three times greater than in the normal pediatric population, there is no direct evidence that reflux causes or favors subglottic stenosis. Nor is it clear whether GER is caused by increased respiratory effort or whether it plays a role in causing it.

Laryngitis may also be due to GER. The posterior larynx is the most affected area. Hyperemia of the mucosa of the posterior commissure may be a normal or nonspecific finding. Mucosal edema seems to be a more direct expression of a cause-effect relationship with reflux. The laryngeal damage that occurs in LPR is not caused by acid alone, but it requires both acid and activated pepsin, and it must be remembered that pepsin remains active even at a pH of 5.4 [20]. When compared to the esophageal mucosa, the laryngeal mucosa is injured with much lower levels of acid/pepsin exposure. It has been accepted that the extrinsic defense mechanisms between the laryngopharynx and the esophagus are markedly different, with the latter having much more resistance to acid peptic exposure. In fact, the intrinsic defense mechanisms of the laryngeal and esophageal mucosa are also different. One of the carbonic anhydrase (CA) isoenzymes, CA III, has been shown to have increased expression in the esophageal mucosa in response to refluxate exposure, whereas the larynx demonstrates a depletion of CA III after chronic reflux exposure. Furthermore, although esophageal mucosal response to acid/pepsin exposure appears to often be readily reversible, laryngeal mucosa can easily be damaged irreversibly [21, 22].

Respiratory Manifestations of Extraesophageal Reflux

The association between GERD and a number of pulmonary diseases including recurrent pneumonia, asthma, bronchitis, bronchopulmonary dysplasia, and cystic fibrosis is well described. In children, growth retardation, esophagitis, and subsequent stricture formation, as well as dysmotility and apnea are recognized complications of aspiration.

Perhaps the strongest association appears to be with "non-asthma" wheeze. Most patients with asthma may also have coexisting GERD. The most common reason for improvement of refractory asthma may be appropriate treatment of GERD. However the cause and effect relationship between asthma and GERD is difficult to establish since either condition may induce the other. An asthmatic attack can cause esophageal reflux of gastric contents by creating a negative intrathoracic pressure that overcomes the LES barrier. Alternatively GERD, either by direct microaspiration mechanism or indirectly by stimulating the distal esophageal sensory vagal nerve, may induce bronchospasm and asthma. Additionally, asthma may produce GERD by having an adverse effect on esophageal physiology by some of the medications used for the treatment of asthma. i, beta2-agonists, and even prednisolone may increase esophageal exposure to acid reflux by affecting the protective mechanisms of reflux.

Limitations of Current Diagnostics for Extraesophageal Reflux

Ambulatory 24-h double-probe (esophageal and pharyngeal) pH monitoring [23] is being overtaken as the gold standard for diagnosing EER, as proximal pH testing has been shown to be lacking in reproducibility. Vaezi et al. [24] demonstrated reproducibility of proximal pH testing as low as 55 % for patients with proximal esophageal acid reflux. Indeed, the outcome of pH testing may also be dependent upon the position of the proximal sensor relative to the upper esophageal sphincter (UES). Use of fixed-spacing catheters placed with reference to the lower esophageal sphincter (LES) results in variable placement of the proximal probe relative to the UES. In a study of 661 patients, McCollough et al. [25] (using a dual-channel esophageal pH sensor with fixed 15-cm spacing pH catheter) observed the proximal pH sensor in the hypopharynx, UES, or proximal esophagus in 9 %, 36 %, and 55 % of patients, respectively, and found that proximal

probe placement within or above the UES substantially reduced the correlation between proximal and distal sensors. In a meta-analysis of studies of proximal pH probe measurements in normal subjects and patients with LPR, Meyer et al. [26] demonstrated that variability in placement of the proximal probe may have a profound impact on our ability to determine an association between proximal reflux and extraesophageal symptoms. Moreover, McCollough et al. [25] noted a significant correlation between the extraesophageal symptoms and proximal esophageal reflux when the UES rather than the LES was used as a reference to place the proximal sensor. All studies that had failed to show such an association had employed a fixed-spacing catheter referenced to the LES.

It is now well recognized that pH monitoring is incapable of detecting nonacidic gastric reflux, which has been shown to be a contributing factor in airway disease. Much of the evidence demonstrating the association between nonacidic reflux and airway disease has been determined by combined multichannel intraluminal impedance (MII) and pH monitoring. This technique offers several advantages over pH monitoring, including differentiation between direction of flow (antegrade and retrograde) of bolus movements, characterization of refluxate constitution (gas, liquid, or solid), the capacity to measure sequential reflux events occurring while intraesophageal pH is less than 4.0, and detection of nonacidic reflux. However, briefly, Wenzl et al. [27] found nonacid rather than acid reflux symptom correlation in 77.6 % of infants with reflux-associated apnea. Tutuian et al. [28] demonstrated that cough was associated with nonacid reflux in 26 % of 50 patients with persistent cough refractory to treatment with proton pump inhibitors (PPIs). The combination of pH/MII and high-resolution manometry has more recently been utilized to assess laryngopharyngeal reflux in more detail and appears to be promising, but is observer dependant and is only available at specialist centers. Although combined MII-pH monitoring has significantly enhanced our ability to detect and characterize reflux, it continues to be expensive, is invasive, and has limited availability. In certain instances, a simpler and less invasive technique amenable to serial testing may be preferred.

Pepsin/Pepsinogen as a Marker of Extraesophageal Reflux

Pepsin is a digestive protease, released by the chief cells in the stomach. It derives from pepsinogen, which is the storage form in the gastric chief cells. When stimulated by gastrin and the vagus nerve, the chief cells and the parietal cells release pepsinogen and HCI, respectively. The acidic pH created by HCI allows pepsinogen to undergo an autocatalytic cleavage into the active enzyme, pepsin [20]. This acid environment is necessary for the enzymatic activity of pepsin, which is inactivated at a higher pH. Although the constitution of gastric refluxate is variable and components, such as acid or bile salts, may or may not be present, all refluxate contains pepsin, but not all reflux occurs below pH 4.0 [29, 30]. Thus, with use of traditional gastroenterology standards for pH-metry, significant LPR may be underdiagnosed. Indeed, pepsin exhibits enzymatic activity at pH levels well above 4, and it is only irreversibly inactivated at a pH greater than 6.5. Thus, a patient could conceivably have a negative pH study (no reflux events pH <4) but might still have significant LPR-related disease. It has been reported that the laryngeal epithelium is far more sensitive to damage by pepsin in the presence of acid than is esophageal epithelium and that may help explain why the patterns of reflux, reflux mechanisms, and clinical manifestations of LPR and GERD are so different [20].

Pepsin assay has the capacity to detect nonacidic reflux and may be used to monitor reflux in patients undergoing treatment with PPIs. Superior to pH and MII testing, pepsin analysis may be performed on samples as easily obtainable as saliva and sputum, thereby facilitating testing. This is particularly relevant in children and the neurologically impaired individuals in whom the more invasive diagnostic investigations are often associated with technical difficulties and in many cases not

tolerated. Pepsin assay also offers the advantage of direct detection of refluxate at sites of airway damage potentially attributable to EER. Although pepsin assay alone does not indicate a causal relationship to airway damage, the presence of pepsin in the airway does indicate reflux. To date, this technique has demonstrated the presence of pepsin in the trachea, lung, sinus, middle ear, combined sputum and saliva, and exhaled breath condensate [31–35]. Currently used methods rely on one of two means for the identification of pepsin in the airways: enzymatic or immunologic.

Enzymatically active, rather than inactive, pepsin is predicted to be most physiologically relevant to disease. Detection of peptic activity typically entails exposure of a sample to acidified substrate and quantification of substrate digestion by protein precipitation and spectroscopy or other methods. The pepsin concentration in the sample is determined by comparing enzymatic activity to that of standard and normalized to total sample protein to allow comparison between samples. Whereas the pepsin precursor, pepsinogen, is only known to be synthesized in the gastric fundus, isozymogens of pepsinogen have been identified in other tissues of the body, and pepsinogen is frequently observed in serum, albeit at lower levels, particularly in patients with gastritis [36]. Pepsinogen in patient samples would be converted to active pepsin upon addition of acidified substrate during the assay, thereby potentially leading to false positives. Thus, appropriate controls, such as detection of pepsinogen messenger RNA in surrounding tissue [37] and comparison of sample pepsin activity [38] should be undertaken to prevent assay interference by local pepsin synthesis and contamination by serum pepsinogen. Because the enzymatic method of pepsin detection is a measure of protein digestion, interference by other proteases must also be considered. Many proteases, such as lysosomal acid hydrolase (cathepsin D), are inactivated by the pH of the assay alone. Assay specificity has been previously documented by abrogating enzymatic activity with the aspartyl protease inhibitor pepstatin or by demonstrating the absence of protease activity in samples obtained from control subjects.

The sensitivity and specificity of pepsin ELISA depend largely on the affinity and specificity of the antibodies employed. To date, relatively few pepsin antibodies have been developed, and many of those currently described are cross-reactive with pepsinogen. Therefore, as with enzymatic pepsin detection, pepsin levels observed in samples must be compared with those of serum to account for contamination with serum pepsinogen. Cross-reactivity with proteins other than pepsinogen has also been reported. In a study to confirm the viability of pepsin as a marker of otitis media, He et al. [39] made an unpublished observation of cross-reactivity of another antibody previously identified in middle ear pepsin to an unknown serum protein questioning the specificity for use in ELISA. However, there has been subsequent development of more specific and better characterized pepsin antibodies. Knight et al. [34] designed an antibody to a region identified by X-ray crystallography to be exposed on the surface of native pepsin, thereby reducing antibody cross-reactivity to pepsinogen to less than 0.03 %. Cross-reactivity to other sample proteins has been further characterized by sodium dodecyl sulfate polyacrylamide gel electrophoresis and mass spectrometry [33]. The antibody used in combination with a polyclonal hum pepsin 3b antibody generated an ELISA that was 100 % sensitive and 89 % specific (according to pH-metry) for diagnosing reflux from the sputum of patients with suspected LPR.

The specificity of immunologic detection may also be improved through the use of alternative techniques such as Western blot analysis. Using the antibody designed by Knight et al. [34], Crapko et al. [33] performed Western blot analysis to demonstrate the presence of pepsin in middle ear effusions of pediatric patients with otitis media. Kim et al. [20] found Western blot analysis of combined sputum and saliva to have a sensitivity and specificity of 89 % and 68 %, respectively (according to pH-metry), for diagnosis of EER and used the assay to demonstrate an increased incidence of sputum pepsin during reflux symptoms relative to rising or before sleep.

Pepsin assay has been used to identify refluxate in the trachea, lung, sinus, middle ear,

combined sputum and saliva, and breath condensate. An immunological pepsin assay of combined sputum and saliva was determined to be 100 % sensitive and 89 %[40] specific for detection of EER (based on pH-metry) and an enzymatic test of nasal lavage fluid (100 % sensitivity and 92.5 % specificity) [41].

O'Reilly et al. determined that pepsin was detectable in the middle ear cleft of 20 % of pediatric patients with OM undergoing tympanostomy tube placement, compared with 1.4 % of controls. Recovery of pepsin in the middle ear space of pediatric patients with OM was found to be an independent risk factor for OM. Patients under 1 year of age were found to have a higher incidence of purulent effusions and pepsin-positive effusions [42].

Tasker et al. [43] using enzyme-linked immunosorbent assay (ELISA) to analyze middle ears secretions, obtained by tympanocentesis, in 54 children with middle ear infection, found concentrations of pepsin and pepsinogen, about three times the magnitude greater than in serum. Albumin concentrations were the same, indicating that the origin of pepsin, in the middle ear secretions were GER and not transudation. However, an epidemiological review of an international literature did not bring any differences to light in the incidence of middle ear infection between newborns and children with a history of GER and controls. There could be even a "protective" relationship between the two. In other words, GER may be associated with a major confounding factor in reducing the incidence of middle ear infection: during diagnostic screening, children with GER may be assessed and treated for allergy resulting in a lower frequency of otitis media.

A prospective study investigating the relationship between GER and chronic otitis media effusion (OME) confirmed the presence of gastric enzyme in the middle ear effusion (MEE) of children with OME. Samples were taken at the time of tympanostomy tube placement and total pepsinogen concentrations of effusions and serum samples were measured with a commercial ELISA using human pepsinogen I specific antibody. Measurable pepsinogen was present in all MEEs from patients, with levels higher than the serum values. The difference between the levels of pepsinogen measured in MEE and serum was statistically significant ($p<0.01$), but albumin levels were higher in serum than in MEE and the difference was statistically significant ($p<0.01$) [44].

Analysis of pepsin/pepsinogen in middle ear effusions was considered a reliable diagnostic marker for assessment laryngopharyngeal reflux (LPR) in children with otitis media with effusion (OME) in another small cohort of 31 patients. Ambulatory 24-h dual-probe pH monitoring was carried out on 31 children with OME. Middle ear effusions were collected from 17 children during myringotomy. Total pepsin/pepsinogen concentrations in effusions were measured by ELISA using antipepsin antibody. Dual-probe pH monitoring showed that 22/31 (71 %) of the studied children had significant LPR. The concentrations of pepsin/pepsinogen in middle ear effusions were found to be up to 4.5–231.44 times higher than the serum levels. There was a significant positive correlation between the level of pepsin/pepsinogen assayed in the effusions of the 17 children and the number of pharyngeal reflux episodes measured by pH monitoring [45].

Evaluation of Lung Fluid

Patients with aspiration-induced pulmonary disease are usually evaluated for dysfunctional deglutition with VFSS and contrast studies. Unfortunately, aspiration due to GERD is rarely seen in barium studies. Alternative methods for diagnosis of GER include esophageal manometry and pH probe monitoring. However, these are only indirect indicators of aspiration-induced pulmonary disease. Bronchial scintigraphy in conjunction with a meal offers several advantages in evaluating GERD. Advantages include the physiologic nature of the study, direct visualization of aspiration, a prolonged observation period, and low radiation exposure.

Evidence that GERD is the etiology in the development of chronic cough and bronchospasm has been, for the most part, indirect and

controversial. Coughing and wheezing have improved following medical or surgical treatment of GER. Patients suspected to have pulmonary disease secondary to aspiration are traditionally evaluated for pharyngeal aspiration due to dysfunctional deglutition. Historically, barium studies and FEES have been very reliable in making this diagnosis. However, these are both dynamic studies therefore making it far more difficult to evaluate pulmonary aspiration occurring due to GERD. Traditional methods of analysis for GER including esophageal manometry and pH probe monitoring have been used only as indirect indicators of aspiration-induced pulmonary disease. Indeed, although barium studies for evaluation of GERD have been very successful, actual detection of gastroesophageal aspiration has been disappointing, even in those patients known to have secondary pulmonary disease. Numerous biomarkers in serum, sputum, and bronchoalveolar lavage (BAL) have been studied, and their role in the recognition of aspiration remains controversial at this time.

Lipid-Laden Macrophages in BAL

Lipid-laden alveolar macrophages (LLAM) are macrophages in which ingested lipid can be visualized inside the cells on microscopic examination and are a well-recognized biomarker for aspiration. The presence of LLAMs in the BAL fluid has long been considered as a marker of lipid aspiration. Corwin and Irwin examined the validity of LLAMs as a marker of aspiration in the BAL of patients with various parenchymal lung diseases in 1985. Semiquantitative determination of LLAM index was calculated in 49 patients with parenchymal lung diseases (9 of them were aspirators and 40 nonaspirators). Macrophages were graded by the amount of lipid in the cytoplasm of each macrophage with a score of 0–4. A total of 100 macrophages were evaluated with a score ranging from 0 to 400. The LLAM index was increased in the lung disease group compared with controls. Moreover, LLAM indices were higher in the aspiration group than in nonaspirators. A LLAM index of 100 or greater was associated with a sensitivity and specificity of 100 % and 57 %, respectively. Accordingly, the authors suggested that LLAM index could be a helpful tool in excluding aspiration as a cause of parenchymal lung disease [46].

There are numerous studies in adults and children that have subsequently reported on LLAM as marker of gastric aspiration [47–50]. Furthermore, the association between aspiration and LLAMs has been more objectively elicited using the standard diagnostic tools to confirm the suspicion of GER-related aspiration. In one cohort of 20 children with refractory respiratory symptoms, LLAMs in BAL were higher in patients who had confirmed GER on pH monitoring, compared with those who had negative pH-metry [51]. Similarly the "lipid index" (reflecting the amount of lipid in 100 consecutive macrophages) was higher in the induced sputum of adults with gastric content aspiration (defined as a fall of pH <4 at the upper esophageal electrode on 24-h pH recording), compared with those without aspiration. No clinical symptoms of aspiration and normal chest radiographs were reported in the 33 patients enrolled in that study [52]. These results have been corroborated in children with chronic chest disease and GER compared with children with recurrent pneumonia without GER [53]. Nussbaum et al. compared a group of 74 children with chronic respiratory disease and documented GER to a group of 41 children with chronic respiratory disease without GER. LLAM were found in 85 % of the GER group and 19 % of the non-GER group ($p < 0.0001$). Published cutoff values for LLAMs, however, vary significantly from 65 to 200 [50, 54, 55]. There has also been significant overlap of LLAM indices between patient groups with underlying lung disease. Moreover, considerable overlap of LLAM indices was observed between healthy children and those with pulmonary diseases. For instance, LLAM indices in children without chronic lung disease were higher than those reported for healthy adults [46]. It has therefore now been recommended that each institution must determine its own LLAM index cutoff value [56]. Only higher values yielded acceptable sensitivity and specificity for aspiration in children [57].

Recent studies did not show a significant correlation between LLAMs and aspiration. In a murine model, detection of starch granules in BAL was superior to LLAM index; the latter had a low specificity, while the presence of starch granules in the BAL yielded 100 % sensitivity and specificity for aspiration. The LLAM index was not different in mice that had starch aspiration versus those who had *Pseudomonas aeruginosa* administered in their airways [58]. These conclusions were corroborated in human studies. While examining the correlation of LLAMs with the diagnosis of chronic pulmonary aspiration in children, Bauer and coworkers [59] found a significant overlap in the LLAM values between the aspirators and the nonaspirators group, which led the author to conclude that the LLAM index cannot stand alone as a gold standard for the diagnosis of chronic pulmonary aspiration. Furthermore, LLAM indices were found to be elevated in children with pulmonary diseases without clinical evidence of aspiration and were similar to indices previously reported in children with pulmonary aspiration. The lack of specificity of LLAMs for aspiration was reiterated when the lipid-laden index was found to be higher in children with chronic respiratory symptoms, particularly in those with cystic fibrosis, and had no correlation with the presence or absence of GER determined by intraesophageal pH monitor [50]. Other studies confirmed the lack of correlation between GER and LLAM indices, in the presence of respiratory symptoms [60] and in those without lung diseases [61], even when the diagnosis of GER was based on pH monitoring and endoscopy [62]. These observations suggest that increased LLAM index can be found in a variety of pulmonary disorders and is not likely to be specific for silent aspiration. In fact, the LLAM index might be affected by other factors, regardless of the presence or absence of aspiration, as was illustrated in neonates receiving intravenous lipid infusion who had higher LLAM indices than those who were not [63]. An elevated LLAM index has also been reported in cases of pulmonary fat embolism, sickle cell anemia, acute chest syndrome, cancer, graft-vs-host disease, and inhalation of organic dusts [64–66].

Lipid-laden alveolar macrophages by themselves seem to lack specificity for diagnosing aspiration, even when they are assessed using quantitative methods. Their role in diagnosing aspiration and guiding its treatment is very limited at this time. Assessment of the LLAM accuracy rests on its relationship to some way of knowing whether chronic pulmonary aspiration is truly present or not. Unfortunately, a gold standard for accuracy for the diagnosis of chronic pulmonary aspiration does not exist.

Pepsin in BAL

The absence of pepsin from the pulmonary and bronchial tissues makes its presence in lung aspirates an indicator of gastric content aspiration. There are a number of investigations that have examined the role of pepsin as a biomarker for aspiration both in humans and in animal models. Using a pepsin assay developed by Anson [67], Badellino et al. tested the above hypothesis in a rabbit model [68]. Human gastric juice (2 ml/kg) was instilled intratracheally into 24 rabbits; similar volumes of isotonic sodium chloride solution were instilled intratracheally in control animals. Bronchiolar lavage (BAL) was performed 15, 30, or 60 min after the instillation of fluid. In the rabbits given human gastric juice, peptic activity was detected in the lavage fluid in eight out of eight animals at 15 min, six out of eight at 30 min, and five out of eight at 60 min. Because the Anson method relies on the presence of proteolytically active pepsin to digest a hemoglobin substrate, it cannot be used to detect pepsin that has been degraded in the alkaline environment of the lung. This factor explains why fewer specimens tested positive for pepsin at the 30- and 60-min times. No peptic activity was present in lavage fluid from control animals at any time. Similar findings were elicited in another experimental investigation where pepsin was detected in the tracheal aspirates of rabbits that were exposed to single or multiple gastric juice aspirations, but not in the control group [69].

Detection of pepsin in tracheal aspiration samples has been proposed as a reliable marker

of gastric contents and microaspiration in children. Using an immunoassay with rooster polyclonal antibodies to purified human pepsin, the role of pepsin as a marker of gastroesophageal reflux (GER)-related pulmonary aspiration was studied in 56 children undergoing anesthesia as part of the workup for GER. The study group was compared with positive controls, who had proven aspiration (milk suctioned from endotracheal tube), and with 13 negative controls without GER or respiratory symptoms. The positive control group had significantly higher BAL pepsin levels compared with the negative controls. However, only patients with proximal GER on pH-metry (but not distal GER) had significantly increased pepsin in BAL. Surprisingly, in children with combined distal and proximal GER, only those who complained of chronic cough had significantly increased pepsin levels [70]. Similarly, 64 children who underwent endoscopy for clinically significant GER were compared with a control group of 34 children scheduled for routine surgeries [38]. The two groups were subdivided based on the presence or absence of associated respiratory symptoms. Pepsin was detected in tracheal aspirates in seven out of eight children with history of chronic respiratory symptoms and in 31 out of the 37 children with both reflux and chronic respiratory symptoms. It was also observed in 7 out of 27 patients who had only reflux symptoms. By contrast, none of the 26 children who had neither reflux nor respiratory symptoms had pepsin in their tracheal aspirates. Overall, children with pepsin-positive tracheal aspirates were more likely to have a clinical diagnosis of GER than the pepsin-negative group [71].

In premature neonates, chronic gastric aspiration is thought to contribute to the development of bronchopulmonary dysplasia. Farhath and colleagues relied on measuring pepsin in the tracheal aspirates on neonates on ventilator support by detecting aspiration due to GER [72]. Serial tracheal aspirates obtained from 45 premature neonates revealed the presence of pepsin in 92 % of the samples suggesting significant aspiration of gastric contents. In those neonates, enteral feeding was associated with a higher level of pepsin compared with unfed infants. Camacho and colleagues extended these observations by reporting the presence of pepsin in 91.4 % of tracheal aspirates of 59 premature neonates of whom 31 developed bronchopulmonary dysplasia [31]. Enzymatic assays in these studies measured both pepsin and pepsinogen because secretion of pepsin is inconsistent and low in infants, and measuring only pepsin in tracheal aspirate samples could have underestimated the prevalence of aspiration in premature infants [73].

There are a number of limitations that are worth mentioning regarding the use of pepsin. First, most of the human studies assumed the validity of pepsin as a marker for aspiration and did not compare it to a gold standard test. However, the relatively consistent results in animal models and human investigations suggest that pepsin might be a useful marker of aspiration, especially in patients who also have aspiration-related pulmonary diseases. Second, because pepsin activity can only be detected in the BAL for a short period of time following aspiration, only events that occur in a controlled environment where specimens can be rapidly collected (i.e., ICU) are likely to be detected. Third, a significant drawback of using molecular markers of aspiration in BAL samples is the inability to standardize the concentration. It is not known how BAL pepsin concentrations change over time following an aspiration event. Elevated levels may reflect less dilution at the time of sampling, high volume and/or high frequency aspiration events, or impaired clearance by the lung itself. Advanced molecular diagnostic techniques are currently under development for using undiluted BAL samples in detecting pepsin.

Soluble Triggering Receptor Expressed on Myeloid Cell 1

The triggering receptor expressed on myeloid cells (TREM) is a family of receptors expressed on polymorphonuclear neutrophils and mature monocytes, characterized by the presence of a single immunoglobulin-like domain. It has been shown that there is an upregulation in the

expression of TREM-1 after TLR activation, and soluble TREM-1 (sTREM-1) was initially thought to be a more specific marker for infection, when measured in body fluids [74–77]. However, other studies questioned the specificity of sTREM-1 for infectious processes. sTREM-1 has been shown to be increased in noninfectious disorders, such as systemic inflammatory response after multiple trauma [78] and inflammatory bowel disease [79], as well as in the synovial fluid of patients with rheumatoid arthritis [80].

The diagnostic utility of sTREM-1 in aspiration syndromes is limited by the scant investigations that are available. One study measured both blood and alveolar levels of sTREM-1 in order to differentiate between bacterial aspiration pneumonia and gastric aspiration pneumonia. A total of 75 patients who had a witnessed aspiration event and 13 controls without underlying pulmonary disease underwent BAL and microbiological analysis of respiratory sections. While plasma sTREM-1 levels were comparable between the controls and those with aspiration syndromes, the alveolar sTREM-1 levels were higher in the aspiration group with culture-positive BAL compared with those with culture-negative BAL. A BAL sTREM-1 cutoff value of 250 pg/ml was 65.8 % sensitive and 91.9 % specific for bacterial aspiration pneumonia [81]. Although promising, the usefulness of measuring sTREM-1 in clinical practice has to be determined prospectively in dedicated studies.

Aspiration syndrome is a frequent problem, which particularly affects a vulnerable population and is often missed or misdiagnosed. When patients are medically evaluated after an aspiration event, it is usually for one of many possible diagnoses or pathophysiologic processes. Patients could be presenting with a reversible noninfectious aspiration-induced chemical pneumonitis, an aspiration-related bacterial pneumonia, or with ARDS. However, the classic assumption that gastric content is sterile and that bacterial pneumonia after gastric aspiration is usually a secondary superinfection following acid-induced lung injury may not be entirely true. Aspiration of nonacidified gastric contents could clearly pick up viable endogenous flora when regurgitated into the oral pharynx before entering the trachea. Additionally, the widespread use of acid suppressive therapy, especially in the population at risk for aspiration, might change the gastric pH allowing for its colonization with bacteria [82]. Furthermore, when food particles are aspirated, it is difficult to assume that they are completely sterile, even when they are aspirated after staying in the stomach for a short duration.

Finding a way to differentiate between the distinct types of aspiration could have significant prognostic and therapeutic implications. Unfortunately, the basic pathophysiologic principles of aspiration syndromes have yet to be materialized into validated clinical tools that would provide distinct “signatures” of aspiration pneumonitis versus bacterial aspiration pneumonia. Alternatively, analysis of cytokine combinations using a multiplex microarray ELISA technique has shown promise in animal models but its relevance in clinical decision-making awaits validation in human trials. Exhaled breath condensate may provide a simple approach to biological samplings but its reproducibility remains under scrutiny. The most crucial question, however, is how to overcome the problem of a lack of a reference for the diagnosis of aspiration. Until an accurate and valid gold standard is established, the appropriate strategy is to gain additional information using different clinical and molecular techniques. The real advantage of biomarkers as an index of infection would be to unveil unrecognized facets of the clinical problem, thereby increasing the validity of clinical estimates.

Summary

In otolaryngologic practice, recognition of many of the clinical manifestations of EER has gained acceptance [1–3]; however, the prevalence of otolaryngologic and respiratory disorders caused by EER remains unknown. In part, this appears to be because currently used diagnostics for EER often rely on testing methods and normative standards that were established for the diagnosis of classic gastroesophageal reflux disease (GERD),

which may not be appropriate for use in diagnosing EER disease.

The current clinical practice of treating children with extraesophageal symptoms for GER is increasing, but there is little data to support it. There is still a lack of accurate means for diagnosing GER; 24-h pH monitoring with double/triple probes (distal and proximal esophageal and/or nasopharyngeal probe) is the "gold standard" for diagnosing ENT manifestations. Recent advances with high resolution offer more promise in particular when used together with videofluoroscopy and pH/MII.

The tools and standards of diagnosis developed for GER lack the sensitivity to detect less frequent and more weakly acidic proximal reflux, which has been associated with upper airway disease. Pepsin has been proven to be the most sensitive and specific marker of EER of any gastric component tested to date. Pepsin assay permits direct detection of reflux in regions of the airway that are beyond the reach of pH and MII monitoring and offers an inexpensive, noninvasive method for the detection of EER. The assay has proven effective in diagnosis of EER from fluids as easily obtainable as combined saliva and sputum, and its simplicity lends itself to the development of platforms for in-clinical testing. Continued characterization of the presence of pepsin in the airways is certain to reveal patterns indicative of airway disease and severity and provide insight into the contribution of pepsin to EER-associated disease.

Aspiration has been shown to be responsible for both acute and chronic respiratory disease. Though pharyngeal aspiration is more easily and frequently detected, GERD aspiration provides an important underlying cause of respiratory disease. Diagnosis of GERD is therefore essential for the treatment of pulmonary disorders. Although multiple diagnostic options exist, only nuclear scintigraphic and barium studies offer direct evidence of aspiration. Unfortunately, at this time none of the available markers provide an accurate tool for guiding the diagnosis and the management of aspiration. Systemic biology approaches in which microarray data are enriched with high-throughput comparative genomic and proteomic analysis may hold the key to future studies in aspiration syndromes.

Continued characterization of the presence of gastric refluxate in the airways and ENT system is certain to reveal patterns indicative of EER disease and severity and provide insight into the contribution of fluid evaluation to EER-associated disease.

Part XIV

Treatment Approaches for GERD: Lifestyle Changes

Feeding Changes and Positioning Therapy for Infants

83

Ahmed Sarkhy and Mike Thomson

Feeding Changes

One of the initial conservative interventions that has been tried for a long time for treatment of gastroesophageal reflux (GER) is to modify the infant feeding by different measures such as feeding babies with small volume, but frequent feeds, or changing the formula composition by adding thickening agents. Several studies tried to evaluate the efficacy of these interventions which had some controversial results. Below is a summary of the available current evidence around these interventions:

Small Volume, Frequent Feeding

One of the commonest reasons for regurgitation is overfeeding. Small volume but frequent feeding technique has been tried to overcome this problem aiming to reduce the amount of gastric contents and therefore reducing the GER events. However, this technique was found to be a time-consuming for the parents and may not satisfy the hunger of a crying baby for more feed. Furthermore, there is a concern that significant volume reduction may deprive the infant from the required calories to grow, and this is even worse in infants who suffer from poor weight gain because of significant GER symptoms. Therefore, this technique was found to be impractical and difficult to apply [1]. Volume reduction is only needed in overfed babies who are thriving well.

Low-Fat, High-Carbohydrate Feed

At one point, a low-fat, high-carbohydrate feed was suggested in GER management in infants hoping to reduce reflux events through avoiding delayed gastric emptying associated with fat content. This technique was found to be ineffective and even associated with higher rate of GER events [2]; therefore, it is not any more recommended in the treatment of GER/GERD.

Hydrolyzed Protein Formula

Because some symptoms of milk protein allergy can overlap with those of GERD in infants, some physicians tend to change the milk protein source particularly if there is a suspicion of allergy. The most recent combined North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) clinical practice guidelines suggest that formula-fed infants with recurrent

vomiting may benefit from a 2- to 4-week trial of an extensively hydrolyzed protein formula [3].

Thickening of the Feeding Formula

Thickening of the feeding formula is a common intervention that is used as a first-line treatment for GER. Different agents have been used to thicken the formula including cereal, rice, carobbean gum, pectin, and cellulose. A thickened formula thought to be retained more in the stomach and therefore tend to reflux less into the esophagus.

The effect of the thickened formula on GER symptoms gets the attention of clinical research for many years. It was found to be associated with less regurgitation events, less crying times, and more sleeping hours in observational studies [4–6]. Several experimental quasi or controlled trials were conducted to evaluate the efficacy of thickened feeds for the treatment of GER in healthy infants [7–15]. In general, these studies agreed on the point that thickened formula found to be helpful in reducing regurgitation events; however, it does not have any effect on the reflux index; no significant adverse events were reported in these trials.

Several systematic reviews were also conducted over the past few years to evaluate the efficacy and safety of this intervention [16–19]. The most recent systematic review with meta-analysis was conducted by Horvath et al. which included 14 RCTs with either a parallel or crossover design. These RCTs included infants who were diagnosed with GER or excessive regurgitation and/or vomiting, but otherwise healthy. The included RCTs evaluated different types of thickening agents that were used with variable durations (1–8 weeks) and compared to the standard non-thickened milk formula. The methodological quality varied significantly among the included studies. The meta-analysis demonstrated that compared to standard formula, "the use of thickened formulas significantly increased the percentage of infants with no regurgitation, slightly reduced the number of episodes of regurgitation and vomiting per day, and increased weight gain per day." The meta-analysis did not find any effect of the thickened formula on the reflux index, the number of acid GER episodes per hour, or the number of reflux episodes lasting >5 min. This review did not find any significant adverse events, and there was no difference between the different types of thickening agents used in those trials [19]. Though there was a significant heterogeneity between the included studies, the findings from this meta-analysis are consistent with the findings from the previously reported systematic reviews [16, 18] that showed a modest effect of the thickened formula feedings in reducing GER events, but not the reflux index. The recent combined NASPGHAN and ESPGHAN clinical practice guidelines of GERD diagnosis and management had the same conclusion [3]; however, as stated in these guidelines, further studies are still needed to study the impact of thickened formula on the natural history of physiologic GER or GERD [3].

Are Thickened Formulas Risk-Free?

Earlier reports raised some concerns about using the thickening agents in infants feeding. Some of these concerns included a potential problem of an excessive energy intake and changing the nutritional components of the feed particularly with the homemade thickened feeds [20]. Another concern was raised about a potential risk of allergy from the added thickening agents [21]. In addition, studies in vitro models demonstrated that thickening agents may affect the absorption of some micronutrients particularly when the indigestible carbohydrates used as thickeners [22]; however, this was not reported in human studies. And finally, one study found an increase risk of coughing in infants given thickened formula [23].

It is important to recognize that some of these adverse events were reported at the time of early use of these thickening agents. Using currently available pre-thickened formulas or what is called anti-regurgitation formulas (AR formulas) which designed to have a similar osmolarity of the stan-

dard formula with no extra caloric density and with a proper nutrient profile eliminate the risk of slow feed flow through the standard nipple holes, excessive energy intake, or changing the nutritional components of the feed; however, parents who are interested to prepare thickened formula at home should be taught how to do it well by their physicians to avoid these risks [13, 20]. Nearly all of the published RCTs did not find significant adverse events when thickened formula used; however, this can be just related to the fact that the RCTs were not designed to evaluate the adverse events which usually need a longer duration of follow-up or a larger number of patients for an adverse event to be detected. In general, we believe that the currently available commercial pre-thickened formulas are safe to be used as a therapeutic trial in infants with uncomplicated GER symptoms.

Position Changes for GERD Management

Finding an optimal body position to treat gastroesophageal reflux (GER) has generated much interest over a number of years. Since infants are lying flat most of the time, they are more prone for regurgitation of the gastric contents postprandially. This led to the introduction of the postural treatment as a therapeutic measure for gastroesophageal reflux, presuming to promote gastric emptying and therefore to reduce GER events, without the need for potentially unnecessary pharmacological interventions. The proposed effect of position change was presumed to be likely to be related to the anatomical configuration of the stomach and gastroesophageal junction [24].

Several studies demonstrated that positioning infants prone or in the left lateral position after feeding reduce the frequency and duration of GER events compared to supine position or right lateral position [24–28]. However, because of the associated risk of the prone position with sudden infant death syndrome (SIDS), it is not any more recommended in GER management. The left lateral position is quite difficult to implement and maintain, and in addition, it is an unstable position for an infant who may fall into the prone position and have a risk of SIDS. Therefore the current clinical practice guidelines from NASPGHAN and the ESPGHAN do not recommend the prone or side-lying position to treat reflux in infants, and, therefore, the supine position during sleep is the least harmful position that infants may sleep at [3].

The question then comes: does head elevation position reduce GER? To answer this question, several studies were conducted. One of the earliest RCTs was conducted by Orenstein SR et al. In this study, nine infants with documented GER participated in a trial with crossover design where infants observed in an infant seat (inclined at 60°) and then in the horizontal prone position for 2 h after feeding. Interestingly, the authors found that positioning infants in an infant seat actually increase reflux compared with the prone position [29]. In another study, the same author tried to determine whether head-elevated prone positioning (at 30°) is better than flat prone positioning in 100 infants with GER using esophageal pH monitoring. The study showed no significant difference in the reflux index between the flat and head-elevated prone positions [30]. Carroll et al. conducted a systematic review to evaluate nonpharmacological therapies for GERD such as position changes in infants. Only two RCTs met the inclusion criteria of this review, both of them utilized esophageal pH monitoring as their outcome measure. The authors concluded that neither the upright position nor using the infant seat reduce the amount of reflux [16]. A Cochrane review published in 2004 looked to the effect of elevating the head of the crib on GER management; five RCT studies with crossover design were included in this review, and all of them used esophageal pH monitoring. Each of these studies looked to the effect of different positions, making it difficult for the reviewers to compare them head to head and based on the interpretation of the individual data. Their final conclusion was that elevating the head of the crib in the supine position does not have any effect on GER [18]. A number of devices such as the anti-regurgitation bed (AR

bed) have been employed and are yet to be properly researched.

In conclusion, the clinical effectiveness of position changes in GER treatment in infants is controversial. The current evidence discourages using the prone position in infants with GER and, in addition, does not recommend the side-lying position of the infants to treat gastroesophageal reflux.

Lifestyle Changes in Children and Adolescents

84

Donald J.S. Cameron

Gastroesophageal reflux (GER) in otherwise well, older children and adolescents is different from that in newborns and young infants. It may be a continuation of GER starting in infancy [13, 14, 15] or subsequently develop without any pre-existing or predisposing factors. In this sense, it is more comparable to adult GER. One large community-based study reported symptoms of GER in 3–5 % of adolescents surveyed [40].

Children with physical or neurological handicaps comprise a different group with their own particular predisposing factors and morbidity patterns and are discussed elsewhere.

The main symptoms of GER can be categorized into those relating to vomiting or regurgitation of gastric contents and those relating to acid reflux and its complications such as esophagitis.

Regurgitation and Vomiting

GER in childhood usually does not result in forceful vomiting, which should be investigated to rule out other causes. The more usual symptom is of regurgitation into the pharynx or mouth of gastric content, which may be expelled or re-swallowed. Some children may seem to be largely untroubled by it, but others will find it distressing and embarrassing. Halitosis is often a problem leading to social difficulties. Potential effects of GER on the airways, larynx, ears, and teeth have been discussed elsewhere.

Acid GER may also be associated with "heartburn" or other pain and discomfort, with or without endoscopically demonstrable esophagitis (GERD vs. NERD).

Unless GERD has progressed to the point of stricture formation, dysphagia, odynophagia, and obstructive symptoms are more likely to relate to infection, eosinophilic esophagitis, other causes of esophageal inflammation, and mechanical or motility problems than to GER itself. The investigation and evaluation of GER is dealt with elsewhere in this text.

Lifestyle Changes

Lifestyle and dietary changes are frequently recommended as first-line treatment. Intuitively, changes that might help GER include posture, position, thickening of feeds, modification of the

DOI 10.1007/978-3-642-11202-7_84

nature and timing of feeds, reduction of the intake of biologically active substances (such as caffeine, nicotine and alcohol), and weight loss.

Theoretically, gastric emptying might be helped by gravity, smaller feeds, and reduced fat intake, but evidence is sparse. There are, however, few data to support lifestyle effects in children and adolescents, and most have been extrapolated from studies in infants and adults or have become accepted strategies with little or no evidence.

Position

Studies in infants have demonstrated that the prone position is associated with significantly less GER than supine and that the left lateral position is better than right. However, because of concerns about SIDS, any sleeping position other than supine cannot be recommended for infants. The evidence for additional benefit from elevation of the head of the bed is conflicting [9, 52].

In contrast to infants, there are no data to support specific recommendations in older children and adolescents. It seems logical to assume that head elevation during sleep should help by bringing gravity into play. Elevation of the head of the bed may have a place, along with left lateral positioning, in alleviating nocturnal symptoms. Studies in adults have shown significantly less acid exposure [20, 22, 29, 50], but this has not necessarily been associated with improvement in symptoms or antacid use [47].

Intuitively, the right lateral decubitus position might seem to be better by putting the gastric outlet on the downhill side; but acid GER has in fact been shown to be increased in the right lateral position compared with the left in infants [52] and adults [31, 32, 35, 53]. This might simply reflect the "sump" capacity of the body of the stomach in that position. Similar studies have not been done in older children or adolescents. A systematic review in adults [30] concluded that elevation of the head of the bed seems to be an effective measure to improve the symptoms of GER in some patients with GERD. The NASPGHAN guidelines [54] concluded that it is likely that older children and adolescents, like adults, may benefit from elevation of the head of the bed and left lateral positioning for troublesome nocturnal symptoms. This has to be offset by the discomfort in sleeping in such a position.

Obesity

The increasing prevalence of obesity in all age groups might be expected to lead to more GER. Mechanisms could include overeating, increased intra-abdominal pressure, hiatus hernia, and metabolic effects. Reported studies in adults have shown conflicting evidence for obesity as a cause of GER [2, 3, 42], although more recent reports in adults have shown a correlation between BMI and GER symptoms [7, 8, 11, 38, 39, 41, 44]. Data from studies using manometry and/or pH monitoring are less clear-cut with some supporting an association between morbid obesity and GER [14, 15, 18, 21, 26, 28, 56] and others not [6, 34, 51].

Several studies have shown correlation between obesity and waist circumference and increased gastroesophageal pressure gradients, esophagogastric junction disruption, and hiatus hernia [10, 12, 16, 44, 60; El-Serag 2007].

Comparison between different studies has been limited by variable definitions and study designs and differences between countries. However, in a meta-analysis published in 2006, the authors concluded that there was a positive association between increasing BMI and GER in the United States, but heterogeneous results from studies from Europe with both positive associations and no association [7, 8].

Whether GER can be reduced by weight loss is less clear. A number of studies have reported improvement in reflux symptoms. Other studies, however, have shown benefit in both symptom scores and pH-metry from weight reduction in those obese patients with GER symptoms [19, 30]. In a recent study of 179 obese and overweight patients enrolled in a weight loss program (and therefore highly motivated), 38 %

reported GER symptoms. A significant improvement in symptoms was noted with 5 % weight loss in women and 10 % in men with complete resolution of symptoms in 66 % and improvement in 16 % [49].

Another study, however, failed to show such an association in 20 obese patients randomized to an unrestricted diet or a weight loss program with 10 % weight loss [33].

While weight loss is likely to be an effective intervention, further studies and randomized controlled trials are required [30].

There are few reports in children and adolescents. In an interim analysis of 75 overweight and obese children, 25 % complained of GERD symptoms [48].

Diet

In infants GER is usually physiological and improves by about 18 months of age. There is good evidence for the contribution of dietary food protein intolerance in some infants [23–25, 27, 43]. However, in older children and adolescents, there is no evidence for food allergy as a cause of ongoing GER (as opposed to eosinophilic esophagitis) or to support or refute the use of elimination diets in its management.

Acidic fruits and juices have traditionally been taken as aggravating symptoms of GER. Seventy-two percent of 400 patients in one study reported increased heartburn symptoms with citrus juice [17]. However, symptoms do not necessarily relate to pH or effects on LESP [30]. Similarly, although patients frequently complain of increased symptoms, there have been few studies on the physiological effects of spicy foods.

There are a number of reports on the effect of caffeine and chocolate on various physiological parameters such as LESP and acid exposure times with conflicting results [4, 37, 45, 57, 59]. Although it is frequently assumed, the relationship between GER symptoms and coffee, chocolate, and caffeine-containing cola beverages remains unclear, and there is insufficient evidence to warrant their automatic exclusion. However, it goes without saying that foodstuffs which cause pain or discomfort should be avoided [30, 54].

Fat Content, Meal Size, and Timing

Theoretically, as dietary fat results in slower gastric emptying, it could result in increased intragastric pressure and GER. However, there is conflicting evidence for its effect on LESP, acid exposure or reflux symptoms, and no firm recommendations about the limitation of dietary fat can be made [46]. Similarly, there is no clear evidence to support the routine modification of meal size or timing, but, again, individuals may find symptomatic benefit from such changes.

Alcohol, Smoking, and Chewing Gum

Alcohol may affect esophageal motility, LESP, gastric emptying, TLESRs, and gastric acid secretion [5], but there are conflicting reports of its effect on acid exposure times and symptomatic GER. Similarly, smoking is reported to reduce salivary flow and to affect LESP. There are, however, no studies showing that reduction or cessation of alcohol or tobacco exposure significantly improves esophageal pH or GER symptoms [54]. Smoking is, however, significantly associated with the development of esophageal carcinoma in adults with GERD [55, 58]. There are, of course, many more compelling reasons to discourage adolescents from smoking.

Chewing gum has been shown to improve esophageal clearance and reduce acid exposure by increasing salivation and swallowing [1, 36]. Whether this is of clinical and practical significance is debated, and further studies are required.

Most of the preceding discussion is based on studies in infants and adult. Few studies have been performed in older children and adolescents, but it seems reasonable to assume that many of the principles also apply. In adults, GER is usually a chronic disease. In contrast, in the majority of young children and many adolescents,

the symptoms of GER are temporary and improve with time and maturity.

Summary

There are few studies on lifestyle changes and GER in children and adolescents. Extrapolating from adult and infant studies, it seems reasonable to reduce obesity and elevate the head of the bed in symptomatic patients. No general recommendations can be made about dietary modification, but individuals may well find that there are specific foods and drinks that aggravate symptoms and should be avoided. Alcohol and tobacco exposure are of less relevance in children than adults and the role of each in GER is debatable. There are, however, many other reasons to recommend moderation and abstinence respectively.

Pharmacologic Therapies

Pharmacological Reflux Therapies

85

Anil Darbari, Sona Sehgal, Nidhi Rawal, and Rachel Imhoff

Principles of Pharmacological Therapies

The management of GERD was revolutionized by the introduction of histamine type 2 receptor antagonists (H2RA) in the 1970s and even more so with the introduction of proton pump inhibitors (PPI) in the 1980s, [1, 2]. The pharmacotherapy for GERD has expanded as our understanding of the mechanisms leading to GERD has advanced from the role of acid to include TLESRs (transient lower esophageal sphincter relaxations) [3, 4] and recognition that nonacid reflux can cause symptoms in some patients. The goals for pharmacotherapy for GERD are to control symptoms, promote gastric and esophageal tissue healing, improve health-related quality of life, prevent complications, and minimize the adverse effects.

Acid Suppressants

Histamine Type 2 Receptor Antagonists (H2RA)

H2RAs are competitive, reversible inhibitors of the histamine type 2 receptor (H2R) in the gastric parietal cells. They have several advantages over antacids, including longer duration of action (4–8 h), greater efficacy, and prophylactic use.

The most common drugs in this class include cimetidine, ranitidine, famotidine, and nizatidine. Multiple randomized controlled trials (RCTs) in adults with cimetidine, ranitidine, and famotidine show that they are superior to placebo in improving symptoms and healing the esophageal mucosa [5]. Studies have shown that the efficacy of H2R agonist (A)s in achieving mucosal healing is much greater in mild esophagitis than in severe esophagitis [6]. Randomized controlled trials of infants and children with erosive esophagitis showed significant improvement in clinical and histopathology scores in the cimetidine as compared to the placebo-treated group. Similar results have been seen for nizatidine as well [7]. H2RAs have relatively short duration of action, a disadvantage when compared with PPIs as well as the development of tolerance, and incomplete inhibition of acid secretion [8].

Proton Pump Inhibitors (PPI)

PPIs are the most potent antisecretory agents, which irreversibly bind to the hydrogen-potassium

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_85

ATPase pump in parietal cells, thereby blocking off the final common pathway in gastric acid secretion. PPIs maintain a higher pH for a longer length of time and inhibit all stages of acid secretion including meal-induced gastric acid secretion which results in improved efficacy.

Studies in adults demonstrate faster and better healing of erosive esophagitis with PPIs than with H2RA [9]. The drugs in this class include omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole. Omeprazole and esomeprazole are approved for use in pediatric patients in Europe and the United States. Lansoprazole is approved for pediatric patient use only in the United States. None of the PPIs are approved for use in infants to date.

Prokinetics

Prokinetic agents enhance gastrointestinal motility, resulting in better esophageal clearance and faster emptying of the stomach contents. They can also effect transient lower esophageal sphincter relaxation (TLESR) [10]. They tend to improve symptoms of regurgitation and vomiting. These drugs work through a variety of different mechanisms. The prokinetic agents include cisapride, metoclopramide, erythromycin, domperidone, bethanechol, and baclofen. Many have significant side effects and there is scarcity of data on their benefit in children [11]. Therefore, they are used in carefully screened patients where their potential benefit outweighs risks.

Adjuvant Therapies

Adjuvant therapies in the treatment of GERD include antacids and surface agents. These tend to provide immediate relief but are recommended for short-term use only.

Antacids

Antacids provide quick but short-lasting symptom relief from GERD. Their effect lasts 1–2 h. Most antacids have magnesium with either aluminum hydroxide or calcium carbonate. They neutralize gastric acid and protect the esophageal mucosa from exposure to acid in the refluxate. In treating esophagitis, pediatric studies have demonstrated that high-dose antacids can be as effective as H2RAs over a 12-week period [12]. However, they are not recommended for chronic because of concern of toxicity especially with aluminum-containing compounds. They are usually used in older children for symptomatic relief.

Surface Agents

Surface-active agents like sodium alginate and sucralfate form a protective coating over the mucosal lining of the stomach, thereby providing a barrier from gastric acid and pepsin. Sucralfate was shown to be as effective as cimetidine in the treatment of peptic esophagitis [13]. Concern for aluminum toxicity from these agents prohibits its chronic use in pediatrics.

Bismuth Compounds

Bismuth compounds include bismuth subsalicylate (BSS) and colloidal bismuth subcitrate (CBS). Bismuth is converted to insoluble complexes by gastric acid and preferentially deposited over ulcer beds where they combine with exposed protein moieties to form a glycoprotein-bismuth complex, providing a barrier from acid and pepsin. They are particularly useful in the treatment of *Helicobacter pylori*-induced disease as they inhibit urease and phospholipase enzymes produced by the bacteria, which help them survive in the acidic environment of the stomach. They are also useful adjuncts in the eradication of resistant *H. pylori* infection in an adults and children [14]. Higher doses and long-term use are associated with significant risks including neurotoxicity, nephrotoxicity, gingivostomatitis, colitis, and osteoarthropathy [15]. The salicylate moiety of BSS does get absorbed by the body and has the potential for causing Reye's syndrome and significant bleeding in patients with coagulopathy or gastrointestinal ulcers.

Combination Therapy

Often, a combination of various pharmacologic agents is used, such as a combination of H2RA and PPI or an acid suppressant and a prokinetic.

In very severe cases of GERD, a combination of pharmacotherapy with acid suppressants and motility agents along with surgical management could be employed.

Combination therapy involves utilization of pharmacologic agents with the same desired effect- such as a combination of acid suppressants. For example, in patients with nocturnal acid breakthrough (NAB) on PPI therapy, the addition of H2RA has shown to be of significant benefit [16]. In an adult study, 64 % of individuals on twice daily doses of a PPI had NAB. The addition of a nighttime dose of an H2RA to the PPI regimen decreased the acid exposure as measured by impedance and pH probe in all but 17 %.

Combination therapy with an acid suppressant and prokinetic may be beneficial in certain groups of patients. These include patients with nonerosive reflux disease who continue to be symptomatic [17]. Patients with certain underlying diseases that predispose to more severe GERD or exacerbation of other systemic diseases like chronic asthma and cystic fibrosis have benefited from combination therapy. In a pediatric study involving children with nonatopic asthma, the group of children receiving a combination of esomeprazole and metoclopramide had much better control of asthma, as good as the control group of children who had undergone fundoplication, while a second group that received only ranitidine alone had significantly more exacerbations [18].

Combination therapy can also be useful in neurologically impaired patients to improve quality of life and decrease the risk of aspiration if they continue having obvious regurgitation and vomiting [19]. Combination therapy also has a role in GERD made worse by abnormal esophageal motility secondary to repaired tracheoesophageal fistula and gastroparesis.

Step-Up vs. Step-Down Therapy

The initial diagnosis of GERD, in children and adults alike, is often based on clinical symptoms. Treatment is initiated to observe a response to therapy and adjustments are made as needed. The dilemma of optimizing treatment and avoiding aggressive therapy when it is not justified or an ineffective approach in patients with severe symptoms or warning signs often dictate the treatment applied. Cost-effectiveness will also influence the treatment [20].

Step-up therapy is usually preferred for mild GERD. It includes lifestyle changes and use of less potent acid suppressants. H2RA are typically employed instead of PPI. Therapy can be escalated by increasing the dose of the medicine or switching to more potent agents as indicated by clinical progression or further evaluation. It could also result in employing combination therapy with acid suppressors and prokinetics. The benefits of this approach are initial low cost of therapy, avoiding unnecessary medication, and decreased side effects from medication.

Step-down approach usually implies the use of potent medications like PPIs in adequate doses and then decreasing the dose or switching to an H2RA as the condition improves. It is employed in endoscopically proven severe GERD or if there are red flags indicating the presence of severe disease. The advantages to this approach are institution of very effective therapy in patients warranting aggressive treatment. It might even be more cost-effective by avoiding potential need for surgery in patients with complications of severe disease.

Common Pharmacologic Agents

Histamine Type 2 Receptor Antagonists

H2RAs reduce gastric acidity by inhibiting the histamine type 2 receptors in the gastric parietal cells. They tend to have a moderate effect on symptoms and healing in patients with esophagitis and are not very effective for severe erosive esophagitis. Their effect appears to be dose related. The knowledge that histamine resulted in gastric acid secretion led to the discovery of cimetidine, the first H2RA introduced in the late 1970s. Other agents subsequently introduced were ranitidine, famotidine, and nizatidine.

Pharmacology

Cimetidine is a 2-cyano- 1-methyl-3-(2-[(5-methyl- 1*H*-imidazol- 4-yl) methylthio] ethyl) guanidine. Replacement of the imidazole ring of cimetidine with furan ring resulted in the development of ranitidine and replacement of the imidazole ring with a 2-guanidinothiazole ring resulted in famotidine. These substitutions resulted in much better tolerability, longer-lasting action, and increased activity. Nizatidine was formed by the substitution of the furan ring of famotidine with a thiazole ring. In general, the latter three are much more potent than cimetidine.

Cimetidine and ranitidine show peak plasma concentration within 90 min of oral administration [21, 22]. They start reducing gastric acidity within 30 min of ingestion. H2RA reduce acid secretion stimulated principally by histamine and to a small extent that by gastrin and cholinomimetic agents through two mechanisms. First, histamine released from enterochromaffin-like (ECL) cells by gastrin or vagal stimulation is blocked from binding to the parietal cell H2-receptor. Secondly, in the presence of H2-receptor blockade, gastrin or acetylcholine has a diminished effect on acid secretion by direct stimulation. H2RAs are particularly effective at inhibiting nocturnal acid secretion, which depends largely on histamine. They have a modest impact on meal-stimulated acid secretion which is stimulated by gastrin and acetylcholine, as well as histamine. The H2RAs suppress acid secretion in a linear, dose-dependent manner [23, 24]. The volume of gastric secretion and the concentration of pepsin are also reduced.

Cimetidine, ranitidine, and famotidine have high first-pass metabolism reducing their bioavailability to about 50 %. Nizatidine undergoes very little first-pass metabolism and has a higher bioavailability [25]. Meals do not affect the bioavailability of H2RAs, but concurrent administration of antacids reduces their bioavailability by 10–20 %. Their effect lasts for about six hours. The response can be prolonged by administering more frequent or higher dose. Intravenously administered H2RAs have a 100 % bioavailability, and therefore, the dose has to be adjusted depending on the route. H2RAs can be effectively administered mixed in parenteral nutrition solutions [26]. H2RA cross the blood-brain barrier and are also secreted in breast milk [27].

H2RAs are cleared by a combination of hepatic and renal mechanisms. Cimetidine is principally metabolized in the liver and then excreted by the kidneys. Famotidine, ranitidine, and nizatidine rely on glomerular filtration and renal tubular secretion for their excretion. Therefore, the dose of all H2RA has to be decreased in renal failure and in premature neonates. The dose does not need to be adjusted in liver disease [1].

Toxicity

H2RA are generally considered to be very safe [28]. However, there are side effects that can mainly be categorized as idiosyncratic reactions, those due to drug-induced hypergastrinemia, and drug-induced hypochlorhydria.

Commonly reported side effects include headache, constipation, nausea, and skin rash. Cimetidine has the highest side effect profile of all the drugs in this class. H2RAs can be associated with different CNS side effects like confusion and mental depression. Cimetidine can especially cause these symptoms in patients with liver failure or renal impairment. In young children and infants, H2RAs can cause symptoms of irritability, headbanging, headache, or sleepiness. Unless the clinician is vigilant, these adverse reactions can be misconstrued as a manifestation of reflux and might result in even a higher dose being prescribed [29]. H2RAs can cause idiosyncratic and immune-mediated reactions like myelosuppression, hemolytic anemia, interstitial nephritis, and fever [30–33]. Cimetidine binds to androgen receptors and results in gynecomastia and other antiandrogen effects in adults [34]. These are generally not seen with other H2RAs.

Prolonged acid suppression has been associated with hypergastrinemia in animal studies [35]. Increased gastrin results in proliferation of enterochromaffin cells, which have been associated with carcinoid tumors [36]. However, its clinical significance in humans has not been demonstrated. Acid in the stomach serves as one of the primary lines of defense against ingested microbes. Prolonged acid suppression has been

associated with increased rates of community-acquired pneumonia in adults and children [37], gastroenteritis in children including *Clostridium difficile* [38, 39], candidemia, and necrotizing enterocolitis in preterm infants [40]. Decreased acid secretion has also been tied to vitamin B12 deficiency in adults [41].

Drug Interactions

Cimetidine binds to the cytochrome P450 enzyme in the liver which is responsible for metabolizing several other drugs. Therefore it may decrease metabolism of a wide number of drugs that rely on this pathway. These include cisapride, anticonvulsants, and benzodiazepines. Ranitidine does not bind avidly to the microsomal cytochrome P450 system and therefore does not interact with medications processed through this pathway. Famotidine and nizatidine do not bind to cytochrome P450 [42].

H2RAs can decrease the absorption of antifungals, cephalosporins, and certain iron compounds that rely on the gastric acidity for conversion to the ferrous form. Acid suppression can also decrease the effect of mesalamine preparations that are pH dependent by causing their premature release.

Drug Resistance

Prolonged use of H2RAs orally or parenterally has been shown to lead to tolerance of their antisecretory effect. A study analyzing intravenous ranitidine in children found loss of the antisecretory effect after 6 weeks of therapy [43]. Tachyphylaxis has been demonstrated in healthy adults with cimetidine, ranitidine, famotidine, and nizatidine [44]. Another study in adults demonstrated rapid development of tolerance over 1–2 weeks. With H2RA given in a single evening dose, tolerance was only evident during the night, whereas tolerance occurred throughout the day and night with the three- and four-times-a-day regimens [45].

Proton Pump Inhibitors

Proton pump inhibitors are very strong acid suppressants and are used in a wide variety of acid peptic disease [46]. They irreversibly inhibit the proton pump, thus blocking the effect of any stimulation for the life of the pump. There are six main PPI drugs: omeprazole, lansoprazole, rabeprazole, pantoprazole, esomeprazole, and dexlansoprazole.

Pharmacology

Omeprazole, lansoprazole, and pantoprazole contain as their core structure, 2-pyridyl methylsulfinyl benzimidazole.

These PPIs differ in their substitution patterns. They are basic compounds with a pKa of around 4.0 (except rabeprazole, with a pKa of 5), becoming activated when the pH of the medium is below their pKa [47]. The rate of conversion to the active form is inversely proportional to the pKa; rabeprazole is the PPI with the highest rate of conversion, followed by omeprazole, lansoprazole, and pantoprazole [48].

After oral administration, the PPIs are absorbed as prodrugs in the small bowel and enter the gastric parietal cells, from where they reach the extracellular canaliculi. At this site, due to the acid medium, they are transformed into the active form, which selectively and irreversibly binds the proton pumps.

Proton pumps (K^+-H^+ ATPase) situated in the parietal cell triggered by a cascade in response to three main stimuli, namely, histamine, acetylcholine, and gastrin. The pumps transport the H^+ ion against the steepest concentration gradient in the body, of 3,000,000:1. Chloride is diffused into the canaliculi of the parietal cell, to join with the H^+ ion to produce hydrochloric acid. The pump is a member of the ion transporting, P-type ATPase family or the ion-motive-phosphorylating ATPase family [49]. This family extends from bacteria to mammals. The classification depends on finding that ion-transport is coupled to a cycle of phosphorylation and dephosphorylation of the enzyme. It is made of two subunits: a larger catalytic alpha subunit responsible for the transport and catalytic functions and a smaller 300 amino acid beta subunit responsible for structural and membrane-targeting functions. The pumps have a relatively large cytoplasmic domain, a membrane domain, and a small extracytoplasmic

domain. The latter two domains are relevant to the mechanism and design of acid pump inhibitors.

The drugs designed to inhibit the pump, bind to it covalently. Thus, the pump has to be synthesized de novo to reestablish acid secretion, though some loss of compound may also occur. The pump half-life has been shown to be about 72 h [50]. The formation of disulfide bridges between the PPI and cysteine residues of the alpha subunit of the ATPase produces inhibition of acid secretion for up to 36 h [51]. The proton pumps are in an inactive state in cytoplasm. After stimulation, such as a meal, the pump is translocated to the membrane of the canaliculus, where it is activated. To inhibit this, omeprazole must reach a sufficient plasma concentration.

The pump turnover however is a dynamic process that varies by the canalicular: tubular ratio of the parietal cell [49]. In a generally stimulated state of the parietal cell, most of the pump population is present in the secretory canaliculus, while in the resting state, the pump is in the cytoplasmic tubules and not associated with the canaliculus. Since the major degradative pathway for the pump, inhibition of acid secretion, which generates decreased canalicular area, leads to decreased pump turnover as occurs with acid blocking agents such as ranitidine. Thus pump inhibitors that change the distribution between tubules and canaliculi change the half-life of the pump.

The duration of suppression of acid secretion does not depend on the peak concentration reached but on the area under the plasma concentration-time curve of the drug. The increase in the dose or the decrease in the dosage interval produces a nonlinear increase in the area under the curve (AUC) of omeprazole. This fact is due to the slower clearance and the effect of the hepatic metabolism [51].

Summary of Pharmacokinetics

These drugs are absorbed rapidly from the gastrointestinal tract. The time needed to reach the peak plasma concentration varies for the different kinds of PPIs.

In the case of immediate release formulations, the T-max was as short as 10 min and from 30 to 300 min for delayed release formulations. The T-max is longest for rabeprazole and shortest for immediate release omeprazole. After absorption, it is rapidly eliminated from the plasma, and in most cases, all the active drug is metabolized in 3–4 h.

The effect of reducing the acidity as measured by the effective time pH remains above 4 is not affected by the plasma drug concentration [52]. It appears to be related to the AUC. Thus in most cases, the drug is rapidly eliminated from the system, but the effect lasts 3–4 days.

86 Mucosal Protective Agent: Sucralfate in the Treatment of Gastroesophageal Reflux Disease in Children

M. Smits and Marc A. Benninga

Introduction

Sucralfate is a mucosal protective coating agent that binds selectively to damaged or inflamed tissue to form a protective barrier. Sucralfate is a basic aluminum salt of sucrose octasulfate. At an acid pH, it forms large complexes with proteins (primary albumin and fibrogen) that adhere to the damaged tissue to prevent back diffusion of gastric acid, pepsin, and bile salts. Sucralfate also inhibits the direct binding of pepsin to ulcer protein and absorbs bile acids.

Another important effect of sucralfate is stimulating the bicarbonate and mucus production by gastric mucosa and the enhancement of cell renewal, the latter by stimulating the increase of prostaglandin E2, epidermal growth factors (EGF), and basis fibroblast growth factors (bFGF).

Despite its aluminum hydroxide components, sucralfate does not alter the gastric pH and thus does not work as an antacid at a normal therapeutic dosage. Also the drug has no apparent effect on gastric acid secretion, gastrin release, or upper gastrointestinal motility.

Pharmacodynamic Properties

Sucralfate is only minimally absorbed from the gastrointestinal (GI) tract, due to its pour solubility and high polarity. Over 90 % of orally administrated sucralfate leaves the GI tract unaffected with the feces.

Studies in animals show that 3–5 % of an oral dose of sucralfate reaches the systemic circulation as sucrose sulfate, which is excreted unchanged in the urine within 48 h. In animals, the elimination half-life of sucrose sulfate ranges from 6 to 20 h.

Since sucralfates act as a therapeutic agent on site of the damaged mucosa, its effect depends on the time the drug stays in contact with these erosions. Binding to the ulcer site has been demonstrated for up to 6 h following oral administration, and 30 % of the dose is retained within the GI tract for at least 3 h.

Pharmacokinetic Properties

Sucralfate has been shown to interact with several types of drugs. These interactions appear to be non-systemic and most likely result from

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_86

binding of the drug to sucralfate in the GI tract. The following agents may be less absorbed due to interaction with sucralfate: ciprofloxacine, warfarin and possibly other anticoagulants, digoxin, phenytoin, tetracycline, naproxen, norfloxacin, and antacids. Therefore, it is suggested not to ingest these agents concomitantly with or within 2 h of a dose of sucralfate.

Clinical Efficacy

Only one clinical trial evaluates the use of sucralfate in management of esophagitis caused by gastroesophageal reflux in children [1]. A total of 75 children from 3 months to 13 years were divided into three groups and treated with either sucralfate suspension, sucralfate tablets (dosage <6 years, 0.5 g four times a day; >6 years, 1 g four times a day), or the H2 receptor antagonist, cimetidine, dosage 20 mg/kg a day in two doses. All groups improved or showed endoscopic healing. Furthermore, in all groups, a decrease in symptoms was seen, but no significant differences between the groups were found. Based on this study in children, it is however difficult to state that sucralfate is effective in children from 3 months to 13 years, since there is a lack of placebo-controlled trials.

In adults, several studies have evaluated the effect of treatment with sucralfate in reflux esophagitis. It seems sucralfate (1 g orally before meals and bedtime) is equivalent to alginic acid/antacid and H2RA in endoscopic and symptomatic improvement and healing of esophagitis [2, 3]. However, these studies are often limited by their relatively small size (40–70 patients) and lack of placebo control. Simon et al. [4] found a statistically proved superiority of sucralfate gel compared to placebo in adults with non-erosive gastroesophageal reflux disease (NERD). Recently, Moayyedi et al. reviewed the effectiveness of several medical treatment options in the short-term management of reflux esophagitis in adults, including mucosal protective agent sucralfate [5]. They concluded there is no statistically significant benefit of taking sucralfate compared to antacid or placebo in healing of esophagitis (relative risk of persistence at 6 weeks, 0.82; 95 % CI, 0.67–1.01).

Sucralfate has been shown effective in preventing the development of stress ulcerations in critically ill patients and can be used topically to treat mucosal lesions from various origins (i.e., in recurrent aphthous stomatitis and epidermolysis bullosa) [6, 7].

Tolerability

Treatment with sucralfate has little side effects, the only major one being constipation, which occurs in 2–3 % of patients. Nausea and headaches occur less often. Sucralfate can cause serious adverse effect such as bezoars, especially when given to premature, neonates, and critically ill patients [8]. Although aluminum uptake in patients with normal renal function is not significantly increased under sucralfate treatment, it is advised to use an alternative agent in children and adults with (acute) renal failure, as their plasma aluminum levels can reach toxic levels during sucralfate therapy [9–11]. The chemical structure of sucralfate may cause interactions with other drugs (see pharmacokinetic properties). To minimize the risk of interaction or decreased absorption, it is recommended to take sucralfate at least 2 h apart from other drugs.

Dosage and Administration

Sucralfate is available in suspension and tablets, which are usually dosed at 1 g four times a day (before each meal and bedtime). In children under 6 years of age, the recommended dose is 0.5 g four times a day [1]. Since the tablets often need to be dissolved in water and the suspension is generally well accepted, the latter might be the preferable form of administration in children.

Systematic Name and Chemical Structure of Sucralfate

Aluminum, [(2R,3S,4S,5R)-2,4-disulfonatooxy-5-(sulfonatooxymethyl)-5-[(2S,3R,4S,5R,6R)-3,4,5-trisulfonatooxy-6-(sulfonatooxymethyl)oxan-2-yl]oxyoxolan-3-yl] sulfate, and trihydrate

87 Antacids and Alginates in the Treatment of Gastroesophageal Reflux Disease

R.E. van der Pol and Marc A. Benninga

Introduction

Antacids neutralize gastric acid and are, partly due to their over-the-counter availability, broadly used in the treatment of gastroesophageal reflux disease (GERD) in adults. They are utilized for more than 2,000 years, though evidence of the effectiveness and safety is limited in infants [1]. Antacids have an effect on the short-term relief of heartburn and the healing of esophagitis. Characteristic antacids consist of alkali complexes of aluminum and/or magnesium, aluminum and magnesium phosphates, magnesium trisilicate, carbonate, and bicarbonate salts [2]. Alginate-based raft-forming formulations vary from conventional antacids by forming a gel on the surface of the gastric contents and contain sodium or potassium bicarbonate. Alginates and antacids components are frequently combined in one product. Because of potential toxicity, prolonged use of antacids should be avoided [3].

Pharmacodynamics and Pharmacokinetics

Antacids act locally and instantly by buffering gastric contents. An incline in pH can be accomplished within minutes. Nonetheless, the antacid is not capable to retain the elevated pH despite gastric emptying rate and continued acid secretion [4]. Alginates contain polysaccharide polymers derived from brown seaweed. In contact with the acid environment of the stomach, alginates form a viscous gel. Combined with an antacid, generally a bicarbonate, the antacid generates carbon dioxide (CO_2) after reacting with the acid gastric contents. The carbon dioxide bubbles up and becomes entrapped in the viscous gel making the raft float. In this manner, a near-neutral barrier exists between the esophagus and the acid compounds of the stomach providing an immediate onset of effect [1, 5–7]. A special alginate for children exists as well (Gaviscon® Infant) containing sodium, magnesium alginate, and mannitol. It does not contain bicarbonate; hence, a "raft" is not formed and acts as a feed thickener instead [8].

DOI 10.1007/978-3-642-11202-7_87

Clinical Efficacy of Antacids

Little evidence of the clinical efficacy of antacids in children exists. In a comparative trial involving 33 children (2–24 months old) with GERD and/or esophagitis, high-dosed antacid showed to be as effective as cimetidine [9]. However, all cases of esophagitis were mild, without erosions or lesion. In another RCT, 80 children with severe gastroesophageal reflux were randomly divided into four groups: group A was treated with domperidone plus magnesium hydroxide and aluminum hydroxide, group B with domperidone plus alginate, group C with domperidone alone, and group D received placebo [10]. At the time of diagnosis and 8 weeks after treatment, patients were clinically evaluated and underwent 24-h pH measurement. After treatment, a complete regression of symptoms was observed in 80 % of patients in group A, in 40 % in group B (A versus B, $p<0.018$), in 45 % in group C (A versus C, $p<0.034$), and in 35 % in group D (A versus D, $p<0.001$). Furthermore, reflux parameters according to pH measurement were significantly lower in the group receiving domperidone with magnesium and aluminum hydroxide compared to the other groups. Yet a significant improvement in all treatment groups was found. Despite widespread use of antacids in adults, definitive evidence of their therapeutic benefit in the treatment of GERD is limited by the paucity of well-designed, large, placebo-controlled trials as well. For the placebo-controlled studies that are available, results are conflicting [11]. In conclusion, antacids might be effective in the treatment of GERD yet valid, sufficient evidence is lacking.

Clinical Efficacy of Alginates

The effect of alginates in children has been studied to a greater extent. A randomized, placebo-controlled, double-blind study using combined pH and impedance measurement in 20 children (between 34 and 319 days old) with gastroesophageal reflux showed no differences in the median number of reflux events/hour, acid reflux events/hour, minimum distal or proximal pH, total acid clearance time per hour (time with pH below pH 4), and total reflux duration per hour between Gaviscon and placebo. Only a minimal, though significant, difference in average reflux height was found [12]. In this study, Gaviscon Infant was used, which, in contrast to the adult form of Gaviscon, does not contain bicarbonate and therefore does not form a raft but acts as a thickening agent. The Del Buono et al. data are in accordance with an earlier study evaluating the effects of thickened feeding on GOR in infants [13]. Wenzl et al. found a reduction in reflux height in patients after they were fed with thickened milk as well. Furthermore, no difference was observed in acid reflux events before and after treatment [13].

In a double-blind, randomized, parallel-group study, conducted at 25 centers in the UK, 90 pediatric patients aged 0–12 months, with gastroesophageal reflux, were recruited in a general practice setting. For the primary efficacy measure, number of vomiting/regurgitation episodes, alginate was significantly superior to placebo ($p=0.009$) [14]. Furthermore, patients receiving alginate achieved superior assessments of treatment outcome by both investigators ($p=0.008$) and parent/guardians ($p=0.002$). The safety profile of alginate was similar to that of placebo [14]. The limitation of this study was that no pH and impedance measurement was performed and a relatively short follow-up period [14]. Two older studies both using pH monitoring described conflicting results [15, 16]. Buts et al. studied 20 infants and children with characteristic symptoms of GERD. Patients were divided at random into two groups which were given either Gaviscon (ten patients, mean age, 21 months) or a placebo (ten patients, mean age, 35 months) for eight consecutive days. Parents reported a decrease of regurgitation episodes during Gaviscon therapy, while no clinical improvement was reported in the placebo group [15]. In contrast, Forbes et al. included 30 infants and children, ranging from 4 months to 17 years with GERD. Patients were randomized to receive metoclopramide, alginic acid with antacid (Gaviscon Infant liquid), or a placebo. Disappointingly, neither metoclopramide nor the alginic acid-antacid compound showed a reduction in the frequency or duration of gastroesophageal reflux [16]. In conclusion all these studies clearly show that there is a lack in well-

designed large placebo-controlled trials evaluating the effect of alginates in the treatment of infants and children with GERD.

Tolerability

Aluminum-containing antacids, when used persistently, can raise plasma aluminum in infants. Several studies in children described plasma aluminum concentrations within reach of levels associated with rickets, microcytic anemia, osteopenia, and neurotoxicity. Constipation as well as diarrhea can occur with magnesium-rich preparations [3]. High dosage or prolonged use of calcium carbonate has the potential to result in milk-alkali syndrome, a triad of hypercalcemia, alkalosis, and renal failure [3]. Aluminum and magnesium containing antacids might chelate drugs in the upper gastrointestinal tract. Drugs to interact in this manner include quinolone antibacterial agents, didanosine, azithromycin, tetracycline, and H2 antagonists. To avoid any interaction, separating the time of administration by 2 h should suffice [17].

Dosage and Administration

The time of intake is of great significance because of the rapid onset of action for both antacid and alginates. Optimal benefit is accomplished while taken in the postprandial period when gastric emptying time is prolonged [1]. Antacids in a dose of 0.5 ml/kg have shown to be effective [18]. Special care is warranted in children with renal impairments since antacids have the possibility to heighten serum aluminum levels.

Conclusion

Antacids and alginates may be useful in the short-term treatment of GERD, although there is a paucity of valid evidence-based proof and result is often inconsistent. Long-standing utilization of antacids should not be advocated because the risk of possible side effects and the availability of other, more properly studied and saver options in the treatment of gastroesophageal reflux disease.

88 Histamine-2 Receptor Antagonist in the Treatment of Gastroesophageal Reflux Disease

Herbert M. van Wering and Marc A. Benninga

Introduction

In the stomach, gastric acid is secreted by the parietal cell. Several factors such as the presence of food, the smell, and/or taste of food and stress have influence on gastric acid secretion. Gastrin, histamine, acetylcholine, and prostaglandin regulate gastric acid secretion through the gastrin, the histamine, the muscarine, and the prostaglandin receptors, respectively (Fig. 88.1). In contrast, the prostaglandin receptor downregulates the gastric acid secretion and protects against the erosive irritation of gastric acid. The presence of food raises the pH in the stomach, which stimulates gastrin cells in the antrum of the stomach to produce gastrin. Subsequently, gastrin is then excreted into the bloodstream and stimulates the receptors at the parietal cell (the direct pathway) as well as the receptors at the adjacent endocrine cell (the histamine pathway). Acetylcholine (neurotransmitter) has a similar working mechanism and demonstrates the neural influence on gastric acid secretion. Histamine is produced by the endocrine cells and stimulates the histamine-2 receptor at the adjacent parietal cells. This stimulation results in an increase of intracellular cAMP, which in turn activates the H^+/K^+-ATPase. Also at the parietal cell, the acetylcholine binds and activates the acetylcholine receptor, which results in the opening of calcium channels. This leads to a calcium influx. In addition, gastrin binds and activates the gastrin receptors, which results in the mobilization of the intracellular calcium pool. These two additional mechanisms help the cAMP to activate the H^+/K^+-ATPase. This process will actively shift H^+-ions into the lumen of the stomach in exchange to K^+-ions (Fig. 88.1). The histamine, gastrin, acetylcholine, and prostaglandin receptors together form a mechanism to balance the gastric acid production for the digestion of food and the downregulation for the protection of the esophagus, stomach, and duodenum.

Pharmacological Properties of Histamine

Histamine stimulates the H_2 receptors and plays a key role in the mechanism of gastric acid production. Histamine-2 receptor antagonists (H_2RAs) have affinity for the H_2 receptors and inhibit the interaction of histamine (Fig. 88.1). Therefore,

The H_2 antagonist competitively inhibits the interaction of histamine at the H_2 histamine receptor illustrated by X

H_2RAs are a suitable selective drug to inhibit gastric acid secretion. In 1976, cimetidine was the first H_2RA that became available for clinical use in adults [1, 2]. Hereafter, other H_2RAs have become available, like ranitidine [3], famotidine [4], and nizatidine [5]. In adult patients the dosage, pharmacokinetics, and efficacy of H_2RA have been established; side effects and complications are well known and infrequent in occurrence. H_2RAs each have specific structural differences (Fig. 88.2), pharmacokinetics, and side effects, which give them their unique clinical use. Although in pediatric patients much of the data is based on small studies, ranitidine [6–9] and cimetidine [10, 11] are well characterized. In contrast, famotidine [12], and nizatidine [13] are less familiar, and the treatment specifics need to be explored more.

Mechanism of Action

H_2RAs inhibit the gastric acid secretion that is regulated by histamine, in a dose-dependent and competitive manner. The effect of inhibition is linear to the concentration of the drug in plasma over a wide range. Since the histamine production is influenced by gastrin and acetylcholine (Fig. 88.1), H_2RAs also inhibit to a lesser extent their influences. Therefore, H_2RAs inhibit the stimulated gastric acid production (in the presence of food) as well as the spontaneous basal (fasting) and nocturnal acid secretion. H_2RA reduces the H^+ concentration in the gastric acid juice as well as the volume of the gastric acid juice. Additionally, the pepsin output is reduced, since the production of pepsin generally falls in parallel with the volume of gastric acid secretion. Furthermore, the intrinsic factor secretion is reduced. Since this secretion is normally in great excess, vitamin B_{12} absorption remains usually adequate. In general, H_2RAs have a wide therapeutic usage in adults as well as in children: gastroesophageal reflux, acid or peptic disease, gastritis or esophagitis with or without hemorrhage, cystic fibrosis with maldigestion, and postoperative hypersecretion after small bowel reduction.

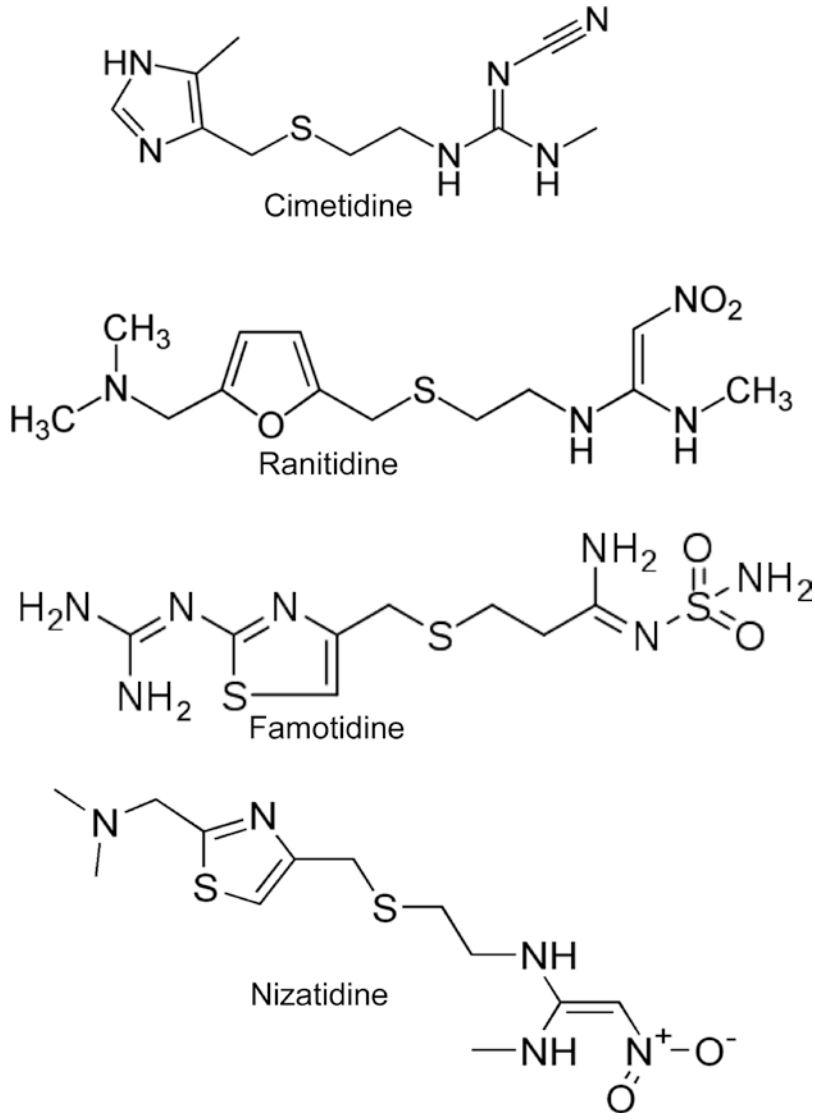

Fig. 88.2 Chemical structure of cimetidine, ranitidine, famotidine, and nizatidine

Pharmacokinetics and Pharmacodynamics

H_2RA pharmacokinetics in adults is similar to the pharmacokinetics in pediatric patients. Taken orally, H_2RAs are quickly and almost completely absorbed. Ranitidine and cimetidine have been extensively described in newborn infants, toddlers, children, and critically ill children [6–11]. In general, both drugs have a shorter half-life and a larger volume of distribution in children compared to adults. Also, children have a higher renal clearance than adults. Ranitidine is pharmacological similar to cimetidine but contains an amino methyl furantoin moiety instead of an imidazole nucleus (Fig. 88.2). This structural difference implies that ranitidine is 5–12 times more potent than cimetidine on a molar basis [14]. The half-life, volume of distribution, and clearance values of ranitidine are similar after an intravenous bolus or an oral dose (1.8 vs 2.0 h, 2.3 vs 2.5 l/kg and 794.7 vs 788 ml/min/1.73 m^2, respectively) in children (3.5–16 years). Due to a significant first-pass effect, the bioavailability of ranitidine averages 48 % in children, and the peak serum concentration is reached after almost 2 h [6]. Around 70 % of ranitidine is metabolized

into nitrogen, sulfoxide, and desmethyl derivat and cleared in the urine. The half-life, volume of distribution, and body clearance values in newborn infants are 3.45 (±0.3) h, 1.52 (±0.91) l/kg, and 5.02 (±0.46) ml/kg/min, respectively [7]. The half-life and clearance in critically ill children are 3.01 (±1.35) h and 8.5 (±3.7) ml/kg/min [8]. Patients with cystic fibrosis have slightly altered pharmacokinetics. The half-life in these patients is 2.7 (±1.4) h, steady-state volume of distribution is 4.6 (±1.7) l/kg, and plasma clearance is 17.03 (±4.8) ml/kg/min [15]. In pediatric patients, the serum concentration around 40–60 ng/ml is necessary to suppress gastric acid secretion by 90%; these concentrations are achieved by an oral dose of 1.25–1.9 mg/kg every 12 h [6].

The cimetidine disposition is best described by a biphasic elimination curve half-life time for cimetidine, and its metabolites: cimetidine sulfoxide and hydroxymethyl cimetidine of 1.39, 2.6 and 4.7 h, respectively, in adults. The body clearance in pediatric patients is higher due to a better renal clearance11.6 ± 3.4 ml/kg/min versus 7.0 ± 2.5 ml/kg/min in adults [16]. Around 70% of the cimetidine is cleared into the urine. After an oral or iv bolus, the half-life and the volume of distribution are 1.38 (±0.43) h and 1.24 ± 0.4 l/kg, respectively, in children (4–13 years) [16]. The half-life of cimetidine in newborn infants ranges from 1.10 to 2.18 h [17]. In critically ill children, the mean apparent volume of distribution and total body clearance are 1.23 l/kg and 10.4 ml/kg/min [18]. The correlation between serum concentration and pH reduction in the stomach is uncertain. Lambert et al. [11] described that after a 10 mg/kg oral dose of cimetidine, 75% of the pediatric patients had a significant gastric acid suppression after 2 h.

The pharmacokinetics and pharmacodynamics of famotidine in children are similar to adults [19]. The famotidine pharmacokinetics are investigated mainly by an intravenous administered dosage in children (>1 years old) [20] and infants [21]. Famotidine is primarily eliminated by glomerular filtration and active renal secretion. In children and adults, between 67% and 73% is eliminated unchanged in the urine within the first 24 h. The inactive sulfoxide is one of the metabolized by-products. In children >1 years of age, the elimination half-life is 3.2 ± 3.0 h and volume of distribution is 2.4 ± 1.7 l/kg. The plasma clearance and renal clearance are 11.7 ± 5.7 ml/kg/min and 7.2 ± 4 ml/kg/min, respectively. Infants younger than 3 months old have a significant decreased plasma and renal clearance, but infants older than 3 months of age are similar to the older children [20]. Also, famotidine renal clearance is diminished significantly in patients with renal failure; accordingly, dosing should be based on glomerular filtration rate [22]. Pharmacodynamic analysis demonstrated that 50% of the maximal effect of famotidine occurs at a serum concentration of 26.0 ± 13.2 ng/ml [19].

The pharmacokinetics of nizatidine in children is similar to the pharmacokinetics in adults [23]. The bioavailability of nizatidine is approximately 70% in adults. This was comparable to the bioavailability in children, who coingested the drug with fruit/vegetable juice. The terminal elimination rate for nizatidine in pediatric patients is 0.58 ± 0.8/h [24]. Nizatidine is 90% excreted unchanged into the urine.

Side Effects and Drug Interactions

H_2RAs are highly selective for the H_2 receptors, and they have little effect on H_1, H_3, or H_4 histamine receptors. Although H_2 receptors are present in numerous tissues, including bronchial smooth muscle and vascular system, they are very seldom inhibited by H_2RAs. Recently, it has been described that any gastric acid inhibitors (H_2RA as well as proton pump inhibitors) raise the risk of acute gastroenteritis [25] and community-acquired pneumonia in children [26]. This increased risk of infection is attributed to the disruption of first-line defense mechanism by the acidic environment of the stomach [27]. In general, any therapy that raises the pH of the stomach alters the absorption rate of weak acidic or weak alkalic drugs [28]. Drugs like cefuroxime, posaconazole, cefpodoxime, as well as itraconazole and ketoconazole are influenced by a higher pH in the stomach. H_2 antagonists may lead to fundamental changes in the absorption

and disposition of other drugs. However, there are similarities and differences between the H_2 antagonists in this respect, depending on the process involved. H_2RAs lower the blood supply of the liver itself, which may inhibit the transformation of drugs with a high first-pass effect, like lidocaine [29]. Cimetidine, but not so much by ranitidine, famotidine, or nizatidine, inhibits the activity of cytochrome P_{450}, thereby slowing the metabolism of many drugs that are substrates for hepatic mixed-function oxidases. Thus, the concentration of drugs like phenytoin, digitoxin, warfarin, and others will be prolonged in the human circulation [28]. The use of ranitidine has been rarely associated with bradycardia [30] and sepsis [31] in pediatric patients. Other general but rare side effects are headache, dizziness, blood count changes, and liver function disruption. Cimetidine has similar side effects, but more frequently and in a wider range compared to ranitidine. Specific side effects of cimetidine are mental confusion, hallucinations, hepatotoxicity, and hypotension. In adult male patients receiving long-term high-dose cimetidine, it has been observed that they develop gynecomastia, loss of libido, and impotence. These effects are presumably described to the antiandrogen working mechanism of cimetidine [32]. These endocrine changes have not been specified in children, although significantly elevated prolactin levels have been shown [33]. These endocrine problems have not been reported with ranitidine, famotidine, or nizatidine. H_2RAs have been investigated during pregnancy and have no effect on major malformations [34].

Clinical Relevance

Although the H_2RA as a group has a selective working mechanism and infrequent side effects, only ranitidine has been extensively investigated and used in pediatric patients. Cimetidine is rarely used in pediatric patients as concerns exist about the effect on cytochrome P_{450} and multiple drug interactions as well as the interference with endocrine function (see pharmacokinetics above). The usage of famotidine and nizatidine has been described in pediatric patients and has some promising usage profile [19–24]. However, these two drugs have only been investigated in very small studies, and more randomized clinical trials are needed to characterize these drugs in pediatric patients. Therefore, famotidine and nizatidine have not been licensed for use in children in the UK and the Netherlands, although they are licensed in the USA. Moreover, ranitidine has a favorable pharmacokinetic profile compared to famotidine [35]. Presently, ranitidine is the most prescribed and recommended H_2RA in a therapeutic role for pediatric patients with gastroesophageal reflux disease [36].

Therapeutic Choices

Ranitidine is widely used in the treatment of children with acid or peptic disease, gastritis or esophagitis with or without hemorrhage [36], cystic fibrosis, postoperative hypersecretion after small bowel resection, and gastrointestinal and pulmonary symptoms caused by gastroesophageal reflux. Gastroesophageal reflux (GER) is a common phenomenon in children, characterized by the regurgitation of the gastric contents into the esophagus. Two recent review articles [37, 38] described the use of ranitidine in GER(D) in children. In summary, for infant GERD ranitidine and omeprazol (PPI) are safe and effective therapy (min. 8–12 weeks) that should provide symptomatic relief and endoscopic and histologic healing of esophagitis. When GERD is refractory to ranitidine, omeprazole demonstrated to be a more effective therapy. In older children ranitidine has similar success rates as omeprazole and is the cornerstone of the therapy for GERD for a minimum of 8–12 weeks [37]. The intermittent use of ranitidine for the treatment of symptoms of GER has been described in children (4–11 years) and demonstrated similarities to adult intermittent treatment effect. This intermittent therapy suppressed the gastric acid production for about 5–6 h [9].

Peptic ulcerations, stress ulceration, and upper GI bleeding have been treated with gastric acid suppression by ranitidine. Recently, data has been published that proton pump inhibitors have

been more successful with less side effects in adults [39, 40].

Other Clinical Usage of H_2RAs

Recksuppaphol et al. have described that a course of ranitidine administered 24 h prior to a Meckel scan improves the sensitivity of this Meckel scan [41]. As part of the triple therapy to eradicate *Helicobacter pylori*, ranitidine has been used extensively, but it has been proven that proton pump inhibitors have a better outcome [42]. Abdominal discomfort in patients with Henoch-Schönlein vasculitis is eased by a treatment with ranitidine as demonstrated by Narin et al. [43]. Others [44] have described the usage of cimetidine orally for the lone treatment of pedal verruca in all age groups.

Dosage and Administration

Oral administration is indicated for GERD, *gastric ulcers and duodenal ulcers* in pediatric patients. The therapeutic regimen in newborn infants is 5 mg/kg/day in two doses and for older children (1 month till 18 years) 6–10 mg/kg daily in two doses, with a maximum dosage of 300 mg/day. Ranitidine has been fabricated for oral use in tablet and syrup, which have an equal effect, but tablets dissolved in water have a better taste, which may lead to a better therapeutic compliance [45]. In the prevention of stress ulcers and as supportive care in gastrointestinal bleeding, ranitidine is given intravenously. For neonates 2.5 mg/kg/day in two doses has been suggested. For older children from 1 month up to 18 years old, 3–6 mg/kg in three to four doses daily has been [38, 46] suggested. The maximum daily dosage is 200 mg. As an alternative, ranitidine can be administered in a continuous intravenous infusion of a total of 4 mg/kg/day. Ranitidine liquids for oral use contain 8 % alcohol. The leads to, when given a maximum dose of 300 mg/day, the patient is also taken 1.6 g of alcohol. This is comparable with 32 ml of beer or 13 ml of wine. One has to keep this in mind when given to patient with liver failure or epileptic seizures.

Proton Pump Inhibitors

89

Licia Pensabene and Geoffrey Davidson

Introduction

Recent years have seen widespread use of potent gastric acidity inhibitors in the management of many upper gastrointestinal disorders, also in pediatric patients [7]. Acid suppression with PPIs is the standard treatment for GERD and erosive esophagitis in adults and is increasingly becoming first-line therapy for children aged 1–17 years [117]. The potential adverse effects of acid suppression, including increased risk of community-acquired pneumonias and GI infections, need to be balanced against the benefits of therapy [125].

Pharmacological Properties of PPIs

Mechanism of Action

PPIs have become the mainstay of treatment for acid-related gastrointestinal disease in adults since their introduction in 1989 [30]. PPIs have several inherent advantages compared to the older medication classes of antacids or histamine type 2 receptor antagonists (H2RAs). H2RAs reduce acid secretion only by competing with histamine receptors located in the parietal cell membrane; other cellular receptors that respond to endocrine (gastrin) and neuroendocrine (vagal stimulation) pathways are not affected [19]. Thus, H2RAs do not completely block gastric parietal cell acid production.

Unlike H2RAs, PPIs demonstrate consistent gastric pH control and do not develop tachyphylaxis with repeated dosing. PPIs inhibit gastric acid secretion by selectively blocking the gastric parietal cell H+,K+-ATPase (also called the proton pump), an enzyme that is involved in the last step of acid secretion in gastric parietal cells [122]. The superior efficacy of PPIs is largely because of their ability to maintain intragastric pH at or above 4 for longer periods and to inhibit meal-induced acid secretion, a characteristic not shared by H2RAs. The potent suppression of acid secretion by PPIs also results in the decrease of 24-h intragastric volumes, thereby facilitating gastric emptying and decreasing volume reflux [17].

Currently available PPIs are omeprazole, esomeprazole, lansoprazole, dexlansoprazole, pantoprazole, and rabeprazole; they differ in their molecular structure, giving rise to certain differences in their pharmacokinetics [43]. The PPIs are benzimidazole derivatives that differ in their substitution patterns. They are composed of two moieties, a substituted pyridine with a primary pKa of about 4.0, which allows selective accumulation in the acidic space of the secretory canaliculus of the stimulated parietal cell (where

the pH is about 1.0), and a benzimidazole with a second pKa of about 1.0 [106]. This implies that they are weak bases that will be minimally protonated at neutral pH (of blood) and maximally protonated in environments of high acidity [43]. The rate of conversion to the active form is inversely proportional to the pKa; rabeprazole is the PPI with the highest rate of conversion, followed by omeprazole, lansoprazole, and pantoprazole [103]. PPIs can be considered acid-activated prodrugs that convert to sulfenic acids or sulfenamides that react covalently with one or more cysteines accessible from the luminal surface of the H+,K+-ATPase [67, 106]. Once covalently bound, the H+,K+-ATPase becomes nonfunctional, and activity only returns by parietal cell synthesis of a new H+,K+-ATPase enzyme system [43]. Because of covalent binding, the inhibitory effects of PPIs are longer than expected from their plasma half-life [106]. However, PPIs cannot inhibit all gastric acid pumps with oral dosing since not all pumps are active during the 90-min half-life of the PPI in the blood. PPIs have a short half-life; thus, only 70 % of the pump enzymes are inhibited. About 20 % of pumps are newly synthesized over a 24-h period, and there may be greater pump synthesis at night than during the day. This led many healthcare providers to increase PPI dosing to twice daily. Disappointingly, bedtime administration of PPIs will not add to inhibition of nighttime acid breakthrough [106]. For example, once-daily esomeprazole 40 mg controls acid for a median of 15.3 h daily (after 3–5 days of therapy), and 40 mg taken twice daily (before morning and evening meals) controls acid for 19.5 h daily [30]. In addition, twice-daily PPI therapy has not been tested in appropriately designed trials with clinically significant end points [30].

The proton pumps are in an inactive state in cytoplasm. After stimulation, such as a meal, the pump is translocated to the membrane of the canaliculus, where it is activated. To inhibit this, omeprazole must reach a sufficient plasma concentration. However, the duration of suppression of acid secretion does not depend on the peak concentration reached but on the area under the plasma concentration-time curve of the drug. The increase in dose or decrease in dosage interval of omeprazole produces a nonlinear increase in the area under the curve (AUC) due to slower clearance and the effect of the hepatic metabolism [105].

Metabolism

Omeprazole and the other PPIs are metabolized in the liver by cytochrome P450. The principal enzymes involved in their metabolism are CYP2C19 and, to a lesser degree, CYP3A4, which transform omeprazole into the metabolites 5-hydroxyomeprazole and omeprazole sulfone; 80 % of these metabolites are excreted in the urine. As demonstrated by Kearns et al., there is marked genetic polymorphism of CYP2C19, which directly affects the pharmacokinetics of omeprazole and the other PPIs [67]. Patients can be divided into three groups according to CYP2C19 polymorphism: homozygous extensive metabolizers, heterozygous extensive metabolizers, and poor metabolizers.

The most common, wild-type, homozygous extensive-metabolizer (HomEM) genotype contains two normal (nonmutated) alleles. HomEMs produce an abundance of the enzyme and metabolize the PPI at a higher rate, limiting the drugs' bioavailability [40]. The heterozygous extensive metabolizer (HetEM) contains one wild-type allele and one mutant allele, resulting in the compromised production of the enzyme and, thus, slower metabolism of the PPI [40]. In the poor metabolizer (PM) genotype, both alleles are mutated, which results in a much slower rate of PPI metabolism, ensuring greater bioavailability. A comparison of the ratio of the area under the plasma concentration curve for PPIs shows that HomEM/HetEM/PM is 1:3.7:20 [32]. Thus, PMs have more than five times the PPI available of HetEM and 20 times that of HomEM. This results in a more profound inhibition of gastric acid secretion as measured by intragastric pH [124]. Therefore, extensive metabolizers have a lower AUC than poor metabolizers and therefore require higher doses of omeprazole to achieve

adequate suppression of acid secretion [39]. Furthermore, there is a higher rate of nonresponders among extensive metabolizers [105].

There are marked ethnic differences in the frequency distribution of these genotypes [136]. The Japanese population has an 18–23 % prevalence of PMs. Further, 15–17 % of the Chinese population are PMs and 13 % of Koreans are PMs. The Asian population has a much greater frequency of PM (12–23 %) when compared to Caucasians (1–6 %) and black Africans (1–7.5 %) [136]. The frequency of PMs in African, African-American, and Middle Eastern populations is very similar to Caucasians. Indigenous populations, such as the Canadian Indians and the Australian Aboriginals, have a high frequency of PMs, which is similar to that of the Asian population [136].

Do differences in genotypes have clinically relevant consequences? Few studies [21, 41, 70, 107, 133] do suggest that the efficacy of PPIs in terms of inhibition of acid secretion may be lower in patients who are extensive metabolizers compared with intermediate and PM, but caution is warranted in accepting these conclusions given the low sample sizes of most published studies [20]. A variant of the CYP2C19 has recently been discovered, allele CYP2C19*17, which affects the metabolism of the PPIs, giving its carriers an extensive-metabolizer phenotype. This variant shows racial variations, being found in 18 % of the Swiss and Ethiopian populations and in only 4 % of the Chinese population [105, 108]. The impact of the CYP2C19*17 allele on the pharmacokinetics of pantoprazole and omeprazole in previously studied children ($n=40$) was explored [66]. When pantoprazole area under the plasma concentration versus time curve (AUC) was examined as a function of CYP2C19 genotype, a significantly lower AUC was observed for subjects identified as CYP2C19*1/*1 and CYP2C19*1/*17. For pantoprazole, a statistically significant relationship was observed between CYP2C19 genotype and both the dose-corrected AUC ($p<0.0001$) and the apparent elimination rate constant (K(el); $p=0.0012$); no significant genotype-phenotype relationships were observed for omeprazole [66].

Pharmacokinetics

Pharmacokinetics research in children has not been extensively studied, but suggests that the dose used should be varied as a function of age, as this factor affects the drug's metabolism [109]. The immaturity of various organ systems leads to differences in the pharmacokinetics and efficacy of the PPIs in children compared to adults. The embryonic development of the stomach is completed between 14 and 15 weeks gestation. The mass of parietal cells is responsible for acid secretion and increases with increasing weight and gestational age. H+,K+-ATPase is present by week 25 of gestation and its expression increases with age. Premature infants born after week 24 of gestation are therefore able to maintain an intragastric pH below 4 from the first day of life [11, 78]. Although gastric pH in newborns is slightly higher than in adults, their maximum acid secretion is similar [11]. Gastric emptying (GE) and intestinal motility vary with age, affecting rates of drug absorption [83]. Neonates have slower GE, and lower motility, leading to a greater absorption of drugs in the neonatal age range [130].

The distribution of PPIs can differ in children due to factors such as tissue perfusion, plasma protein concentration, body composition, and variation with age [45, 83]. Hepatic and renal functions also vary with age, affecting drug metabolism and elimination. At birth, there is a low level of activity of the enzymes CYP2C19 and CYP3A4; adult levels of activity are reached in early childhood [75]. At 2 years of age, children have a greater oxidative capacity than adults, whereas glucuronidation develops more slowly. As children approach puberty, their metabolism becomes approaches that of adults [109]. Premature and newborn infants present a lower level of elimination of metabolites, favoring accumulation, whereas this is uncommon in older infants and in children [109]. Furthermore, it is important to note that the metabolic activity, and therefore the pharmacokinetic parameters of the hepatic P450 enzyme systems, will be affected by maturation changes in these systems [2]. These findings corroborate a developmental dependence

in the activity of these enzyme systems, the extent of which is sufficiently significant to alter dose-concentration-effect relationships and, therefore, demand age-specific individualization of dosing to ensure efficacy and safety [75].

Children 1–10 years of age appear to require a higher dose per kilogram for some PPIs than adolescents and adults. Young children require higher per-kilogram doses to attain the same acid blocking effect or area under the curve [3, 78, 134]. This may not apply to all of the PPIs [50]. There is little pharmacokinetic data on PPIs in infants, but several studies indicate that infants younger than 6 months may have a lower per-kilogram dose requirement than older children and adolescents [92, 132]. Thus, multicenter safety and efficacy studies are warranted to assess the most appropriate dosage of PPIs for different pediatric age groups [19].

Bioavailability

Despite their efficacy in the management of acid-related disorders, PPIs have limitations as a consequence of their pharmacologic characteristics [125]. Oral bioavailability of PPIs varies from first to subsequent doses [101]. Omeprazole has a low initial oral bioavailability of 35–40 %, rising to 65 % on repeated administration, whereas lansoprazole, when used in doses higher than 20 mg, has a constant high bioavailability of between 80 % and 91 % and demonstrates linear plasma drug concentrations [43, 101]. Bioavailability of PPIs can be affected by the time of administration in relation to food ingestion [43]. The ingestion of food stimulates proton pumps, so high PPI serum concentrations at the time of meal ingestion result in the most effective acid suppression [30]. PPIs should, therefore, be given at a time that enables their complete systemic absorption before a meal, which is typically 30–60 min beforehand [30]. They must be taken once per day before breakfast and must be protected from gastric acid by enteric coatings. Some studies have shown that food may delay absorption and reduce bioavailability of lansoprazole, even less so for omeprazole (and pantoprazole) [25, 27]. Most available PPIs are therefore regarded as "delayed-release" preparations. Achievement of maximal acid suppression can take up to 4 days [63]. However, a summary of adult data suggests that PPIs can also be used for "on-demand" treatment of symptoms [88]. Dexlansoprazole MR is said to be less dependent on being taken on an empty stomach. Dexlansoprazole, a pure enantiomer of lansoprazole, is a PPI that, with a novel dual delayed-release formulation, provides prolonged inhibition of gastric acid secretion [87] resulting in marked improvements in symptoms of GERD with high maintenance rates and good tolerability [26]. There are no pediatric clinical trials and the drug is not approved for use in children. Pantoprazole is a PPI that has been shown to be safe and effective in the treatment of GERD in adults and children in randomized controlled clinical trials [4, 102, 113]. Pantoprazole has a relatively long duration of action compared with other PPIs, and a lower propensity to become activated in slightly acidic body compartments [90]. Pantoprazole delayed-release granules for oral suspension were developed as an age-appropriate formulation for use in infants and young children unable to swallow tablets [129].

PPIs currently approved for use in children in North America are omeprazole, lansoprazole, and esomeprazole. At this moment, in Europe, only omeprazole and esomeprazole are approved. No PPI has been approved for use in infants younger than 1 year of age. Nevertheless, the number of PPI prescriptions written for infants has increased manyfold in recent years despite the absence of evidence for acid-related disorders in the majority [71, 91, 123]. Although the effectiveness of PPIs in children is under debate, PPI use in infants and children with GERD has increased enormously during the last decade [5, 48].

Current Evidence Regarding PPI Therapy in Different Clinical Settings

GERD Symptoms

Recently published guidelines relating to the diagnosis and management of pediatric gastroesophageal reflux, conducted by the European

Society for Pediatric Gastroenterology Hepatology and Nutrition and the North American Society for Pediatric Gastroenterology Hepatology and Nutrition [125; Sherman et al. 2009], show there are no symptoms or group of symptoms that can reliably diagnose GERD or predict treatment response. Moreover, for mild infant GERD, parental guidance and education combined with feed thickeners and/or positioning therapy will often suffice [122]. However, when pharmacologic treatment is indicated, antisecretory agents play a key role, and usually PPIs are on the front row. However, a recent systematic review of the available evidence underlines that if the primary aim is to treat GERD symptoms in infants, PPIs should not be prescribed [122]. In fact, clinical trials reveal that PPI therapy is not an effective treatment for common infant GERD-associated symptoms [62], despite the finding that acid suppression only occurred in the PPI group [89, 92, 94], maybe because of a lack of specificity of symptom-based diagnosis of GERD in this age group.

In summary, for the reduction of GERD symptoms in infants, PPIs were more effective in one study (lansoprazole was more effective compared with hydrolyzed formula [68]), not effective in two studies (omeprazole compared with a placebo was not effective in reducing GERD symptoms in two studies [89, 92]), and equally effective in two studies (lansoprazole and pantoprazole were equally effective compared with placebo, in two studies [94, 129]). Moreover, evidence supporting safety of PPI use in infants is conflicting [62]. The largest placebo-controlled trial to date [94] found that rates of adverse events were increased in the PPI group compared with the placebo group, whereas the other trials reviewed reported no difference in adverse effects with the use of PPIs. Therefore, if the primary aim is to treat GERD symptoms in infants, PPIs should not be prescribed [122].

Moreover, guidelines [125] underline there is no evidence to support an empiric trial of acid suppression as a diagnostic test in infants and young children where symptoms suggestive of GERD are less specific. In fact, one study of infants with symptoms suggestive of GERD who were treated empirically with a PPI showed no efficacy over placebo [94]. However, expert opinion [125] suggests that a time-limited (2-week) empiric, antisecretory treatment for infants with crying and distressed behavior may be considered if irritability persists with no explanation other than suspected GERD, although clinical recovery may be ascribed to a placebo reaction or physiologic symptom resolution with time.

Extrapolation from adult data suggests that in *older children and adolescents with heartburn*, on-demand therapy with buffering agents, sodium alginate, or H2RA may be used for occasional heartburn [88, 95, 96]. Expert opinion [125] suggests that an older child or adolescent with typical symptoms of *chronic heartburn* should be treated with lifestyle changes if applicable (diet changes, weight loss, smoking avoidance, sleeping position, no late-night eating) and a 2–4-week trial of PPI. The treatment period required to achieve uniform therapeutic responses with PPI therapy probably varies with disease severity, treatment dose, and specific symptoms or complications [120]. The 2-week "PPI test" lacks adequate specificity and sensitivity for use in clinical practice. In an older child or adolescent with symptoms suggesting GERD, an empiric PPI trial is justified for up to 4 weeks [125]. If symptoms resolve, PPIs may be continued for up to 3 months. However, improvement of heartburn, following treatment, does not confirm a diagnosis of GERD because symptoms may improve spontaneously or respond by a placebo effect. In some patients, abrupt discontinuation of treatment may result in acid rebound that precipitates symptoms; therefore, it is recommended that antisecretory therapy be weaned slowly [8, 38]. If symptoms persist on PPI therapy or recur when therapy is weaned or discontinued, upper endoscopy may be helpful to determine the presence and severity of esophagitis and differentiate reflux-related esophagitis from nonreflux pathologies such as infection or eosinophilic esophagitis (EoE) that may present with heartburn [53, 58].

However, a recent systematic review of the available evidence [121] showed that, for *children and adolescents*, PPIs were equally effective in reducing GERD symptoms compared with

what was given in the control groups, alginates, ranitidine, or a different PPI dosage. When comparing the different groups to baseline, GERD symptoms were significantly reduced in all groups [122]. The authors of two studies [9, 24] found that PPIs were more effective at reducing gastric acidity than alginate or ranitidine, but the reduction of macroscopic and histological scores during endoscopy was similar in all study groups (PPI versus ranitidine or alginate) compared with baseline. For gastric acidity, in infants and children, PPIs were more effective (compared with placebo, alginates, or ranitidine) in four studies [24, 89, 92]. For reducing histologic aberrations, PPIs showed no difference (compared with ranitidine or alginates) in three studies [94, 122]. Six studies [49, 93, 113, 118, 129] reported no differences in treatment-related adverse events (compared with placebo or a different PPI dosage). PPIs are generally well tolerated [56] but have some shortcomings and may increase susceptibility to acute gastroenteritis and community-acquired pneumonia [15, 73], respiratory infections [112], gastric polyps [98], and bacterial overgrowth [112]. Despite PPIs seeming to be well tolerated in the short term, there is insufficient evidence to support the effectiveness and safety of PPIs in the treatment of GERD in children and adolescents [122]. Therefore, physicians should be careful when prescribing PPIs, medications that are not approved for infants and have potential adverse effects, unless there is documented disease or with careful monitoring [122].

Reflux Esophagitis

Initial Treatment

In pediatric patients with endoscopically diagnosed reflux esophagitis or established nonerosive reflux disease, PPIs for 3 months constitute initial therapy [125]. For healing of erosive esophagitis and relief of GERD symptoms, PPIs are superior to H2RAs [125]. Initial treatment for 3 months is advised. If adequate symptom control is not achieved within 4 weeks, the dose of PPI can be increased. Patients who require higher PPI dose to control symptoms and produce healing are those with conditions that predispose to severe, chronic GERD and those with higher grades of esophagitis or Barrett's esophagus (BE). In most cases of chronic-relapsing esophagitis, symptom relief can be used as a measure of efficacy of therapy, but in some circumstances repeat endoscopy or diagnostic studies may be indicated.

Most patients require only one daily dose of PPI to obtain symptomatic relief and heal esophagitis [36, 52, 55, 115]. The optimum dosage regimen is a once-daily dose 15–30 min before the first meal of the day; routine use of twice-daily doses is not indicated [125]. When acid suppression is required, the smallest effective dose should be used. It is not necessary to make patients achlorhydric to relieve symptoms or heal esophagitis, and, in light of the data on infections and other complications of acid suppression by H2RAs or PPIs, it is probably not desirable to do so. Not all reflux esophagitis is chronic or relapsing [9], and therefore trials of reduction of dose and withdrawal of PPI therapy should be performed after the patient has been asymptomatic for some time, that is, after 3–6 months on treatment. This approach will minimize the number of children that unnecessarily receive long-term treatment.

PPIs should not be stopped abruptly, because rebound acid secretion may cause recurrence of symptoms [8, 38]. Instead, PPI should be tapered for at least 4 weeks. Recurrence of symptoms and/or esophagitis after repeated trials of PPI withdrawal usually indicates that chronic-relapsing GERD is present, if other causes of esophagitis have been ruled out. At that point, therapeutic options include long-term PPI therapy or antireflux surgery.

In open-label studies of children with erosive esophagitis, PPIs produced healing in 78–95 % with 8 weeks of therapy and in 94–100 % with 12 weeks of therapy. Symptoms improved in 70–80 % of the group treated for 12 weeks [9, 36, 116]. Most patients in these studies had lower grades of erosive esophagitis, and the studies did not include patients with underlying conditions such as NI (define), repaired tracheoesophageal fistula (TOF), chronic lung disease, or hiatal hernia (HH). PPIs have been shown to heal higher

grades of esophagitis (grades 3–4) in children with these underlying conditions, even in some when esophagitis had been refractory to treatment with H2RAs, prokinetic agents, and even antireflux surgery [52, 55, 56]. However, in these selected cases resistant to standard management, high per-kilogram dose and long duration of therapy (up to 6 months) may be required for healing and symptom control [52, 55, 56]. In uncontrolled studies of children with erosive and nonerosive reflux disease (NERD) treated with PPIs, 70 % experienced relief of "typical symptoms of GERD," that is, heartburn [36, 116]. A significant percent of patients remained symptomatic, albeit at lower intensity. Suboptimal symptom relief may be due to large per-kilogram dosing variation. Studies in adults have shown generally poorer therapeutic response to PPI in patients with NERD compared with patients with erosive esophagitis [29, 35].

An international, multicenter, randomized, parallel-group, double-blind (for dose) study showed that an 8-week course of esomeprazole treatment (0.2–1.0 mg/kg) effectively heals macroscopic and microscopic erosive esophagitis in children aged 1–11 years with endoscopically or histologically confirmed GERD. Of 109 patients, 49 % had erosive esophagitis, and 51 % had histologic evidence of reflux esophagitis without erosive esophagitis. Of the 45 patients who had erosive esophagitis and underwent follow-up endoscopy, 89 % experienced erosion resolution [117].

Maintenance Treatment

Although the benefits of short-term treatment with PPIs in pediatric patients with reflux esophagitis has been demonstrated [44, 55, 115], there are few data on long-term maintenance treatment with PPIs in this population. Although the guidelines [125] advocate the short-term use of PPIs in children older than one for the relief of GERD symptoms, the issue of maintenance therapy is not discussed in depth. A recent systematic literature analysis identified five studies that evaluated the *efficacy of PPI maintenance therapy* (6–90-month follow-up) in pediatric patients *after healing of reflux esophagitis* [64]. Of the five relevant studies identified, one was a prospective placebo-controlled study [9], two were prospective single-treatment studies [10, 55], and two were retrospective studies [97, 98]. Three found no relapse of reflux esophagitis or reflux symptoms during PPI maintenance therapy; however, a low relapse rate (1/14) was also found in the placebo group of the only prospectively controlled study. Two of the five studies (both prospective) reported relapse of reflux esophagitis at half the original healing dose of omeprazole (7 of 51 patients relapsed after 3 months; 8 of 32 within 21 months), which resolved again in most patients when the healing dose or higher was given [64]. In the only placebo-controlled prospective study, by Boccia et al. [9], 46 children were randomly assigned after healing of reflux esophagitis (defined as at least grade II according to the Hetzel et al. classification [61]) to a 6-month maintenance therapy with omeprazole, 0.7 mg/kg/day (single daily dose) ($n = 16$), ranitidine, 10 mg/kg/day (divided into two doses) ($n = 16$), or placebo ($n = 14$). Histological, endoscopic, and symptomatic scores were assessed 3 months after discontinuation of maintenance therapy. Reflux esophagitis and reflux symptoms did not relapse in any of the 16 patients taking omeprazole during the 6-month treatment and subsequent follow-up [9]. However, only one patient had relapse of reflux esophagitis (grade II according to the Hetzel et al. classification) in the placebo arm, and there were no relapses in the ranitidine arm, suggesting that the natural propensity to relapse was inherently low in this pediatric population. It is notable that this study specifically excluded children with chronic conditions such as cerebral palsy, repaired esophageal atresia, neurological impairment, or repaired tracheoesophageal fistula (TOF) [64]. In the first of two retrospective studies [97], regular endoscopic assessments during a mean follow-up of 4.4 years showed that healed reflux esophagitis was maintained in all 15 children while taking omeprazole (doses used during the follow-up period were not specified; reflux esophagitis was defined as at least grade II according to the Hetzel et al. classification). The second study [98] was a retrospective

chart review of 31 children who received >6 months of omeprazole maintenance therapy for reflux esophagitis. Endoscopy was repeated in these patients until reflux esophagitis was healed and then annually thereafter. In all of the patients, reflux esophagitis significantly improved (details not specified), as did their reflux symptoms. These improvements were sustained during omeprazole maintenance treatment (mean dose 1.5 mg/kg/day, range 0.6–3.3 mg/kg/day) during a mean follow-up of 31 months (range 6–90 months). In both of studies, the majority of patients had chronic conditions such as cerebral palsy, repaired esophageal atresia, neurological impairment, or repaired TOF [64].

Further indirect evidence for the efficacy of PPI maintenance therapy is provided by a study that screened hospital databases for records from pediatric patients with GERD who took PPIs continuously for at least 9 months [56]. In 166 individuals (mean age at time of index 7.8 years, range 4 weeks to 17 years), the median number of symptoms declined significantly from three (interquartile range two) at first presentation to one (interquartile range one) on the last encounter. The median follow-up between presentation and last encounter was 3 years, during which PPIs (omeprazole [85 %], lansoprazole [4.2 %], omeprazole, and þ lansoprazole [6 %]) were used for a median period of 2.75 years, omeprazole at a median dose of 1.1 mg/kg/day, and lansoprazole at a median dose of 1.4 mg/kg/day. All of the patients who were followed-up underwent esophageal endoscopy at some point during the study period. Although reflux esophagitis (classification system not reported) was endoscopically confirmed in 81 (48.8 %) of these 166 patients, specific details for rates of healing or relapse of reflux esophagitis were not given. Seventy-nine percent of the patients had comorbid conditions such as neurological disorders, esophageal atresia or TOF, or chronic lung disorders [64].

In summary, few studies have documented the efficacy of maintenance treatment with PPIs in pediatric patients after healing of reflux esophagitis. The small number of studies identified in a recent review [64] suggested that PPI maintenance therapy in pediatric patients aged 1–17 years is associated with low relapse rates for reflux esophagitis (0–25 %) and reflux symptoms (0–34 %) for follow-up durations of 6–90 months. Indeed, no relapses of reflux esophagitis in 6-month to 4.4-year follow-up were reported during PPI treatment in three of the five studies reviewed. In the remaining two studies, relapse of reflux esophagitis (14 % and 25 %) and reflux symptoms (14 % and 34 %) (after 3- and 21-month follow-up) occurred only when half the healing dose was used but resolved again in most patients when the healing dose or higher was given. The relapse rates observed for reflux symptoms and reflux esophagitis in patients receiving suboptimal PPI doses suggest that long-term therapy at the full maintenance dose is needed in some children.

In a recent open-labeled, uncontrolled, prospective study [74] to evaluate the effects of three treatment strategies after 8 weeks of lansoprazole therapy for GERD in children, 37 erosive reflux disease (ERD) and 20 NERD patients were divided into three groups by symptom assessment at 8 weeks: (1) observation without treatment in the "symptoms-resolved" group, (2) "on-demand" treatment for an additional 16 weeks in the "symptoms-attenuated" group, and (3) continuous treatment in the "symptoms-persistent" group. For ERD, six (100 %) out of six patients in the "symptoms-resolved" group remained improved at weeks 16 and 24. Sixteen (72.7 %) out of 22 patients in the "symptoms-attenuated" group had improvement of symptoms at 16 weeks and 18 (81.8 %) patients at 24 weeks. Six (66.7 %) out of nine patients in the "symptoms-persistent" group remained improved at weeks 16 and 24. For NERD, seven (100 %) out of seven patients in the "symptoms-resolved" group remained improved at weeks 16 and 24. Eight (80.0 %) out of ten patients in the "symptoms-attenuated" group remained improved at week 16 and 10 (100.0 %) patients at week 24. None out of three patients in the "symptoms-persistent" group remained improved at weeks 16 and 24. In conclusion the selection of each alternative for long-term management according to the results of the assessment of symptoms at week 8 was useful and well tolerated. "On-demand" therapy was equally effective. The 16-week therapy had the same efficacy as

the 24-week therapy with regard to long-term lansoprazole treatment [74].

A recent systematic literature analysis [64] identified four studies [9, 23, 28] that evaluated *relapse of reflux esophagitis and/or reflux symptoms after stopping PPI therapy*. Reflux symptoms recurred in 18–76 % of patients across all four studies [64]. In studies where patients stopped PPI treatment after healing, rates of relapse of reflux esophagitis and reflux symptoms were variable: 2.2 % and 30 % [9, 28] for reflux esophagitis and 18–76 % for symptoms [9, 28]. (The duration of follow-up was 2 and 3 months in two studies and not specified in the other two studies.) In the four studies that assessed the safety of PPI maintenance therapy, adverse events were infrequent and of low severity [64]. In the study by Hassall et al. [56], PPIs were used in 86 patients (52 %) for 0.75 to 3 years and 80 patients (48 %) for 3–11 years; omeprazole was the most commonly prescribed PPI (91 %), followed by lansoprazole (10 %). Only six adverse events potentially related to PPI use (nausea, vomiting, diarrhea, rash, agitation, and irritability) were recorded among four children, three of whom were taking omeprazole. A subgroup of 62 patients in this study had > one set of gastric biopsies during routine clinical care. Assessment of these biopsies showed that children did not develop atrophic gastritis, carcinoid tumors, or clinically significant enterochromaffin cell-like hyperplasia [94].

In a retrospective study of 113 children receiving continuous lansoprazole or omeprazole (mean ages, 6.7 and 8.3 years, respectively) for at least 1 year (64 % lansoprazole [mean dose, 1.42 mg/kg/day], 22 % omeprazole [mean dose, 1.15 mg kg/day]), adverse events were reported by 12 % of children, with diarrhea (5 %) and constipation (4 %) being the most common [114]. No clinically apparent adverse events were observed in the study by Pashankar et al. [97]. In addition, in the study from Hassall [55], omeprazole was well tolerated and no serious adverse events could be attributed to the drug. Thus, the evidence indicates that maintenance therapy, when required, should provide a favorable benefit-to-risk ratio [64].

The guidelines [125] attribute the recurrence of symptoms after repeated trials of PPI withdrawal to chronic-relapsing GERD and recommend long-term PPI therapy or surgery as therapeutic options in such situations. The low relapse rates observed by Boccia et al. [9] suggest that reflux esophagitis in pediatric patients who do not have certain chronic comorbidities may require only PPI healing treatment and not maintenance therapy. Conversely, patients with reflux esophagitis who have underlying predisposing disorders are likely to need long-term PPI maintenance treatment. This view is supported by the study of Hassall et al. that found 131 (79 %) of 166 patients (mean age 7.8 years) taking PPIs for longer than 9 months had these underlying conditions [56].

In summary, pediatric patients with GERD and certain chronic comorbidities (such as neurological impairment, repaired esophageal atresia, or TOF.) appear to have the greatest need of maintenance PPI treatment after healing of reflux esophagitis [64]. In patients requiring maintenance therapy, PPIs appear to be well tolerated and effective in maintaining remission of reflux esophagitis and reflux symptoms [64].

Barrett's Esophagus (BE)

The management of nondysplastic BE is the same as that of erosive esophagitis, that is, long-term PPI or antireflux surgery [54, 126]. BE per se is not an indication for antireflux surgery. In BE, symptoms are often a poor guide to adequacy of treatment, and some advocate more aggressive acid suppression, based on esophageal pH monitoring [126]. Although it is unclear whether progression of dysplasia is slowed by acid control, higher doses of PPI may be considered in BE than in esophagitis without metaplasia [104].

Dysphagia, Odynophagia, and Food Refusal

In patients with dysphagia, odynophagia, and food refusal, therapy with acid suppression without earlier evaluation to rule out other conditions

(such as barium esophagogram and upper endoscopy) is not recommended [125].

Apnea or Apparent Life-Threatening Event

In the majority of infants with apnea or apparent life-threatening events (ALTEs), GER is not the cause. In the uncommon circumstance in which a relation between symptoms and GER is suspected or in those with recurrent symptoms, MII/pH esophageal monitoring in combination with polysomnographic recording and precise, synchronous symptom recording may aid in establishing cause and effect [125] and the need for long-term medical or surgical antireflux therapy.

Reactive Airway Disease

In patients with *asthma* who also have heartburn, reflux may be a contributing factor to the asthma. Despite a high frequency of abnormal reflux studies in patients with asthma who do not have heartburn, there is no strong evidence to support empiric PPI therapy in unselected pediatric patients with wheezing or asthma. Only three groups—those with heartburn, those with nocturnal asthma symptoms, and those with steroid-dependent difficult-to-control asthma—may derive some benefit from long-term medical or surgical antireflux therapy [125].

Finding abnormal esophageal pH exposure by esophageal pH monitoring, with or without impedance, before considering a trial of long-term PPI therapy or surgery may be useful, although the predictive value of these studies for this purpose has not been established. The relative efficacy of medical versus surgical therapy for GERD in children with asthma is unknown. Although adult studies show only limited, if any, benefit from PPI or surgical therapy, it is possible that selected patients with heartburn, nocturnal asthma, or steroid-dependent, difficult-to-control asthma may derive some benefit. Symptom reporting is less reliable in infants and children than in adults. Other causes of wheezing should be ruled out.

Recurrent pneumonia and interstitial lung disease may be complications of GER due to aspiration of gastric contents. No test can determine whether GER is causing recurrent pneumonia. An abnormal esophageal pH test may increase the probability that GER is a cause of recurrent pneumonia but is not a proof. A trial of nasogastric feeding may be used to exclude aspiration during swallowing as a potential cause of recurrent disease. A trial of nasojejunal therapy may help in determining whether surgical antireflux therapy is likely to be beneficial. In patients with severely impaired lung function, antireflux surgery may be necessary to prevent further pulmonary damage, despite the lack of definitive proof that GER is causative [125].

Upper Airway Symptoms

Extrapolation from adult studies suggests that PPIs will not benefit most children with upper airway symptoms [125]. Patients with chronic hoarseness, chronic cough, sinusitis, chronic otitis media, erythema, and cobblestone appearance of the larynx should not be assumed to have GERD without consideration of other potential etiologies.

A recent Cochrane systematic review [18] of 19 studies (six in infants/children and 13 in adults) has shown a lack of high-level evidence that the treatment of GERD-associated *cough* improves cough measured by subjective methods (i.e., subjective cough). Studies on milk formula thickening yielded inconsistent results, and the single randomized controlled trial (RCT) on PPI in pediatrics (162 children) found no significant difference between groups for cough as primary outcome (95 % CI of number needed to treat for benefit (NNT-B) of 11 to number needed to treat for harm (NNT-H) of eight) or other cough outcomes. Importantly, serious adverse events, particularly lower respiratory tract infections, occurred significantly more frequently in the lansoprazole group compared with the placebo group; the NNT-H after 4 weeks was 11 (95 % CI, 3–232). In adults, there was no significant effect in the pooled analysis, and the beneficial

effect was seen only in the subgroup analysis. The OR for cough resolution pooled from four adult studies was not statistically significant (NNT-B of 4 to NNT-H of 90). This review also highlights the large placebo and time–period effect of treatment for chronic cough.

Because GERD and otitis media with effusion (*OME*) are two of the most prevalent diseases in young children, a number of investigators have taken preliminary steps to demonstrate a causative link between the diseases. Of particular interest has been the presence of gastric enzymes in the middle ear space. Studies on rats with repeated middle ear exposure to pepsin have demonstrated impaired eustachian tube function [60] as well as impaired mucociliary clearance of middle ear contents [128]. In a study by Tasker et al. [111], middle ear effusions were sampled from 54 children aged 2–8 years who underwent myringotomy. More than 80 % of the children were found to have pepsin concentrations of up to 1,000-fold greater than serum levels, suggesting a contributory role of GERD in OME [111]. Subsequent studies of middle ear fluid in children aged 1–7 years with RAOM (define) or OME demonstrated the presence of pepsin in 73–77 % of effusions [22, 59, 77]. One study of 31 children with OME showed middle ear pepsin/pepsinogen to be present in concentrations up to 231 times higher than serum levels from the same children [1]. A correlation was also identified between the concentration of the enzyme and the number of reflux episodes using 24-h pH-probe monitoring [1]. A recent prospective study [93] found that pepsin was detectable in the middle ear cleft of 20 % of 509 patients with OME undergoing tympanostomy, compared with 1.4 % of controls undergoing cochlear implantation.

Helicobacter pylori, which is a known pathogen for several inflammatory gastric disorders, also has been postulated as a factor in the development of OM (otitis media). In a study by Yilmaz et al. of 18 children with OME [131], *H. pylori* was identified by reverse transcription–polymerase chain reaction in 67 % of middle ear effusions. Additional research is necessary to determine the significance of these findings.

Although basic science studies suggest that GERD has a role in the pathogenesis of OME, there have been few clinical studies evaluating GERD in patients with OM. In a recent prospective study of the QOL effect of antireflux therapy on otologic disease [85], 37 young children (6 months to 7 years) with OM with effusion or recurrent acute OM and GERD have improved quality of life following treatment with antireflux therapy. Mean (SD) change scores for OM six-item quality-of-life survey were 1.6 (1.1) at second visit and 1.5 (1.1) at third visit ($P = 001$ and $P = 0.004$, respectively). Hearing loss demonstrated on audiometric testing was significantly improved following therapy, as were laryngeal findings of reflux on fiber-optic laryngoscopy (FOL), although a validated scale for assessment is lacking. The authors conclude that reduction of GER may play a role in the prevention of OM and avoidance of tympanostomy, although additional high-quality clinical trials are warranted.

Dental Erosions

An association between GERD and dental erosions has been established. The severity of dental erosions seems to be correlated with the presence of GERD symptoms and, in adults, with the severity of proximal esophageal or oral exposure to an acidic pH. Young children and children with neurological impairment appear to be at the greatest risk [125].

Dystonic Head Posturing (Sandifer Syndrome)

Sandifer syndrome (spasmodic torsional dystonia with arching of the back and opisthotonic posturing, mainly involving the neck and back) is an uncommon but specific manifestation of GERD. It resolves with antireflux treatment [125].

Group at High Risk for GERD

Certain conditions are predisposed to severe, chronic GERD. These include neurological

impairment, obesity, repaired esophageal atresia or other congenital esophageal disease, cystic fibrosis, hiatal hernia, repaired achalasia, lung transplantation, and a family history of GERD, BE, or esophageal adenocarcinoma.

Although many premature infants are diagnosed with GERD because of nonspecific symptoms of feeding intolerance, apnea spells, feeding refusal, and pain behavior, there are no controlled data that confirm reflux as a cause. Although reflux may be more common in infants with bronchopulmonary dysplasia, there is no evidence that antireflux therapy affects the clinical course or outcome of this condition.

Pediatric patients with GERD and certain chronic comorbidities (such as neurological impairment, repaired esophageal atresia, or TOF.) appear to have the greatest need of maintenance PPI treatment after healing of reflux esophagitis [64].

Helicobacter pylori Infection

In pediatric efficacy studies for the management of *H. pylori* eradication in children, the most commonly tested regimen has contained a combination of PPI, clarithromycin, and amoxicillin, followed by triple therapies containing PPI, clarithromycin, and nitroimidazoles [19]. Thus, PPIs are an integral part of triple therapy for *H. pylori* eradication in children with gastroduodenal disease. Almost all published efficacy studies in pediatric patients have been performed with omeprazole and lansoprazole used in combination therapies for the first-line treatment of *H. pylori* eradication.

PPIs have been shown to exert a specific antibacterial activity against *H. pylori* in vitro [110]. However, in vitro antimicrobial activity does not necessarily indicate that the drug will demonstrate an effect in vivo. In vivo, PPI alone suppresses *H. pylori* growth but does not lead to eradication of the organism [69, 127]. The main reason to use PPIs in *H. pylori* eradication regimens is to achieve a favorable intragastric pH window that facilitates the antimicrobial effects of antibiotics [101]. Acid-sensitive antibiotics such as amoxicillin and clarithromycin require rapidly acting PPIs to create an optimum pH window for optimum antibacterial effect [101]. Increasing intragastric pH has been shown to achieve higher *H. pylori* eradication rates as well as ulcer healing rates by stabilizing acid-labile antibiotics, which increases the concentration of antibiotics in gastric juice [30]. In addition, the synergistic effect of PPIs and antibiotics in vivo is due to the fact that PPIs not only increase intragastric pH but reduce gastric juice volume [46, 124]. Goddard and Spiller [47] showed that omeprazole decreases gastric juice viscosity by its effect on pH, implying a reduction in the mucus barrier function of the stomach. Both of these actions will improve local drug delivery to the gastric mucosa and surface epithelial cells that serve as the habitat for *H. pylori* colonization of the stomach. Pediatric studies suggest that PPIs are safe and effective drugs for use in the eradication of *H. pylori* infection and management of peptic acid-related disease.

Critically Ill Children

PPIs can be used intravenously in critically ill children for the prophylaxis and treatment of gastrointestinal hemorrhage, although there is still little experience with this. In critical patients, acid secretion is induced by gastrin or histamine released by stress. This acid secretion injures the gastric mucous producing digestive bleeding. Morbidity and mortality are increased in critically ill adult and pediatric patients who are at high risk of gastrointestinal hemorrhage. Mechanical ventilation for more than 48 h, coagulation disorders, shock, neurosurgery, respiratory failure, and sepsis are factors that increase the risk of gastrointestinal hemorrhage [12]. Prophylaxis for gastrointestinal hemorrhage is therefore recommended in critically ill children and adults [109]. The most widely used drugs for prophylaxis are the H2 receptor antagonists and the PPIs [12, 80, 100]. Pharmacokinetics studies are necessary to analyze the most adequate omeprazole dose and interval in critically ill children.

Safety Profile

Most adverse effects occurring during the treatment with PPI are mild, self-limiting, and unrelated to patient age, the most common being diarrhea, headache, abdominal pain, nausea, constipation, and dizziness. These may resolve with decreased dose or change to a different PPI [125]. There appears to be a minimal risk of adverse effects in humans with long-term administration [99]. Acid suppression leads to increased levels of circulating gastrin in most patients [79]. Gastrin stimulates gastric acid secretion by parietal cells directly by binding to its specific receptor and indirectly through the stimulation of histamine release from enterochromaffin-like cells. Moreover, gastrin exerts a trophic effect on both parietal and enterochromaffin-like cells [81D]. When high-dose PPIs were administered to rats, hypergastrinemia, endocrine cell hyperplasia, and carcinoid tumors developed [99]. Elevated gastrin levels have been observed in patients receiving omeprazole, but serum gastrin normalized once the drug was discontinued [99]. In addition, benign gastric changes such as parietal cell hyperplasia and gastric polyps have been observed in children and adults receiving long-term PPI therapy [79, 114]. However, no carcinoid tumor formation ever has been reported in humans [79]. A recent retrospective study of children treated with PPIs for up to 11 years found only mild grades of enterochromaffin-like cell hyperplasia [56]. A high percentage of children (61 %) receiving long-term PPI continuously for up to 10.8 years (median, 2.84 years) develop minor degrees of ECL hyperplasia. This has no known clinical significance. Children on PPIs for this duration do not appear to develop atrophic gastritis or carcinoid tumors [57].

The issue of gastric adenocarcinoma in patients treated long term with PPIs has been long debated. Recently, the discussion has focused on the interaction between PPI and *H. pylori* leading to atrophic gastric as precursor of gastric adenocarcinoma [79]. In the late 1990s, Kuipers et al. [72] reported the development of atrophic gastritis in *H. pylori*-positive patients on long-term omeprazole, compared to no risk in *H. pylori*-negative patients. A recent long-term follow-up study confirmed a progression toward atrophic gastritis in *H. pylori*-positive patients on long-term omeprazole therapy [81]. Thus, the last consensus conference on *H. pylori* infection recommended *H. pylori* eradication in patients requiring long-term maintenance treatment with PPI [82].

In a recent study [94], infants treated with PPI had a significantly higher rate of all adverse effects compared with the placebo group. Lower respiratory tract infections were the most frequent among these adverse effects, although the difference in respiratory tract infection rate between treated and placebo groups did not achieve statistical significance. It has been repeatedly reported that the suppression of gastric acidity predisposes to infection by a variety of pathogens, but only recently has the increased risk of infection induced by gastric acidity inhibitors (GAIs) been investigated systematically at clinical and laboratory level [84]. Gastric juice consists of HCl and pepsin and can kill bacteria within 15 min when the pH is less than 3.0. If the pH is raised above 4.0, a state defined as hypochlorhydria, bacterial overgrowth and infections are more common [31]. Berni Canani et al. [16] reviewed recent clinical studies performed in adults, children, and neonates exploring the possible association of gastric acidity inhibitors' use with intestinal infections. Many studies and systematic reviews demonstrate an increased risk of bacterial infection in adults taking acid suppressors [14, 34, 37, 42, 76]. Little evidence is derived from the pediatric population. A recent case-control study of risk factors for *Salmonella enteritidis* in the Netherlands showed an increased risk of gastroenteritis induced by these pathogens in children taking GAIs (OR 3.6, range 1.9–6.9) [33]. A prospective study performed in pediatric patients showed that the use of GAIs is associated with an increased risk of acute gastroenteritis and community-acquired pneumonia in GERD-affected children [6]. The authors obtained data on 186 participants from four pediatric gastroenterology centers: 95 healthy controls and 91 GAI users (47 on ranitidine

and 44 on omeprazole). The two groups were comparable for age, sex, weight, length, and incidence of acute gastroenteritis and pneumonia in the 4 months prior to enrollment. Rate of acute gastroenteritis and community-acquired pneumonia was significantly increased in patients treated with GAIs compared with healthy controls (acute gastroenteritis, 47 vs. 20 %, $P = 0.001$; pneumonia, 12 vs. 2 %, $P = 0.03$) during the 4-month follow-up period. In the GAI-treated group, the rate of acute gastroenteritis (20 vs. 47 %, $P < 0.0001$) and community-acquired pneumonia (3 vs. 12 %, $P = 0.02$) was increased when comparing the rates 4 months before and after the enrollment. No differences in acute gastroenteritis and pneumonia incidence were observed between ranitidine and omeprazole users in the previous 4 months and during the follow-up period. On the contrary, in healthy controls, the incidence of acute gastroenteritis and pneumonia remained stable. It is interesting to note that in this study authors observed an increased incidence of intestinal and respiratory infections in otherwise healthy children taking GAIs for GERD treatment. On the contrary, the majority of the previous data showed that the patients most at risk for pneumonia were those with significant comorbidities such as diabetes or immunodeficiency, and this points to the importance of gastric acidity suppression as a major risk factor for infections. The effect on infection susceptibility seems to be sustained even after the end of therapy. Authors observed a similar incidence of acute gastroenteritis and pneumonia during the use of GAI drugs and in the 2 months following stopping their use as observed previously in adult patients [121]. How long this effect can last remains to be defined in future studies. Children exposed to PPIs therapy seem to be at higher risk for the development of *Clostridium difficile*-associated disease [119]. The use of PPI was significantly higher in *C. difficile*-positive group compared with *C. difficile*-negative group (odds ratio [OR] = 4.5; 95 % confidence interval [CI] = 1.4–14.4).

It has been recently reported in a retrospective study that at least 30 % of neonates received treatment with GAIs at the time of discharge from NICU and an additional risk of infections and necrotizing enterocolitis (NEC) in newborns treated with GAIs was observed [51]. In addition, there is no clear evidence of benefit of the use of GAIs in many clinical conditions typical of neonatal age. These observations suggest the importance of a more careful use of GAIs in these patients, in particular, if other risk factors for severe infections are present [16].

Other adverse effects have been reported in elderly patients on chronic PPI therapy, such as deficiency of vitamin B12 and increased incidence of bone fractures, but these findings have not been confirmed by recent studies [65, 114]. Based on current knowledge, routine testing for vitamin B12 deficiency is not recommended in long-term PPI users [79]. Likewise, osteoprotective prophylaxis is not recommended in patients with long-term PPI use [79]. Moreover, PPIs are considered to be the most common cause of acute interstitial nephritis in adults [13]. This adverse effect is considered to be an idiosyncratic reaction, more frequent in elderly adults. No childhood cases have been described.

Finally, physicians should be aware of emerging data suggesting a potential role for acid-suppressive medications in the pathogenesis of certain manifestations of food allergy such as eosinophilic esophagitis [86]. Recent studies have elucidated a plausible mechanism whereby antisecretory agents, by interfering with the peptic digestion of dietary proteins and by increasing mucosal permeability, might predispose to food allergy. This association warrants future epidemiological investigations.

Conclusion

Despite PPIs seeming to be well tolerated in the short term, there is insufficient evidence of effectiveness and safety in the treatment of GERD in children and adolescents. Therefore, physicians should be careful when prescribing PPI, medications that have potential adverse effects, unless there is documented disease or with careful monitoring. A proper utilization of these drugs, particularly for patients at high risk, is imperative in order to reduce deleterious effects on infection risk and to optimize cost-effectiveness ratio.

Prokinetic Therapy

90

Gigi Veereman-Wauters

Impaired esophageal motility may be the cause or the consequence of GERD and esophagitis. Transient lower esophageal sphincter relaxations lead to GERD in premature infants [1]. It remains unclear whether esophageal motor abnormalities contribute to GERD in children [2, 3], but esophageal inflammation causes altered motility [4]. Pharmacological agents that restore normal motility patterns would be highly desirable. Unfortunately, efficacious and safe prokinetic agents are currently lacking for routine clinical use.

Prokinetic agents act on the humoral or neuromotor network. In addition to the intended effects on gastrointestinal motility, these agents have central nervous system effects thus side effects. Many agents, such as bethanechol that was used 20 years ago, have more side effects than proven benefits and therefore are abandoned.

Cholinergic Agonist

Bethanechol increases lower esophageal sphincter pressure [5], but side effects such as dystonia have prohibited its use [6].

Dopamine Receptor Antagonist

Erythromycin facilitates gastric emptying. Safety profile needs to be considered, especially for cardiac effects [7]. The relationship between gastric emptying and GERD is unclear, and the effect of erythromycin on GERD is unknown.

Antidopaminergic Agents

Domperidone and metoclopramide are antidopaminergic agents that facilitate gastric emptying.

Metoclopramide has largely been abandoned because of disturbing neurological side effects such as irritability and dystonia in addition to a questionable effect on GERD [8].

Domperidone is used as antiemetic and has no proven effect on GERD. A study in newborns showed an unexpected increase in reflux episodes [9]. Domperidone occasionally causes extrapyramidal central nervous system side effects and rarely produces QTc prolongation on electrocardiogram.

Serotonergic Agent

Cisapride facilitates the release of acetylcholine at synapses in the myenteric plexus, thereby improving overall gastrointestinal peristalsis. This well-known prokinetic agent has been

Table 90.1 Dosages for prokinetics

Metoclopramide 0.1 mg/kg/dose qid/AC
Cisapride[a] 0.2 mg/kg/dose qid/AC
Erythromycin 3–5 mg/kg/dose tid-qid/AC
Domperidone pediatric doses not defined
Bethanechol 0.1–0.3 mg/kg/dose tid-qid/AC

AC ante cibum
[a]Restricted or unavailable

withdrawn from the markets because of the risk for prolongation of the QTc interval on electrocardiogram and lack of well-demonstrated efficacy on GERD [10, 11].

Gamma-Aminobutyric-Acid Receptor Agonist

Baclofen inhibits transient lower esophageal sphincter relaxations. A reduction of emesis and improvement of reflux parameters were demonstrated in children with cerebral palsy [12]. Likewise GERD and gastric emptying improved in otherwise healthy children [13]. The safety profile of this drug again precludes routine use: dyspeptic symptoms, drowsiness, dizziness, fatigue, and seizures (Table 90.1).

According to the most recent guidelines, there currently is insufficient evidence to justify the routine use of domperidone, baclofen, cisapride, metoclopramide, erythromycin, or bethanechol for GERD [14].

It is hoped that new compounds will be developed and proposed for pediatric clinical trials.

Defining Gastroesophageal Reflux

Gastroesophageal reflux GER is defined as a return of gastric contents into the esophagus with or without regurgitation and vomiting. GER is a normal physiologic process occurring several times per day in healthy infants, children, and adults [309]. Most episodes of GER last less than 3 min and occur in the postprandial period, with few or no symptoms [267].

It is common for infants to have recurrent problems with "spitting up" or "vomiting" during the first year of life. The severity of symptoms varies from an occasional burp to persistent emesis. Evaluation of most of these infants reveals no definable anatomic, metabolic, infectious, or neurologic etiology. Gastroesophageal reflux (GER) should cause concern only when associated with additional problems such as abnormal persistence, growth retardation, and respiratory symptoms. The spectrum of clinical symptoms in pathological GER is wide and complications are at times severe so that recognition of possible pathological vomiting followed by appropriate diagnostic makes therapeutic steps essential. About 60–65 % of such infants without treatment are essentially free of symptoms and in good health by 2 years of age. The remaining have persistent and significant symptoms until at least 4 years of age, and about 4 % of the total group develop esophageal strictures. Carré estimated a mortality of 5 % in those without strictures, usually from inanition or infection [59].

Factors Related to GER

Anatomy and Genetics

The esophagus develops from the primitive foregut which lies immediately caudal to the pharynx. As the neck and trachea develop, the esophagus lengthens rapidly from above downward, traveling through the neck, the posterior mediastinum, and the esophageal hiatus to end in the cardia of the stomach. Between the fourth and seventh weeks of gestation, the stomach moves caudally, and failure of this process results in a short esophagus [327] and a partially thoracic stomach that was described by Carré.

The length of the esophagus varies depending on age, sex, and individual habitus. The tubercle of the cricoid cartilage is the single constant landmark of the upper esophageal opening. We believe that division into cervical, upper, middle, and lower thoracic and abdominal segments is adequate. Talking about GER, the lower thoracic and abdominal segments are the most important, since the antireflux mechanism, which prevents return of gastric material into the esophagus, depends on their anatomy and physiology (Fig. 91.1).

The formation of the gastroesophageal junction results from a complex but coordinated development of the esophagus, diaphragm, and stomach together with the autonomic nerve innervation and the blood supply of these viscera [172]. Failure of this process of development and maturation results in structural defects and functional abnormalities that can lead to GER.

Lately, attention has focused on the possibility that gastroesophageal reflux disease may have a genetic basis. A specific locus associated with pediatric GERD has been identified on chromosome 13. The identification of the molecular mechanisms underlying familial pediatric GERD will have important consequences both for our understanding of the pathophysiology of this common and costly disorder and for our ability to more accurately target treatments at those mechanisms [139, 140, 225].

Pathophysiology

The pathophysiology of gastroesophageal reflux disease involves contact of the esophageal epithelium with acid/pepsin in the refluxate. For this contact to occur with sufficient duration, there must be a combination of defects in antireflux and luminal clearance mechanisms for acid/pepsin to overwhelm an intact epithelium; otherwise, defects within the epithelium develop that subsequently enable normal acid contact times to become damaging to the epithelium (Table 91.1). Three major tiers of defense serve to limit the

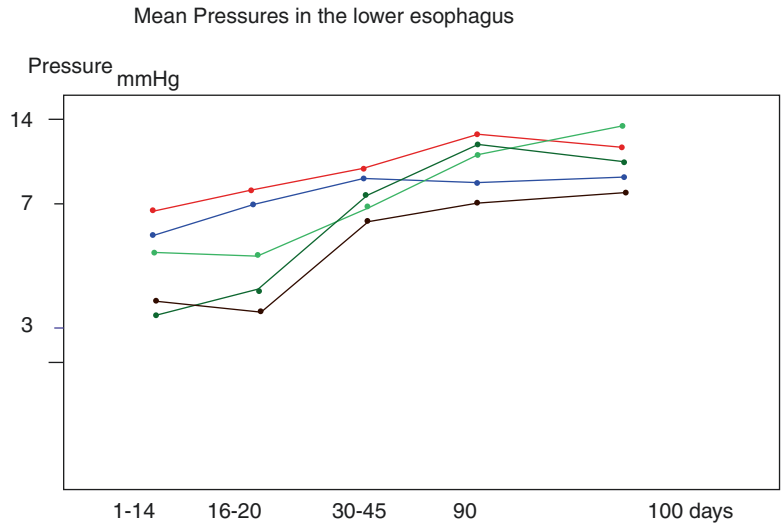

Fig. 91.1 Mean pressures in the lower esophagus, independent of perinatal factors, converge at 5–9 weeks to their effective maturation. The length of the abdominal portion of the esophagus is the decisive factor in the antireflux mechanism. Boix-Ochoa and Canals [32]

degree of GER and to minimize the risk of reflux-induced injury to the esophagus.

The first line of defense is the "antireflux barrier," consisting of the lower esophageal sphincter (LES), and the diaphragmatic pinch cock and angle of His; this barrier serves to limit the frequency and volume of refluxed gastric contents. When this line of defenses fails, the second "esophageal clearance" assumes greater importance, to limit the duration of contact between luminal contents and esophageal epithelium. Gravity and esophageal peristalsis serve to remove volume from the esophageal lumen, while salivary and esophageal secretions (the latter form esophageal submucosal glands) serve to neutralize acid.

The third line of defense, "tissue or esophageal mucosal resistance," comes into play when esophageal clearance is defective or not operative (e.g., motility disorders, sleep).

The Antireflux Barrier

Lower Esophageal Sphincter: Dysfunction

In 1956, as a result of the development of esophageal manometry, a high-pressure zone (HPZ) near the esophagogastric junction was described. A sphincter muscle in the lower esophagus was proposed as the mechanism for maintaining this pressure [111]. Meticulous dissections of the esophagus revealed an oblique gastroesophageal ring caused by a meager increase in muscle mass [181]. The well-defined HPZ exists in the lower esophagus, referred to as the LES.

The esophageal peristalsis normally begins in the pharynx, progressing down the esophagus and producing, at the appropriate time, relaxation of the LES [47]. This relaxation is brief, but the mechanism results in effective and rapid passage of ingested food and saliva from the pharynx to the stomach [13]. Presumably, afferent and efferent vagal neural pathways controlled by brain stem nuclei mediate this sequence of events [199]. The cause of the HPZ remains conjectural, but it is unlikely to be solely the result of a true muscle sphincter [181]. Patients who have had surgical removal of the distal esophagus (esophagogastrectomy) have, in manometric studies, an HPZ at the thoracoabdominal junction that relaxes on swallowing and increases with a rise in intra-abdominal pressure [173].

Intra-abdominal Esophagus: Anatomical Anomalies

The presence of an intra-abdominal esophagus is vital to the antireflux barrier [40, 228] and is the key to the whole system [31, 85]. The determining factor is the length of the esophagus exposed to intra-abdominal pressure [150, 320, 326]. The greater the length of the intra-abdominal esophagus, the more esophageal valve becomes [293].

The segment of intra-abdominal esophagus, which is a soft tube, is collapsed when intra-abdominal pressure increases. The diameter of the esophagus is one fifth than that of the stomach. Hence, according to Laplace's law, the pressure in the esophagus to enable it to act as a closing valve should increase by only one fifth of the pressure of the stomach. A sufficient segment (>2 cm) of abdominal esophagus is the best guarantee of an effective antireflux choice of surgical procedure [40]. In newborns and older infants, we have demonstrated that the pars abdominalis is the cornerstone of the antireflux barrier [32].

Pinch-Cock Action

The esophagus crosses the diaphragm at the hiatus, a sling-shaped orifice formed by the right crux of the diaphragm. The anatomical disposition of this diaphragmatic sling pulls the esophagus to the right and downward, narrowing its lumen during deep inspiration [201]. As the esophagus passes through the hiatus, it is surrounded by the phrenoesophageal membrane. The insertion of the phrenoesophageal membrane [6, 69, 86] marks the level at which the esophagus changes from an intrathoracic to an intra-abdominal structure [39, 190, 310]. This pinch-

cock action of the diaphragm [222] can easily be observed during endoscopy and functions to increase the LES pressures [7–200] through the interaction of the axial movement of the LES and the diaphragmatic contraction [23, 43].

Angle of His

The angle of His is formed by the esophagus at its union with the stomach. In children with an abdominal esophagus of normal length, the angle of His is acute which creates a double antireflux effect. When the patient attempts to vomit, more gastric contents strike the fundus than escape through the esophagus. Pressure of the contents striking the fundus narrows the angle and compresses the esophagus. However, if the angle is obtuse (e.g., as occurs from a short esophagus, hiatal hernia, or esophageal atresia), the upper stomach is converted into a funnel and the fluids are directed into the esophagus. The concept of the angle of His must be kept in mind when considering the most appropriate surgical technique to correct reflux in children [33].

Mucosal Rosette

In the presence of a normal angle of His, there is a convoluted fold of mucosa with a rosette-like configuration at the gastroesophageal junction. With increases in intragastric pressure or with negative pressure in the thoracic esophagus, these mucosal folds squeeze together and act as a weak antireflux valve [240].

Crural Diaphragm: Loss of Extrinsic Support

The crural diaphragm constitutes the external mechanism of the LES [83]. The phrenoesophageal ligament anchors the distal esophagus to the crural diaphragm [43]; therefore contraction of the crural diaphragm exerts with the sling fibers of the right crus a pinch-cock-like action on the LES [173, 271]. Changes in the LES pressures are also related to contractions of the crural diaphragm. Normally these contractions are linked with respiration. Each inspiration increases the pressure [191–257]. The pressure gradient between the esophagus and the stomach is constantly changing and the esophagogastric junction pressure must constantly adapt to counteract these changes. This adaptive response is mediated through contraction of either the intrinsic esophageal sphincter or the crural diaphragm. The rapid contraction of the crural diaphragm, a fraction of a second earlier than the costal diaphragm, counteracts this increase in gastric pressure maintaining the antireflux barrier [191, 271].

Which minimum anatomical conditions and physiological pressures we have to achieve to ensure the antireflux barrier? Two pillars emerge as cornerstones for maintaining competence: a critical sphincter pressure to counteract increases in intragastric pressure and sufficient length of intra-abdominal esophagus to counter increases in intra-abdominal pressure. If either is reduced, the other one must increase if competency is to be maintained [7, 40]. A hiatal hernia or a short esophagus leading to an incompetent intra-abdominal esophagus, an obtuse angle of His, a weak mucosal choke, and reduction of the effective overall length of the LES weakens these cornerstones and permits GER [205]. Thus, a major goal when surgical therapy is indicated is always to create a sufficiently long intra-abdominal esophagus. We have been able to demonstrate in our pediatric patients that this length varies between 1.5 and 2 cm.

The competency of the antireflux barrier, LES, depends on [40, 331] a sphincter pressure above the 2.5 percentile (>6 mmHg), an intra-abdominal esophageal length in at least the 5th percentile (>1 cm), and an overall length of the LES above the 2.5 percentile (>2 cm) [129].

The reflux occurs when opening pressures exceed closing pressures, which is not always due to the incompetence of the antireflux barrier and may be due to a pathological increase of opening pressures [6, 87–89]. We have always said that a door will not open if nobody pushes it; therefore, it would be illogical to surgically reinforce normal mechanisms without paying attention to abnormal forces that are pushing [37]. Lately this traditional view held for many years has changed abruptly. The majority of cases with reflux is no more a problem of a weak antibarrier reflux or a pathological increase in opening pressures that opens a door. The problem now

is that the door opens automatically in the middle of normal parameters [246] the so-called transient lower esophageal sphincter relaxation" (TLESR) [304].

Opening Pressures

The retention and dilatation of the stomach creates a distracting force producing an increase in the tension of the gastric wall in the direction of the muscle fibers extending from the esophagus. This reduces sphincter length until the sphincter opens. The damaging effect of increased diameter could only be reversed by increasing the sphincter length, but gastric distension logically shortens the overall length of the intra-abdominal segment taking away the patient's last chance against reflux [169].

Delayed Gastric Emptying

In a study of the patterns of reflux, patients who had reflux in the upright position tended to have their reflux episodes within 2 h after a meal [84]. A radionuclide gastric emptying study in one of these patients showed significant DGE. A follow-up on this observation studied patients with symptoms suggestive of GER [185]. Gastric emptying was normal in those with reflux but without esophagitis and in the controls, but those with esophagitis had significant DGE. The techniques and clinical usefulness of radionuclides in the study of gastric emptying revealed that studies with radionuclide techniques showed DGE in more than 40 % of patients with GER [137]. Gastric emptying in patients with reflux was studied before and after fundoplications [188]. With both liquid and solid meals, gastric emptying was significantly more rapid 6 months after fundoplication than preoperatively.

Studies have shown DGE of water in children with GER [97], but other studies have found no significant differences in gastric emptying (using apple juice as the vehicle for the radionuclide marker) between patients with and without reflux [156]. In a separate study, the latter investigators focused on the relationship of gastric emptying to retching symptoms occurring following antireflux surgery [157]. This proved complex.

Experience with a large group of children treated surgically for GER has advocated pyloroplasty in conjunction with fundoplication when preoperative DGE is found [108]. In a review of 420 children treated surgically, the conclusion was that reflux and DGE were often a part of a more generalized intestinal motor disorder. Some 50 % of children with symptoms of reflux also have DGE, and this percentage is much higher in those with severe mental impairment. Again, the high risk of DGE with refluxing children who have serious mental retardation is emphasized [105].

Evaluation of gastric emptying in 99 children with GER revealed 28 with DGE [233]. Of the patients with DGE, 75 % were neurologically impaired (NI).

Some reported findings in NI children with GER are totally at variance to the above [193]. Another retrospective study in refluxing children with neurologic disorders confirmed that pyloroplasty was of little benefit [57].

Because there is no way to predict which patients with normal gastric emptying preoperatively would show DGE postoperatively and because the large majority of those with DGE preoperatively demonstrate normal gastric emptying afterward, a gastric drainage operation at the time of the antireflux procedure is not felt to be warranted [51].

Clearly, this issue remains unsettled. Because an antireflux operation often results in more rapid gastric emptying and because many children with DGE revert to normal gastric emptying patterns, perhaps it is reasonable not perform a gastric drainage procedure before the antireflux operation.

Total gastric emptying is delayed in 10–33 % of adult patients with GERD. Patients with GERD might have exaggerated postprandial fundus relaxation with retention of food and triggering of TLERs. Using simultaneous gastric emptying and esophageal pH impedance, some studies show that the slower the emptying, the higher the pH and proximal extent of the refluxate [94].

Breaking the Barrier

Why does GER occurred? Until the 1980s, the fault was believed to be low basal pressures in the

LES. On average, the basal pressure of the LES is lower in refluxing patients than in normal individuals, but there is a great deal of overlap. Surprisingly, GER is not uncommonly associated with a hypertensive LES [162]. In a study of asymptomatic people using combined continuous recordings of the esophageal pH and pressure, reflux occurred during transient drops in pressure (sphincter relaxations) not coincident with swallowing. These inappropriate TLESRs occurred spontaneously or immediately following the brief period of normal relaxation stimulated by swallowing (Fig. 91.1). Most of the episodes of reflux occurred within 3 h after eating. Extending these studies to patients with symptomatic GER, more than 80 % of reflux episodes occurred during periods of TLESR. Absent basal lower esophageal pressure became a significant mechanism with increasingly severe esophagitis and was associated with 23 % of GER episodes in the study group with most severe esophagitis.

These same monitoring techniques were used to study 29 children (ages 5 days to 2 years) with symptoms suggesting reflux [321]. Transient increases in intra-abdominal pressure (spontaneous or induced by stress) accounted for 54 % of reflux episodes, and TLESR accounted for 34 %. In a later study of another group of children with reflux using esophageal pH and pressure monitoring, all patients without esophagitis and 77 % of those with esophagitis had reflux episodes secondary to TLESR [71]. TLESR episodes have also been found to be the predominant mechanism of GER in 94 % of premature infants [214].

Recognition of TLESR, rather than low basal LES, as the primary mechanism of reflux clearly is a major step in our understanding of this disease. In TLESR, the drop in pressure is abrupt and profound and lasts, on average, considerably longer than the normal LES pressure drops associated with swallowing. TLESR is not associated with a peristaltic wave effective in esophageal clearance; the esophageal mucosa is exposed to the noxious effects of acid gastric contents for relatively long periods. Nonetheless, the previously described parts of the antireflux barrier remain essential to the prevention of reflux, whatever the exact causative mechanism of the reflux episodes may be. Hence therapy, medical or surgical, must continue to address and correct, whenever possible, the deficiencies in the antireflux barrier mechanism.

Once the gastric juice achieves the esophagus, the damage depends on the balance between the aggressive factors and the defense mechanism (Table 91.2).

Aggressive Factors

Refluxate

Refluxated gastric juice into the esophagus may damage the epithelium through the presence of hydrochloric acid (HCl), pepsin, bile salts (conjugated and deconjugated), and pancreatic enzymes (trypsin, lipase). However, when gastric pH is acidic, the major injurious factors are HCl and the acid-activated proteolytic enzyme, pepsin [294]. Deconjugated bile salts and pancreatic enzymes are ineffective at acid pH because acidity renders them either insoluble or inactive [184, 261]. Although acid/pepsin is crucial for the generation of the symptoms and signs of GERD, the rates of gastric acid and pepsin secretion in patients with GERD remain similar to those of healthy subjects. This similarity indicates that fundamentally GERD is not a disease of offensive excess but instead a disease resulting from the breakdown of one or more elements within the esophageal defensive system.

ions obviously is intimately related to the volume and acid of gastric secretion. We have demonstrated [30, 61] that patients with GER and elevated maximal acid output are at high risk of clinical symptomatology. However, studies in adults fail to show a direct correlation between esophageal mucosal damage and gastric hypersecretion. Further investigation in this area is required.

Defensive Factors

The hallmark of esophageal defense is represented by the luminal acid clearance mechanisms and the tissue resistance.

Esophageal Clearance

A prompt and efficient clearing of the esophagus by normal peristalsis is necessary to avoid prolonged contact between the vulnerable esophageal mucosa and gastric contents. We now know that essentially normal esophageal peristalsis occurs in healthy preterm and term babies. In both infants and children, peristaltic waves ranged from 2 to 6 s in all age groups [120, 133]. In newborns and infants (14 days to 11 months of age) with gentle regurgitation and with normal growth, peristaltic waves following swallowing were comparable with those of nonregurgitating infants in terms of duration, pressure, and progression.

A study of infants with significant reflux, however, shows a different picture. Thirty-four infants were evaluated for possible GER [11, 133]. Peristalsis was normal in those with vomiting but who were otherwise healthy. In those with failure to thrive or recurrent pulmonary disease, the amplitude of the peristaltic waves was significantly reduced and the frequency of nonperistaltic contractions was significantly increased.

Those patients with severe esophageal mucosal disease (esophagitis, stricture, Barrett's esophagus) showed impaired esophageal peristalsis that increased with the severity of the mucosal injury. Patients with reflux and esophagitis were compared with normal patients without reflux and to patients with reflux without mucosal inflammation [165]. The amplitude of peristaltic waves was lower in the esophagitis patients, and the degree of lowering increased with the severity of the esophagitis.

Esophageal peristalsis was studied in 27 infants with reflux, 3–20 months of age, by dividing the patients into those with esophagitis and those without [70]. Those with esophagitis had significantly lower amplitude of esophageal peristalsis than those with reflux alone, and nonspecific motor defects were more frequent in the first group. Most of the reflux episodes in both groups resulted from inappropriate (i.e., not associated with swallowing) relaxations of the LES, and this mechanism was more frequent in those with esophagitis. Thus, impaired esophageal peristalsis clearly is a feature of those patients with reflux complicated by esophagitis alone or with progression to stricture or Barrett's esophagus. Whether the impairment of motor function of the esophagus is a primary element of the disease or is secondary to acid reflux is not clear, but the available evidence weighs in favor of a secondary phenomenon [95].

Acid clearing, the interval while intraesophageal pH is <4 after a traditional acid reflux event, is a potential "blind spot" during pH monitoring, when reflux of acidified gastric contents may occur undetected by the pH probe. This is termed "acid rereflux." Acid rereflux comprised 61 % of acid reflux events in severe GERD. The detection of acid rereflux by impedance, manometry, and scintigraphy and the impact on acid-clearing pathophysiology will give an indication of the severity of antireflux barrier incompetence [266].

Tissue Resistance

Although clearance mechanisms minimize contact between acid and epithelium, the cumulative acid contact time, 1–2 h per day, even in healthy subjects, is significant. This observation emphasizes the necessity of having a third tier to esophageal defense against reflux injury. Tissue resistance is not a single factor but a group of dynamic mucosal structures and functions. For discussion purposes, tissue resistance can be broken down into three areas: pre-epithelial, epithelial, and postepithelial defense [219, 220].

The pre-epithelial defense is poorly developed with neither a well-defined mucous layer nor the

capacity of surface cells to secrete bicarbonate into the unstirred water layer.

The epithelial defense in the esophagus consists of structural and functional components. Structural components include the cell membranes and intercellular functional complex. These protect by limiting the rate of HCl diffusion into and between the cells. The functional components of tissue resistance include the ability of esophageal epithelial cells to buffer and to transport acid. The postepithelial defense in the esophagus is provided principally by the blood supply. Blood flow delivers oxygen, nutrients, and bicarbonate and removes H+ and CO_2. These functions provide protection by maintaining the normal tissue acid-base balance.

Traditional dogma states that GERD is a motor disease, primarily resulting from defects in the antireflux barrier. A strong case can be made, however, for GERD, at least in part, being due to an impairment in tissue resistance [220, 221].

GER: Lethal Vicious Circle

Exposure of the esophagus to gastric contents coupled with insufficiency esophageal clearance leads to esophagitis [25]. Esophagitis is not the end of the process; it is the starting point of a vicious circle. Esophagitis damages the vagal nerve fibers with consequent impaired motility both of the esophagus and stomach and leads to further esophageal damage.

As a result of the contact of the acid with the esophageal mucosa, there is an increase in the regional blood flow, increasing the local tissue content in prostaglandin E2. Prostaglandin increases the permeability of the mucosa to acid, which enhances the susceptibility of the mucosa for inflammation. Inflammation of the mucosa of the lower part of the esophagus causes an impairment of the LES (favoring GER), causing a dysmotility of the LES (favoring GER), finally causing esophagitis. The contact of acid on the esophageal mucosa causes an irritation, dysfunction, and inflammation of the local vagal nerve endings, causing an impairment of the LES and a pylorospasm. Both pylorospasm and impaired function of the LES favor GER.

Effective treatment depends on measures to block this vicious circle. Esophageal strictures [34] and Barrett's esophagus are the worst complications [63]. In Barrett's esophagus a columnar epithelium replaces the normal squamous epithelium in the lower esophagus [16, 20, 44]. Although a rare complication in children, the possibility of progression to adenocarcinoma makes early diagnosis and treatment clearly important [45–277].

Gastroesophageal Reflux Disease

GER associated with additional problems as abnormal persistence, growth retardation, and respiratory symptoms is the GERD. So GERD is present when the reflux of gastric contents causes troublesome symptoms and/or complications.

Groups at high risk for GERD are in Table 91.3. Certain conditions are predisposed to severe, chronic GERD.

Symptomatology and Complications

The complications of GER or GERD are the consequence of one of the following mechanisms: a chemical irritation of the distal esophageal mucosa, the loss of calories due to vomiting or refusal of food, and the aspiration of gastric contents or reflex mechanisms between esophageal innervation and the upper and lower airway. In some patients, more than one mechanism exists (Table 91.4).

Choking, otitis, sinusitis
Apnea
Seizure-like events
Sandifer's syndrome
Infantile arching

Regurgitation is, by far, the most common symptom of GER in infancy. A distinctive type of regurgitation begins early in infancy, usually within the 1st week of life. The regurgitation usually is effortless and occurs with burping or when the infant is returned to his or her crib after feeding. The vomitus does not contain blood or bile. This type of vomiting, termed chalasia, is benign and self-limited and rarely requires more than the simplest of treatment [210]. Occasionally, however, the regurgitation or vomiting is forceful or even projectile so that other causes, such as pyloric stenosis, must be considered. Most babies with such vomiting grow normally and do not develop other complications. Carré's study of the natural history of refluxing infants found that almost two thirds were asymptomatic by 2 years of age without treatment and that most improved before or at the time of weaning to solid foods [60]. Vomiting of this character may be considered physiologic and requires little in terms of either diagnosis or treatment.

A considerable number of vomiting infants develop significant problems. Some fail to thrive and become malnourished due to the vomiting. Others refuse feedings; perhaps swallowing is painful because of esophagitis [141]. Irritability is another symptom, which like refusal to eat, may be secondary to esophagitis and its associated discomfort. Respiratory symptoms are particularly important in babies with GER and range from coughing, wheezing, or stridor secondary to aspiration to acute life-threatening respiratory events such as apnea and near-miss sudden infant death syndrome (SIDS) [82, 159]. Because many respiratory symptoms in infants obviously arise from other sources, primarily the lungs, the causal relationship between such symptoms and GER is essential to determine prior to surgical treatment [9, 153]. Gross aspiration of gastric contents obviously can produce pneumonia, but this mechanism is rare with GER. Microaspiration with acidification of the trachea is more common, leading to laryngospasm or bronchospasm [290].

Spasm of the larynx and bronchi may also be caused by gastric acid stimulation of vagal afferents in the esophageal wall. Esophagitis probably enhances this mechanism [82, 153].

The effects of GER on premature infants with respiratory problems have been studied [138]. Most of these infants were intubated for varying periods owing to respiratory distress syndrome or bronchopulmonary dysplasia. In the former group, GER was responsible for deteriorating pulmonary status requiring reintubation. In the latter, deterioration of pulmonary status plus failure to thrive and anorexia led to the diagnosis of GER. All improved with correction of the GER [286].

In children, in contrast to infants, regurgitation is less frequently seen, and the symptoms of esophagitis predominate, as with adults. Heartburn, or substernal pain, is common.

The pain is increased with acid juices and relieved by antacids. There may be pain on swallowing. Some of the children also complain of dysphagia. The esophagitis may progress to stricture with severe obstructive symptoms in addition to pain. Carré's long-term study of untreated children found that about 4% developed strictures. With better management, that figure is now substantially lower.

Barrett's esophagus denotes a condition of metaplasia of the squamous epithelium of the lower esophagus with replacement by columnar epithelium. Chronic injury by reflux of gastric contents into the esophageal epithelium is

thought to be responsible. Although Barrett's esophagus does not produce specific symptoms, the condition is serious owing to the potential complications of stricture, ulcer, and adenocarcinoma. More than half of the children have associated strictures [124, 230]. Neither the response to treatment nor the risk of carcinoma in these children is as yet clearly defined. These children are obviously at high risk, and vigorous treatment to control or eradicate the reflux plus long-term surveillance is imperative.

The child with Sandifer's syndrome moves his or her head, neck, and sometimes upper trunk into strange and contorted positions. Torticollis without spasm of the neck muscles is common. The neck may be extended or twisted. The movements may be more striking with eating but cease with sleep. This syndrome, although rare, is associated with GER [189]. Owing to dystonia and bizarre posturing of the head, neck, and back, some children may be misdiagnosed as having a neurologic or even a psychiatric disturbance when the problem is GER and the solution is appropriate management of the reflux [46].

Diagnosis

Diagnostic procedures other than clinical evaluation should be used when the results will strongly influence treatment or will identify complications [98, 164]. For the infant with frequent regurgitation but who is thriving and is otherwise well, none are needed.

Tests are useful to document the presence of pathologic reflux or its complications to establish a causal relation between reflux and symptoms, to evaluate therapy, and to exclude other conditions. No test can address all of these questions, so test must be carefully selected and the limitations of each test must be recognized.

Radiologic Examination

When the diagnosis of obstruction is considered or when complications of GER are present, a barium study of the esophagus, stomach, and duodenum is appropriate. In expert hands, the diagnosis of reflux itself is made with a high degree of accuracy. A skilled, experienced radiologist is essential. Associated abnormalities are relatively uncommon, but conditions such as esophageal stricture, hiatal hernia, achalasia, tracheoesophageal fistula, pyloric obstruction, intestinal malrotation, or some other anatomic lesions responsible for vomiting can occasionally be clearly identified [5]. The barium study provides important anatomic information not available by other tests. However, the study is rarely useful for quantitation of the reflux. Routine performance of upper gastrointestinal series to diagnose reflux or GERD is not justified [309].

The radiologist can also evaluate the esophagus with respect to possible structural or mucosal irregularities. Esophageal peristalsis also may be usefully evaluated together with an estimation of the efficiency of esophageal clearance. Owing to the inert nature of the barium meal, the study does not permit a critical evaluation of gastric emptying.

Scintigraphy

This technique, using a technetium isotope, would appear to have a number of advantages. Reflux is accurately demonstrated. The study can be prolonged for perhaps an hour until the isotope has left the stomach, thus permitting images to be taken while the infant is quiet and undisturbed. It can be used with meals or formulas that neutralize gastric acidity, an advantage over pH monitoring in this circumstance. Some measure of esophageal clearance is possible. Evaluation of aspiration by detection of the isotope in the lungs would be a major contribution from the technique, but, unfortunately, its sensitivity for this purpose is low [21, 99]. Late postprandial acid exposure detected by pH monitoring may be missed with scintigraphy. The technique is of use in measuring gastric emptying. Nuclear scintigraphy is not recommended in the routine diagnosis and management of GERD in infants and children.

24-h Esophageal pH Monitoring

This technique was developed in the early 1970s for use in adults [150], but it was soon adapted for children [35]. A pH electrode of appropriate

size is positioned transnasally at the junction of the middle and lower thirds of the esophagus (usually 2.5–3 cm above the LES). The pH is continuously measured and recorded either on a strip chart or by a computerized pH recorder. A pH of 4.0 or less denotes reflux of acid gastric contents. The frequency and duration of reflux episodes are recorded. The number of such episodes longer than 5 min, the longest episode, and the percentage of time with pH less than 4.0 are also determined RI. An RI >7 % is considered abnormal, an RI <3 % is considered normal, and RI between 3 % and 7 % is indeterminate. RI is the most commonly used summary score. Finally, with the help of a parent or nurse, the relationship of reflux to a variety of activities is noted: sleeping, position, eating, and symptoms. Normal values have been determined, and a number of patterns of reflux have been demonstrated [66–151]. In the past, the study usually was performed in the hospital, but many are now being done quite satisfactorily at home. The test is the most reliable study available for finding occult episodes of reflux and for correlating reflux and symptoms [35]. The percentage of time the pH is under 4.0 (reflux index) is clinically useful as well as reliable with a sensitivity and specificity of 94 % or more [151].

The 24-h pH monitoring study is indicated in the following several specific circumstances:

1. Infants who have respiratory symptoms (apnea, near-miss SIDS)
2. Infants who are irritable, intractably crying, and anorectic
3. Children who have reactive airway disease (asthma) or unexplained or recurrent pneumonia
4. Children who are unresponsive to medical measures and in whom the role of GER in their symptoms is uncertain

Also, the study should be done in those children who again become symptomatic after fundoplication. On the other hand, the study generally is not useful or necessary for infants with uncomplicated regurgitation, children with esophagitis already found by endoscopy and biopsy, and children with dysphagia or heartburn thought to be caused by GER. Three patterns of reflux have been described in symptomatic infants as determined by extended esophageal pH monitoring [151]: continuous, discontinuous, and mixed. Those infants with the discontinuous type rarely required a surgical antireflux operation, whereas approximately half of those with the other two types did. One should keep in mind that medical treatment at the time of this study was much less effective than in the early 2010s. Nonetheless, this study indicates that pH monitoring can be useful in sorting out infants with GER who may or may not require an antireflux procedure [66, 148]. Incidentally, all of the infants in this study, including normal controls, refluxed frequently in the first 2 h following feeding (apple juice for this study). Esophageal pH monitoring is insensitive to weakly acid and nonacid reflux events. Abnormal esophageal pH monitoring has not been shown to correlate with symptoms severity in infants. But multiple case series report the use of esophageal pH monitoring to select the children reported to benefit from antireflux surgery.

Manometry

Esophageal manometry measures esophageal peristalsis, upper and lower sphincter pressures, and the coordinated function these structures during swallowing.

Manometry is responsible for much of our knowledge concerning GER. Maturation of the LES in early infancy was first demonstrated by this technique, only to be disputed later with the advent of more sophisticated micromanometric assemblies [214, 215]. The crucial importance of TLESR to reflux changed our entire concept of the cause of GER. The technique demonstrates normal and abnormal patterns of esophageal peristalsis and clearance. Pharyngeal swallowing has been shown to be the primary factor in clearing refluxed gastric fluid in the esophagus by a study using esophageal pH monitoring in conjunction with manometry. Development of smaller and more sophisticated pressure transducers and recording devices has permitted 24-h esophageal motility monitoring on an ambulatory basis. With

this method, deterioration of esophageal motility has been shown to parallel increasing degrees of esophagitis secondary to reflux in adults, and its use has been extended to children [284].

Esophageal manometry may be abnormal in patients with GERD, but the findings are not sufficiently sensitive or specific to confirm a diagnosis of GERD, nor to predict response to medical or surgical therapy. Manometric studies are useful to confirm a diagnosis of achalasia or other motor disorders of the esophagus that may mimic GERD. It does have a role in the child with a repaired esophageal atresia who develops reflux [269]. The lower esophagus in such a child characteristically has poor and disorganized peristalsis, and such an impairment is a major factor in determining treatment. Actually the most promising device that needs further development is the "sphinctometer" a solid-state "sleevelike system" that has been reported to record LES pressure in the ambulatory setting. The major advantage of this system is that it does not require any water infusion; therefore, it is convenient for prolonged LES pressure recording in the ambulatory setting [238]. However, only a handful of studies have been reported with this system, and it is not clear whether it can record TLESRs, the major mechanism of gastroesophageal reflux in normal subjects and patients with reflux disease.

Multiple Intraluminal Impedance

We have always assumed that retrograde flow of acid material from the stomach to the esophagus was the basic pathologic event of reflux disease. However, the situation has never been this straightforward. Trying to tie symptoms other than spitting and vomiting to pH-probe-detected reflux episodes has been particularly problematic. For example, in babies with spells of choking or colicky crying, a close association between pH-probe-detected acid reflux and these symptoms is not routinely found. Some spells coincide with episodes, but many do not.

With the use of the impedance monitor, which measures the movement of fluids, solids, and air in the esophagus rather than luminal pH changes, we are able to learn more about what is really going on in the esophagus [319].

During the last years some studies have evaluated esophageal impedance monitoring in adults and children, and these studies also raise more new questions.

The studies [312] indicate that the pH probe does not simultaneously detect the majority of reflux events defined by impedance monitoring, presumably because the fluid boluses are not acid.

Multichannel intraluminal impedance (MII) allows detection of bolus movements without the use of external radiation or radiolabeled substances. The principles of MII are based on changes in resistance to alternating electrical current (impedance) induced by the presence of various boluses within the esophagus. The timing of changes in multiple impedance-measuring segments in the esophagus allows determination of the direction of bolus movements. Combined MII and manometry provides simultaneous information on intraesophageal pressures and bolus transit, offers the ability to monitor all types of reflux, and allows the detection of the physical (liquid, gas, or mixed) and chemical (acid, non-acid) characteristics of the gastroesophageal refluxate [298].

Infants receive frequent milk feeds, and because milk is a potent buffer of gastric acidity, esophageal impedance should detect more reflux than pH recording. Indeed, impedance has the advantage over pH monitoring of being independent of pH, being better adapted to measure reflux during postprandial periods when reflux is buffered and to detect symptoms associated with non-acid or weakly acid reflux episodes. The high cost of the material and the investment in time necessary for interpretation of the recording remain a handicap in pediatrics [308].

The enhancement of the esophageal impedance may significantly change the definition of what is normal and what is abnormal for one of the most common conditions we treat [316].

Combined multichannel intraluminal impedance and pH-metry (MII-pH) is a technique that enables monitoring of gastroesophageal reflux independent of its acidity. Nonacid reflux can be associated with symptoms in patients with GERD symptoms.

The ability to detect non-acid or weakly acidic reflux events and to discern true reflux events from swallows could make it a more powerful tool than pH detection alone. Studies done in normal subjects and in GERD reveal that non-acid or weakly acidic reflux occurs frequently. MII has revealed non-acid reflux to be less common in untreated GERD subjects than in normal subjects. GERD subjects have greater degrees of liquid-type reflux events compared to normal subjects who have more gas-type reflux events. In treated GERD subjects and normal subjects, proton pump inhibitors do not seem to decrease the amount of reflux but render the non-acid or weakly acidic in nature [319, 328].

Multiple intraluminal impedance and pH electrodes can and should be combined on a single catheter and will provide useful measurements. Ambulatory MII-pH monitoring is a diagnostic tool, which is capable of detecting more than one type of reflux and achieves higher sensitivity and specificity to detect GERD than endoscopy or pH-metry. It is useful in patients with either typical or atypical reflux symptoms who are refractory to proton pump inhibitor therapy [136]. pH/MII facilitates a more focused therapeutical approach to patients with PPI-resistant GERD [17].

What is the real role of the multichannel intraluminal impedance technique in infants and children [303]?

New diagnostic trends: The acid rereflux, "acid clearing, the interval while intraesophageal pH is <4 after a traditional acid reflux event (RE)," is a potential "blind spot" during pH monitoring, when reflux of acidified gastric contents may occur undetected by the pH probe. This is termed "acid rereflux" [266]. Detecting acid rereflux in addition to traditional acid rereflux is most likely to occur in patients with severe esophagitis, postprandially, and in the recumbent acid provides a more reliable indication of the severity of antireflux barrier incompetence than the pH probe alone [242].

The combination of MII with manometry enables determination of the relationship between esophageal pressures and flow and, therefore, enhances evaluation of esophageal function in terms of assessment of mechanisms of esophageal volume clearance. This technique will improve our understanding of physiological mechanisms in pediatric GERD.

To distinguish primary peristalsis (to bolus swallowing) from secondary peristalsis (to spontaneous esophageal clearance) and to calculate the time of spontaneous bolus clearance (BCT) based on 24-h monitoring and multichannel intraluminal impedance allowed to determine the impact of surgical treatment [81]. So new diagnostic tools such as combined MII and pH-metry and Bravo capsule are described by some authors. Innovative techniques such magnification, narrow band imaging, and computed virtual chromoendoscopy are also reviewed [317].

Ultrasonography

Ultrasonography is not recommended as a test for GERD but can provide information not available through other technology. It can detect fluid movements over short periods of time and non-acid efflux events, can detect hiatal hernia, length and position of the LES relative to the diaphragm, and magnitude of the gastroesophageal angle of His. At present, there is no role for ultrasound as a routine diagnostic tool for GERD in children because there are low specificity (11 % color Doppler 15 min postprandially) but 95 % sensitivity when compared with the results of 24-h esophageal pH testing [149].

Endoscopy and Biopsy

Suspicion of esophagitis is the prime indication for this diagnostic technique. Irritability and anorexia in infants and heartburn or upper abdominal pain in children raise this suspicion. Dysphagia is another indication. The study is of particular value in NI children with vomiting, growth failure, and other confusing symptoms. The endoscopist may be unable to discern esophagitis on gross inspection [24, 197]. One study recorded abnormal mucosa in only 52 % of children with documented reflux. When the study showed inflammation, however, the finding was 100 % specific, and mucosal inflammation was found in none of the nonrefluxing patients. Owing to the lack of sensitivity of esophagos-

copy alone, mucosal biopsies are essential. Biopsies and microscopic diagnoses are both highly specific and sensitive (95 %) in the diagnosis of esophagitis [25, 68]. The histologic criteria for esophagitis on biopsy examination are well established. Intraepithelial inflammatory cells, eosinophils particularly, and morphometric measures of basal cell layer thickness and papillary height are highly specific for esophagitis. Clearly, the biopsy diagnosis of esophagitis is a most important finding because it demands prompt and vigorous treatment. The primary role for esophageal histology is to rule out other conditions in the differential diagnosis; GERD is likely the most common cause of esophagitis in children, but other disorders such as eosinophilic esophagitis, Crohn's disease, infections (*Candida albicans*, herpes simplex, cytomegalovirus), caustic ingestion, and connective tissue disease, graft-versus-host disease postsclerotherapy, radiation, and chemotherapy also cause esophagitis.

Esophagoscopy shows other esophageal abnormalities as well, particularly ulcer, stricture, and Barrett's esophagus. All three are severe complications of long-standing reflux and often coexist. Combining 35 patients from three separate studies on Barrett's esophagus in children, 16 strictures were identified [68–117]. The endoscopist often does not recognize the characteristic pink-red velvety appearance of Barrett's esophagus, emphasizing the importance of biopsies. The typical gross appearance of Barrett's esophagus at endoscopy occurs in only a minority of patients; the diagnosis rests on histologic biopsy examinations [68, 75]. Three types of metaplastic columnar epithelium may be identified: cardiac, fundic, and intestinal. There does appear to be some correlation between the type of columnar epithelium found and the potential for dysplasia or carcinoma [122].

In addition to esophagitis and its complications, esophagoscopy also may show isolated patches of gastric epithelium, thought to be of congenital origin, in the proximal esophagus. Postoperative complications of repaired esophageal atresia, such as stricture or recurrent fistula, may be visualized.

Summary of Diagnosis and Clinical Findings

Consideration of the symptoms, on the one hand, and the results of investigation on the other enable the diagnosis of GER to be made with a high degree of certainty. Abnormal physical signs may not exist, but note should be taken of the child's habitus and pulmonary findings. Despite knowledge of the natural history of GER, diagnostic delay is by no means unusual, particularly in those children whose GER leads to failure to thrive or in the group with respiratory problems. In these two groups in particular, various differential diagnoses must be considered, always bearing in mind that GER frequently coexists with other conditions. This is particularly true when GER is associated with comorbidity, as in children with neurological impairment or following esophageal atresia repair.

The following diagnoses can be recognized, but there may be overlap from one group to another.

1. The "spitters": These represent the majority of babies and infants with GER and have been well described by Jolley. A clinical diagnosis can usually be made, but under special circumstances, including parental anxiety, limited investigation may be required – rarely more than a radiographic study. Provided adequate explanation is combined with appropriate communication, there is no reason why this need adds to parental anxiety.
2. Where clinical suspicion is high, but the diagnosis may be in doubt. In this group, further investigation is required and this may take the form of 24-h pH-metry, multiple intraluminal impedance or esophagoscopy and biopsy or both.
3. Additional symptoms are present, e.g., irritability and "heart burn" (which is difficult to evaluate in children), and thorough investigation is essential, the nature of which will depend on modalities available. Manometry may be helpful; gastric scintigraphy has a definite role. In the final analysis, the pathway to follow is ideally the same as for the second group.

4. Clinical suspicion is aroused and investigation reveals an esophageal stricture. Endoscopic examination will usually determine the severity and response to dilatation.
5. When Barrett's esophagus is present, the symptoms are those of GER and/or an associated stricture.
6. Respiratory symptoms dominate the clinical picture – either the GER produces these symptoms or GER is a result of respiratory tract disease. This group requires a high degree of suspicion, particularity with asthmatic children or following repair of esophageal atresia, which should lead to appropriate investigation [256].
7. A miscellaneous group, including the Sandifer's syndrome, and in the neurologically impaired child [167, 280].

ln summary, therefore, diagnosis of GER should not be difficult, but difficulties arise, particularly when the symptomatology is atypical. Particular note should be taken of respiratory features because life-threatening episodes may be associated with aspiration into the respiratory tract.

It is important to know the technical aspects, indications, advantages, and disadvantages of each diagnosis method in order to appropriately use any of these tests.

History

Bright, in 1836, called attention to a partial stomach herniation, although there had been previous references in the literature (Billard P 1828 and Frank JP 1950).

During the following century, various authors described esophageal lesions, peptic esophagitis, hiatal hernia, and esophageal stenosis without relating their pathogenesis until 1935, when Winkelstein described for the first time the gastroesophageal reflux syndrome, already suggested by Jackson in 1922. Allison, in 1943 and 1951, described the pathogenesis and physiopathology of gastroesophageal reflux and suggested an anatomical repair of the hiatal hernia. In 1947, Neuhauser and Berenberg [210] brought reflux to the attention of pediatricians and coined the term "echalasia"; they outlined the clinical findings and suggested positional therapy for reflux.

Carré [59, 60] who described the "thoracic stomach" and demonstrated the salutary therapeutic effects of gravity on infants in the upright position and Roviralta [258, 259] who developed the concept of phrenicopyloric syndrome, in the 1950s, offered a basis for conservative treatment. Since the late 1960s, GER has increasingly been recognized as a condition that affects children frequently and, at times, with serious consequences. In the 1960s, it was characterized by the appearance of various types of operative procedures. Lortat-Jacob, Hill, Belsey, and Nissen and Rosetti [211] contributed most importantly to the operations employed today. From the 1960s to the present, the greatest progress has been made in diagnostic methods and in the investigation of the pathogenesis of gastroesophageal reflux and its complications. In 1977, Casasa and Boix-Ochoa assessed MAO as an objective indication of the need for operation. Normal secretion after stimulation with pentagastrin in an infant, according to the method described, is below 5 mEq/h/10 kg body weight. In symptomatic patients, gastric secretion did not recede, and MAO levels higher than 5 mEq/h/10 kg were observed. In 250 patients studied with this test, failed postural treatment was usually accompanied by a high MAO. In the last years, esophageal manometry, esophagoscopy and esophageal biopsy, "esophageal clearance" and immunologic defense of the esophageal mucosa, acidity tests, 24-h pH esophageal monitoring, scintiscan, alterations in gastroduodenal motility, duodenogastric reflux, multichannel intraluminal impedance, and factors that influence the peptic activity of the gastric content on the esophageal mucosa have been the subjects of publications.

Gastroesophageal reflux is perhaps one of the aspects of pediatric surgery that has advanced most over the last few years and generated the most interest, due to its variety of pathologic manifestations and associated complications. Synonymous for a long time with "hiatal hernia," that term has been abandoned for the more appro-

priate "gastroesophageal reflux," which denotes the incompetence of the antireflux barrier, while "hiatal hernia" only describes an anatomical anomaly that may or may not be accompanied by reflux.

Until the 1990s, medical treatment was relatively ineffective, and in all likelihood most of those babies and children who did become asymptomatic were taking advantage of the natural course of the disease. This left a large number who continued to have significant, at times life-threatening, complications, and surgeons eagerly rushed to fill this void. A number of effective and safe antireflux procedures were developed during these years, and by adopting one or more of these techniques, pediatric surgeons were soon performing large numbers of such operations [31–211]. Antireflux procedures now rank second or third in frequency of major operations performed by pediatric surgeons. Long-term results in several large series are excellent with open surgery, and complications are relatively few [108]. However, significant complications and failures do occur, and long-term results, although generally good, are by no means perfect.

At least two major advances in management are changing the therapeutic scenario in GER. First, of most importance, the proton pump inhibitor omeprazole has revolutionized medical treatment. This drug cures esophagitis with an effectiveness that is truly amazing in comparison with antacids, histamine receptor antagonists, and motility-enhancing drugs. Second, antireflux operations are being performed laparoscopically in increasing numbers. Although not a fundamental change in concept, this technique has proved to reduce both short-term postoperative morbidity and long-term complications such as intestinal obstruction.

In addition to these clinical advances, basic investigations have focused on mechanisms of reflux and emphasized the cause of reflux itself and the patterns and effectiveness of esophageal clearance. Much information has come from studies of lower esophageal pressure profiles in normal human beings and in patients with reflux esophagitis [88]. A wide variation in the basal LES pressures was found that bore little relationship to reflux, refuting the widely held concept of a direct relationship between a low basal LES and reflux. Instead, reflux occurred most often during periods of inappropriate, complete LES relaxation. These relaxations were inappropriate in the sense that they were not secondary to esophageal peristalsis initiated by pharyngeal swallowing.

These findings have been confirmed, and the proposition that such inappropriate LES relaxations are the primary mechanism leading to reflux has been widely adopted. Additional research using similar technical approaches has expanded our knowledge of esophageal peristalsis, normal and abnormal, the role of the diaphragm in prevention of reflux, and the unsolved question of delayed gastric emptying (DGE) as important factors in this knotty puzzle. Our understanding of the multiple and complex factors controlling the esophagogastric junction has increased remarkably but remains far from complete.

The detection of gastroesophageal reflux has been limited to acid exposure observed on 24-h pH monitoring. It is clear that non-acid reflux can be a significant clinical problem. Impedance technology with the capacity to detect all types of reflux (acid, non-acid, liquid, mixed, and air) has allowed to redefine GER. Over half of GER events were not detected by pH studies [15].

GERD has multiple etiologies, and understanding of these is important for determining which patients are the best surgical candidates. Proton pump inhibitors have become the mainstay of current treatment for primary GERD. Although laparoscopic surgery appears to be better than open surgery, there remain some morbidity and complications that careful patient selection can minimize. So, surgery for GERD should be performed only after failure of medical management or for specific problems [187].

Medical Treatment Approaches

After GER has been detected and diagnosed, the question is, which treatment should be applied, conservative or surgical? [31]. The decision

should be individual, depending on age, anatomical type, severity, and social environment. In the majority of cases, conservative treatment is the therapeutic of choice.

Conservative treatment is based on three pillars, feeding, posture, and drugs, which combined have the effect of potentiating the natural tendency of GER towards cure [72–223]. With this treatment, we have obtained 90 % of good results in 3,000 patients of less than 1 year, with a follow-up of more than 25 years in some cases and with the experience that each single patient needs his own tailored treatment.

Dietary Modifications

The emptier the stomach, the less possibility of vomiting; therefore the rule was less volume, more frequently, so it is almost important to avoid the preservation of large gastric volumes available to reflux.

It is difficult to formulate dietary guidelines for children with GERD. However, it should be taken into account that whatever diet is formulated, the nutritional needs of the infant should always be satisfied. In older children, dietary suggestions include a diet with normal to low fat and the avoidance of chocolate, coffee, tea, gaseous drinks, and spicy foods.

If emesis persists despite postural therapy and dietary recommendations including milk thickening, acid alginic can be given. The latter works by forming a floating viscous layer on top of the gastric contents and has been shown to decrease emesis frequency as well as intraesophageal acid exposure in infants and older children with symptomatic GER [53].

Thickening of infant formulas can be useful to reduce the frequency of emesis. It is possible that the increased viscosity of thickened feedings determines a more prolonged persistence a food in the stomach; however, controlled studies by using intraesophageal pH testing have shown that thickened feedings do not always reduce esophageal acid exposure as measured by intraluminal pH-metry [14]. It is likely that uncontrolled thickening of feeds can give rise to high-osmolality or high-viscosity meals with consequent gastric emptying delay and triggering an increase of reflux episodes as a result of TLESR [263].

In older children and adolescents, lifestyle changes include modification of diet and sleeping position, weight reduction, and smoking cessation.

Positional Therapy

The seated semi-upright position for an infant with reflux has been recommended since 1956 [60]. In the 1960s Carré showed that 60 % of children with GER treated in this way improved by the age of weaning and an additional 30 % improved by 4 years of age [59]. Other studies confirmed the effectiveness of this approach [259], and in Europe positional therapy in the chalasia chair remained the therapy of choice for many years. However, it is possible the improvement found in the symptoms was simply due to the natural evolution of the illness since a series of articles published between 1976 and 1983 showed by means of pH monitoring the semi-upright position worsened GER both in adults [84] and children [224, 243]. The European Society of Gastroenterology and Nutrition (ESPGAN) then recommended to lie babies in semi-elevated prone position until, in 1993, the British Department of Health recommended lying babies in the supine position, as prone position was found to be an independent risk factor for sudden infant death syndrome. Today, the ESPGAN still recommends the 30° prone position, but only as the second step after thickening of feedings has failed in improving symptoms.

In our experience, a program of semi-seated position (30–45°) 24 h a day and thickened and frequent small feedings to avoid overfilling the stomach gives satisfactory results in 80–90 % of babies under 14 months of age. Once instituted, this regimen should be continued for at least 6 months.

Failure of postural therapy may be related to social problems, chronic infections, or impaired

gastric clearance. In older patients postural treatment is impractical because of the virtual impossibility of maintaining the desired semi-sitting posture. Close attention to the details of how this plan is followed by the family members is most important to its success [223].

Esophageal pH and combined pH/MII monitoring show that reflux is quantitatively similar in the left-side-down and prone positions. Adolescents, like adults, may benefit from the left lateral decubitus sleeping position with elevation of the head of the bed.

Pharmacological Therapy

If symptoms persist despite a well-monitored program of postural therapy and dietary modifications, pharmacologic measures should be added.

Medical therapy includes the administration of one or more drugs that either increase esophageal peristalsis, increase LES pressure, increase gastric emptying, or lessen gastric acid production. In the last years the pharmacological therapy has changed.

The Prokinetic Drugs

The prokinetic drugs (bethanechol, metoclopramide, domperidone, cisapride) that were ordinarily tried first now are a second option. The drug most commonly used in the past which was cisapride (0.2–0.3 mg/kg dose) nowadays has been demonstrated that produces prolongation of the Qtc interval on electrocardiogram, and its use has been restricted to limited access, finding increasing risk of sudden death syndrome [239].

Although it has not been proven to diminish the frequency of TLESR, it increases the basal pressure of the sphincter, improves esophageal clearance, and accelerates gastric emptying; all are beneficial effects in the treatment pathological reflux. So, its use was been recommended by some on the basis of a clinical diagnosis alone [307] because we thought that cisapride was free from significant side effects. The experience has demonstrated the opposite. Because of recent concerns about safety, a critical and in-depth analysis of all reported adverse events was performed and resulted in the conclusions and recommendations by the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition that cisapride should only be administered to patients in whom the use of prokinetics is justified according to current medical knowledge. If cisapride is given to pediatric patients who can be considered healthy except for their gastrointestinal motility disorder, and the maximum dose does not exceed 0.8 mg/kg per day in three to four administrations of 0.2 mg/kg (not exceeding 40 mg/day), no special safety procedures regarding potential cardiac adverse events are recommended. However, if cisapride is prescribed for patients who are known to be or are suspected of being at increased risk for drug-associated increases in QT interval, certain precautions are advisable [18]. Such patients include those (1) with a previous history of cardiac dysrhythmias, (2) receiving drugs known to inhibit the metabolism of cisapride and/or adversely affect ventricular repolarization, (3) with immaturity and/or disease causing reduced cytochrome P450 3A4 activity, or (4) with electrolyte disturbances. In such patients, ECG monitoring to quantitate the QT interval should be used before initiation of therapy and after 3 days of treatment to ascertain whether a cisapride-induced cardiac adverse effect is present [179].

Measures to reduce gastric acidity should be added to this regimen in patients with complicated reflux, especially with esophagitis [91].

Histamine

H2 receptor antagonists decrease acid secretion by inhibiting histamine 2 receptors on gastric parietal cells. In one study of infants, ranitidine (2 mg/kg per dose orally) reduces the time that gastric pH is <4 by 44 % when given twice daily and by 90 % when given three times per day [287].

H2 receptor antagonists have a beneficial effect for patients whose respiratory symptoms are suspected of being caused by microaspirations. Other H2 receptor antagonists, such as cimetidine, have been associated with an increased risk of liver disease [247] and with gynecomastia [112].

Proton Pump Inhibitors

An antisecretory agent, omeprazole, has been demonstrated to reduce gastric acid production to zero [142–332]. It is a very powerful drug that affects gastric acid production for 72 h after cessation of administration. Proton pump inhibitors inhibit acid secretion by blocking Na+/K+ ATPase, the final common pathway of parietal cell acid secretion, often called the proton pump.

A prospective study determined the therapeutic dose range (0.7–3.3 mg/kg/day), efficacy, and safety of omeprazole for children. Up to date, changes due to hypergastrinemia observed in the gastric mucosa of children with long-term treatment with the drug (up to 4 years) are benign (fundic polyps, expansion of the parietal cells, and pseudohypertrophy of individual parietal cells) [127, 147].

Actually proton pump inhibitors (PPIs) are mainstay of treatment of the GER disease in children, because all the antacids or histamine receptor agonists (H2RAs) reduce acid secretion only by competing with the histamine receptor located in the parietal cell membrane, but the parietal cell receptors that responds to endocrine or vagal stimulation are not affected and there is not an effective blockade of the gastric acid production.

The pharmacology of every PPI involves targeting the gastric acid or proton pump (H+/K+-ATPase), which is situated in parietal cell membranes. Active drug irreversibly binds to cysteine residues within the H+/K+-ATPase via a covalent bond. Consequently, PPIs inhibit the final step of gastric acid secretion by blocking proton production [235].

Experience with these drugs in children indicates that they can be used in very resistant esophagitis and in special situations, such as GERD in neurologically impaired individuals. An initial dosage of 0.7 mg/kg/day has been suggested, with subsequent adjustment by repeated prolonged intraluminal esophagogastric pH-metry [142, 332].

A study has shown that omeprazole is highly effective even in grade IV esophagitis [143]. A dosage of 0.7 mg/kg/day healed 45 % of patients and 1.4 mg/kg/day healed another 30 %. On a body weight basis, the dosages required in children are generally higher than those in adults. For children unable to swallow the whole capsule, it is suggested to open the capsule and give the granular contents in a weakly acidic vehicle such as orange juice, yogurt, or cranberry juice. The granules are stable in acid but are degraded in a neutral or alkaline pH. Actually new PPIs competing in excellence are in the market: lansoprazole, rabeprazole, pantoprazole, esomeprazole, and dexlansoprazole in the line to offer better medical possibilities [1, 62, 171, 265].

But the pediatric surgeon has to bring to discussion if we are delaying the final treatment, looking for a better quality of life. PPIs appear to be well tolerated for short-term use (3–7 months), but studies to assess long-term safety are needed because the significance of chronically elevated gastrin levels in children is unknown.

There are potential risks associated with acid suppression results from PPI therapy in infants [226].

There are four main categories of adverse effects related to proton pump inhibitors: idiosyncratic reactions, drug-drug interactions, drug-induced hypergastrinemia, and drug-induced hypochlorhydria. Idiosyncratic side effects occur in up to 14 % of children taking this drugs. The most common are headache, diarrhea, constipation, and nauseas, occurring in 2–7 %. Every solution opens new questions. What is the effect of proton pump inhibitors PPI on gastric emptying? The delaying effect of PPI on gastric emptying of solid meals is consistent, whereas the effect of PPI on the emptying of liquids is inconsistent. Some hypothesis are that gastric emptying involves a process of peptic hydrolysis. PPIs impair the hydrolytic digestion by inhibiting acid-dependent peptic activity, thereby delaying the solid emptying. Gastric emptying of liquids largely depends on volume and energy density of intragastric contents. Hypergastrinemia has been considered to delay gastric emptying. The delayed emptying of solids due to PPI therapy may have clinical implications in the management of gastroesophageal reflux disease [264].

The GABAβ Agonist Baclofen

The GABAβ agonist baclofen recently has been demonstrated that in normal subjects, *it significantly inhibits gastroesophageal reflux* by inhibition of transient LES relaxations [180]; these findings suggest that GABAβ agonists may be useful as therapeutic agents for the management or reflux in patients with GER disease inhibiting the triggering of TLESR by acting centrally on the pattern generator in the brainstem [26–48]. Baclofen reduces postprandial acid and non-acid reflux and their associated symptoms. GABAβ agonists may have a role in treating GERD. Actually it is the most promising drug and in the next years a research field as the major inhibitory neurotransmitter within the central nervous system controlling the rate of TLESRs, the key mechanism underlying most episodes of GER. Compared with other available agents, baclofen is available as an oral agent and does not have adverse effects on basal LES pressure or acid clearance. Side effects are common, however, and include drowsiness, nausea, and the lowering of the threshold for seizures. It is hoped that new compounds with more specific and better targeted action will be developed in the future [109, 248, 312] (Table 91.5).

Surgical Treatment Approaches

Surgery is the next step and one that should be effected without delay when conservative treatment fails or age, type of anatomical anomaly, severity, respiratory complications, and social environment make it necessary. In the 1990s effective and safe antireflux surgical procedures were developed, and pediatric surgeons had been performing large numbers of antireflux procedures. In the 2000s they continue to rank second or third in frequency of major operations performed by pediatric surgeons. At present, a surgical decision is easier to make than 25 or 30 years ago, seeing as short- and long-term results and few complications make this a safe therapeutic method with very few risks [106]. On the other hand, results of surveys affected among parents show that 97 % of them were satisfied with the postoperative results, different from surgery in adults, whose symptoms persist in 27–54 % of patients. All the surgical techniques are good, but have a different philosophy.

A variety of operative techniques result in long-term control of reflux with low mortality and few complications [36–158, 278, 315].

Table 91.5 Therapy of reflux

Conservative
Position – semi-seated
Avoid large meals, tight clothing
Avoid foods and medications that lower LES
Pharmacology
Proton pump inhibitors
TLESR inhibitors: GABA – baclofen
Surgical: laparoscopic fundoplication
Two philosophies:
Restoring physiology
Boix-Ochoa, Thal, Toupet
Creating a valve: Nissen fundoplication

Nissen Fundoplication

Two different concepts govern the most commonly used operative procedures. In the first, a "tight valve" is constructed as a permanent substitute for the child's ineffective antireflux mechanism. The Nissen FP is the prototype utilizing this concept. Recent research in adults suggests that this "mechanical mechanism" has its functional counterpart in the form of inhibition of triggering of transient LES relaxations and prevention of the completeness of LES relaxation.

In the second concept, the aim is to correct the abnormal anatomy so as to permit the normal physiological antireflux mechanisms to become effective.

Thal-Ashcraft and Boix-Ochoa Techniques

The Thal-Ashcraft and the Boix-Ochoa operations are examples. The essentials of these approaches are provision of a sufficiently long intra-abdominal esophagus, fixation of the

intra-abdominal esophagus in place, and restoration of the angle of His. Both the Thal-Ashcraft and the Boix-Ochoa techniques allow a physiologic degree of GER, avoid gas bloat, and even permit vomiting (Table 91.5).

Results of both approaches are excellent, at least in neurologically normal (NN) children, although the Nissen procedure is followed by a higher incidence of complications [126–289].

The aim of the Boix-Ochoa procedure is to restore the anatomic relationships and the physiologic characteristics of the lower esophageal sphincter mechanism (Fig. 91.2). This may be achieved by restoring the length of the intra-abdominal segment of the esophagus, repairing the widened esophageal hiatus in the diaphragm and anchoring the esophagus to its margins, and restoring the angle of His. The final step comprises the opening up or unfolding of the fundus of the stomach (as in opening umbrella) by inserting suspending sutures between the fundus and the diaphragm. The procedure has the effect of increasing the length of the intra-abdominal segment of esophagus, which restores the normal closing pressure mechanism. Reconstruction of the angle of His provides the mechanism for compressing and closing off the esophagus, while unfolding the fundus of the stomach buffers the effect of raised intragastric rpessure and enhances the mechanical closing of the esophagus. Between 1966 and 1992, a total of 2,566 patients were assessed for gastroesophageal reflux: 65 had major hiatal hernias. The total number undergoing antireflux surgery was 224 (8.7 %). Follow-up studies on 180 patients 2–18 years after the operation revealed excellent radiological and clinical results in 168 (93 %) cases. In 12 patients reflux could be demonstrated on radiological assessment but the children were asymptomatic. Two patients required reoperation. In this series the complications were adhesion obstruction 3, postoperative pneumonia 5, mediastinitis secondary to perforation 1, and esophageal stenosis 2 [33].

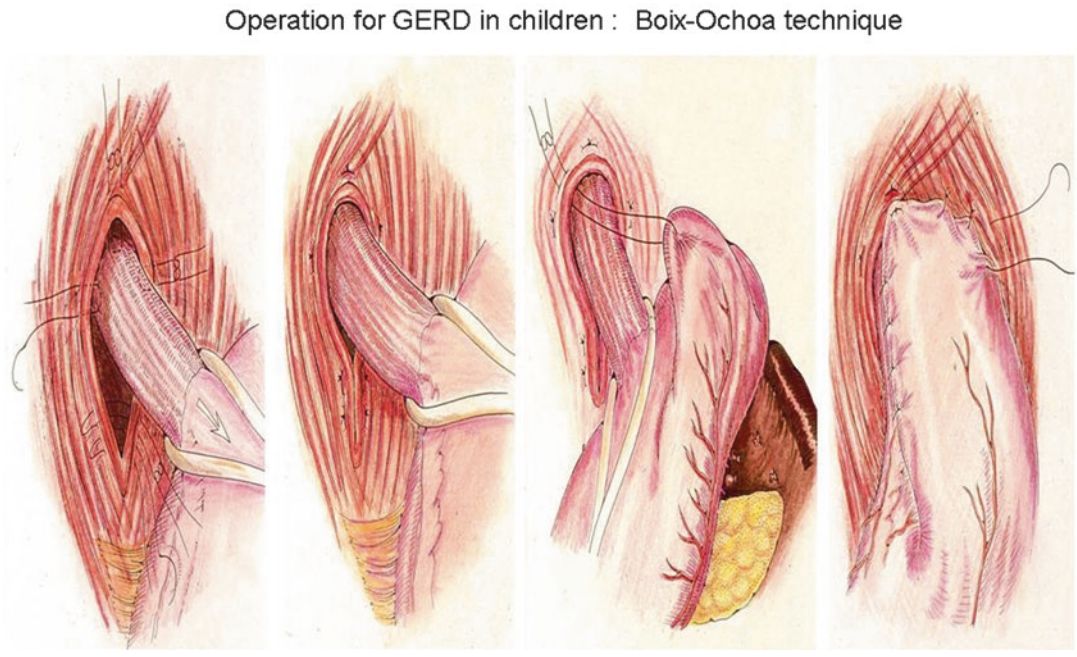

Fig. 91.2 Operation for GERD in children Boix-Ochoa. The length of intra-abdominal esophagus is restored, the esophagophrenic ligament sutured to the edges of the crura, and the crura tightened. The angle of His is restored by a suture taken from the fundus, well down on the fundus at the level of the highest short gastric vessels, to the rim of the hiatus superiorly and on the *right*. Reinforcing sutures maintaining the stomach in this position are placed between the fundus and the anterior esophageal wall. Suspending sutures tacking the fundus to the diaphragm unfold or open up the fundus like an umbrella

Still, the most widely used procedure is that described by Nissen and Rosetti [33]. The technique consists in wrapping the gastric fundus around the intra-abdominal esophagus and the gastroesophageal junction. This wrap acts as a valve to impede reflux. The Nissen fundoplication has been used much more frequently than any other operation. The lower esophagus is mobilized so that an adequate intra-abdominal length is assured. By passing the fundus from left to right behind the esophagus, a 360-degree wrap is performed. This usually requires division of at least some of the short gastric vessels. The right and left margins of the wrap are sutured together anteriorly; these sutures include the anterior esophageal wall. The superior margin of the wrap is fixed to the hiatus with a few additional sutures. The wrap should be relatively short (depending on the age of the child) and constructed loosely (floppy). The wrap transmits intragastric pressure to the lower esophagus, raises the LES pressure, and acts as an effective one-way valve. A gastrostomy is often added for a vent in case the child develops gas bloat or for feedings [52, 108]. It is almost routinely added in NI children [213].

Early postoperative complications are uncommon [177, 282]. Small bowel obstruction has been reported in 4–9 % in the first 2 years after operation [155–299]. Most of these resulted from intra-abdominal adhesions. A more significant problem is failure of the wrap, occurring in from 4 % to 12 % in the larger series [79–244]. These failures usually resulted from disruption of the wrap or herniation of the wrap upward through the hiatus. Reoperation on those with a failed wrap was successful on a long-term basis in about 75–80 %, and overall long-term good results are reported at about 90 % [177, 299, 324].

In the Thal procedure, the lower esophagus is freed and the crura approximated posterior to the esophagus as in the previous techniques. A partial, 180-degree anterior fundal wrap is then constructed; this partial wrap attaches to the intra-abdominal esophagus. Like our procedure, it is technically simpler than a Nissen procedure and has a shorter operating time. The incidence of postoperative intestinal obstruction is low (<1 %), probably due to a transverse upper abdominal incision with minimal exposure of the intestine [291]. In a series of 1,150 patients, disruption of the fundoplication and recurrent GER have occurred in only 2 % and with recurrent hiatal hernia in another 2 %. A distinct advantage of a lesser wrap is the very low incidence of gas bloat syndrome, so that a gastrostomy is rarely done. These children are able to burp or even, when necessary, vomit. Overall good results exceed 90 %. In both series, the number of NI children was low, whereas in most other large series, the incidence of NI children is often 50 % or higher [12].

Partial Wrap Method, Toupet Procedure

Another partial wrap method is the Toupet procedure, also developed to minimize the gas bloat problem. In this operation a partial, 270-degree wrap is positioned posterior to the esophagus. The preliminary steps of the technique are identical to the previous two procedures. The Toupet procedure can be performed through an upper abdominal transverse incision, so that exposure of the intestine is largely avoided. After the crura have been approximated to restore the size of the hiatus to normal, the gastric fundus is passed posterior to the esophagus. The posterior aspect of the wrap is sutured to the right crura. The margins of the wrap on either side are then sutured to the right and left margins of the esophagus, leaving the anterior esophageal wall free. Experience with this operation in 112 patients revealed that 30 % were NI [19]. The early postoperative courses were generally benign, but two developed intestinal obstruction. On late follow-up evaluation, the outcome was excellent in 90 %.

Minimal Invasive Surgery: Laparoscopic Fundoplication

Laparoscopic approaches to fundoplication are being reported with increasing frequency. In 1991, the feasibility of performing Nissen fundoplication in 12 adults using a laparoscopic

approach was demonstrated [77]. Laparoscopy has changed the promise in terms of reducing short-term postoperative morbidity and decreasing number of complications as intestinal obstruction for a reality nowadays. Pediatric laparoscopic fundoplication is achieved with five trocars placed in the upper abdomen [116].

The dissection of the histus is begun by dividing the gastrohepatic ligament, then the phrenoesophageal ligament is incised, the short gastric vessels are divided, the fundus is separated from diaphragm, and the cura is dissected. Care is taken to avoid vagal nerve trunks. For a Nissen fundoplication a 2 cm wrap is constructed with interrupted sutures by attaching the fundus to itself anteriorly at the 10 o'clock esophageal position. The fundoplication is then secured to the undersurface of the diaphragm with two or three nonabsorbable sutures to prevent migration of the wrap into the chest. A "loose" Nissen wrap is preferred. A Maloney dilator is placed within the esophagus to fully dilate it and prevent narrowing while the wrap is constructed [114]. The experience with 268 laparoscopic fundoplications showed recurrence rate about 8 %, with 12 % in the Toupet group and 5.5 % in the Nissen fundoplication group [231, 260].

In rapid succession, additional reports appeared confirming the practicability and safety of this technique in adults. To show how the pendulum has swung in some quarters vis-à-vis medical treatment, a recent report proposed laparoscopic fundoplication as a reasonable alternative to omeprazole [10]. Reports of endoscopic antireflux operations performed on children appeared soon after with documentation of both feasibility and satisfactory short-term results [115, 186]. One group's experience not only detailed the learning curve but also described a rapid drop in the percentage of cases in which conversion to an open operation was required, from 30 % after the first 20 cases to a cumulative rate of 7.5 % after 160 cases [195]. A similar drop in complication rate was also noted, falling from an early 12 % rate to a final cumulative rate of 7.4 %.

Esposito C. et al. published in 2000 results about laparoscopic approach in 289 children affected by GERD, ages between 4 months and 17 years, 141 Nissen Rossetti and 141 Toupet, and the duration of surgery was between 40 and 180 min and conversion to open surgery 1.3 %.

The same results published by Ostlie DJ et al. and length of stay 1.2 days, operating time 91 min, time to initial 7.3 h, and time to full feedings 21.8 h in laparoscopic fundoplication in children (Table 91.6) concerning length of stay.

Similar results were published by J Gill et al. also in 2007 after the learning curve of a single surgeon over a 10-year period: operative time 86 min, length of stay 1.2 days, and conversion to open operation 2 %.

The utilization of esophageal mobilization to create a 2–3 cm length of intra-abdominal esophagus has been practiced very frequently for many surgeons. Recently, a retrospective study coordinated by the Children's Mercy Hospital in Kansas City and University of Alabama in Birmingham (St Peter et al. 2010). suggested that minimal esophageal mobilization with no violation of the phrenoesophageal membrane may reduce the risk

Table 91.6 Operative conversions to open procedures decrease with experience, not the number of reoperations Gill J, Booth MI, Stratford J, Dehn TC. The extended learning curve for laparoscopic fundoplication: a cohort analysis of 400 consecutive cases. *J Gastrointest Surg*. 2007;11(4):487-92.

of postoperative migration of the fundoplication wrap into the lower mediastinum and the need for a redo operation.. This study analyzes 177 patients between 2 years, and transmigration rate was 30–7.8 %. The reoperation rate was 18.4 % in the mobilization group and only 3.3 % in the group with minimal esophageal mobilization. The mean operative time was 82.5 ± 2.2 min and 83.9 ± 21.0 min in both groups, maximal and minimal esophageal mobilization,

Transhiatal wrap migration is the dominant mode of failure after laparoscopic Nissen fundoplication with relatively high rates of reoperation reported in large case series.

As has been found in most other studies of fundoplication operations, the complications occurred significantly more often in the NI than in the neurologically normal. The early complications after laparoscopic Nissen were 41 % in NI patients versus 17 % in NN patients. The late complications occurred in 13 % of NI patients and 0 % of NN patients. The authors conclude that the laparoscopic technique is superior to the open method in the performance of Nissen antireflux procedures [144, 161].

Results

The results of the combined experience with antireflux operations from seven large pediatric surgical departments are encouraging [107] A total of 7,467 children were included. Significant clinical improvement was recorded in 94 % of NN children and in 84.6 % of the NI group. Major postoperative complications were recorded in an average of 4.2 % of the NN patients and in 12.8 % of the NI patients. These data show the significant differences between NN and NI children, but more important, they emphasize the satisfactory overall outcome in both groups.

Laparoscopic Nissen fundoplication has largely replaced open Nissen fundoplication as the preferred antireflux surgery for adults and children, due to its decreased morbidity, shorter hospital stays, and fewer postoperative problems. In a series of 456 children undergoing surgery younger than 5 years of age, Diaz et al. reported that those with laparoscopic Nissen fundoplication had a higher reoperation rate than those with open Nissen fundoplication. Average time to reoperation with laparoscopy was 11 months versus 17 months for open surgery. In children with comorbidity, the probability of reoperation was 18–24 % after laparoscopy, compared with 6–16 % for open surgery [90]. The annual number of antireflux operations has been on the increase in the United States, especially in children younger than 2 years [176]. In contrast, in adults, rates of fundoplication are declining in the United States and have dropped 30 %.

The larger question is not which operation, but, rather, when. Until the mid-1990s, the indications for surgery were reasonably easy to define. The results of nonoperative therapy for the severe or potentially dangerous complications of reflux were generally unsatisfactory; hence failure of medical management was common in those children at the highest risk of significant morbidity or even death. As a consequence of omeprazole, the most appropriate therapy for children with severe GER is evolving, and our present concepts of the indications for surgery are changing, in front of the appearance of new drugs that they have enhanced the medical treatment. But how long is the medical treatment? Which are the consequences of a long medical treatment from infancy to adulthood? That is the unsolved question!

Both medical and surgical treatments have advantages and drawbacks. Omeprazole does not control reflux directly; rather, omeprazole is effective by reducing gastric acidity almost to the vanishing point. This permits healing of even severe esophagitis in many children and prevents acid reflux into the esophagus, thus quite possibly preventing some of the respiratory complications. However, its effectiveness disappears when the drug is stopped; gastric acidity returns and the original problems of the disease reemerge. Hence, lifelong treatment appears to be a requirement for lifelong effectiveness. Fundoplication, ideally, is a one-time episode that is both effective and long lasting. Often this is true, and a number of series with long-term follow-up evaluation show highly satisfactory

eventual results in more than 90 % of the children [107] concerning long-term effectiveness and complications. Combined study with follow-up with omeprazole in children by contradict some of the data and conclusions [128]. They point to the relatively high morbidity of antireflux procedures in high-risk children such as those who are NI and those who had previous repairs of esophageal atresia. The excellent short-term results with omeprazole in these high-risk groups make the medication a viable alternative. Fundoplication is believed to be best reserved for those with proven or probable risk of aspiration from below and for the NN children whose results from surgery generally are excellent [292]. At the least, such drug therapy may provide a considerable amount of relief and permit postponement of the decision for or against surgery for considerable time.

There is no consensus on the indications for surgery in GERD. Patients who are well maintained on medical therapy have more to lose with surgical intervention than to gain. Nowadays, clear candidates include patients with anatomic abnormalities, large hiatus hernia, or symptoms despite medical therapy, carefully selected patients with extra-esophageal disorders, incomplete response to medical therapy, and persistent plus demonstrable reflux on pH or impedance testing [300]. Careful selection of patients is the key for surgery in GERD. Antireflux surgery may be of benefit in children with confirmed GERD who have failed optimal medical therapy, or who have failed optimal medical therapy, or who are dependent on medical therapy over a long period of time, or who are significantly nonadherent with medical therapy, or who have life-threatening complications of GERD. Children with respiratory complications of GERD are at the highest risk for operative morbidity and operative failure. Before surgery it is essential to rule out non-GERD causes of symptoms and ensure that the diagnosis of chronic-relapsing GERD is firmly established. It is important to provide families with appropriate education and a realistic understanding of the potential complications of surgery, including symptoms recurrence.

Discussion of the Surgical Techniques

In medicine, as in life, time teaches you that nothing is absolute. Therefore no technique is the best and the antireflux operation should be tailored to the child's situation [128].

One has to be very cautious in interpreting the results published, since the groups are different in its percentage of composition [279–325]. The results with the Boix-Ochoa procedure are too good in comparison with other publications; the key is that we are dealing with a group, where only 7 % of the patients are neurologically impaired in contrast with other groups [41, 192]. And the neurologically impaired patient is the most difficult to deal with and has more complications [217, 283].

How I see the problem of choosing a procedure nowadays? It depends on the child's situation, if it is possible to restore the normal physiology or there is a severe damage. In changing the normal physiology and creating a valve, the side effects are greater [76, 330] as happens with the Nissen technique. Inability to burp or vomit and gas bloating are linked to the competence of the valve, and the dumping syndrome perhaps is due to the reduction of the gastric volume related to the operation [301]. But which seemed a disadvantage, it is the clue why Nissen procedures work better than other techniques in the worst cases [58, 198]. Long-term results are excellent, but significant complications and failures do occur, and long-term results are no perfect.

Some authors has described the failures, causes, and feasibility in laparoscopic redo fundoplications (Lopez (2008) Laparoscopic redo fundoplication in children: failure causes and feasibility). Would it be possible to decrease redo fundoplications in the future? The reoperation rate was 18.4 % in the laparoscopic group with maximal esophageal mobilization. It is high than in open fundoplication. Laparoscopic fundoplication in the future must improve the technique in order to achieve the best results and lower redo fundoplications.

The investigations show that fundoplication through the extrinsic compression of the LES

segment by the wrap provides a nadir and basal LES pressure in the absence of the same and a reduction of TLESR due probably to a reduction in the degree of fundic distension [145, 169].

In our experience, the Boix-Ochoa antireflux procedure should be the procedure of choice in the surgical treatment of GER in otherwise normal children, while the Nissen fundoplication is preferable in neurologically impaired children and in patients with GER following esophageal atresia repair [65].

Impedance monitoring can be useful to evaluate the different endoscopic antireflux procedures on the different types of reflux episodes with regard to gas-liquid composition and pH, as well as on volume clearance and the proximal extent of the reflux [67].

The best technique is the operation that gives a solution to the patient, not the surgeon. So GER doesn't need surgery but GERD needs good technical surgery. Discrimination between both GER and GERD is essential.

GERD in Special Situations

GERD and Neurologic Impairment

The most difficult clinical problem in the field of GER is the overall management of the severely neurological impairment (NI) child with persistent vomiting. Vomiting is much more common than in normal children; 15 % of institutionalized, severely retarded children had recurrent vomiting with a frequency of at least eight episodes per month [276]. Three quarters of the vomiting children were shown to have GER. Earlier, such vomiting was largely felt to be psychogenic in origin or simply part of the primary neurologic disease, and little effort was made to critically investigate the cause. Perhaps for this reason, although the vomiting often began early in infancy, diagnosis was usually made relatively late. In those for whom a surgical antireflux procedure was eventually done, the average age at operation was considerably higher than for normal children. Retarded children's representative average and mean ages at operation were 7.5 and 5.9 years, respectively [279, 305].

A number of manifestations or complications of the primary neurologic disease are common. This may both delay the diagnosis of and predispose the child to the development of GER. Vomiting is the most common of these complications, and its misinterpretation is a major factor in delay of diagnosis. Difficulty in feeding and even refusal of feedings are frequent problems in these children, problems not uncommon with GER as well. The vast majority of the NI children are nonverbal; communication and proper identification of symptoms may be exceedingly difficult. A similar proportion also are nonambulatory; therefore, gravity as an aid to esophageal propulsion is not helpful. Increased intra-abdominal pressure also probably plays a role. Scoliosis, spastic quadriplegia, and seizures all are problems in many of these children and all result in periodic elevations of intra-abdominal pressure, enough to overcome the normal antireflux barrier and allow chronic reflux. Severe growth retardation is also common in these children. Complications of GER itself are generally more advanced in NI children than in the normal group. Esophagitis is the most prominent of these. Esophagoscopy has been used as a major diagnostic tool in many reported studies, and esophagitis has been a common finding (66–100 %) [29, 54]. Esophageal stricture, as expected, is frequently identified [325]. Barrett's esophagus, a condition associated with both esophagitis and stricture, also has been found much more commonly in NI than in NN individuals. In one study of institutionalized adults, 26 % had Barrett's esophagus changes on esophagoscopy and biopsy [252]. Another study in children and young adults found a strikingly higher incidence in the mentally retarded group as compared with the normal group [274]. Respiratory problems, particularly repeated episodes of pneumonia, are common and almost always require hospitalization. Various investigators have documented these problems in from 35 % to 85 % of the patients [279–325]. One group of investigators found that 18 % of the children had a history of apneic episodes prior to surgery [280]. Obviously, many of these complications, both of the disease and of GER, are interrelated, and a careful, methodical evaluation is essential when

planning appropriate management. Equally obvious, most of these children have a serious and advanced degree of reflux disease [274].

Quality of life of children with neurological impairment who receive a fundoplication for GERD was improved from baseline in several domains 1 month after surgery [281].

NI had longer lengths of stay and higher mortality rates than did neurologically normal children after antireflux procedures [176].

Diagnostic studies in this group of children are basically the same as in the NN group, but a few modifications are in order. The radiologist, while performing the barium upper gastrointestinal series, must pay particular attention to the possibility of orotracheal aspiration. An antireflux procedure may not be helpful if oropharyngeal aspiration is significant, and, indeed, the problem of aspiration might be worsened. Abnormal esophageal motility is relatively common, perhaps secondary to esophagitis. Hiatus hernia is more often found in NI patients than in the NN group, 51 % in one study [56]. Extended esophageal pH monitoring can be accomplished as a standard method, but in some, the probe is poorly tolerated and may be pulled out at the slightest provocation. Endoscopy with biopsy is helpful as noted previously, because the incidence of esophagitis, stricture, Barrett's esophagus, and hiatus hernia is relatively high [118, 275].

Enteral Feeding in NI with GERD

The provision of adequate nutrition in NI children is often the primary goal. Enteral feedings via a nasogastric tube generally were considered impractical, except as a short-term method in infants with malnutrition secondary to GER. In one study, 12 infants (11 NN) were treated with continuous infusion of formula through a small-caliber nasogastric feeding tube for 11–13 days. Of the 12 infants, 8 had a favorable early response with adequate weight gain and cessation of vomiting [100].

Gastrostomy is the most common long-term solution for enteral feeding. The procedure can be done by a standard Stamm gastrostomy or by the percutaneous endoscopic gastrostomy (PEG) method [113]. The Stamm gastrostomy can be done via a laparotomy or laparoscopically. PEG is a quick and simple technique and has been widely adopted, although it has some unique complications of its own. A substantial number of children without prior clinical evidence of GER develop reflux after a gastrostomy, irrespective of whether the procedure is a Stamm or a PEG [119–322]. About two thirds of children who have normal studies prior to gastrostomy develop GER postoperatively, and about half eventually become symptomatic [175]. Why gastrostomy causes GER remains undetermined; widening the angle of His by pulling down the fundus during the procedure is one possible explanation. Owing to the high incidence of reflux following gastrostomy, routine antireflux operations have been recommended and practiced in a number of pediatric surgical centers. Many, however, feel that all patients referred for feeding gastrostomy should be evaluated for GER and that only those with significant clinical reflux should have a concomitant antireflux procedure. For those who develop clinical reflux postoperatively, the antireflux procedure may be done at that time [146]. Fundoplication after gastrostomy is a much more difficult procedure than fundoplication with gastrostomy.

One should realize that an antireflux operation is not necessarily mandatory in the NI child with reflux whose primary problem is nutrition. Converting bolus gastrostomy feedings to continuous feedings can dramatically resolve vomiting and result in excellent weight gain and markedly diminished pulmonary complications [22]. Another option in NI children who need a feeding gastrostomy and who have minimal to moderate reflux is to place the gastrostomy tube on the lesser curvature, thus fixing the stomach to the posterior right rectus fascia as in a boerema anterior gastropexy. This modification was reported in nine NI children, only two of whom had moderate GER preoperatively. All did well without clinical symptoms of GER and with marked nutritional improvement. Postoperative barium studies in eight did not show reflux [28, 285].

Still another approach in these children is to use a jejunostomy. By one technique, a percutaneous gastrostomy is established under fluoroscopic

control while a small plastic tube is threaded through the gastrostomy tube and guided into the jejunum. Comparison of this technique with a Nissen fundoplication showed a strikingly lower incidence of complications in the former [3]. Obviously, this same principle could be achieved by passing the jejunal tube through a preexisting gastrostomy. One annoying problem in such methods is occasional displacement of the feeding jejunal tube upward into the stomach and the necessity for its replacement under fluoroscopic control. This technique does not directly treat the GER, and medical management must be continued. A final method along these same lines is a Roux-en-Y jejunostomy for feeding. A gastrostomy for decompression is done at the same time if one is not already in place [78]. This procedure obviously is more complex, but the results in a small series have been excellent in terms of improved nutritional status and dramatic decrease in GER symptoms.

Antireflux Surgery in NI

The exact percentage of NI children without demonstrable GER who receive an antireflux procedure in conjunction with a feeding gastrostomy is difficult to determine, but in one series the indication for the antireflux operation was prophylactic in 30 % [213, 272].

All of the various antireflux surgical procedures have been used in NI children. The Nissen has been most often used, as with NN children, but the Thal operation has also been used almost exclusively in some series [245, 297]. The most vexing problem with these children is the high rate of both postoperative complications and deaths within the perioperative period as compared with NN children undergoing the same procedures. One series noted an early complication rate of 11 % and a late complication rate of 26 % [236]. All but one of the early complications were small bowel obstructions; more than half of the later complications were wrap herniations or wrap failure. NN children from this same institution had one third the number of early complications and less than half the rate of late complications. Reoperation for late complications was required in 19 %. The Nissen fundoplication was used in about 80 % of the NI children, and Thals in the remainder. Another series reported on 35 profoundly disabled children who had antireflux procedures, almost all of which were Nissens [272]. The results of the anterior gastropexy of Boerema in 50 NI children were similar: 25 early and 9 late complications, 17 reoperations, and 2 deaths related to the operation [41]. A still larger series reported distressingly high complication rates following Nissens in 193 patients [192]. Both of the fundoplication authors questioned the advisability of continuing with operations that were designed to improve the quality of life in these children but that were plagued with numerous problems.

Experience using the Thal operation suggests a more optimistic picture with an 8 % failure rate and an 11 % complication rate [297]. The complication rate is about the same as with the NN children, but the failure rate in the NN is only 2 %. In a series of Thal procedures in 141 NI children, recurrent GER or recurrent hiatal hernia required reoperation in 10 % [245]. Only 6 % required a later pyloroplasty due to DGE for symptoms of gagging and retching.

It is more than apparent that antireflux operations in NI children carry a considerably higher risk than in otherwise normal children. However, in all the series cited, most of the children were much improved, and parents and other caregivers expressed a high degree of satisfaction with the outcome. In a study that examined this important issue, feeding indices were improved and the child's comfort and quality of life were perceived to be significantly better [217]. Furthermore, the level of frustration in caring for the child was less and the quality of life for the parents as well as for the child was improved.

Esophageal Atresia and GER

GER following repair of esophageal atresia malformations is common. The frequency is difficult

to establish precisely, but significant reflux occurs in at least 50 % of these babies [76–96]. In cases of isolated esophageal atresia (no tracheoesophageal fistula [TEF]), the incidence of GER following primary repair was 100 % in a series of nine infants [183].

The cause of the GER has been assumed by many to be secondary to the repair of the esophageal atresia itself. Tension on the anastomosis with upward displacement of the lower esophageal segment may shorten the intra-abdominal esophagus and widen the angle of His. Dissection of the TEF and the lower esophageal segment may damage the vagal innervation, or scarring secondary to the dissection may have the same effect. In fact, a study of 25 such children revealed that excessive tension at the anastomosis was the only factor studied that was associated with an increased incidence of GER [152]. However, most investigators in the field now believe that the cause is a primary, probably congenital, defect in the motor function of the distal esophagus [227]. Esophageal dysmotility, aperistalsis, nonprogressive contractions with low amplitude, and disorganized contractions all have been observed. The lack of distal esophageal contractions is well documented and the key of GERD after repair of esophageal atresia [169]. The long-term follow-up of 22 adolescents or young adults who had repair of esophageal atresia and distal TEF as newborns examined some of these problems [295]. The technique used was a combination of 24-h esophageal manometry and pH monitoring on an ambulatory basis. Half had a pattern of long nocturnal episodes of reflux with very slow clearance. All had markedly diminished esophageal contractibility, disorganized propulsive activity, and absence of acid-clearing capacity. Propulsion of ingested fluids and solids and clearance of refluxed fluids were accomplished largely by gravity. GER was noted in more than half of these patients, so that it is clear that the reflux noted early in life in these children persists indefinitely.

The clinical manifestations of reflux are similar to normal children with GER. Respiratory symptoms, such as recurrent pneumonia, are common, and life-threatening episodes of apnea or cyanosis may occur [96, 234]. Failure to thrive due to recurrent vomiting, dysphagia, and esophagitis is often a problem. The esophageal anastomosis may become tight, and the stricture often does not respond to dilation, presumably due to the frequent reflux of acid fluid. Esophagitis is particularly common.

Conventional medical treatment is effective in about half of the children. This includes upright positioning and thickening of the feedings. Owing to dysphagia, supplemental gastrostomy feedings may be necessary. Infusion gastrostomy feedings are probably more effective than bolus because less vomiting results. Omeprazole is helpful for this infants because esophagitis and persistent strictures are common.

When medical measures are not effective and complications such as failure to thrive, apneic spells, recurrent pneumonia, or anastomotic strictures persist, some form of antireflux surgical procedure is necessary. Many reports document excellent results. But postoperative long-term follow-up until the patients reach adulthood is absolutely necessary to ensure that development of a Barrett's esophagus is not overlooked [135].

Fifteen infants with tight anastomotic strictures failing to respond to repeated dilations were reported [241]. The cause was felt to be frequent episodes of reflux, and all were managed by an antireflux operation. The stenoses were cured in all. Another group of children was reported to have excellent but slightly less spectacular relief of stricture, vomiting, pneumonia, and dysphagia [108]. Nissen fundoplications were performed in all nine with no major complications and with relief of their reflux symptoms in all. Respiratory problems were markedly diminished and the strictures were successfully managed. Surgical treatment of reflux in this group of children has been uniformly successful. The experience with fundoplications used in 14 children with GER following repair of esophageal atresia and TEF was reported to be

distressing [74]. All had competent fundoplications on follow-up study, but all also had absent esophageal peristalsis below the anastomosis. Another report relates similar problems using Nissen fundoplications in this scenario [324]. The investigators felt that the dysphagia was secondary to the inability of the defective distal esophageal motility to overcome the increased resistance of the fundoplication.

What appeared to be excellent short-term results proved to be poor long-term results with fundoplications in another report [183]. In other reports, the problems are not as severe. Reoperation was required in 18 % of those children with a Nissen fundoplication and in 15 % of patients who had a Thal fundoplication following esophageal atresia/TEF repair [182, 275]. Reoperation rates, of course, do indicate failure but do not necessarily reflect the total incidence of morbidity following antireflux surgery.

Achalasia and GERD

Patients with achalasia are at increased risk for chronic GERD, esophagitis, and Barrett's esophagus following treatment by either pneumatic dilatation or myotomy. The benefit of antireflux therapy at the time of myotomy remains controversial. All the patients with a history of achalasia or history of esophageal atresia repair require follow-up for possible complications of GERD.

Chronic Respiratory Disorders

Intraesophageal pH studies in children with chronic respiratory disorders detect a much higher prevalence of pathologic GER reflux, but is silent in the majority. Bronchopulmonary dysplasia, a chronic lung disease of infancy with varying degrees of alveolar growth arrest, airway branching abnormalities, and peribronchiolar fibrosis, has been associated with GERD.

Lung Transplantation

Severe GERD is common in patients presenting for transplantation, and high incidence of GERD occurs following lung transplantation in children and adults. Complications of GERD are a common source of morbidity in patients with transplantation. Pneumonectomy seems to contribute to esophageal and gastric motor dysfunction. It has been suggested that in the allograft lung, nonimmune-mediated injury because of reflux contributes to the development of bronchiolitis obliterans syndrome [204].

Consequences for Young Adults

In about 4 % esophageal strictures will develop and 5 % will die because inanition or pulmonary infection [59]. Potentially serious consequences are esophageal stricture and Barrett's esophagus.

The treatment of esophageal stricture secondary to esophagitis has changed little in the past 30 years [216]. Esophagoscopy is essential initially to demonstrate the type and extent of the lesion and the possibility of dilatation. Dilatations are then initiated. If the stricture is particularly tight or long, a gastrostomy will be necessary not only for alimentation but also for the placement of an indwelling string to permit retrograde dilatations. Even with improvement from dilatations, some form of antireflux operation is necessary; and dilatations may need to be continued postoperatively for some time [34]. Rarely the stricture is limited to a short segment which allows for resection and anastomosis. If the stricture is long and unyielding, esophageal replacement occasionally may be required, either by gastric tube or colon replacement. Better knowledge of the consequences of GER and its pathophysiology, earlier diagnosis, and effective therapy account for the fact that strictures from reflux esophagitis are now seen less frequently than in past decades. Why strictures develop in some patients but not in others remains an unanswered question. The answer

may well be found in variability of the mucosal defense mechanisms and the noxiousness of the refluxate.

In the last years our group is treating the severe strictures with "autoexpanding" prosthesis, with excellent result, lower morbidity, longer time between dilatations, family and child satisfaction, and a high percentage of full success [49, 50].

A large number of reports confirm the effectiveness of omeprazole in the treatment of esophagitis in children [80–132]. The drug has an important role as an adjunct in managing reflux strictures. Although its effectiveness in esophagitis is apparent, its success in truly advanced esophagitis is not as impressive; less than half of grade 4 esophagitis healed with omeprazole. Recurrence seems to be inevitable when the drug is stopped.

Barrett's esophagus is a complication of esophagitis and is often accompanied by stricture [42]. Although usually regarded as quite uncommon in childhood, the incidence has been reported at 4 % and 14 % of children with GER in two series. In another report, Barrett's esophagus was found in 25 % of the children with reflux strictures. In adults, progressive increase in the incidence and severity of dysplasia in the columnar epithelium has been documented on repeated endoscopic and biopsy observations over a period of years [251].

The progressive increase in the incidence and severity of dysplasia, together with the development of carcinoma, makes Barrett's esophagus most worrisome [134]. Two cases of carcinoma arising in Barrett's esophagus in children were reported from one institution [2]. One patient was 11 and the other 14 years of age at diagnosis of the malignancy. There is a report of an esophageal adenocarcinoma located adjacent to the esophagogastric junction in a 20-year-old woman who had repair of esophageal atresia and TEF as a newborn [125]. She was managed by an extensive resection with restoration of continuity by a colon segment interposition. The specimen did not show Barrett's epithelium, but certainly there is a reasonable possibility that Barrett's esophagus was, in fact, present at one time but was obliterated by the tumor.

How to best handle the child with reflux and Barrett's esophagus is obviously a major problem. One child, 12 years of age, was treated by antireflux operation with an excellent clinical result. Two years later, on both gross endoscopic examination and histologic review, there was distinct evidence of regression with replacement of the columnar epithelium by squamous epithelium, and this regression continued over a further 3-year period. In another case, complete regression followed antireflux surgery [63].

Generally, however, Barrett's esophagus in childhood does not regress after antireflux surgery. Prolonged follow-up evaluation with endoscopy and biopsy is recommended if dysplastic changes are to be found and carcinoma either can be prevented or found at an early stage [261]. The use of endoscopic laser ablation of the epithelium has been reported [103, 130].

Other questions related are about the risk of esophageal adenocarcinoma after antireflux surgery. Is it able to prevent later development of adenocarcinoma? Follow-up evaluation study for cancer incidence in the antireflux surgery group in Swedish population showed antireflux surgery cannot be considered to prevent the development of esophageal or cardia adenocarcinoma among persons with reflux [174].

Experimental models of duodenogastroesophageal reflux have studied the effect of ingestion of sodium nitrite solution on the genesis of adenocarcinoma and have described the important role of nitrites in the genesis of adenocarcinoma associated with Barrett's esophagus [203].

GERD is associated with allograft dysfunction after lung transplantation. Patients with symptomatic GERD demonstrated an increased incidence of bronchiolitis obliterans syndrome. So more sensitive and specific diagnostic tools should be implemented in all lung transplantation recipients to investigate the impact of symptomatic and silent GERD and thus improve outcomes after lung transplantation [204].

Where the Emphasis Is Likely to Lie in the Future

GERD is one of the most common health problems, and it affects more than 50 % of the world's population.

The use of the laparoscopic approach to perform antireflux procedures has increased since its introduction in 1991 but the goal in the future will be to identify the risks and benefits of laparoscopic antireflux procedures [161].

When it is possible, laparoscopic fundoplication is the preferred surgical option. And laparoscopic redo Nissen fundoplication for a failed antireflux procedure is safe and effective for some authors [255]. But laparoscopy procedure has several limitations: two-dimensional imaging, restricted instrumentation motion, and ocular fatigue and headaches in surgeons. Also haptic feedback (force and tactile), natural hand-eye coordination, and dexterity are not necessary. The physiologic tremors of the surgeon are readily transmitted through the length of rigid instruments. This limitations make more delicate dissections difficult and it is because some techniques like Boix-Ochoa antireflux procedure are more difficult by laparoscopy than in open surgery.

During the last few years, minimally invasive robot-assisted surgery has continued to expand into different surgical procedures. The benefits include three-dimensional images, which allow surgeons' superior visibility. Also the robotic system has a 360° range of motion, maintains steadiness, and has surgical tools with greater degrees of freedom. Since the first report of robot-assisted fundoplication (RAF) published in 1997, computer-assisted fundoplication has become increasing [8, 131, 196]. But controversy remains. Is it a promising technical innovation [207, 329] or does it just add time and increase the cost [92, 178, 206, 209, 237]?

The answer is still unclear but probably in the next years there will be more information about this problem. Some authors don't find significant differences in outcome and there are no clear benefits of using Nissen fundoplication as a robotic-assisted versus laparoscopic procedure in children [4, 208].

RAF is one of the latest approaches in the evolution of endoscopic surgery also in pediatrics. Perhaps in the future with the development of new instruments, better positioning, an independent optical command system, especially adapted tools for digestive surgery, tactile sensitivity, and force feedback, complex surgical procedures will be performed easily and accurately. And obviously the operation times will be decreased, and the costs may decrease as well as surgical complications [195].

In the future there will be new developments in esophageal surgery: long-term outcomes after laparoscopic antireflux surgery, the use of surgically placed implantable device for LES augmentation (Linx), the use of mesh for hiatal hernioplasty, and prone and nonthoracic approaches to minimally invasive esophagectomy [273]. But the indications must remain identical for open and laparoscopic procedures [296].

What would be the endoluminal therapy role in robotics era [110]? There are not enough scientific and clinical data on safety, efficacy, and durability to support the use of endoluminal therapies for GERD in routine clinical practice for some authors. But controversy is still alive for others [313].

Several endoscopic antireflux techniques have been developed to enhance the function of the lower esophageal sphincter or alter the structure of the angle of His with the goal of recreating or augmenting the reflux barrier. Many methods are no longer available, and some await regulatory approval [311].

What are the risk factors for recurrent gastroesophageal reflux disease after fundoplication in pediatric patients? Would we be able to reduce the redo procedures in the future [212]? Factors associated with increased risk of redo GERD are age of less than 6 years, preoperative hiatal hernia, postoperative retching, and postoperative esophageal dilatation.

What would be the best way to evaluate the results of surgical therapy for gastroesophageal

reflux disease? Some authors have performed pH monitoring and esophageal manometry in this evaluation and have concluded that Nissen fundoplication is effective for the treatment of GERD and didn't affect esophageal motility but this procedure decreases in contraction time.

Impedance testing is useful in the management of GERD [27].

Not to all obviously, new answers will generate new questions about GERD [249, 268].

Conclusion

We have to recognize that nowadays some of the mysteries of GER lies in the brain stem and the vagal control of the esophagogastric junction and once again we are in the threshold of a new era and the most encouraging fact for the investigator is that the sphincter is like a sphinx that gives up its secrets grudgingly, so we must continue to investigate, because today's knowledge is not tomorrow's truth and there is nothing as permanent as change.

Following other paths and achieving novel findings all around, the pathophysiology of esophageal inflammation should enhance our understanding of GERD and its complications and provide new treatment insights. The complex process involving multifaceted inflammatory mechanisms, expression of inflammatory mediators in GERD, and their potential cellular sources is a new field in knowledge. What is the contribution of inflammatory mediators to complications of GERD, motility abnormalities, fibrosis, and carcinogenesis [250]?

We would however stress that conservative treatment should be thought of first, as it is impossible to improve an already healthy child by surgery.

The pathophysiology of GERD involves contact of the esophageal epithelium with acid/pepsin in the refluxate. For this contact to occur with sufficient duration, there must be a combination of defects in antireflux and luminal clearance mechanisms for acid/pepsin to overwhelm an intact epithelium or defects within the epithelium develop that subsequently enable normal acid contact times to become damaging to the epithelium.

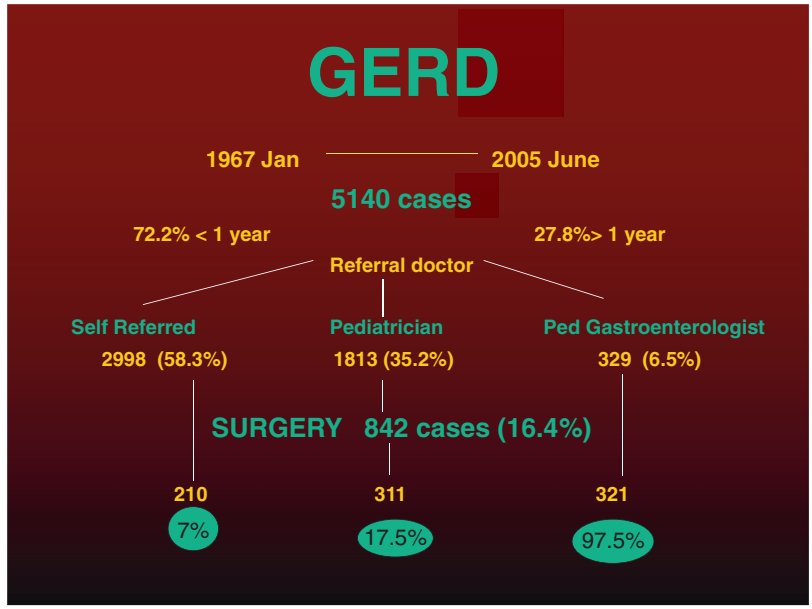
Two methods directly measure fluid flow: [1] scintigraphy, which directly measures radiolabeled liquid gastric contents flowing into the esophagus and [2] MII, a new method that recognizes the flow of gastric contents into the esophagus by detecting impedance falls from a high (esophageal mucosa) to low (gastric contents) value across electrode pairs placed throughout the esophagus; MII can also distinguish liquid from gas refluxant [163, 270, 302, 314].

PPIs are recommended as initial therapy in children with erosive esophagitis. Initial treatment for 3 months is advised. If adequate control of symptoms is not achieved within 4 weeks, the dose of PPI can be increased. Most patients require only 1-day dose of PPI to obtain symptomatic relief and heal esophagitis [101]. The optimum dosage regimen is to administer a once-daily dose 15–30 min before the first meal of the day. PPIs should not be stopped abruptly, because rebound acid secretion may cause recurrence of symptoms. PPI should be tapered for at least 4 weeks.

Before surgery it is essential to rule out non-GERD causes of symptoms and ensure that the diagnosis of chronic-relapsing GERD is firmly established.

After Boix-Ochoa experience on 5,140 children, some of them with more than 30-year follow-up, under 3 years of age with GERD 3,711 under 1 year and 1,429 over 13 months with surgical treatment of 16,4 % of them, the conclusion is the highest % of patients with lowest surgical treatment where patients self-referred (7 % surgery) or referred by pediatricians (17.3 % operated) and the highest rate of surgically treated patients is logically referred by pediatric (Table 91.7) gastroenterologists (97,5%). Where is the border between medical treatment and surgery? Which kind of medical treatment and how

Table 91.7 Gastroesophageal reflux disease



long and when patients begin to be a surgical patient? Our experience shows that patients, who consult a surgeon earlier, have better results, than patients that are being managed long time by medical treatment only. We hypothesize "early GERD surgical treatment" as the best treatment for the patient against long medical treatment that reduces GERD but don't heal.

Careful selection of patients is the key for best results in GERD surgery.

The Spectrum of Surgical Anti-reflux Procedures: Which Operations Work?

92

E.M. Kiely

Introduction

Most of the underlying pathophysiology of gastro-oesophageal reflux (GER) has been elucidated in adults. The underlying mechanism giving rise to reflux is transient relaxation of the lower oesophageal sphincter (TRLES). This is combined with relaxation of the diaphragmatic crura and also with oesophageal shortening [1, 2].

The same mechanisms have been shown to occur in the paediatric age group, both in neurologically normal (NN) and neurologically impaired (NI) children with GER [3]. The cause of the sphincter relaxation has not been established, but is considered to be partly related to gastric distension [4].

Nonoperative treatment is directed at lessening the damage produced by acid and pepsin digestion of oesophageal mucosa as well as reducing the supra-oesophageal effects on airways, lungs and dentition.

The underlying pathology is unaffected by medical treatment. Surgical therapy appears to affect the behaviour of the lower oesophageal sphincter (LES), and the reasons for this are unclear at present [5].

Common presenting symptoms include pain, vomiting, failure to thrive, respiratory complications and the consequences of oesophagitis [6].

The spectrum of associated conditions in children is greater than that found in adult practice. A number of structural abnormalities predispose to reflux – oesophageal atresia (EA) and congenital hiatus hernia. The respiratory consequences of reflux include apparent life-threatening events (ALTEs) in infants, secondary chest infections, asthma and bronchiectasis in older children. NI children frequently have pathological reflux resulting in pain and haematemesis. A group of children exist where severe oesophagitis, haematemesis and structuring present early, and finally a group of normal children may present with no structural problems, but for whom GER produces troublesome symptoms.

The aspects of diagnosis have been dealt with above. Before contemplating surgical management of GER, an upper gastrointestinal study is mandatory both to define the anatomy and to give some information on the presence or absence of reflux. Depending on the X-ray findings, oesophagoscopy may be considered appropriate. Surgery is undertaken when medical treatment fails or is unsatisfactory. Children may have many decades of life ahead of them, and a lifetime of medication may be the alternative to an operation. There are no data on the safety of decade-long treatment

with proton pump inhibitors (PPIs). There is also a concern about the development of Barrett's oesophagus if GER continues indefinitely.

Unfortunately, the results of operation are not predictable, although the great majority of children are considered to have a good outcome from surgery [7]. It is also clear that outcomes from surgery differ among different patient groups. NI patients and those *with repaired* EA, for instance, do less well than NN children [8, 9]. Finally, there are no very long-term (>15 years) results of surgery available.

Indications for Operation

Surgery is generally performed for intractable symptoms, unresponsive to medical treatment. In prematures with chronic lung disease, discontinuation of ventilation may be delayed or impossible because of reflux and aspiration. In addition, repeated chest infections may worsen ongoing lung damage. Apparent life-threatening events (ALTEs) and apnoeas may be associated with reflux in young infants. These may be abolished by successful anti-reflux surgery. Vomiting and failure to thrive are features of severe reflux in infancy. The nonoperative management of these problems is dealt with above but if weight gain remains poor, surgery may be the sole option.

Respiratory complications in older children include recurrent chest infections, asthma and bronchiectasis. Pathological reflux is also common in cystic fibrosis. When reflux is confirmed in these children, a trial of full anti-reflux treatment is undertaken but if significant symptoms persist, surgery should be considered.

Severe oesophagitis – ulceration and stricturing – is uncommon in children. Long-term relief of symptoms is possible with continued anti-reflux treatment. Stricturing usually responds well to fundoplication.

Severe reflux is common in NI children [10]. Up to 70% may be affected. Symptoms include pain, irritability, vomiting, haematemesis, recurrent chest infections and poor weight gain. All of these symptoms may be seen in the same patient over time.

Many of these children will already have a gastrostomy in place because of unsafe swallowing. The later development of pathological reflux suggests a progressive foregut dysmotility, and abolishing reflux by surgery may transform the child's life.

Uncommon indications for anti-reflux surgery include those undergoing major airway reconstruction and those who have had lung transplantation. In the former group, continued reflux may jeopardise the repair and, in the latter group, compromise lung function.

Reflux in older children and adolescents often presents as effortless regurgitation, halitosis, dental erosion and pain. When symptoms persist over years and are not completely abolished by medical treatment, surgery may be requested.

Surgery is the sole means of repairing a hiatus hernia. While minor degrees of hiatus hernia may not mandate operation, major degrees of herniation will do so.

Available Operations

At the present time, fundoplication is the favoured anti-reflux operation. Most perform the 360° Nissen fundoplication and a minority the various forms of incomplete wrap – Thal, Toupet and Boix Ochoa. The type of procedure performed depends mainly on surgical preference, and there is a paucity of literature comparing one with the other. A recent prospective randomised trial from Oxford in the UK suggests that the Nissen fundoplication compared to the Thal, across a broad range of children with co-morbidities, produced better results [11]. Nonetheless, many prefer to use an incomplete wrap when oesophageal motility is considered markedly abnormal.

In the era of minimally invasive surgery, none now argue that open operation is preferable if the same procedure can be done without the trauma of access. Laparoscopic fundoplication is now considered the standard of care [12]. The relative ease of performance of the Nissen operation has probably deterred many from wishing to undertake any of the incomplete wraps. The Nissen can

be completed with perhaps three sutures, and the alternative operations need many more.

Up to now, the standard approach in performing a fundoplication has been to divide the phreno-oesophageal ligament and fully dissect the oesophagus from the pleura and mediastinal structures. As St. Peter et al. pointed out [13], this is a replication of adult practice. Wrap herniation is a significant post-operative problem in children, and minimal mobilisation may reduce this problem to a marked degree. In this paper, the instance of post-operative hiatus hernia was reduced from 30 % to 7.8 % [13]. This approach is not possible in all, but most children with reflux do not have a hiatus hernia and, consequently, can have the procedure performed with very little mobilisation.

It is unclear if division of the short gastric vessels is beneficial or not. Published reports and our own experience suggest that a floppy wrap is possible for most without dividing these vessels. In some, the wrap cannot be performed without the release of at least the upper short gastric vessels. The experience of Esposito et al. [14] is probably representative – they divided the vessels in 6 (2.5 %) of 300 patients undergoing fundoplication. This pragmatic approach has much to recommend it. Others divide the vessels as a routine [13].

There is no agreement either on the need for an oesophageal bougie during construction of the wrap. Many authors use a bougie sufficient to fill the oesophagus at the time of operation [15]. There are no studies to demonstrate that this is necessary or that it reduces the chances of forming a wrap which is too tight.

There is also no clear advice on when to perform a gastric drainage procedure. It is clear that gastric drainage is abnormal in some at the time of diagnosis. Delayed or accelerated gastric drainage may become problematic many months after successful fundoplication. Some authors recommend radionuclide scans in NI children as part of the diagnostic workup and perform pyloroplasty if the result is abnormal [16].

Oesophagogastric disconnection (OGD), described by Bianchi [17], is mainly reserved for NI children who are incapable of feeding orally and who are gastrostomy dependent. The oesophagogastric junction is divided, the stomach closed, and a Roux loop of the jejunum brought up and anastomosed to the oesophagus. This allows the child to swallow saliva and some food if possible, but the bulk of calories is delivered by gastrostomy.

Some authors use this as the primary procedure in NI children, but others only when the first or second fundoplication has failed [18, 19]. This operation is not widely used as a primary procedure but continues to be of use in a minority of patients after a failed fundoplication.

The Collis gastroplasty to gain length is used when oesophageal length is problematic [20]. This is a particular problem when managing children after repair of pure oesophageal atresia. It is clear from the published literature that this operation may succeed where the previous fundoplications have failed [21, 22]. However, as the tubularised stomach produces acid and pepsin, the distal oesophagus will suffer from acid reflux indefinitely. The effects of this are uncertain and concerning. It is not clear if Barrett's oesophagus will inevitably result in these children.

The various endoluminal techniques are addressed below.

Results of Surgery

The reported results of anti-reflux surgery present widely differing outcomes, both in terms of success, complications and also in regard to the need for repeat surgery. Many of these differences are related to differing patient populations and in particular to the number of NI children undergoing surgery. In addition, prospective series give different results from retrospective reviews and are in a minority.

Perioperative complications including visceral perforation, haemorrhage and splenic injury are reported in all the large series. These occur after open or closed surgery and rates of 5–10 % are common [8, 14]. Occasional children are unable to tolerate the pneumoperitoneum because of chronic lung disease, congenital heart disease or severe spasticity.

Dysphagia is the commonest early postoperative problem and is usually managed by dilatation of the wrap. A recent report noted an incidence of 23 % dysphagia after fundoplication, and, in most of these children, the dysphagia resolved without intervention [23]. Four percent of the total needed dilatation and 2 % revision of the wrap.

The report dealing with the advisability of oesophageal mobilisation noted that 8.5 % of patients who had undergone extensive mobilisation needed dilatation of the wrap versus 0 % of those who had minimal dissection at the hiatus [13]. Severe dysphagia may be more common after a Nissen than a Thal fundoplication [11].

Recurrence of symptoms ascribed to reflux is common in NI children. Strecker-McGraw et al. [24] reported recurrent symptoms within 3 months of surgery in 3.6 % of their patients. One-third of these had reflux confirmed on pH study.

With longer-term follow-up, 71 % developed troublesome symptoms, and recurrent reflux was again confirmed in one-third [25]. This latter report dealt with the management of NI children only.

Gas bloat is more likely as a complication of Nissen than Thal complications. The incidence varies and may not be influenced by neurological impairment. Mathei et al. [23] reported gas bloat as a significant problem in 15 % with spontaneous resolution in all. Kimber et al. [26] noted an incidence of intractable gas bloat needing revision surgery in 10.6 %, all of whom had undergone a Nissen fundoplication.

Adhesion obstruction has been a problem after open operation. Rates of about 3–8 % have been reported [7, 25]. This is rarely seen as a complication after laparoscopic anti-reflux surgery.

The distressing symptom complex of choking – gagging – retching is familiar to all surgeons who deal with NI children. Smith et al. [8] note that this was present in 11 % of their patients prior to surgery and in 23 % after operation. Similarly, Martinez et al. [25] note an overall incidence in NI children of 13 % pre-op and 29 % postoperatively.

Despite all these potential complications, the results of anti-reflux surgery are considered good. In a multicentre review of over 7,000 patients, good results were obtained in 95 % of NN children and in 84.6 % of NI children [7].

Reoperation is considered the main criterion of failure. It is clear that fundoplication is a very successful operation in NN children who have no serious co-morbidities. Esposito et al. [14] reported a repeat operation rate of 2.5 % in 300 NN children undergoing laparoscopic Nissen, Toupet or Thal procedures in three different hospitals.

In the prospective study by Kubiak et al. [11], the overall failure rate was 5.9 % for Nissen fundoplication and 15.9 % for Thal fundoplication. All but one child who needed repeat surgery was neurologically impaired.

A high failure rate is also reported in children who have undergone repair of oesophageal atresia. The report from Ann Arbor in 1993 probably reflects widespread experience – a failure rate of 33 % after Nissen fundoplication, compared to a 10 % failure rate in the remainder of non-oesophageal atresia patients [9]. In addition, there were three deaths in this series from complications related to the anti-reflux operation.

A similar report from Toronto and Washington in 1998 noted a 25 % failure rate in this group of patients [27]. The only NN patients who needed repeat surgery were patients with repaired oesophageal atresia.

The case against anti-reflux surgery has been made quite cogently by Hassall [28]. Using undefined criteria for surgery other than an apparent determination not to refer children for operation, the rate of fundoplication had been reduced from 40 to 50 operations per year down to four to five operations per year in the British Columbia Children's Hospital. It is not clear whether or not the unoperated children with reflux were better or worse off. Tellingly, in the clinical vignette used to demonstrate dilemmas of management, the fundoplication which had been performed subsequently failed.

Prospective randomised studies of medical versus surgical therapy in children have not been performed to date. The same criticism cannot be maced for adult practice. A Swedish study with 5-year follow-up compared the two modes of treatment and found surgery to be superior to

omeprazole [29]. When the dose of omeprazole was increased, the superiority of surgery did not reach statistical significance.

A long-term study from the Veterans Administration in the United States [30] described the outcome of medical versus surgical therapy with 10 years follow-up. Sixty-two percent of the surgical patients were again taking anti-reflux medication but their symptoms of gastro-oesophageal reflux were significantly less than the non-operated group. An unexplained finding in this study was an excess mortality in the surgical group from cardiovascular diseases. This was an unexpected finding and was unexplained.

A systematic review of six randomised trials and three cohort studies comparing anti-reflux surgery with medication showed consistently superior results in the surgical groups [31]. In three of the studies examined, the medical therapy was a PPI and the results of surgery remained superior.

A caregiver's assessment of surgical results in NI children was reported in 1996 [32]. The results showed improvement over a wide range of questions which included ease of feeding, ease of caring and comfort of the child.

The results of the oesophagogastric disconnection have not been studied or reported in the same numbers. A small prospective study enroled 26 patients and compared Nissen fundoplication and disconnection [18]. The follow-up was short – 12 months – but the disconnection patients were considered to have a better outcome across a broad range of assessments. These included weight, haematocrit, feeding time and the results of a parental questionnaire. Similar results were reported from the Alder Hey Hospital in Liverpool [19] and from a caregiver's perspective in Manchester [33]. All of these reports described the results in NI children.

At the present time, therefore, anti-reflux surgery in the form of fundoplication is successful in most children. The Nissen operation is the most popular and probably the most effective. The main complications are the significant failure rate and the introduction of new symptoms after surgery. Patients with NI have a much worse outcome after surgery, and repeat fundoplication carries a failure rate in the region of 40 % [34].

The surgeon who is called upon to operate should be very clear of the possible outcomes of surgery. Appropriate advice may then be given to the parents such that the correct decision for the individual child is made.

Fundoplication in Infants and Children

93

Oliver J. Muensterer

Introduction

Gastroesophageal reflux is a physiologic phenomenon in infancy before the lower esophageal sphincter matures. In otherwise healthy infants, it rarely causes more than an inconvenience for the caregivers in the form of frequent spit-ups after feeds. As long as the child is thriving and otherwise asymptomatic, no specific treatment is necessary. When gastroesophageal reflux is severe enough to compromise normal growth, cause respiratory symptoms, or lead to inflammation of the esophagus, treatment is indicated. Nonoperative therapies such as thickened feeds, promotility agents, H2-receptor blockers, proton pump inhibitors, or elevating the head of the bed were all found to have only marginal benefit in the treatment of gastroesophageal reflux in young children [1–3]. Complications of untreated pathologic gastroesophageal reflux include failure to thrive, respiratory compromise, and esophageal peptic strictures [4].

There are three physiologic mechanisms to prevent gastroesophageal reflux in humans (Fig. 93.1). First, the lower esophageal sphincter (LES) is a concentration of circular muscle fibers at the lower end of the esophagus proximal to the gastric cardia [5]. The LES is a dynamic barrier that relaxes at the end of an esophageal peristaltic wave to allow a food bolus to pass into the stomach. At other times, it maintains a certain resting tone to prevent gastric content to backflow into the esophagus. Second, the esophagus joins the stomach at a sharp angle, the angle of His [6]. This angle acts as a one-way valve, allowing food to pass from the esophagus into the stomach, but closing when the fundus of the stomach is distended. A corresponding mechanism is found in other organ systems such as the urinary tract, in which vesicoureteral reflux is avoided by the ureter entering the bladder at a physiologic angle. Finally, the most distal portion of the esophagus is normally located within the abdominal cavity. This decreases the pressure gradient across the gastroesophageal junction, because the pliable wall of the esophagus transmits the ambient pressure to its lumen. Thereby, the physiologic pressure gradient between the abdominal and the thoracic compartment is not applied to the gastroesophageal junction, but proximal where it cannot exacerbate gastroesophageal reflux. All surgical fundoplication procedures aim to favorably influence the factors above.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_93

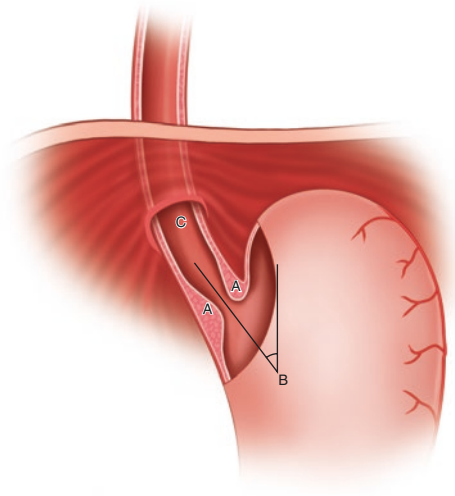

Fig. 93.1 Physiologic and anatomic anti-reflux mechanisms. The lower esophageal sphincter (*A*) is a dynamic concentration of circular muscle that usually remains closed in the resting state but opens up at the end of a peristaltic wave. The normal esophagus joins the stomach at a sharp angle, the angle of His (*B*), creating a vale-like configuration. Usually, the most caudal portion of esophagus is located in the abdomen (*C*), lowering the pressure gradient across the gastroesophageal junction due to the pliable nature of the esophagus

The first surgical intervention for gastroesophageal reflux was the hiatal hernia repair described by Allison in Leeds, England, in 1943 [7]. The recurrence rate was high, prompting the development of many different techniques of actual fundoplication over the following decades. Nissen's first fundoplication was performed in 1937 while he was the chief of surgery in Istanbul to reinforce the esophageal anastomosis he performed after resecting an ulcer [8]. Only later was this technique adapted for the actual treatment of gastroesophageal reflux disease and published by Nissen in 1956 [9]. Toupet described the posterior fundoplication in 1963 [10], and Thal proposed an anterior fundoplication in 1968 [11], to mention only the most popular procedures currently performed in children.

In 1991, the first laparoscopic fundoplication in adults was described by Dallemagne in Liege, Belgium [12]. Georgeson in Birmingham, Alabama, and Lobe in Memphis, Tennessee, published the first series of pediatric laparoscopic Nissen fundoplication independently in 1993 [13, 14].

This chapter describes the indications, techniques, and outcomes of fundoplication for the treatment of gastroesophageal reflux disease in children.

Indications for Fundoplication

As mentioned above, the main indications for a fundoplication in children are emesis of enteral feedings precluding the ability to thrive, aspiration of refluxed gastric content into the airways, persistent inflammation of the esophagus despite medical management, peptic stricture, and apparent life-threatening events found to be correlating with gastroesophageal reflux episodes.

Several patient groups have been shown to be at higher risk of gastroesophageal reflux. Based on the clinical presentation, some authors recommend early fundoplication in these children. For example, up to 80 % of patients who underwent esophageal atresia repair are at risk of developing symptomatic gastroesophageal reflux [15]. Therefore, the pediatric surgeon's threshold for performing a fundoplication in such patient may be lower, particularly because prophylactic proton pump inhibitors have not been shown to reduce stricture formation [16].

Patients with congenital diaphragmatic hernia are another target group in this regard. In one study, congenital diaphragmatic hernia (CDH) patients with an intrathoracic liver and patch repair had shorter postoperative hospitalization times and lower incidence of gastroesophageal reflux at 1-year follow-up when a fundoplication was performed concomitantly with the diaphragmatic hernia repair [17]. A similar study confirmed the predictive value of having intrathoracic liver and patch closure at the time of diaphragmatic hernia repair for requiring a later fundoplication [18]. Some surgeons have therefore recommended performing a modified anterior fundoplication in high-risk patients at the time of CDH repair [19].

Children with type I spinal muscular atrophy may be good candidates for laparoscopic fundoplication. Early surgery increased the nutritional status of these patients and was associated with fewer

hospitalizations in the year following the procedure compared to the year before the operation [20]. Similarly, laparoscopic Nissen fundoplication at the time of gastrostomy tube placement was shown to improve survival in both type I and severe type II spinal muscular atrophy [21].

Age or weight should not preclude fundoplication in infants with significant gastroesophageal reflux symptoms or sequelae not responding to medical treatment. Laparoscopic Nissen fundoplication has been performed safely in small infants with low complication rates [22, 23]. Previous open surgery should also not be considered an automatic contraindication to laparoscopic fundoplication. In fact, several studies have shown excellent success rates and low conversion rates for laparoscopic fundoplication in children with previous open abdominal operations [24, 25]. Furthermore, fundoplication in general [26] and laparoscopic fundoplication in particular [27] were not found to increase the risk of shunt infection in children with ventriculoperitoneal shunts.

Laparoscopic fundoplication is feasible and beneficial to treat pathologic gastroesophageal reflux in children who underwent lung or heart-lung transplant with acceptable complication rates and outcomes [28]. Although fundoplication generally facilitates weight gain and nutritional status in children with severe congenital heart disease [29], children with hypoplastic left heart syndrome may have a higher morbidity and mortality during and after open fundoplication [30]. In these children, other nutritional options such as transpyloric feedings may have to be considered as an alternative until the patient has developed more stable physiology.

Most studies indicate that a fundoplication should not be added routinely to gastrostomy tube placement in neurologically impaired children [31, 32]. Postoperative morbidity was increased for patients having a routine fundoplication with their gastrostomy, and only 17 % of patients who underwent gastrostomy alone required a subsequent fundoplication at a later date for gastroesophageal reflux symptoms. Therefore, a more tailored approach is advised [33]. It is not clear what preoperative workup is necessary and which abnormal results should prompt a prophylactic fundoplication at the time of gastrostomy placement. Abnormal pH probe study alone was not a good marker to decide which neurologically impaired patients would benefit from a fundoplication at the time of gastrostomy placement [34]. In one study, clinical assessment had a 95 % positive predictive value in identifying patients who would require a gastrostomy [35].

Diagnostic Workup

Before considering a fundoplication, other entities that can mimic the symptoms of gastroesophageal reflux such as *H. pylori* infection, cyclic vomiting, rumination, gastroparesis, and eosinophilic esophagitis should be ruled out by careful medical evaluation.

A fluoroscopic contrast study of the upper gastrointestinal (GI) tract is usually the first step in the workup of gastroesophageal reflux disease. This examination allows the evaluation of the anatomy of the esophagus, the gastroesophageal junction, the stomach, the duodenum, and the ligament of Treitz. It allows the pediatric surgeon to rule out other anatomic reasons for reflux and vomiting, such as webs, stenosis, or malrotation. It also can detect hiatal hernia or peptic strictures of the lower esophagus which may modify the surgical plan or approach. In a study on 656 patients, significant findings other than gastroesophageal reflux or hiatal hernia were found in 4.5 % of upper GI studies performed in the workup for fundoplication [36]. Since it is merely a snapshot in time, and gastroesophageal is a dynamic disease that changes over the course of the day, the upper GI contrast study is not a sufficient examination to rule out or confirm gastroesophageal reflux. Its reported diagnostic sensitivity for gastroesophageal reflux is only about 31 % [36].

Reflux detected on pH probe in infants and children is extremely variable and depends on many factors such as age, feeding pattern, and positioning. It is therefore difficult to interpret the results. Boix-Ochoa proposed calculating the

relative time in which a pH below 4 is detected in the lower esophagus and counting reflux episodes lasting more than 5 min [37]. If a pH probe is ordered, it is important to standardize the circumstances as much as possible, discontinuing acid blockers for at least 3 days before the study and recording feeding and positioning as accurately as possible [38, 39].

A pH probe will not detect nonacid reflux due to gastric contents buffered by feeds or bile reflux. This drawback is circumvented by the more novel impedance study, in which the electrical resistance between multiple electrodes on an esophageal probe is measured. When gastroesophageal reflux is present, the electrodes are surrounded by liquid, conductivity increases, and consequently the electrical resistance drops. Therefore, the impedance study detects all types of reflux independent on the pH and has been found to be more sensitive for the overall detection of gastroesophageal reflux in children [40]. Despite these advantages, the interpretation of the results and their clinical significance faces similar challenges as discussed for pH probe above [41].

A pragmatic and low-cost method to assess for pathologic gastroesophageal reflux in children with either a nasogastric tube or a gastrostomy is performing a bolus feeding challenge under controlled condition during hospitalization. Goal bolus feeds are fed into the stomach, and clinical judgment is used to determine the presence of significant gastroesophageal reflux. If the patient vomits or shows other signs of intolerance such as posturing or coughing, a fundoplication may be indicated.

Some have argued that preoperative delayed gastric emptying does not adversely affect outcome of fundoplication, and therefore preoperative workup with a gastric emptying scan is not helpful [42].

Ultimately, the most important question in the workup of a child who may be a candidate for fundoplication is to predict the benefit the patient may have from the procedure. The current literature suggests that preoperative pH probe and even impedance study are poor predictors of surgical outcome after fundoplication [43, 44]. The workup for gastroesophageal reflux and the indication for fundoplication at this time remain a complex decision that should be individualized for each patient and should not be based on one sole study or clinical finding alone. With this in mind, it is not surprising that pediatric surgeons often decide on performing an anti-reflux procedure on nonobjective data such as parent preference, clinical impression, and recommendations by the pediatrician [45].

Techniques

Contrary to widely prevalent belief, the aim of a fundoplication procedure is not to simply create a tight lower esophageal sphincter. Rather, a well-performed fundoplication changes the geometry of the gastroesophageal junction based on the anatomic and physiologic anti-reflux mechanisms detailed in the introduction. It thereby creates a valve allowing the passage of food into the stomach, but preventing its reflux back into the esophagus.

Many different techniques using the same basic principles for this goal have been described (Fig. 93.2), including those by Nissen [46], Toupet [47], Thal [48], Colles [49], Boix-Ochoa [50], and Watson [51].

The type of fundoplication employed depends mainly on the experience and training of the particular surgeon. Some comparative studies have been performed. In a prospective randomized controlled study, laparoscopic Thal fundoplication had a higher recurrence rate (16 % versus 6 %), but a lower rate of severe postoperative dysphagia (2 % versus 12 %, respectively), compared to laparoscopic Nissen fundoplication [52]. Open Nissen fundoplication has been found to have higher long-term success rates than the open Boix-Ochoa technique, in which the fundus is placed anteriorly onto the esophagus and tacked to the margin of the right crus and diaphragm [53].

In the Nissen-Colles fundoplication, a stapler is used to vertically extend the esophagus into the stomach. It has been described for children and may be particularly useful in patients with previous esophageal atresia repair, in which the operation is limited by a short intra-abdominal segment of the esophagus [54, 55].

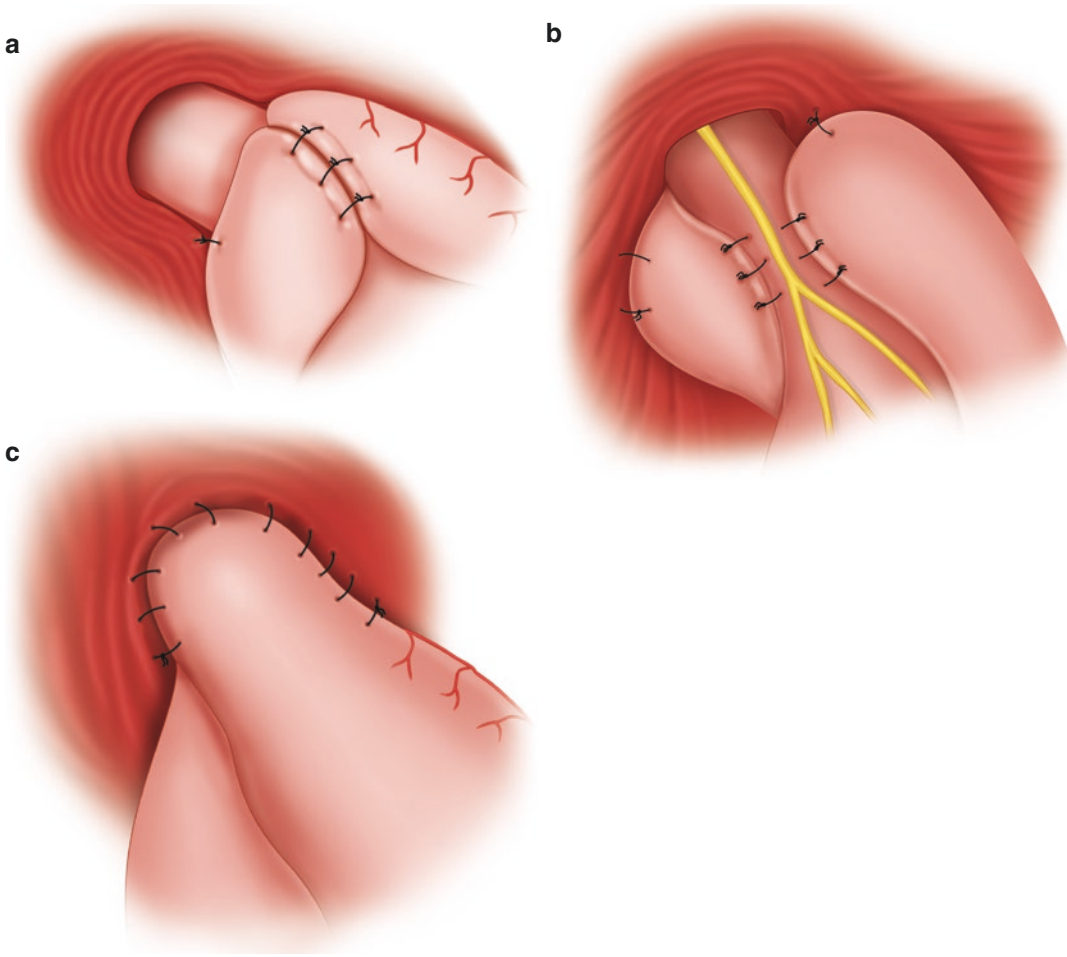

Fig. 93.2 The most commonly performed fundoplications in children are the Nissen fundoplication (**a**), in which a full 360° esophageal wrap is created and sutured around the lower esophagus. In the Toupet fundoplication (**b**), the fundus is pulled through a retroesophageal window and sutured to the anterolateral esophagus and the diaphragm, creating a 270° posterior cuff. The Thal (also called Dor) technique (**c**), consists of a 180° anterior fundoplication

Technically, a laparoscopic Nissen fundoplication is feasible in children without dividing the short gastric vessels (the so-called Rossetti modification) [56].

A complete fundoplication seems to be more effective in the treatment of gastroesophageal reflux, but partial fundoplication may have the advantage of less postoperative dysphagia [57]. This is still an ongoing debate. In a comparison of partial versus complete fundoplication, there were no differences in postoperative symptoms or complications, but more children achieved long-term medication-free recovery in the partial fundoplication group [58].

Regardless of technique, many surgeons place an esophageal bougie for calibration of the wrap before Nissen fundoplication. Recommended bougie size varies from 20F in patients around 2.5 kg to 40F for larger children around 15 kg. Wrap length generally varies between 1.5 and 3 cm [59].

Open Versus Laparoscopic

Since first described two decades ago, laparoscopic fundoplication has become the standard of care in many pediatric centers. In a large analysis

of 33,533 children, laparoscopic fundoplication was associated with less in-hospital mortality, shorter length of stay, and lower hospital charges, as well as decreased rates of decubitus ulcers and postoperative sepsis compared to open fundoplication [60]. Similarly, in a retrospective comparison of 50 laparoscopic versus 50 open fundoplication, the advantages of laparoscopic fundoplication included shorter length of stay, quicker feeding, and lower equipment, hospital room, and pharmacy charges. The main advantage of open fundoplication was shorter operating times and associated charges, while total charges were the same [61].

Recently, evidence has surfaced that minimal dissection of the esophagophrenic ligaments during laparoscopic fundoplication may decrease the rate of wrap migration into the chest [62]. This finding was confirmed by a subsequent prospective randomized controlled trial [63].

Gastric Emptying Procedures at the Time of Fundoplication

In the past, the question was posed whether a pyloroplasty or pyloromyotomy should be performed during fundoplication, either as a routine procedure or in cases where the preoperative workup shows delayed gastric emptying [64]. While some studies have shown improved gastric emptying with these types of procedures [65, 66], others have argued that preoperative delayed gastric emptying does not adversely affect outcome of fundoplication anyway [42] and that fundoplication promotes gastric emptying per se, making a synchronous gastric drainage procedure unnecessary [67].

Laparoscopic Nissen Fundoplication: Technical Description

The following is a description of the author's technique for laparoscopic Nissen fundoplication. The patient is positioned at the foot of the operating table. In small children, the legs are taped in a crossed configuration with padding. In older children, a modified lithotomy position in stirrups is preferred. A preoperative dose of prophylactic antibiotics is given, and an esophageal bougie of age-appropriate size [59] is placed. The first trocar is placed in the umbilicus and the capnoperitoneum is insufflated. Additional trocars are placed under laparoscopic vision in the midepigastrium, entering the abdomen just to the left of the falciform ligament, and in the left flank area anterior and inferior to the lower spleen tip. A liver retractor is introduced through a stab incision from the right upper quadrant and lifts up the left lobe of the liver, exposing the hiatus (Fig. 93.3a). The 30° camera can be changed to an additional trocar in the future gastrostomy site to give a more direct view onto the hiatus. The gastrohepatic ligament is then divided using the monopolar hook cautery up to the hiatus (Fig. 93.3b). The right esophagophrenic ligament is divided, and a retroesophageal space is dissected bluntly just posterior to the esophagus, respecting the posterior vagus nerve and leaving the hiatus as intact as possible without deliberate dissection toward the chest. The fundus of the stomach is then rotated medially anterior to the esophagus, exposing the gastrosplenic ligament and the short gastric vessels on the left (Fig. 93.3c). Only the most superior gastrosplenic attachments are taken down using the monopolar hook to expose the left esophagocrural ligament. The ligament is divided and at this time the retroesophageal space is completely patent. Only if the hiatus is open, one or two crural stitches are placed to approximate it posteriorly (Fig. 93.3d). All stitches are performed using 2-0 silk sutures and a ski-shaped needle. At this time, an instrument is passed through the retroesophageal space from right to left, and the esophagus is lifted gently anteriorly. Usually, the fundoplication is visible when the camera is oriented to look through the retroesophageal window from the patient's right side. The fundus is grasped, pulled through the space behind the esophagus, and the anteriorly remaining fundus is sutured to the transposed fundus using three silk sutures. A small portion of the lower esophageal muscle fibers is incorporated into the stitch (Fig. 93.3e). The suture line of the fundoplication should be

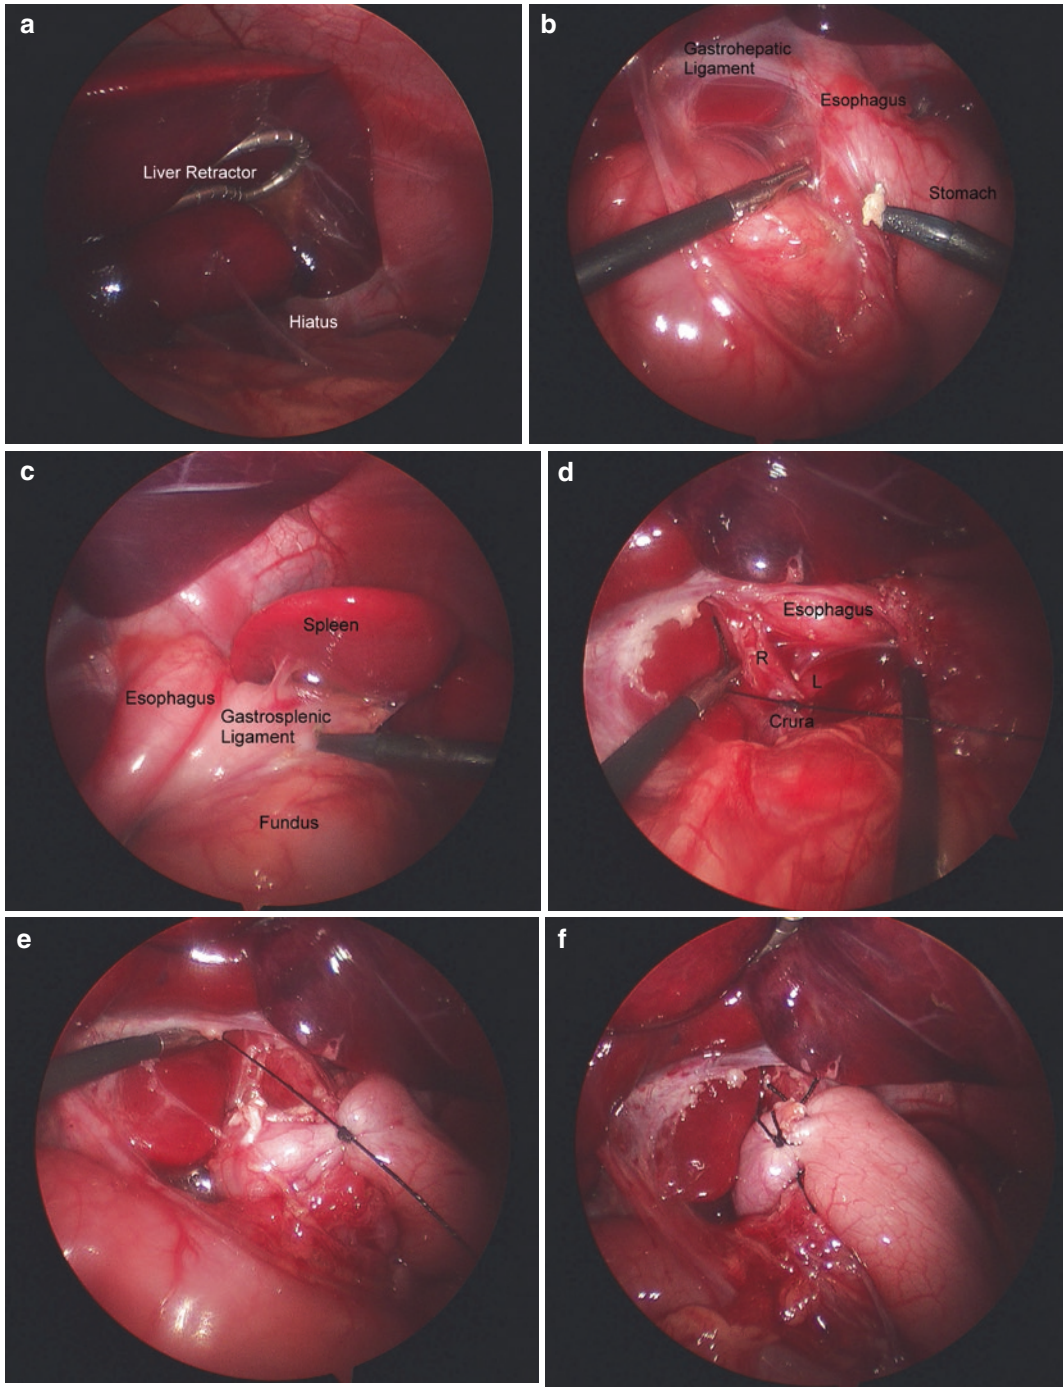

Fig. 93.3 Intraoperative images of laparoscopic Nissen fundoplication (see text for detailed explanation). The liver is retraced anteriorly, exposing the hiatus (**a**). The gastrohepatic ligament is opened to allow dissection of the space between the right crus and the esophagus (**b**). On the left, the superior part of the gastrosplenic ligament is divided as well (**c**). In this case, a crural stitch was placed posteriorly between the right (*R*) and left (*L*) crura (**d**). The posterior fundus is stitched to the anterior fundus around the lower esophagus (**e**). When completed, the suture line of the fundoplication is slightly medial and anterior (**f**)

located at the 10–11 o'clock position on the esophagus (anteromedially, Fig. 93.3f). Once completed, the bougie in the esophagus is withdrawn by anesthesia under vision. The capnoperitoneum is then desufflated and the endoscopic equipment is removed. Patients are allowed to have clear liquid diet when awake and advance to a no-chunk diet as tolerated. The no-chunk diet is maintained for approximately 3–4 weeks after the procedure, at which time regular diet is resumed.

Combination with Gastrostomy Tube

Laparoscopic gastrostomy tube placement can easily be performed along with laparoscopic fundoplication using the T-fastener or U-stitch technique [68]. Also, a percutaneous endoscopic gastrostomy (PEG) tube can be placed at the time of laparoscopic Nissen fundoplication with good results. Laparoscopic observation of the PEG placement may lower the procedure's complication rate [69].

Laparoscopic fundoplication in children who already have a gastrostomy tube in situ is feasible without increased complications [70]. Some surgeons prefer to take down the gastrostomy before fundoplication and perform a new gastrostomy thereafter, while others place the trocars around the gastrostomy site and leave it untouched. In this case, removing the gastrostomy tube before the sterile preparation and placing a sterile Foley catheter or similar into the gastrostomy site during the procedure are advisable.

Robotic and Innovative Approaches

Series of robotic-assisted fundoplication have been reported in children [71]. While it is more expensive, no clear benefits of the robotic approach have been shown in the clinical setting [72]. Operating times for the entire procedure were similar, although the dissection phase was about one third shorter with the robot. This temporal advantage was counteracted by a prolonged setup time for the robot [73]. The robotic approach has also been reported for redo Nissen fundoplication and fundoplication after gastrostomy tube placement in neurologically impaired children with acceptable perioperative complication rates and outcome [74]. One case-match control study comparing laparoscopic versus robotic versus open fundoplication including 50 pediatric patients in each treatment arm demonstrated longer operating times for robotic (160 ± 61 min) and laparoscopic (107 ± 31 min) compared to open fundoplication 73 ± 27 min, $P < 0.05$) with similar complication rates [75]. In an experimental study on infant pigs, conventional laparoscopic and robot-assisted fundoplication was equally effective, and there was a lower incidence of hemorrhage and pneumothorax in the robotic approach [76].

A single-incision laparoscopic approach for Nissen fundoplication has been described in ten children with complication rates and outcomes comparable to the conventional multi-trocar technique [77]. With the single-incision laparoscopic technique, all instruments and the laparoscope are brought in through a single incision in the umbilicus. When a synchronous gastrostomy is performed, the later gastrostomy incision is used as an additional access site, allowing for some ergonomic triangulation during the procedure. The most challenging part of the single-incision laparoscopic fundoplication is knot tying.

Inpatient admission and postoperative hospitalization for several days after a fundoplication are the current standard of care, although same-day outpatient laparoscopic Nissen fundoplication has been reported in a highly selected group of 19 children without any reported perioperative complications [78].

Recently, laparoscopic cardiaplication has been described as an alternative in patients with anatomic variants precluding formal fundoplication [79]. The technique entails a limited dissection along the most cranial greater curvature and subsequent imbrication of the cardia. It needs more formal evaluation before being universally recommendable.

The use of pledgeted mattress sutures rather than simple sutures for both the hiatal closure and the fundoplication reduced postoperative

recurrent reflux from 23.4 % to 5.7 % in a study of 384 children [80]. In another longitudinal study of a single surgeon using different methods to perform a Nissen fundoplication, additional sutures of the wrap to the diaphragm did not lessen the chance of failure, which was as high as 26 %, but reinforcing the actual fundoplication sutures with a second suture line eliminated wrap failure in 21 patients [81].

Radio-frequency application to induce circular collagen (scar) tissue in the area of the lower esophageal sphincter (Stretta procedure) has been reported in children, but has yielded only mediocre short-term outcome [82].

Results of Fundoplication

Fundoplication has made a tremendous difference in the lives of countless pediatric patients over the last half century. Studies show clear improvement in the children's symptoms and quality of life, particularly in those with neurological impairment [83, 84]. In a follow-up study of 40 patients who underwent a laparoscopic fundoplication, the parameters for growth, respiratory symptoms, proton pump inhibitor use, and global gastrointestinal quality-of-life index improved significantly after the operation. In this study the positive changes were similar in the 21 neurologically impaired and 19 healthy patients [85]. Furthermore, fundoplication leads to objectively measured improvement of gastroesophageal reflux measured by pH probe without adversely affecting esophageal motility [86].

The documented effects of fundoplication on respiratory symptoms are less striking. While 87 % of gastrointestinal reflux symptoms resolved in 151 children after Nissen fundoplication, only 45 % of patients with reactive airway disease had improvement in asthma symptoms or episodes of pneumonia postoperatively [87]. However, children with apparent life-threatening events (ALTEs) benefited from fundoplication, decreasing the readmission rate for ALTEs from 78 % before to 4 % after fundoplication in a cohort of 81 patients and follow-up times between 4 and 6 years [88].

Despite the unquestionable benefits of fundoplication, some pediatricians are concerned of inadvertent sequelae such as dysphagia, retching, dumping, and gas-bloat syndrome. In a systematic review of 15 studies of open and laparoscopic fundoplications, these complications were as high as 50 % in open procedures [89] and much higher than in the more recent laparoscopic studies. When counseling patients, it is important to take into account these advances. The reduction in morbidity due to the shift from open to laparoscopic technique may be one of the driving forces behind the increase in referrals for fundoplication in children over the last several decades [90].

The outcome of 385 open anti-reflux surgeries has been assessed by postoperative pH probe measurements, showing excellent efficacy and an immediate failure rate of just 2.9 % [91]. However, in a follow-up study on 176 children who underwent open fundoplication, dysphagia was recorded in 30 % and dumping syndrome in 3 % of the patients postoperatively [92]. Similarly, high rates of postoperative dumping (11.5 %), recurrent reflux (12.2 %), and dysphagia (12.8 %) were recorded in 148 patients who mostly underwent open fundoplication [93]. Of note, even with mortality rates as high as 13 % and major complications in 11 % of cases after open fundoplication in a cohort of 93 children, most parents were subjectively satisfied with the postoperative results on long-term follow-up [94].

In one of the first comparative retrospective studies on 120 patients, Collins et al. found a significantly shorter mean postoperative hospital stay (6.8 versus 10.7 days) and earlier time to full feeds (2.3 versus 4.8 days, respectively) for laparoscopic versus open fundoplication with similar complication rates [95]. The outcome of Nissen fundoplication in the laparoscopic era has dramatically improved. In a large analysis of 1,050 planned laparoscopic fundoplications in a single center, there were only two conversions to open technique. In this cohort, average operating times decreased from 109 min at the beginning of the observation period to 38 min in the last 30 procedures. The wrap failure rate was 4 %, and intraoperative complications occurred in only 0.26 % [96]. Another 5-year follow-up study of 238

neurologically normal children who underwent laparoscopic Nissen, Toupet, or Thal fundoplication demonstrated a 5 % intraoperative and 5.4 % postoperative complication rate. The incidence of dysphagia was 2.9 %, and only 2.5 % underwent a redo fundoplication during the observation period. At the 5-year follow-up mark, 96.3 % were free of reflux symptoms and without medications [97].

Although the postoperative cytokine response was found to be no different between open and laparoscopic fundoplication in a randomized trial of 40 children, postoperative immunosuppression measured by monocyte class II MHC was less pronounced in the laparoscopic group [98]. The same authors found no difference in postoperative analgesic requirement between open and laparoscopic Nissen fundoplication. However, fewer children retched, and there was a more pronounced decrease of insulin levels as an indicator of lower cortisol levels after laparoscopy [99].

In an analysis of 7,083 pediatric fundoplications across the United States between the years 2005 and 2008, 56 % were performed laparoscopically. Laparoscopic fundoplication was associated with much shorter length of stay (4 days versus 10 days) and lower cost (US$ 13,000 versus 22,000) when compared to open fundoplication. Furthermore, the laparoscopic group had a 21 % lower wound infection rate and a 51 % lower overall complication rate [100].

A recent systematic review of 17 prospective trials on fundoplication for gastroesophageal reflux disease including a total of 1,280 children found a median success rate of 86 % in providing complete relief of reflux symptoms without medication [57]. The surgical mortality rate was well below 1 %, and there were no cases of gas bloating reported in any of the included trials. Some studies reported less dysphagia with techniques that employ a partial wrap, with no other significant differences in outcome between techniques. Similar findings of shorter hospital stay, earlier feeding, and less morbidity with the laparoscopic approach were obtained in a meta-analysis of five studies [101]. Interestingly, robotic fundoplication was also associated with shorter postoperative stay compared to laparoscopic or open fundoplication in a study on 150 children [75].

Mortality after fundoplication does not usually result from the procedure, but rather from the comorbidities that prompted referral for the procedure in the first place. In a prospective observational study on 244 children who underwent Nissen fundoplication, 20 % died at a median follow-up time of 2.8 years [102]. The risk factors associated with mortality were cerebral palsy, female gender, and concomitant gastrostomy placement. Patients with cerebral palsy and gastrostomy placement had a particular high mortality rate of 41 % at 5 years follow-up, underlying the fact that many of these children have multiple morbidities contributing to the increased mortality.

Complications, Risks, and Alternatives

Despite the advances discussed above, fundoplication still has a relatively high failure rate (3–10 %) compared to other routine procedures in pediatric surgery in which the complication rates are usually around 1 %. Consequently, a detailed discussion about possible wrap dislocation, disruption, or migration and the potential need of a redo procedure is advisable with the patient and family before scheduling the operation. As discussed in the chapter on redo fundoplication, some patients may be predisposed to wrap failure, particularly those that exhibit preoperative retching with feeds.

Unfortunately, there is no reliable method to avoid postoperative retching. Some surgeons advise decreasing the feeding rate or venting the gastrostomy between feeds and when retching occurs. According to one study, a pureed gastrostomy tube diet in lieu of the more conventional formula feeds may reduce the incidence of postoperative gagging and retching after fundoplication by modulating stomach emptying [103].

At times, the intraoperative findings preclude the completion of a planned fundoplication. Severe adhesions may increase the risk of the hiatal dissection, or the stomach may not be large enough to perform the desired loss wrap. In these cases, a Roux-en-Y feeding jejunostomy may be

an alternative [103], although the complication rate was found to be as high as 51% [104]. Placing a gastrostomy for later gastrojejunostomy tube placement is another option [105]. In an observational study, this approach had similar outcome to fundoplication in terms of survival or postoperative pneumonias [106].

Conclusions

Fundoplication has conferred immense benefits to countless children suffering from gastroesophageal reflux disease. When performed laparoscopically and using contemporary technique, outcome is usually excellent, and the morbidity and mortality from the procedure are low.

Reoperative MIS Fundoplication

94

Oliver J. Muensterer, Carroll M. Harmon, and Keith E. Georgeson

Introduction

Nissen fundoplication has become the procedure of choice in children with gastroesophageal reflux disease (GERD) refractory to medical therapy [1]. Most procedures are performed laparoscopically, with a low perioperative complication rate and minimal morbidity. Unfortunately, these excellent short-term results are dampened by a relatively high long-term failure rate of 2.5–25 % [2–4]. At our own institution, the long-term failure rate over the last decade is around 12 %. The most common underlying mechanisms for fundoplication failure include hiatal herniation into the chest, as well as slippage, misplacement, or breakdown of the wrap [5]. This can lead to recurrent gastroesophageal reflux and the sudden onset of recurrent symptoms. This chapter describes the risk factors and mechanisms of fundoplication failure, the indications for redo fundoplication, and the surgical technique.

Risk Factors for Failure

Pediatric surgeons must be well aware of the risk factors for fundoplication failure before performing the procedure in a child. This awareness impacts on surgical indications, the discussion with the caregivers about the procedure, and selection of the technique most appropriate for the individual patient. General risk factors for fundoplication failure are neurologic impairment, younger age, lower body weight, and surgery performed via the open rather than the laparoscopic approach, while the presence of a gastrostomy and older age seems to have a protective effect in multiple regression analysis [6].

Specifically, a matched case-control study of over 400 pediatric patients under 6 years of age showed that the presence of a hiatal hernia or dysphagia associated with an esophageal stricture were preoperative risk factors for recurrent GERD after a fundoplication [7]. In the same study, 7.2 % of 417 laparoscopic fundoplications performed at this particular center were redo procedures, of which 80 % presented with recurrent reflux symptoms and 20 % with dysphagia and a tight wrap. One-third of the patients who underwent a redo procedure were neurologically impaired. Furthermore, previous esophageal atresia repair was identified as a potential preoperative risk factor for fundoplication failure in up to one-third of these patients [8].

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_94

Neurologic impairment is well documented as one of the prime factors associated with recurrent reflux after fundoplication. In a retrospective analysis of 127 children, gastroesophageal reflux eventually recurred after laparoscopic Nissen-Rossetti fundoplication in 12 % of neurologically impaired children, but in only 2 % of their neurologically normal peers [9]. However, the recurrence rate in neurologically impaired children has been recorded as low as 6 % elsewhere [10]. In another report, 19 of 252 open pediatric Nissen fundoplications underwent reoperation, with an average interval between the procedures of 1.6 years (range 1 month to 5.5 years), and 11 of the 19 children being neurologically impaired [11]. Neurologic impairment was also found to be an independent risk factor for postoperative complications in 12 out of 106 kids who underwent laparoscopic Nissen fundoplication [12].

The main mechanism of failure in this cohort was herniation of the fundoplication through the hiatus in eight, and incompetence or dehiscence of the wrap in six cases. At our own institution, lower age, the presence of retching, and performing postoperative esophageal dilatations were identified as postoperative risk factors [13]. Although retching has also been associated with fundoplication failure in older studies [14], a causal nature has not been confirmed so far [6].

Intraoperative technique may predispose to fundoplication failure in children. In a recent randomized controlled multicenter study on 177 children who underwent fundoplication, performing an extensive versus minimal dissection of the hiatus increased the risk of recurrent GERD from 7.8 % to 30 % and the need for redo fundoplication from 3.3 % to 18.4 % [15]. The current standard should therefore be to leave the esophagocrural and esophagophrenic attachments intact during the dissection phase of the procedure.

Hiatal hernia was the most common cause of fundoplication failure in 30 of 66 (46 %) retrospectively reviewed children requiring redo fundoplication, followed by a combination of herniation and disrupted fundoplication in 22 (3 %), disruption of the wrap alone in 10 (15 %), and too tight a wrap in 4 (6 %) patients [14]. There is some evidence that the mechanisms of failure may be different for laparoscopic versus open fundoplication. While most laparoscopic failures were found to be due to herniation and fundoplication dehiscence, wrap slippage was the primary reason for failure in the open group [16].

Indications for Redo Fundoplication

Redo fundoplication is indicated when symptoms of gastroesophageal reflux recur after a fundoplication, and cannot be managed by conservative means such thickened feeds, positioning, proton-pump inhibitors, or prokinetics. In some cases, when the wrap is partially intact, the antireflux effect of the wrap may not be completely annihilated, and the addition of medication may avoid the need for redo surgery. If conservative methods are unsuccessful, or if a hiatal hernia is present, redo fundoplication should be performed.

In many cases, the caregivers can describe a discrete time point at which the patient started vomiting again or experienced a significant deterioration of clinical status. Anatomically, up to 75 % of fundoplication failures are associated with a hiatal hernia, and in 49 %, the wrap is intact [17]. As mentioned above, the wrap may have become too lose, and occasionally, the wrap can slip to a location below the esophagogastric junction, rendering it ineffective.

The diagnostic procedure of choice in patients with recurrent reflux symptoms is a radiographic upper gastrointestinal contrast study, either via the oral route or, if present, through a gastrostomy tube if the patient cannot tolerate liquids by mouth (e.g., in cases of aspiration). The study is performed to evaluate the fundoplication, which, if intact, is usually visible as an indentation at the level of the gastroesophageal junction, and to rule out an associated hiatal hernia. In some cases, frank gastroesophageal reflux is evident, although the contrast study can only document a snapshot over a discrete, limited time period. In clinically ambiguous cases, esophageal 24 h pH-probe

recording, manometry, or impedance measurements are indicated to confirm recurrent reflux. Esophagoscopy can also be helpful, either by identifying an anatomic abnormality such as hiatal hernia, frank esophagitis, or the presence of lipid-laden alveolar macrophages in bronchoalveolar lavage [18].

Treatment and Technique

Over the last decade, fundoplication by laparoscopy has been established as the standard and preferred technique in children. However, many pediatric surgeons still revert to an open procedure to treat recurrence. There is no doubt that redo fundoplication is technically much more challenging than the primary operation, illustrated by the relatively long mean operating time of 140 min for the redo procedure, with a range of 110–240 min [7]. Several studies have looked at the technical aspects and practicability of laparoscopic versus open redo fundoplication.

In one report, laparoscopic reoperation was feasible in 10 out of 15 cases, and the redo operation was more likely to be completed laparoscopically after a previous laparoscopic than after an open initial fundoplication (7 of 8 versus 3 of 7 cases, respectively). Also, it was easier to perform after a previous Thal or Toupet fundoplication compared to an initial Nissen fundoplication [19]. In a smaller study, one out of four attempted laparoscopic redo fundoplications was converted to the open procedure [20].

During laparoscopic redo fundoplication, care must be taken while placing the first trocar. Due to the previous operation, bowel loops may be adherent and need to be identified. We always perform a blunt, open access technique, but would recommend it especially for all laparoscopic redo operations.

In most cases, dense adhesions are found between the esophagus, the stomach, the diaphragm, and the liver (Fig. 94.1a). Sharp dissection of these adhesions using the Metzenbaum scissors under traction and countertraction is usually most effective. The operation itself can be quite bloody, and we generally attach unipolar electrocautery to the scissors in the laparoscopic procedure, so that small bleeding vessels can be cauterized immediately during the dissection without changing instruments. Occasionally, newer tissue sealing instruments can be helpful, although collateral heat dissipation to the stomach or esophagus is a concern which makes sharp dissection with the cold scissors the safer option. Because of the potential for bleeding, a suction-irrigation system should be set up and available during the procedure. It is advisable to have blood available intraoperatively in case significant hemorrhage is encountered.

Because fundoplication failure may be due to many factors, a tailored approach is required. In some cases, hiatal hernia repair may be required only, while in others, the actual wrap must be revised as well [21].

In principle, the hiatus of the diaphragm must be dissected (Fig. 94.1b) and a potential hiatal hernia reduced. The hiatus is subsequently closed securely anteriorly and posteriorly around the esophagus with a dilator in place using permanent braided sutures (we prefer 2-0 silk on a ski-type needle, Fig. 94.1c, d). If the wrap has unraveled, it should be completely taken down, and a new, geometrically sound and secure wrap is created (Fig. 94.1e, f). In cases where the wrap is loose or stretched, simple reinforcement and tightening with additional sutures can be attempted. Laparoscopic redo fundoplication has been performed in the Nissen, Nissen-Rossetti, and Toupet technique [7].

Some surgeons have proposed using a patch to reinforce the hiatal closure in redo fundoplication. In adults, a posteriorly placed polypropylene mesh has been used for this purpose in both laparoscopic Nissen and Toupet fundoplications [22]. Using this approach, only 2 of 66 patients developed a recurrent hiatal hernia over a follow-up time of 5 years. In children, one study described no recurrences in eight redo Nissen fundoplication cases repaired with a Surgisis mesh compared to 31 % of 13 patients repaired without mesh in a mean follow-up time of 26 months [23]. While reinforcing the hiatus with

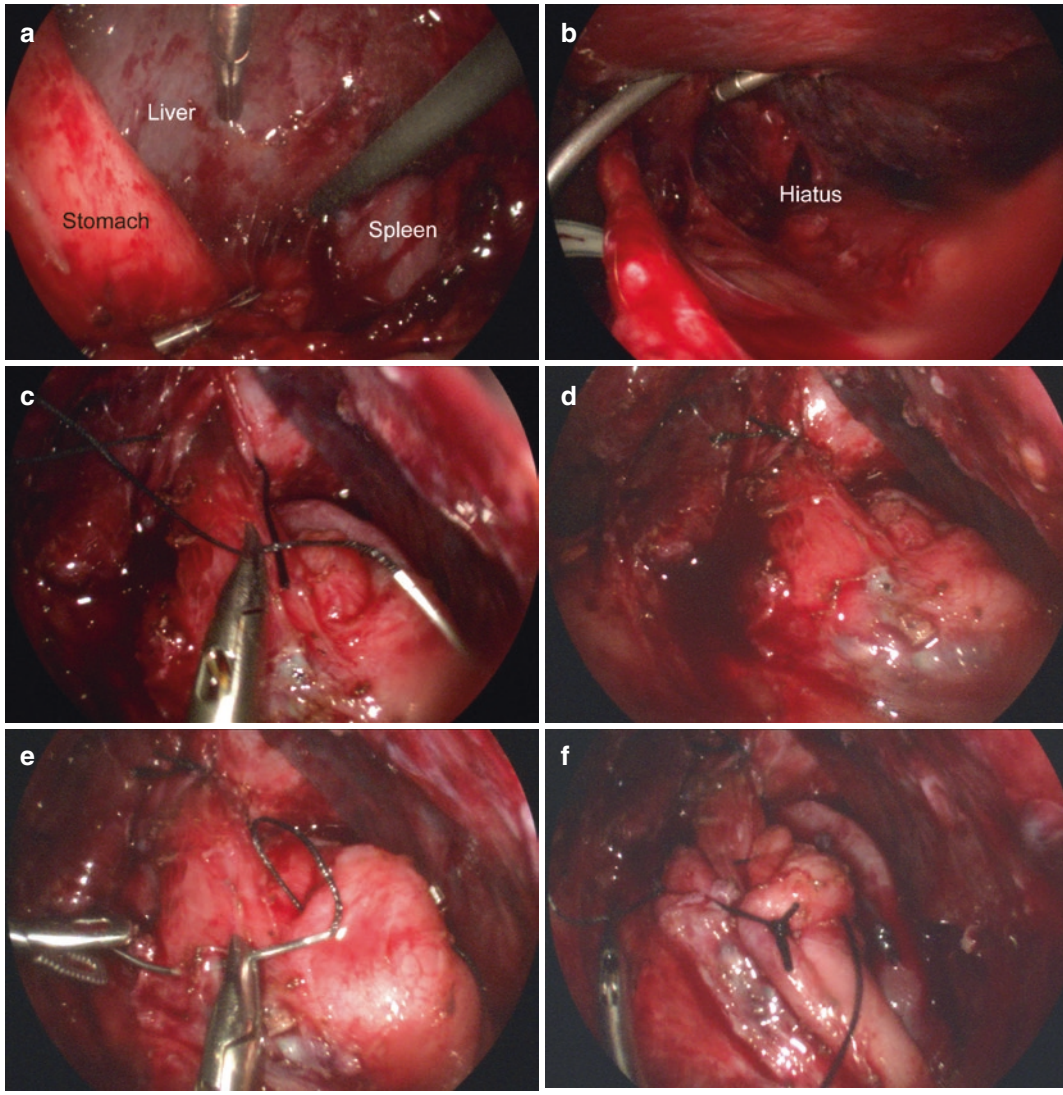

Fig. 94.1 Every redo fundoplication requires a tailored approach. In most cases, dense adhesions must be taken down carefully (**a**) to expose the hiatus and the anatomical problem, in this case an unraveled wrap and a widely open esophageal hiatus (**b**). With the largest possible size dilator in the esophagus, the hiatus is closed anteriorly (**c**). Subsequently, the unraveled wrap is exposed (**d**) and recreated (**e**, **f**)

a mesh may decrease the recurrence rate, the scarring and adhesions induced by the patch make any future operation more challenging in our experience.

An alternative to redo fundoplication may be lower esophageal sphincter radiofrequency ablation [24]. Of six patients treated in this fashion, five were asymptomatic 3 months after the procedure, and half discontinued antacid medications. One patient went on to undergo a redo fundoplication, and in another patient, the radiofrequency ablation was repeated 10 months later.

Another option described for children with neurological impairment who are exclusively tube fed is the esophagogastric separation. However, this procedure carries a high complication rate, with half of patients not tolerating their saliva, and reoperations for either a colonic perforation or

paraesophageal hernia in two of ten patients [25]. It should therefore be reserved for particularly severe and otherwise unmanageable cases.

Results of Redo Fundoplication

Early Results

As mentioned before, fundoplication, in general, and redo fundoplication, in particular, are some of the most complication-prone operations in pediatric surgery. In adults, the success rate of laparoscopic redo fundoplication was only 86 % [26], similar to the 17 of 19 (89 %) children reported to be free of symptoms after open redo fundoplication in a recent study [11]. In another report, redo fundoplication failed to resolve symptoms in 20 % of 66 children with recurrent reflux, and 5 of those eventually were treated by a second redo fundoplication [14].

Laparoscopic redo fundoplication was found to be more challenging in adults, and resulted in a hospital stay that was three times longer than after primary fundoplication (3 days versus 1 day), as well as significantly higher costs [27].

In one study, redo fundoplication was successfully completed laparoscopically in 89 % of first operations and 68 % of redo operations, highlighting the increasing degree of difficulty and intraoperative conversion rate. Consequently, the average operating times of redo fundoplication were over 2 h [17]. On the other hand, all 118 laparoscopic redo Nissen fundoplications were completed without conversion in a single-surgeon case series, with an average operating time of 100 min, and a failure rate of only 6 % [28].

Long-Term Results

In general, the risk of recurrent gastroesophageal reflux increases with every redo fundoplication performed in a patient. Roughly one-quarter of patient required another redo procedure after the first one [17]. Neurologic impairment again is a significant risk factor, with new reflux symptoms appearing in 6 out of 30 patients (20 %) after a follow-up period of 2–12 years, 5 of which were neurologically impaired [7]. Half of neurologically impaired children with recurrent reflux symptoms after a fundoplication eventually failed conservative treatment and eventually underwent a redo fundoplication [12].

Table 94.1 Results of redo fundoplication at the Children's Hospital of Alabama [11]

	1st redo ($n=72$)	2nd redo ($n=19$)	3rd redo ($n=3$)
Conversion to open surgery	8 (11 %)	6 (32 %)	1 (33 %)
Operation time (min)	132 ± 60	156 ± 54	204 ± 18
Length of stay (days)	5.0 ± 4.8	4.9 ± 3.2	6.0 ± 3.0

In a cohort study of 221 adults, redo fundoplication was less effective in suppressing reflux symptoms than the primary operation. Average quality of life scores were lower as well after a redo procedure, compared to the first fundoplication, particularly on long-term follow-up more than 2 years after surgery [29].

At the Children's Hospital of Alabama [17], conversion rates were higher, and operative times were longer with each redo procedure attempted laparoscopically on a patient (Table 94.1).

Complications and Risks

Apart from the risk of recurrent reflux highlighted in the previous section, other perioperative complications have been described. In a recent publication, one pleural perforation occurred in 30 redo fundoplications [7]. Intraoperatively, pleural perforation may lead to pneumothorax, and sudden respiratory deterioration of the patient. Whenever the ventilatory status of the patient acutely changes, one must think of this possibility. A chest radiograph and tube thoracostomy may be indicated.

In at least one instant, a Dacron patch placed around a large hiatal defect eroded into the esophagus and required reoperation [21]. For this reason, we prefer to use bioabsorbable patches made from porcine or bovine collagen.

As discussed previously, intraoperative complications can also include significant bleeding when taking down extensive adhesions. An increased risk of esophageal or gastric perforation has also been described [11].

When discussing the complications of a redo fundoplication, one must weigh them carefully against the risks of not performing the operation. Children without protective airway reflexes may aspirate refluxed gastric contents into their lungs, leading to pneumonia or even asphyxia. In a long-term follow-up study [30], 80 % of 20 patients who underwent an open redo fundoplication did well after the procedure. One of the remaining four patients who again presented with recurrent reflux symptoms underwent a third Nissen fundoplication and also did well. The others were managed conservatively, and one of these eventually died.

Conclusion

Fundoplication is a procedure with a high recurrence rate. A pediatric surgeon who performs fundoplications should be familiar with the signs and symptoms of recurrent gastroesophageal reflux, knowledgeable on the diagnostic work-up of children with suspected wrap failure, and skilled in performing a redo fundoplication if indicated. The laparoscopic approach may be superior to open methods, even for these more difficult redo cases. Depending on the mechanism of recurrent reflux, the fundoplication wrap may require tightening or complete reconstruction, and a hiatal hernia should be repaired. The risk of recurrent reflux in a patient increases with the number of redo fundoplications performed.

Endoscopic Approaches to the Treatment of GERD

95

Mike Thomson

Gastroesophageal reflux disease (GERD) is symptomatic reflux associated with sequelae. These include failing to thrive, refractory wheezing coughing aspiration, acute life-threatening events, apnea, chronic otitis media, sinusitis, hematemesis, anemia, esophageal strictures, and Barrett's esophagus [1, 2]. A follow-up of 126 children with gastroesophageal reflux disease in infancy showed 55% were symptom-free by 10 months and 81% by 18 months of age [3]. However, those with frequent symptoms (>90 days) in the first 2 years of life are more likely to have symptoms by 9 years of age [4].

Gastroesophageal reflux treatment aims to achieve symptom relief while preventing complications. Patients who fail to achieve control with medical therapy may have persistent severe esophagitis or become long-term dependent on antireflux treatments. In such cases an antireflux procedure may be indicated [1, 5]. The principle of surgery in gastroesophageal reflux disease is to form some kind of reconstruction of the antireflux barrier, although exactly how efficacy is achieved is not fully understood. Open Nissen's fundoplication has been the treatment of choice to date, but is invasive and associated with morbidity and mortality [6, 7]. In recent years laparoscopic fundoplication has become popular and, in general, has replaced the open Nissen's procedure, although superior efficacy and safety has yet to be demonstrated [8]. With the laparoscopic procedure, cosmesis is clearly superior, and in adult studies, complications appear less common, with good success rates [9, 10]. It could be argued therefore that there remains little or no place for open antireflux procedures in pediatrics.

Three endoscopic techniques have been devised and used for treatment of pediatric GERD. These are described below.

Endoscopic Suturing Devices

Endoluminal gastroplication makes use of an EndoCinch® sewing machine attached to the endoscope (gastroscope) placing three pairs of stitches below the gastroesophageal junction to create three internal plications of the stomach [1–16]. Plications may be applied in any manner dependent on operator preference. These may be applied circumferentially or longitudinally. The authors have a preference of placing two plications circumferentially 1.5 cm below the gastroesophageal junction and one 0.5 cm below the gastroesophageal junction, which we believe anatomically may be superior to other formations [11, 12] (Figs. 95.1, 95.2, 95.3, and 95.4).

DOI 10.1007/978-3-642-11202-7_95

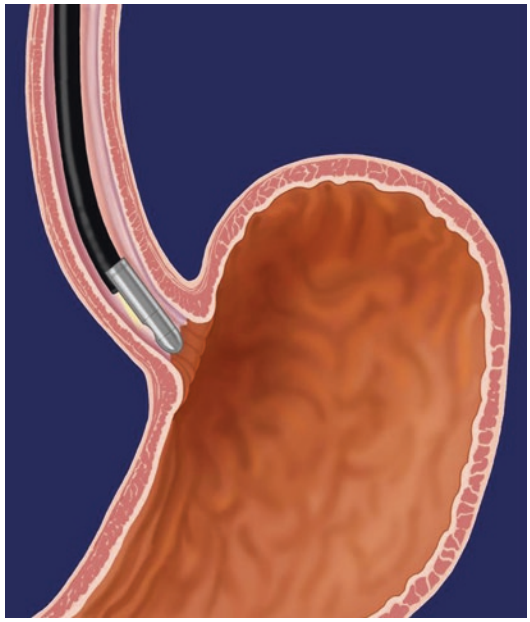

Fig. 95.1 EndoCinch front-mounted on endoscope

Endoluminal gastroplication is now routinely carried out as a day-case procedure in adults. Preliminary studies have shown it to be quick, noninvasive, effective, and safe [11, 17]. Results are comparable to the laparoscopic fundoplication in adults [8, 10, 11, 17], which has been studied as a preferable alternative choice to an open Nissen's fundoplication [11, 18].

Recently, the authors have reported use of EndoCinch® (endoscopic gastroplication using a flexible endoscopic sewing device) in the treatment of 17 children (8 males, median age 12.9 years, range 6.1–17.7; median weight 45 kg, range 16.5–75) with gastroesophageal reflux disease refractory to, or dependent on (>12 months) proton pump inhibitors [19]. All patients showed posttreatment improvement in symptom severity, frequency, and validated reflux-related quality of life scores ($p<0.0001$) (Fig. 95.5). At 36 months median follow-up, 11/17 patients were asymptomatic and off all antireflux medica-

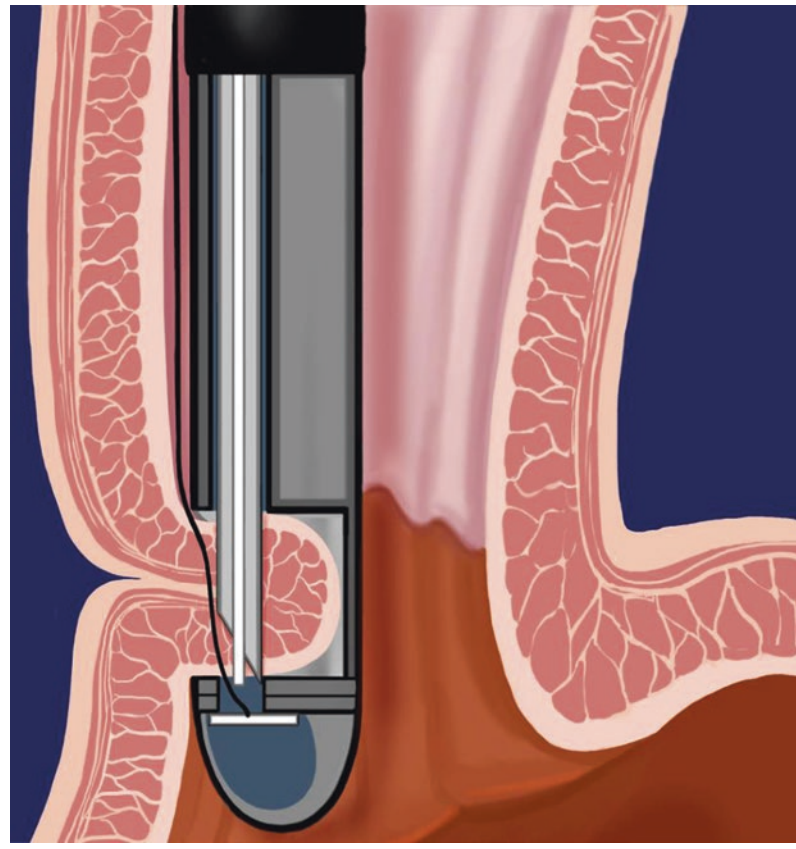

Fig. 95.2 Suction applied and full-thickness tissue capture followed by needle and pusher wire placement of stitch

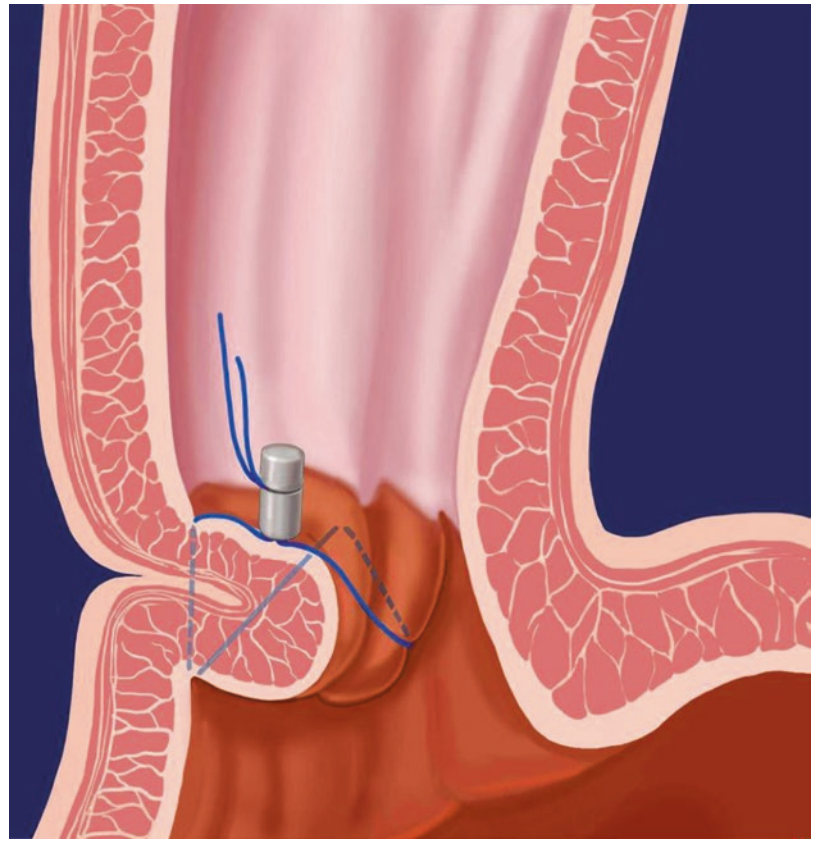

Fig. 95.3 Endoscopic gastroplication. This figure the pattern of a zigzag stitch when applied with an EndoCinch® sewing machine

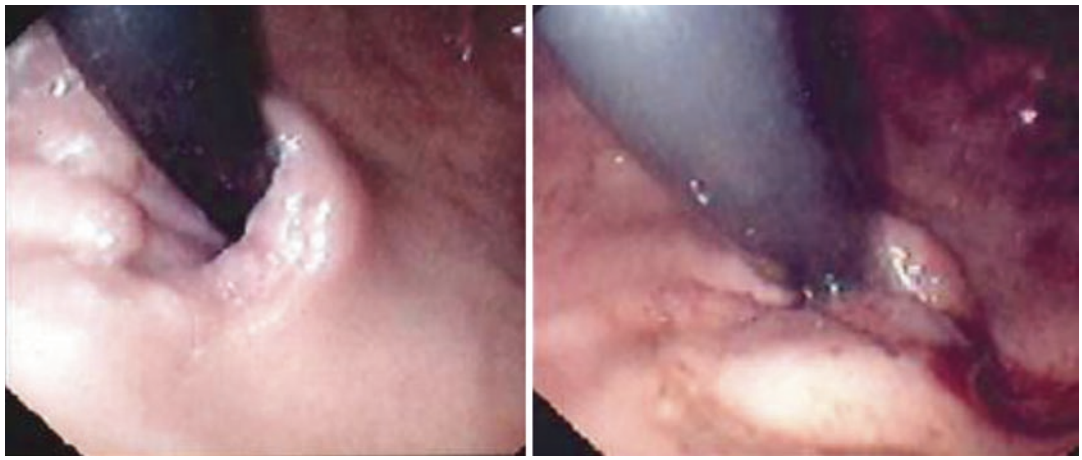

Fig. 95.4 View (J maneuver) of a lax GE junction in a child with major reflux after application of stitch with the EndoCinch®

tions. At 12 months follow-up, all pH parameters improved and had returned to normal in eight out of nine who underwent pH studies (reflux index fell from 16.6 % (0.9–67 %) to 2.5 % (0.7–15.7 %) ($p < 0.0001$)) (Fig. 95.5).

The duration of action is open to ongoing assessment and debate and has not been particularly impressive in adult studies. The reasons for superior efficacy and duration in children may be conjectured and may be due to some or

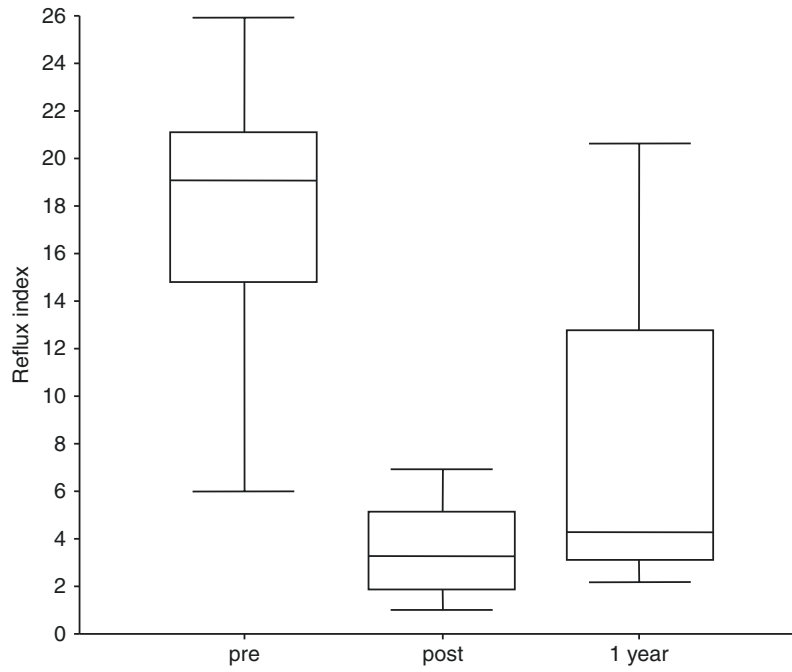

Fig. 95.5 EndoCinch® pediatric series pH efficacy at 1 year

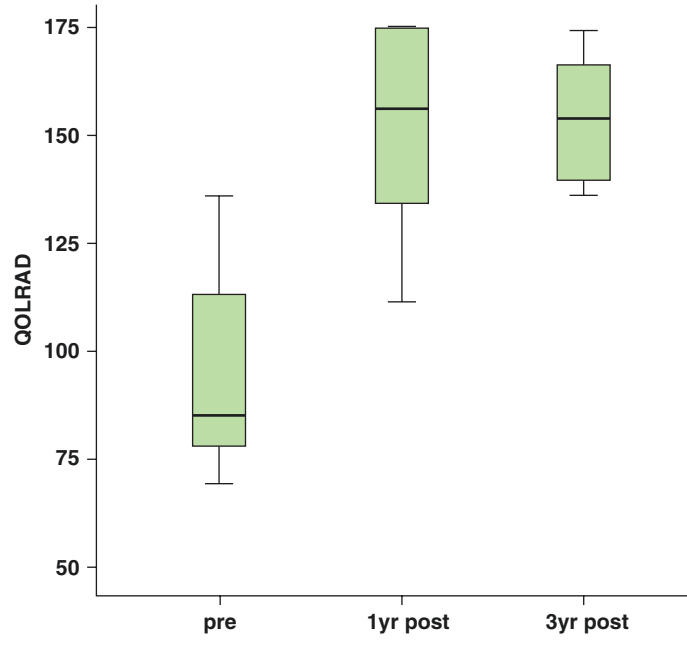

Fig. 95.6 Significant improvement in the total QOLRAD score 1 and 3 years after gastroplication with the EndoCinch®

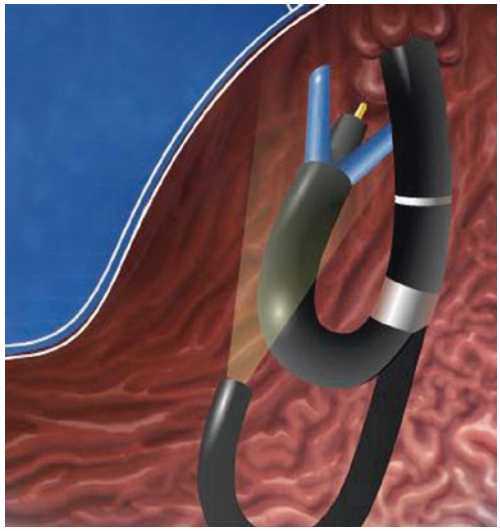
all of the following: three pairs vs two pairs of sutures, greater time and care taken by the operator allowed by general anesthetic with the added advantage of the absence of movement or retching during the procedure, and lastly the relatively deeper suture depth in the thinner pediatric esophagus compared to the larger adult one. Data are now available indicating medium term success in terms of reflux-related quality of life scoring at 3 years post-EndoCinch and in terms of avoidance of PPI need in the majority of patients [20]. This is a small study but worthy of mention (Fig. 95.6).



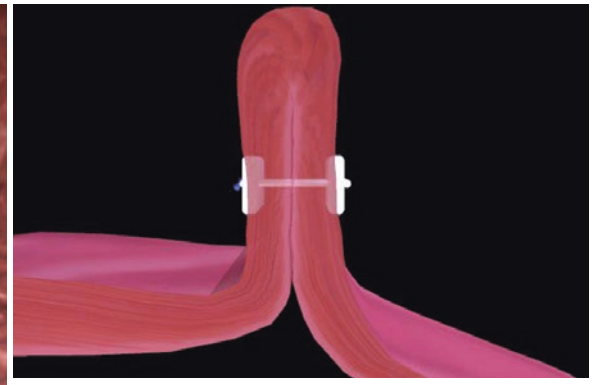


Fig. 95.7 and 95.8 Application of the Full-Thickness Plicator® (NDO Surgical)

Despite the loss of sutures on observational follow-up studies, some efficacy has been maintained, and the human and porcine endo-ultrasound studies of Liu et al., along with cadaveric analysis of the porcine model post-EndoCinch®, may throw some light on this observation [21]. They suggest that the tissue remodeling in response to the foreign body, which is the suture, resulting in significant hypertrophy of the circular muscle layer of the esophagus may be the reason.

Nevertheless, EndoCinch® has not maintained its initial enthusiastic uptake and has been recently superceded by the next generation of full-thickness gastroplication trans-oral endoscopic techniques.

The next to appear was the Full-Thickness Plicator® (NDO Surgical). This is placed under direct vision with a neonatal size endoscope passed through a specially designed endoscopic delivery system with an outer diameter of more than 20 mm. The retroflexion of both allows observation of firstly the opening of the jaws of the device, followed by the insertion of the corkscrew into the fundal tissue allowing capture of the fundus and withdrawal into the jaws which are then closed. A pre-tied full-thickness plication is then applied by the mechanism of shutting the jaws, and a serosa to serosa plication is made (Figs. 95.7, 95.8, and 95.9). A multicenter adult study has shown acceptable efficacy and a reduction of PPI requirement in a small adult cohort [22], and further study is necessary before this should be applied to children – the device is size- and age-constrained due to its large outer diameter.

EsophyX

This device is representative of an alternative to the Plicator technology along a similar theme, although not identical.

The novel Trans-oral Incisionless Fundoplication (TIF)® procedure using EsophyX® mimics antireflux surgery in constructing an anterior partial fundoplication with tailored delivery of multiple fasteners during a single-device insertion (Figs. 95.10 and 95.11) [23]. The TIF procedure was designed to restore the antireflux competency of the gastroesophageal junction through reducing small hiatal hernias, increasing lower esophageal sphincter (LES) resting pressure, narrowing the cardia, and recreation of the acute angle of His [24–28].

Clinical results with TIF at 1, 2, and 3 years support its efficacy in eliminating heartburn and regurgitation, reducing the daily use of PPIs, nor-

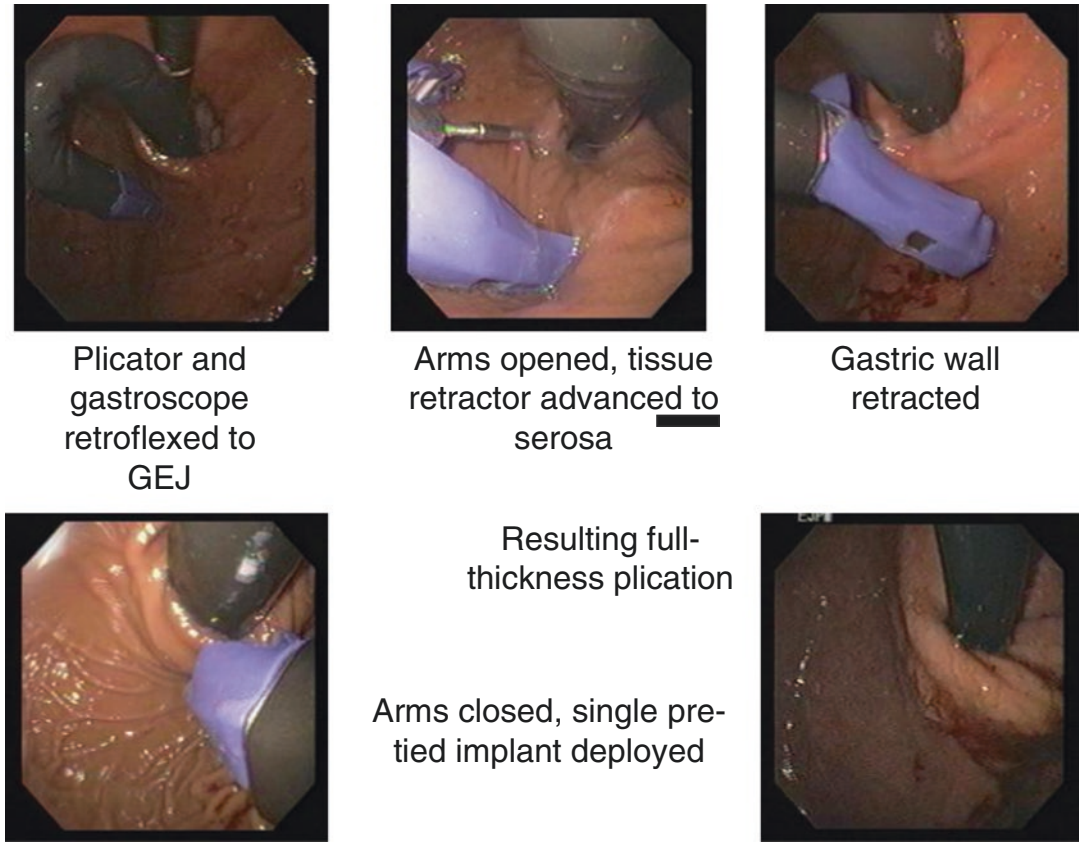

Fig. 95.9 Retroverted views of stages of application of Full-Thickness Plicator® (NDO Surgical)

malizing esophageal acid exposure, and reducing proximal extent of refluxate [24, 27, 29–31]. Based on a 1-year result, FDA cleared EsophyX in September 2007 for the treatment of GERD and small (<2 cm) hiatal hernia [24].

The TIF procedure has been demonstrated to be safe in adults. Post-TIF adverse events are mild and transient and include musculoskeletal and epigastric pain, nausea, and dysphagia up to 1 week secondary to sore throat [24, 29]. Only three esophageal perforations have been reported to date for 3,000 cases performed worldwide. None of the subjects experienced chronic dysphagia, gas bloating, and diarrhea at long-term follow-up [24].

A feasibility study was started in December 2008 after obtaining appropriate training in the use of the EsophyX® device in its second iteration – the so-called TIF2 procedure. The feasibility study was conducted with 12 children (8 male) with a median age of 12.25 years (8–18 years) and weight of 38.2 kg (26–91) [32]. The median duration of GERD symptoms was 45 months (24–70), and all subjects were on GERD medication for more than 6 months. The median pre-TIF2 reflux index of treatment was 11.4 % (6–48). Hiatus hernia was present in 17 % (2/12). Median operative time was 42 min (range 25–94). Adverse events were experienced by three subjects and consisted of mild or moderate pharyngeal irritation and epigastric pain. Two of the three subjects also had retrosternal chest pain and were subsequently found to have pneumomediastinum on CT chest but no leak on barium swallow. One of these two patients had pyrexia accompanying chest pain and was treated for possible mediastinitis and discharged home after 5 days of intravenous antibiotics. Subsequently, CO_2 insufflation was employed, and more rapid absorption resulted in no further periprocedural mediastinal gas leak.

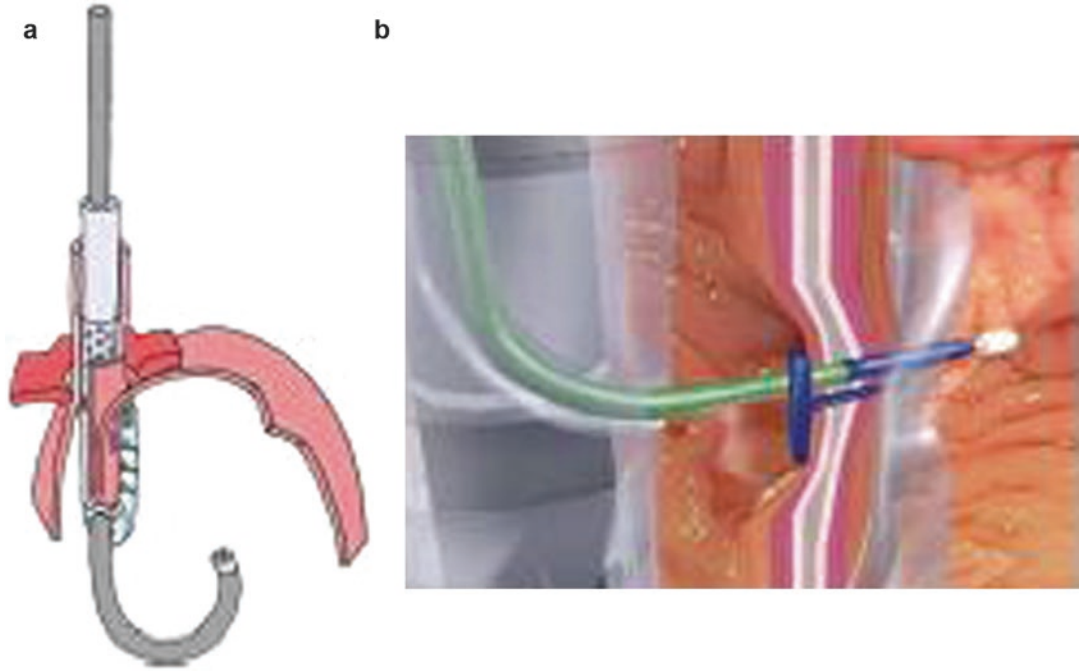

Fig. 95.10 Distal end of the EsophyX® device (**a**) and SerosaFuse Fastener (**b**). The valve is constructed by drawing tissue into the device with the aid of a helical retractor. The tissue mold is then closed over the retracted tissue and the fasteners are deployed. The fastener is delivered by a pusher that slides over a stylet (Illustration from Jobe et al. [25])

At 6-month follow-up, all subjects ($n=10$) discontinued PPIs; 80 % were asymptomatic and 70 % had normalized or clinically significantly reduced reflux index (10 % time pH <4). The results of this feasibility study showed that the TIF procedure was feasible, safe (with CO_2 insufflation), and clinically effective in treating GERD in children. Ongoing studies are occurring.

Delivery of Radiofrequency Energy (the Stretta® System)

The Stretta® system has two parts, one a Stretta® catheter and the other Stretta® control module. The Stretta® catheter is a flexible, handheld, single-patient use device that delivers radiofrequency energy generated by the control module (Fig. 95.12). It is inserted into the patient's mouth and advanced to the gastroesophageal junction. A balloon is inflated and needle electrodes are deployed into the tissue. Radiofrequency energy is delivered through the electrodes to create thermal lesions in the muscle of the lower esophageal sphincter and gastric cardia. As these lesions heal, the tissue contracts, resulting in a reduction of reflux episodes with improvement in symptoms. The Stretta® control module delivers this radiofrequency, while at the same time providing feedback to the physician regarding treatment temperatures, tissue impedance values, elapsed time, catheter position measurement, and irrigation rate.

This treatment has been used in adults since 1999. Complications are rare, but among reported are ulcerative esophagitis with gastroparesis, esophageal perforation, and a case of aspiration following the procedure [32–34]. Short-term (1 year) success was reported in an open-label trial. In a prospective study (nonrandomized controlled trial) of 75 patients (age 49 ± 14 years, 44 % male, 56 % female) undergoing laparoscopic fundoplication and 65 (age 46 ± 12 years, 42 %, 58 % female) undergoing

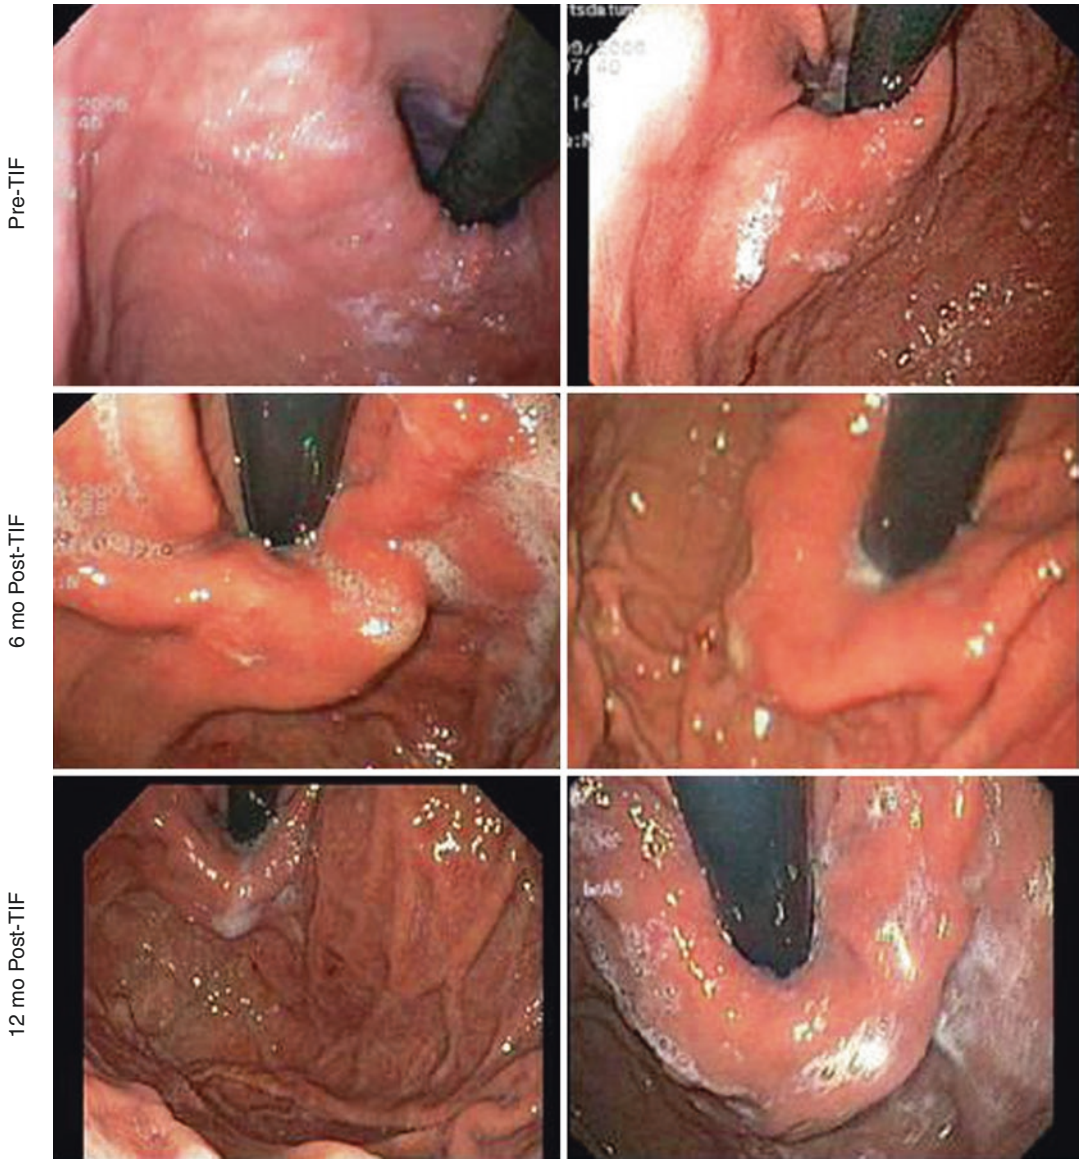

Fig. 95.11 Endoscopic images of gastroesophageal valves from two subjects before and at 6 and 12 months after TIF1 (Illustration from Cadiere et al. [24])

the Stretta® procedure, at 6 months, 58 % of Stretta® patients were off proton pump inhibitors, and an additional 31 % had reduced their dose significantly. In comparison, 97 % of laparoscopic fundoplication patients were off PPIs [35]. With long-term follow-up of these patients receiving the Stretta® treatment, beyond 2 years, 56 % had discontinued use of all antisecretory drugs [36].

This treatment has been reported in an uncontrolled study of a group of eight children with a variable follow-up period of 5–15 months [37]. It was reported that six out of eight children improved, and the cohort included three neurologically impaired children who also had concomitant PEG placement. One of this group had a postprocedure aspiration which was successfully treated. Of the two failures, one remained

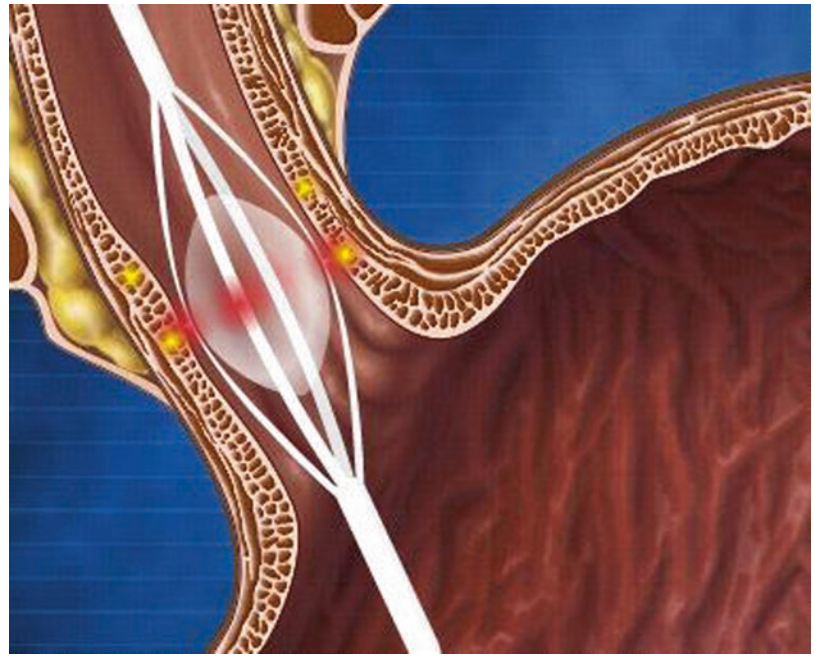

Fig. 95.12 The Stretta® system. The use of a balloon to deliver radiofrequency energy via needle electrodes to the mucosa

dependent on PPI and the other had a successful Nissen's fundoplication.

Pediatric gastroenterologists may be guarded in using this form of treatment as clearly using thermal energy treatment in a 70-year-old is different to a child who may have unknown consequences in the long term. Hence this is not recommended.

Gastroesophageal Biopolymer Injection

In the EnteryX® procedure, a liquid polymer is injected into the lower esophageal sphincter (LES) with a needle catheter via an endoscope. After the injection, the polymer solidifies into a sponge-like permanent implant. This improves the gastroesophageal junction, by supporting and improving its elasticity and therefore reducing the degree of gastroesophageal reflux (Fig. 95.13).

Cohen, in an international open-label clinical trial on 144 patients, showed greater than 50% reduction in PPI in 84% at end of 1 year and 72% by 2 years with elimination in 67% of patients [38]. In a prospective, randomized trial, endoluminal gastroplasty (EndoCinch®) was compared with EnteryX® in 51 consecutive patients dependent on proton pump inhibitor therapy. At 6 months, proton pump inhibitor therapy could be stopped, or dosage was reduced by more than 50% in 20 of 26 (77%) EndoCinch®-treated patients and in 20 of 23 patients treated by EnteryX® (87%, $p=0.365$). Approximately 25% of the patients in both groups required retreatment in an attempt to achieve symptom control. To date an estimated 3,800 patients have been treated with the EnteryX® device, which was approved in 2003 by the FDA. To date there are no published records of its use in pediatrics.

However, the FDA and Boston Scientific Corp. notified healthcare professionals and patients about serious adverse events, including death, occurring in patients treated with the EnteryX® device. Based upon reports filed with the FDA, patients suffered leakage, swelling, and ulcers in the esophagus. One elderly patient died after some of the polymer had been injected into the woman's aorta, which ruptured, causing her to bleed to death.

On September 23, 2005, Boston Scientific Corp. ordered a recall of all EnteryX® Procedure Kits and EnteryX® Injector Single Packs from commercial distribution. The com-

Fig. 95.13 Injection of liquid polymer into the esophageal mucosa. The EnteryX® procedure

pany's recall notice stated some doctors accidentally punctured the wall of the esophagus while injecting the substance, causing adverse events. Additionally, Boston Scientific Corp. recently suspended sales of its EnteryX® device after more than two dozen reports of problems. The notice was posted on the company's Web site, during the week of September 19, 2005 [39].

Summary

The most promising results seem to accrue in the midterm with the suturing devices which attain full-thickness plications, increase the intra-abdominal portion of the esophagus (most likely by plication tags inserting through the diaphragmatic crura as well as the full thickness of the esophageal wall, i.e., actual change in anatomy), and raise intra-sphincteric length and resting pressure. Endo-ultrasound may provide a more controlled and sophisticated approach to this technology in the future.

Repair of Hiatus Hernia

96

Balgopal Eradi and Richard J. Stewart

Introduction

Hiatus hernia in children represents a heterogenous group of conditions, the common factor being protrusion of abdominal content into the chest via the oesophageal hiatus. It is the most common form of herniation of abdominal content through the diaphragm. Yet it does not find prominence in most textbooks of paediatric surgery. This may be because the commonest variety is almost synonymous with gastroesophageal reflux, and the other types are relatively rare. This chapter will deal with the different types of hiatus hernia in children in terms of aetiopathogenesis, epidemiology, clinical features, treatment and outcome. A few case studies are included to demonstrate the heterogeneity of hiatus hernia in children, and the operative strategies that may have to be devised to effectively deal with the problem.

Anatomy of the Oesophageal Hiatus

The oesophagus enters the abdomen from the chest through an opening in the diaphragm – the oesophageal hiatus. Accompanying the oesophagus are the right and left vagus nerves, oesophageal branches of the left gastric artery and lymphatics of the lower oesophagus. Structurally, the diaphragm consists of a central tendinous portion into which circumferentially arranged muscle fibres attach. The crura are musculotendinous structures that anchor the diaphragm to the lumbar vertebrae and blend with the anterior longitudinal ligament of the vertebral columns. The medial fibres of both crura may arise from the median arcuate ligament which arches over the aorta as it enters the abdomen from the chest (Fig. 96.1).

The right crus is longer and broader and is attached to the anterior surfaces of the bodies and intervertebral discs of lumbar vertebrae 1–3 [24]. In the standard pattern, it passes cranially and anteriorly, dividing into a large right and smaller left limb which surround the oesophagus and decussate anteriorly before each attaching with the central tendon. The left crus is small and usually takes no part in the formation of the hiatus. It does, however, decussate with the right crus to the left of the oesophageal hiatus. Deviations from this standard pattern are common. The left crus may be completely separate and not

decussate at all with the right. Or it may provide increasing contribution to the formation of the oesophageal hiatus such that rarely, the hiatus is formed completely by the left crus [13].

Phreno-oesophageal Membrane

The phreno-oesophageal membrane has been described as a creamy-white layer that bridges the gap between the diaphragm and the oesophagus. It is an arrangement of elastic and collagenous fibres that derive from the peridiaphragmatic fascia and fan out to penetrate the distal 2–3 cm of the oesophageal muscle. It is thought to tether the distal oesophagus within the hiatal tunnel and maintain the oesophagogastric junction in its correct intra-abdominal position. The main component is formed by the fascia on the abdominal aspect of the diaphragm. This divides at the level of the hiatus into a thick inferior limb and a thin superior limb that passes upward to meet with the contribution from the endothoracic fascia. The membrane inserts into the oesophagus in layers of elastic fibres with small areolar spaces in between. Fat is absent in this structure [13]. Its elastic component allows the normal physiological movement of the lower oesophagus [63].

In infants, the oesophagus is firmly anchored by the phreno-oesophageal membrane as well as the thickened crus around the hiatus – sometimes called a "hiatal tunnel". Both the membrane and the "hiatal tunnel" become progressively attenuated with age [13].

Definition and Classification (Fig. 96.2)

The term hiatus hernia describes any form of herniation of abdominal content into the chest through the oesophageal hiatus. Sliding hiatus hernia, also called type I, refers to the presence of the gastroesophageal junction and a portion of the adjoining stomach in the mediastinum either transiently or continually [32]. In practice, however, the term hiatus hernia used in isolation is almost synonymous with the sliding variety.

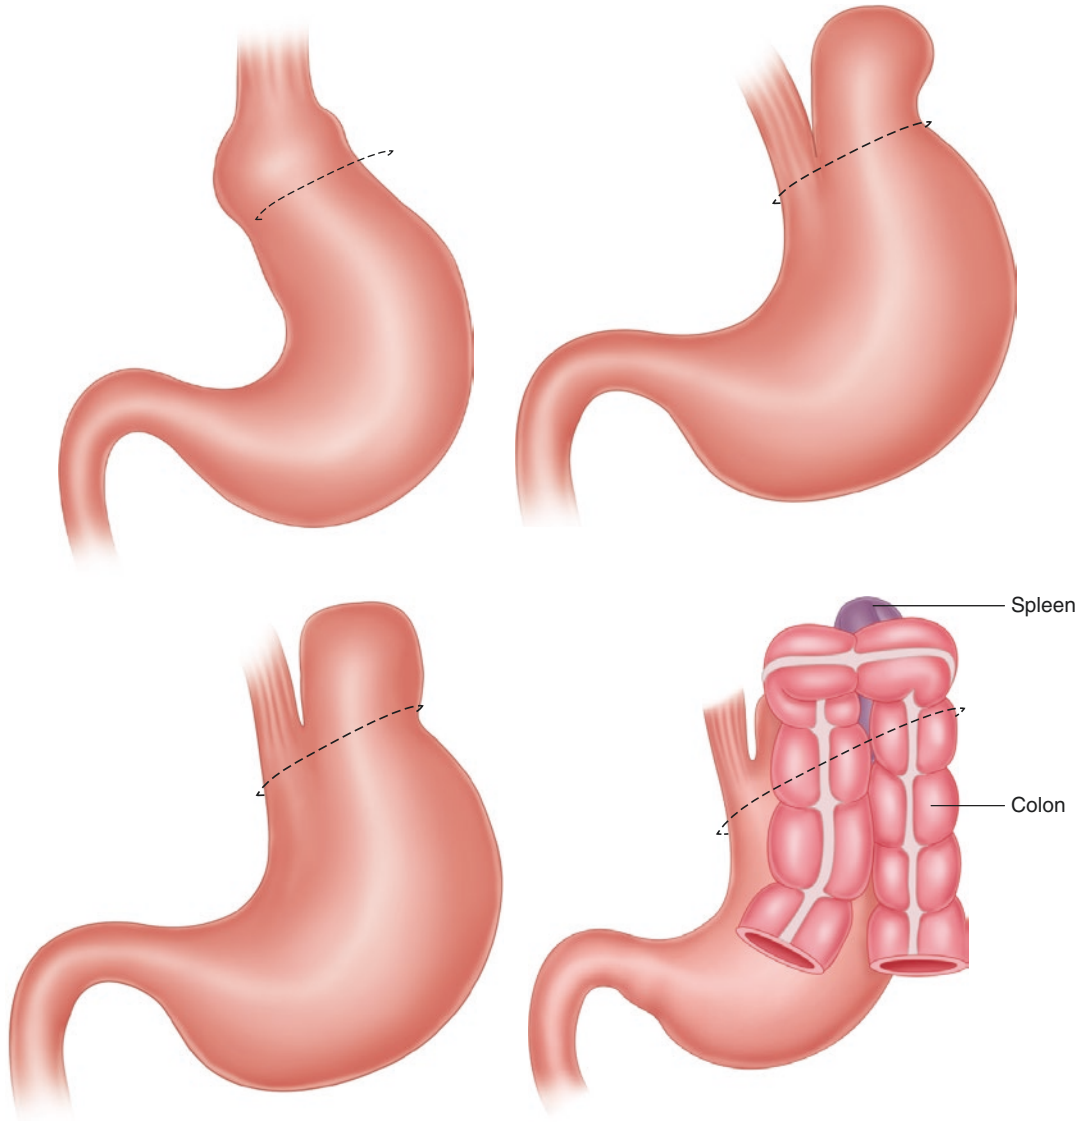

Fig. 96.2 Classification of hiatus hernia – a diagrammatic representation. Type I, sliding; type II, rolling; type III, mixed; type IV

In sliding hiatus hernia, the hiatal muscular tunnel is progressively enlarged and its normal slit-like configuration becomes a rounded opening. There is laxity of the phreno-oesophageal membrane, and this laxity determines the extent to which the stomach herniates into the chest. The membrane, however, is intact so that the herniated stomach is confined to the posterior mediastinum [40]. Initially, it is the extraperitoneal (bare) area of the stomach that is drawn upward, but as the condition progresses, the serosa-lined stomach is drawn in as well resulting in a peritoneum-lined sac. The sac is always empty except for the presence of the stomach [61].

Type II hiatal hernia is also known as paraoesophageal or rolling hiatus hernia. In this

defect, the gastroesophageal junction remains within the abdomen, usually held in place by fascia posteriorly and to the right toward the median arcuate ligament and the aorta. The gastric fundus forms the lead point and herniates into the chest alongside the oesophagus. The most common finding is to have the anterior wall of the fundus herniate into a ventral recess, anterior to the gastroesophageal junction. There is an associated defect in the phreno-oesophageal membrane or it is markedly attenuated. In older patients, the theory is that the pressure difference between the thorax and abdomen causes a progressive increase in the proportion of herniated stomach. The end result is that in time, the entire stomach herniates into the chest such that the pylorus and gastroesophageal junction are found in close approximation with organoaxial volvulus. This anomaly has been referred to as the "upside-down stomach" or type IIA [61]. In paediatric patients, however, there is little doubt as to the congenital nature of the defect, and an upside-down stomach may be detected at birth.

In most instances, as the type II defect progresses, the gastroesophageal junction becomes mobile as well and herniates through the hiatus into the mediastinum forming a mixed or type III hiatus hernia [61].

In type IV hiatus hernia, other abdominal viscera such as the small bowel, colon and spleen may be found within the chest [61].

Paraoesophageal hiatus hernia with more than a third to half of the stomach in the chest has been variously described as giant or massive paraoesophageal hernia [5, 25].

Antenatal Diagnosis

Congenital hiatus hernia has been diagnosed on antenatal ultrasound scans. Sonographic features that suggest the presence of hiatus hernia are (1) A hypoechogenic structure in the posterior mediastinum, anterior to the vertebral bodies and posterior to the heart. (2) The absence of mediastinal shift or pleural or pericardial effusion. (3) Abnormal location of the stomach which may be identified in a median position in the abdomen when it is partially herniated. If the stomach has herniated completely, the intra-abdominal gastric bubble may be absent. (4) The dynamic aspect of the stomach, i.e. its up-down movement through the enlarged hiatus into and out of the thorax. This last feature is considered the most helpful in the diagnosis. The differential diagnoses on prenatal ultrasound scans are oesophageal atresia and congenital diaphragmatic hernia [7, 19, 49, 57, 70].

Magnetic resonance imaging can help to confirm the antenatal ultrasound based diagnosis [57].

Genetics and Inheritance

Hiatus hernia in children as well as in adults is largely sporadic in incidence. However, familial incidence is well known. The incidence of sliding hiatus hernia in siblings of affected children has been estimated as being 10 % which is 20 times the estimated childhood population incidence of 0.5 % [67]. An autosomal dominant pattern of inheritance of sliding hiatus hernia has been suggested based on the identification of families in whom the condition occurs in numerous members over multiple generations [17, 18]. Though a genetic basis for severe gastroesophageal reflux disease in children has been suggested [50], no genetic basis has been identified for hiatus hernia, and despite numerous instances of familial clustering of both sliding and paraoesophageal hiatus hernia, no firm conclusion can be drawn as to the mode of inheritance [6, 22, 31, 55, 72].

There are reports of paraoesophageal hiatus hernia in the neonatal period associated with Marfan's syndrome [2, 35, 51, 52]. The hiatus hernia is the result of laxity of the ligamentous attachments of the oesophagus and stomach. Other connective tissue disorders like Ehlers-Danlos syndrome may also be associated with hiatus hernia [51]. Menkes disease, a rare disorder

of copper metabolism, has also been reported in association with hiatus hernia [60].

Embryology

The foregut is that part of the gastrointestinal tract that extends from the pharynx to the ampulla of Vater. As the foregut grows, a bulge appears which is destined to become the stomach. The diaphragm develops around the foregut, cephalad to the stomach. The dorsal and ventral mesogastrium in the region of the developing diaphragm forms the ligamentous attachment of the oesophagus to the diaphragm known as the phreno-oesophageal membrane. Variations in the length and fixation of this membrane allow abnormal mobility of gastroesophageal junction and are directly responsible for the occurrence of sliding hiatus hernia [43].

During development of the diaphragm, blind pouches form on either side of the dorsal and ventral mesogastrium extending into the mediastinum and communicating with the peritoneum. With the rotation of the gut, these peritoneal recesses come to lie anterior and posterior to the oesophagus. The recesses are described as being transitory, but their persistence may be responsible for paraoesophageal hiatus hernia. Thus this form is a hernia into a pre-formed peritoneal recess comparable to paracaecal and paraduodenal hernia [43].

Defective differentiation of the splanchnic mesenchyme has also been implicated in the aetiology of a paraoesophageal hiatus hernia. According to this theory, normal rotation of the midgut depends upon the position of the duodenum, which in turn depends on the normal development of duodenal musculature from splanchnic mesenchyme. The splanchnic mesenchyme also gives rise to the diaphragm around the foregut. Interference in the process of smooth muscle differentiation could result in both paraoesophageal hernia and associated malrotation [20].

Mixed hiatus hernias are likely to reflect a combination of laxity of the phreno-oesophageal ligament and persistence of peritoneal recesses [53].

Sliding (Type I) Hiatus Hernia

Incidence

Prior to 1951, only 93 children had been reported to have a hiatus hernia [14]. The diagnosis of hiatus hernia became much more prevalent consequent to evaluation of greater numbers of vomiting infants by contrast radiography. Carré estimated a childhood population incidence of 0.5 % [67]. However, the frequency with which sliding hiatus hernia is found depends upon the aggressiveness of the radiologist. Using abdominal compression, radiologists claim to be able to demonstrate a small hiatus hernia in 50–80 % of the adult population. It is believed that approximately 10 % of the adult population of North America will demonstrate a sliding hiatus hernia during barium swallow [61].

Presentation and Natural History

Carré has published the most comprehensive long-term cohort studies of infants diagnosed with hiatus hernia [14–16, 38]. His experience comprises 710 infants studied prospectively. Eighty patients have been followed up for more than 30 years. The initial presentation of sliding hiatus hernia in infants is by regurgitation or vomiting of feed. In Carré's series, 65 % of infants with symptomatic hiatus hernia become symptom free by 2 years of age without any treatment. This group of patients will improve clinically on weaning. Thirty-five percent of patients will worsen or fail to improve after weaning and will have troublesome reflux beyond the age of 4 years. Fourteen percent of patients who fail to improve on weaning will develop an oesophageal stricture if untreated.

If treated by postural therapy, 90 % will be free of symptoms by a year of age. About half the patients will have occasional heartburn as adults, though this is no more than the stated population incidence. The hiatus hernia will, however, continue to be demonstrable by radiological means in 40 % of patients after 20 years. Radiological resolution occurs by 4–6 years.

Though older children have poorer rates of resolution, 40 % will still respond to conservative measures.

Hiatus Hernia and Gastroesophageal Reflux

A competent gastroesophageal junction is essential to prevent gastroesophageal reflux. The functional integrity of the gastroesophageal junction has been attributed to numerous factors. A hiatus hernia has potential to cause disturbance to many of these. Progressive anatomical anomaly caused by the hiatus hernia results in decreased effect of the crural sling, straightening of the angle of His, loss of the abdominal segment of oesophagus and failure to maintain the lower oesophageal sphincter in the abdomen [39]. In addition, clearance of gastric acid from the oesophagus is impaired in patients of hiatus hernia [65]. This effect is particularly marked in patients who have non-reducing hiatus hernia [39]. The impairment in oesophageal clearance of acid in patients of hiatus hernia further accentuates gastroesophageal reflux-induced oesophageal mucosal injury [65].

The relationship of hiatus hernia with gastroesophageal reflux in terms of symptoms or complications is far from straightforward. As mentioned earlier, there are numerous patients who have a hiatus hernia without gastroesophageal reflux and vice versa. Hiatus hernia is therefore not an all or none phenomenon but a continuum of progressive disruption of the gastroesophageal junction. Large hiatus hernias are more significant clinically and are therefore more likely to require surgical intervention [39].

Diagnosis

Hiatus hernia is a radiological diagnosis made on contrast radiography. The indication to perform an upper gastrointestinal contrast series is prompted by symptoms attributable to gastroesophageal reflux that are "troublesome" or associated with complications [59].

The predominant radiological features that indicate the presence of a hiatus hernia are (1) a supradiaphragmatic lower oesophageal sphincter, (2) gastric mucosal folds above the hiatus, (3) a very wide hiatus or a wide portion of oesophagus above it and (4) a lateral notch representing the incisura angularis seen above the diaphragm [64].

The ability to make the diagnosis is dependent upon the experience of the radiologist, the use of adequate contrast and the time spent doing the study [36].

Management

The management of hiatus hernia is almost synonymous with that of gastroesophageal reflux disease which has been dealt with in detail in preceding sections of this book. The mere presence of a hiatus hernia does not alter management though it is more likely that the reflux and associated problems will fail to respond to conservative measures alone.

The indications for surgery are similar to those in patients of gastroesophageal reflux in the absence of a hiatus hernia and have been elucidated in previous sections.

Operative Treatment

The story of the evolution of modern anti-gastroesophageal reflux surgery from operations aimed at curing hiatus hernia is fascinating (Table 96.1). Over time, surgery to correct what was ostensibly an anatomical anomaly became one aimed at restoring the physiology of the gastroesophageal junction. Currently, reduction of the sliding hiatus hernia and narrowing of the hiatus, i.e. restoration of the anatomy of the oesophageal hiatus, are only a component of the overall procedure.

Congenital Paraoesophageal Hernia (Types II, III and IV)

Paraoesophageal hernias represent only 2–5 % of all hiatus hernias in series comprising adult patients [6, 41]. Paraoesophageal hernias that

1919	Soresi	Describes operative repair of a paraoesophageal hernia [62]
1926	Akerlund	Coins the term "hiatus hernia" and provides a classification [66]
1928	Harrington	Describes operative correction of various hiatus hernias [27]
1937	Nissen	Reconnects a patient's oesophagus to his stomach following gastric resection for a perforated ulcer at the cardia. To reinforce his anastomosis, he mobilised the stomach and wrapped it around the oesophagus "in much the same manner as the rubber tube in a Witzel's gastrostomy" [47]
1951	Allison	Recognises that sliding hiatus hernia caused disturbance of the gastroesophageal junction leading to symptoms of gastroesophageal reflux. Devises a method for anatomical correction [3]
1942–1957	Belsey	Defines the technical principles of antireflux surgery – restoration of a competent valvular mechanism at the cardia rather than reduction of the internal hernia – "a physiological rather than anatomical solution" [11, 12]
1954	Barrett	Calls attention to other mechanisms, in particular the gastroesophageal angle, to prevent gastroesophageal reflux [10]
1955	Boerema	Describes anterior subhepatic gastropexy [68]
1956	Nissen	Describes similar procedure. Though initial results are encouraging, gastropexy in isolation is soon abandoned [48]
1956	Nissen	Examining the patient from 1937 16 years later, he noticed there were no subsequent symptoms of gastroesophageal reflux
		He adopts this method of wrapping the fundus of the stomach around the oesophagus to treat patients of hiatus hernia [47]
1977	Rosetti	Modifies Nissen fundoplication to obviate dysphagia and to preserve vagal innervation. The modification involved using only the anterior wall of the fundus for the wrap around the oesophagus and ensuring that this was done loosely [56]
1986	DeMeester	Further elucidation of the physiological basis of Nissen fundoplication. Advocates "short and floppy" fundoplication [23]

present in childhood or infancy are considerably rarer. Fewer than 130 patients have been reported in English language literature [1, 4, 6, 8, 9, 21, 26, 28, 30, 31, 33–35, 41, 42, 44–46, 54, 58, 69, 71]. Of these, nearly half are reported in a single series over 42 years from South Africa [41]. While it is very likely that there are numerous unreported cases, paraoesophageal hiatus hernia in infants and children remains a rare condition.

Presentation and Natural History

The average age of presentation based on reports in infants and children is around 2 years though symptoms may occur at any time after birth. There is no predilection for either sex; males and females are affected in equal measure. Unlike in sliding hiatus hernia in which there is physiological derangement of the gastroesophageal junction, most symptoms of paraoesophageal hernia

are mechanical in origin. The mass effect of the paraoesophageal hernia on the respiratory apparatus is responsible for its most common constellation of symptoms – respiratory distress and/or recurrent respiratory infections. An unusual noise in chest which may be exacerbated by feeding has also been described [34, 35, 54].

As the stomach herniates into the chest, the pylorus and gastroesophageal junction approximate each other and the greater curvature of the stomach rotates upward resulting in organoaxial volvulus. This may cause obstruction at the pylorus, gastroesophageal junction or both. Alternatively, obstruction may occur at the middle of the body of the stomach. Recurrent vomiting, which is usually non-bilious but may occasionally be bile-stained is the next most common mode of presentation.

In older children, presentation may be insidious with epigastric or retrosternal discomfort which may be related to feeds, nausea, dysphagia and occasional vomits. Diagnosis is often delayed due to the nonspecific nature of the symptoms.

A significant proportion of patients are anaemic. The anaemia is microcytic and hypochromic and represents chronic blood loss. The blood loss occurs due to reflux oesophagitis or due to ulceration of the inflamed, oedematous mucosa of the incarcerated stomach [34, 41].

Though patients may be quite ill due to respiratory infection and chronic malnutrition, catastrophic presentation with complete obstruction or strangulation and gangrene of the stomach has not been described in the paediatric age group.

Other features that have been reported include sweating, potentially due to vagal effect and self-induced vomiting.

Anomalies associated with paraoesophageal hernia are summarised in Table 96.2.

Diagnosis

A chest radiograph is often the initial modality. Features of paraoesophageal hernia on plain chest radiograph are paracardiac opacity or air fluid level in the chest. The fluid level is seen behind the cardiac shadow on a lateral film. In the appropriate clinical setting, a plain chest radiograph may be all that is necessary to proceed to surgical correction. Differential diagnosis on plain chest radiograph includes congenital diaphragmatic hernia – usually right-sided, Morgagni hernia, eventration of diaphragm, lower lobe pneumonia, pleural effusion, pneumothorax, pneumatocele and bronchogenic cysts. Insertion of a nasogastric tube is helpful to differentiate a primary lung or thoracic condition.

Definitive diagnosis is by contrast upper gastrointestinal series. The contrast study will conclusively demonstrate the herniation of the stomach into the chest. It is often difficult however to ascertain the exact location of the gastroesophageal junction and the orientation of the stomach. Sometimes, the sac may be empty or may only contain omentum at the time of the contrast study, and this may confound the diagnosis.

CT of the chest and abdomen has been used to gain additional anatomical information [9], but generally, cross-sectional imaging does not contribute to the management [30, 41].

Management

It is generally agreed that surgical intervention is warranted as the condition is likely to progress, and there is no likelihood of spontaneous resolution.

Due to alteration of the anatomical relations of the hiatus, oesophagus and the fundus of the stomach, the physiology of the gastroesophageal junction is affected resulting in gastroesophageal reflux in nearly 2/3 of patients following repair of the hiatus hernia alone [41]. A concomitant anti-reflux procedure is therefore advisable though some would debate this [29].

Some authors also recommend gastropexy either by fixation of the fundus posteriorly or by Stamm gastrostomy to decrease the chance of recurrence [34, 35].

Results

In series that have reported a reasonable length of follow-up, the overall results are good. Mortality has been reported in four patients. Three neonates from a single series [35] died due to multiple associated anomalies, pneumonia secondary to neonatal Marfan's syndrome and fungal sepsis. A 4-month-old with compromised lungs due to recurrent aspiration died postoperatively due to pneumonia and the resulting sepsis and respiratory insufficiency [33].

Recurrence of the paraoesophageal hernia has been reported in three patients, none of whom had a gastropexy at the initial operation [35, 71].

The most common complication reported is intestinal obstruction due to adhesions, reported in eight patients overall [35, 41].

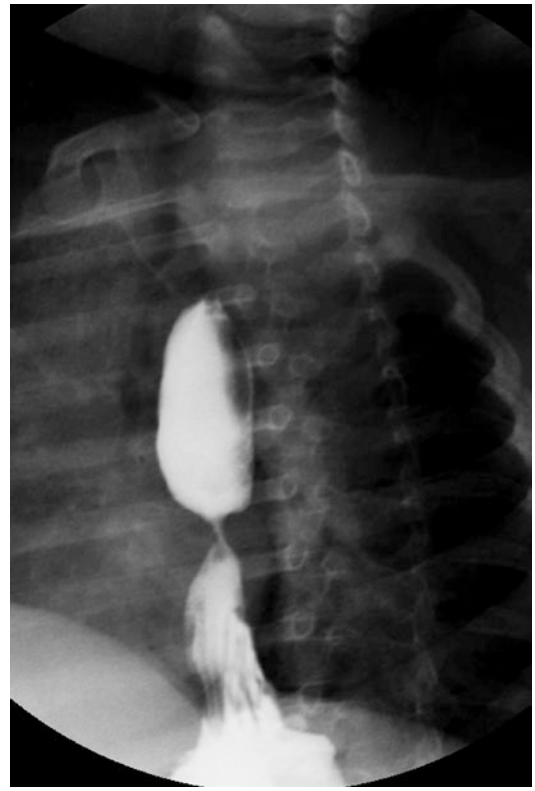

Fig. 96.3 Contrast swallow demonstrating an oesophageal stricture and hiatus hernia

Case Studies

Sliding Hiatus Hernia Complicated by Oesophageal Stricture

A 13-month-old child was referred with progressive difficulty in feeding for 4 months having been treated conservatively with gastroesophageal reflux from the age of 3 months. Contrast swallow was performed which revealed a hiatus hernia and an oesophageal stricture (Fig. 96.3). A laparoscopic Nissen fundoplication with concomitant oesophageal dilatation was performed. A "short and floppy" wrap was created over a bougie. As the operation has been described in detail in preceding chapters, it will not be further elaborated upon here.

Following the operation, the child has been free from symptoms.

Type III Hiatus Hernia in Newborn

A newborn baby was transferred to us with failure to tolerate any feeds due to vomiting and associated choking episodes. The symptoms prompted a contrast upper gastrointestinal contrast series (Fig. 96.4) which showed the entire stomach had herniated into the chest.

Fig. 96.4 A previously unreported neonate with herniation of the entire stomach into the chest. The pylorus and proximal duodenum are clearly seen in the chest

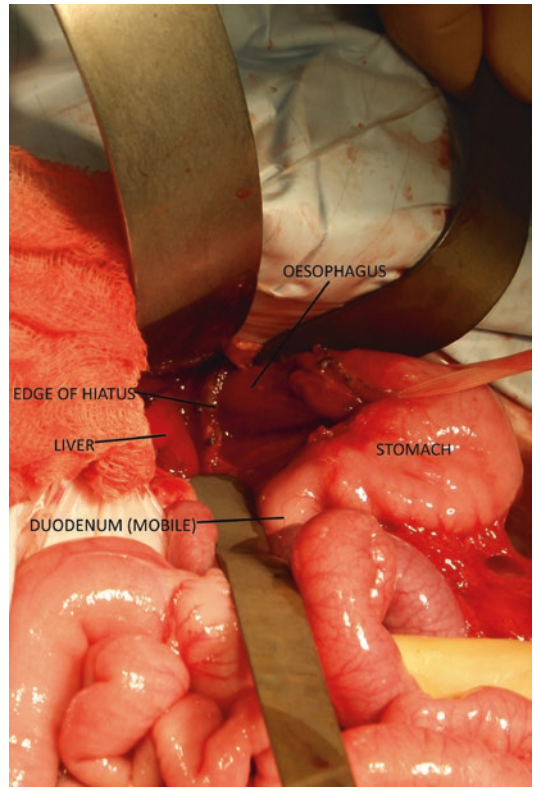

Fig. 96.5 Operative photograph after reduction of stomach from the chest. The sac has been excised to delineate the hiatal defect

Laparoscopic repair was attempted but had to be converted to open procedure. Dilated bowel loops resulted in paucity of space and poor visibility. A left upper transverse incision was used to gain access to the upper abdomen.

The left triangular ligament of the liver was divided, and the left lobe of the liver retracted out of the way to enable a good view of the oesophageal hiatus. The stomach was delivered out of the chest. There was no difficulty in reducing the contents of the hernia which is in keeping with the experience of other authors [41, 69]. With gentle traction on the stomach, the peritoneal sac is evaginated and the peritoneal reflection divided. The dissection is continued to divide the most superficial layer, taking care to avoid the vagus nerves. The sac was gradually dissected free and excised as much as required to permit a good view of the edges of the hiatal defect (Fig. 96.5). The hiatal defect was then loosely approximated posterior to the oesophagus. A large nasogastric tube was placed within the oesophagus to ensure that the hiatal repair is not too tight.

The author's preference is to use nonabsorbable suture (Gore-Tex^{tm} 3-0 or 2-0 depending on the age and size of the child). Interrupted sutures were placed taking good "bites" of the edges of the hiatus which are then loosely approximated. The stitches are placed taking variable thickness of the muscle to avoid separating the muscle fibres.

A posterior 270° fundoplication and Stamm gastrostomy were also performed.

Postoperative recovery was uneventful. Currently, the child is thriving and asymptomatic. As he is feeding well orally, his gastrostomy tube has been removed.

Hiatus Hernia Around a Gastric Pull-Up

A 3-year-old child with pure oesophageal atresia, who had a gastric pull-through at another institute, was admitted with worsening respiratory distress. A chest X-ray revealed herniation of the bowel into the chest (Fig. 96.6).

Herniation of the small bowel into the chest through the oesophageal hiatus was confirmed on laparoscopy. It was possible to reduce the herniated bowel and define the edges of the hiatal defect laparoscopically (Fig. 96.7a). The edges of the defect were then approximated to the wall of the duodenum which was seen entering the oesophageal hiatus. Gore-Tex 3-0 was used and the knots were tied intracorporeally (Fig. 96.7b).

Postoperative recovery was uneventful and there have not been any subsequent problems.

Large Hiatus Hernia Secondary to Congenital Diaphragmatic Hernia

A term baby with antenatally diagnosed congenital diaphragmatic hernia underwent repair of the posterolateral Bochdalek-type diaphragmatic defect after a difficult period of preoperative stabilisation. Postoperatively, the child failed to tolerate feeds. A repeat upper gastrointestinal contrast series demonstrated a large hiatus hernia and duodenal obstruction (Fig. 96.8).

As the large hiatus hernia secondary to congenital diaphragmatic hernia was not likely to resolve, the patient underwent operative correction. Laparotomy was performed via a left upper abdominal transverse incision. The stomach was

mobilised to gain a length of intra-abdominal oesophagus. The hiatal edges were approximated loosely around the lower oesophagus. A posterior 180° fundoplication and a Stamm gastrostomy were also done. The duodenal obstruction was relieved by dividing adhesions. Following this, the baby made an uneventful recovery and is currently doing well.

Conclusion

Hiatus hernia in infants and children represents a diverse group of disorders with marked difference in presentation, treatment and outcome. Marcel Bettex, among others, considered all these to be a continuum of worsening pathology from gastroesophageal reflux without hiatus hernia, a condition he and others term "chalasia" to herniation of the entire stomach and organoaxial volvulus (upside-down stomach) [12].

Others such as Carré, who have also studied the natural history of these disorders, have not demonstrated such progression [14, 38]. Indeed, adults with type I or sliding hiatus hernia do not seem to develop large mixed or type III hernias over time. Also, if type III hernias always progressed from type I hernias, then in theory, type II or rolling hernia, in which the gastroesophageal junction remains within the abdomen, should never occur. Karpelowski et al. who have published the single largest series of paraoesophageal hernia did not observe sequential progression either [41].

That the defect is congenital in at least some individuals is beyond doubt due to the antenatal and neonatal diagnosis of paraoesophageal hiatus hernia. Whether the paraoesophageal hernia seen in adults represents the same condition or is a separate, acquired one is not clear at present. Certainly, it would be interesting to study the effect on the incidence of the condition in later years of life once antenatal diagnosis becomes more widespread and accurate.

97 Endoscopic Treatment of Benign Esophageal Strictures with Removable or Biodegradable Stents

Yvan Vandenplas, Bruno Hauser, Thierry Devreker, Daniel Urbain, and Hendrik Reynaert

Introduction

Although pediatric literature on esophageal stents is limited, there is substantial literature on this topic in adults. The main indication in adults is palliative therapy in patients with unresectable esophageal cancer, but stenting in adults is also used for the management of benign conditions such as esophageal fistulas, leaks, perforation, and benign strictures. The major pediatric indication is refractory or recurrent esophageal stricture, followed by tracheoesophageal fistula, esophageal perforation, and anastomotic leak [1]. Esophageal strictures in children are most frequently the consequence of esophageal atresia, ingestion of caustic (alkaline) products, or a consequence of gastroesophageal reflux disease. Management of esophageal perforation may be another indication.

Treatment of Esophageal Strictures in Children

Repetitive dilatations are the standard therapeutic approach of esophageal strictures [2]. The younger the child, the more balloon dilatations are considered standard care. In older children, Savary-Miller dilatators are more frequently used, similar as in adults. The role of high doses of steroids in the prevention and treatment of esophageal stenosis and in the mechanism of scar formation (mainly caustic injury) is still heavily debated [2]. Systemic high doses of methylprednisolone (1 g/1/73 m [2]) have been advocated to reduce the number and the severity of the strictures [3]. However, early treatment (within 24 h after ingestion of the caustic product) versus delayed treatment or short versus long treatment (less than or more than 21 days) was reported to make no difference [4].

Topical application of mitomycin has also been applied with some success (about two thirds) in the treatment and prevention of scar formation [5, 6]. Esophageal resection and colon interposition or gastric pull-through is proposed in the most severe, relapsing cases [7, 8]. After a median follow-up of 33.3 (11–41) years, 23 (43 %) of 53 individuals experienced mild symptoms of reflux; scoliosis, 12 (22 %) of 53; and/or other complications, 15 (27 %) of 53 required further surgery [7].

The Use of Stents in Benign in Esophageal Strictures

Clinical experience with stents is mostly derived from adults with esophageal cancer, but with the development of new types of stents, more and more stents are placed to treat benign conditions.

Various manufacturers provide different types of stents. They differ in stent material, design, luminal diameter, radial force exerted, flexibility, degree of shortening after placement, and extent of coverage. Every stent type has its proper characteristics with advantages and disadvantages. It is important to recognize not only the benefits but also the shortcomings and complications of the various stents before deciding to insert a stent in a patient. Currently, self-expandable plastic stents (SEPs) and self-expanding metal stents (SEMs) mostly made from nitinol (alloy of nickel and titanium) dominate the market because of their removability (SEPs) or because of their ability to conform to anatomical angulations (SEMs) [1].

Self-Expandable Metal Stents

The first expandable stents available were uncovered and were made of stainless steel. These stents had the advantage over the classical plastic prostheses in the way that they were only 3 mm in diameter before deployment, which made the insertion easier, and dilatation of the stricture prior to the stent insertion was often not necessary. After expansion, stent diameter increased to 16 mm [9]. The newer stents are made of nitinol and have a diameter up to 23 mm after expansion [1]. Nitinol is a biocompatible alloy with a shape memory and high elasticity. Nitinol stents are flexible, are highly kink resistant, and exert a low chronic radial outward force, which makes them very attractive to manage cancer strictures.

Although the palliation for dysphagia caused by esophageal cancer was not better, in most studies, the complication rate of SEMs was significantly lower than with the plastic prostheses [10]. Major complications of SEMs comprise hemorrhage, aspiration, perforation, food impaction, and migration with sometimes bowel obstruction. Early minor complications include chest or throat pain, nausea, fever, and reflux. Stents that are close to the upper esophageal sphincter induce a high degree of intolerance due to pain and globus sensation, as well as an increased risk of complications such as tracheoesophageal fistula and aspiration pneumonia. Therefore, it is recommended to put a stent at least 2 cm below the upper esophageal sphincter. In the long-term, ingrowth of tumor in the uncovered stents is a problem [11]. Thus, covered SEMs were developed. In fact, these covered stents were only partially covered, allowing the uncovered part embedding and anchoring in the mucosa. In adults with malignant esophageal stenosis, covered SEMs are reported to be preferable to uncovered stents because there is less recurrent dysphagia due to tumor ingrowth and obstructing mucosal hyperplasia. On the other hand, there is a trend to have more migration with covered stents [10, 12].

Experience in the use of SEMs in benign strictures is by far more limited than in malignancy. Several limitations of SEMs preclude their routine use in benign esophageal strictures. The most important reason not to use SEMs in benign strictures is their difficulty in removing them because of tissue embedment that occurs in the uncovered portion. Traumatic removal results in complications such as bleeding, but also the development of new strictures at the site of injury caused by tissue granulation. Moreover, SEMs placed for benign disease are associated with significant other complications such as high migration rates, fistula, erosion into vital structures, and even death [13]. Stent migration is more likely to occur with covered than with uncovered stents. Based on the high complication rate, partially covered SEMs in their current form cannot be recommended for treating benign esophageal stenosis [1].

Self-Expandable Plastic Stents

This type of stent is made of polyester netting embedded in a silicone membrane. The proximal end of the stent is flared in an attempt to prevent

distal migration. The upper and lower parts of the polyester mesh are covered with silicone to prevent tissue damage and thus granulation. The diameter of the delivery device is 12–14 mm, which makes dilatation before stent insertion mandatory. Similar to SEMs, the stent should cover the whole length of the structure with an additional 1–2 cm above and below the stricture. Retrieval and repositioning of this fully covered stent can be done with a foreign body forceps or a standard polypectomy snare [1].

SEPs have been shown to be efficient and safe in the management of malignant esophageal strictures. Success rate of insertion is high (>90 %), and in most patients, dysphagia improves. Major complications include stent migration, food impaction, bleeding, and death. Tumor ingrowth does not occur, but tumor or hyperplastic overgrowth was observed in a significant proportion of patients. Minor complications include chest pain, nausea, fever, and reflux [14, 15].

Trials comparing SEMs to SEPs demonstrate that the stents are equally effective in palliating malignant obstruction, but SEMs are associated with significantly fewer complications, especially migration, than SEPs [16].

SEPs are increasingly used to treat benign esophageal disease including strictures, fistulas, anastomotic leaks, and perforations. Advantages of SEPs over SEMS in benign esophageal disease include the option of retrieval, limited local tissue reaction, which might limit the formation of new strictures, and lower cost. Up to now, there are no large RCTs evaluating the role of SEPs in benign esophageal strictures, but there are several case series. Initial results were very promising with relief of dysphagia in a high number of patients (up to 95 %), not only during stenting but also after removal of the stent [17]. In more recent series, however, the long-term success rate was far lower (17–30 %). Moreover, the complication rate was high in some series, including food bolus impaction, stent migration, severe pain, hemorrhage, perforation, and death [18, 19]. A pooled-data analysis from ten studies including 130 patients who were stented for benign esophageal strictures showed a favorable risk/benefit [20]. This study supports the idea that SEPs could be a valuable alternative to repeat endoscopic dilatation for benign disease before referring patients to surgery.

Fully Covered, Retrievable SEMs

Fully covered retrievable SEMs have been developed and approved for malignant disease, but they are theoretically also promising for treating benign disease. The stent is composed of a nitinol wire covered with polyurethane. Nylon loops are woven into the ends; they can be grasped with a forceps, which will narrow the stent and make retrieval easier and less traumatic. Moreover, a specific stent retrieval system has been designed [1].

Some small series reported that the stents relief dysphagia in most patients with benign esophageal strictures. Stents were removed after 8 weeks. However, stent migration was frequent (up to 80 % at 8 weeks), and new/recurrent stricture formation was seen in about 50 % [21, 22].

Recently, a stent that is fully covered internally but not externally has been developed. It is postulated that this kind of stent will migrate less. The first data with this stent are promising, but only few patients have been treated for benign strictures.

Prospective data from RCTs are needed before general recommendations on the use of fully covered retrievable stents can be made.

Biodegradable Stents

A recent evolution is the development of biodegradable stents. This type of stent is made of degradable synthetic material. The stent integrity and radial force is maintained for a period of 6–8 weeks following implantation. Stent disintegration occurs 11–12 weeks after insertion. Dual flared ends reduce the risk for migration. In a Japanese case series, stent migration was observed in 77 % of 13 adult patients. However, no symptoms of restenosis were observed, and further endoscopic therapies were not required [23]. More data are needed before the use of these stents can be recommended.

Pediatric Experience

The number of pediatric studies is very limited. And all reports are retrospective, have small number of patients (or are case reports), and use a wide variety of stenting techniques. As a consequence, close collaboration with an experienced adult gastroenterologist is recommended.

In Turkey, surgical placements of stents for corrosive esophageal structures have been introduced already in 1989. Stenting provided a much better outcome, leading to a healing in 68 % of the patients compared to 33 % with the "classic" therapy (dilatations). Poor patient compliance and GER resulting from esophageal shortening of the esophagus during scar formation were the most important reasons for failure of the stenting [24]. Another Turkish series reported a series of 11 patients with esophageal stents in 10 years time [25]. Eight patients had a normal feeding pattern, also after stent removal, with a mean follow-up of 3.5 years after stent removal. Long-term stenting was suggested to decrease the need for surgical reconstruction and to decrease esophageal stricture incidence. The Turkish experience regards "closed stents," which means that the food needs to pass between the esophageal mucosa and the stent, comparable to the effect of a large nasogastric tube.

A Chinese series of 33 patients suggested laparotomy to bring the esophageal stent in place 2–3 weeks after ingestion or even immediately in case of esophageal perforation [26]. In this series, 18 children (1–14 years) were included. The stent was constructed from a silicone rubber tube of 10–12 mm inner and 14–16 mm outer diameter with a length of 40–60 cm. A catheter was fixed to the proximal end of the stent as the distal end of the stent was used as a gastrostomy. Stents were removed after 4–6 months. The results were excellent as 85 % of patients had normal food intake 3 months after stent removal. This kind of stenting is however not comparable with the new less invasive techniques.

A SEPs (Polyflex/Rüsch) was inserted in ten patients between 6 months and 23 years with benign esophageal stricture, mostly after corrosive ingestion [27]. All patients were previously included in a dilatation program without success. Stents were placed over the stenotic area after performing a dilatation. Fifty percent of the patients received one stent; the others needed two or more stents because of restenosis. Stents were left in place from 20 to 133 days. Five patients were completely cured; others needed further stent treatment. The children experienced nausea and vomiting during several days after placement of the stent. These episodes were related to the length of the stent. Treatment with midazolam and ondansetron reduced the symptoms. Pain relieving medication was required during the first days after stenting. Patients also needed acid blocking medication while the stent was in place. Since the stent results in a constant "open" esophagus, often with the stent also dilating the lower esophageal sphincter, it is logic that there is increased reflux. Long-term tolerance of the stent was most of the time excellent and stents allowed the children normal feeding.

Fully covered tracheobronchial stents were endoscopically placed under general anesthesia in seven pediatric patients (6 months to 7 years old) with benign esophageal conditions [28]. All patients had several unsuccessful dilatations before stent placement. Balloon dilatation was performed before stent insertion. The diameter of the stent was selected according to the age and estimated esophageal diameter; the length was chosen in order to provide 2 cm of stent on each side of the stricture(s). In some patients, serial stents with increasing diameter were inserted. Stents were removed between 3 and 15 days without complications by using a forceps. As stents were left in place longer, it was more effective. Six of seven patients did benefit from the stenting. There were no complications during placement. One patient did not benefit from esophageal stent placement, because the stent migrated downward (ad). One patient had some gagging, which led to early removal of the stent, and the stent was removed in emergency in one patient for respiratory distress.

Zhang and colleagues reported on their experience with covered retrievable expandable nitinol stents in 8 children with corrosive esophageal stenosis [29]. The stents were placed in all patients without complications and were success-

fully removed 1–4 weeks after insertion. After stent placement, all patients could take solid food without dysphagia. Stent migration occurred in one patient; in this patient, the stent was repositioned. During the 3-month follow-up period after stent removal, all children could eat satisfactorily. After 6 months, two children required balloon dilatation (three times in one and five times in the other).

The first two cases of successful implantation of a biodegradable stent in children with caustic esophageal stricture were performed in Minsk, Byelorussia, in 2006. However, this experience was not reported in international literature. We reported a positive experience with an SX-Ella biodegradable esophageal stent in a child [30]. A major advantage of this stent is the fact that it remains in place for 6–12 weeks and that it must not be removed endoscopically. A drawback is that this stent is currently only available in large diameter and cannot be inserted in small children. As the stent is degraded by acid, PPIs must be administered to prevent early degradation.

Discussion and Conclusion

The major indication for esophageal stenting is malignant disease in adults. Extrapolation of the experience in this patient group to children with benign esophageal disease is impossible. There has been increasing interest in the use of stents in benign disease. Data on the use of SEMs and SEPs in the management of refractory benign esophageal strictures have been mixed. Until there is significant improvement in the design, these stents cannot be routinely recommended for this indication. The use of self-expandable stents for the management of anastomic leaks and perforations seems promising. The development of removable, fully covered stents increases the potential uses for stents in children expanded to include treatment of a wide variety of congenital and acquired esophageal strictures [31]. However, long-term prospective data obtained from controlled trials on the use of retrievable SEMs and biodegradable stents in the management of benign esophageal lesions are awaited. In the mean time, stents may offer a solution to some children with recurrent or chronic benign esophageal stricture. Since experience in children is (still) very limited, it is evident that esophageal stenting in children should be performed in referral centers.

First-line treatment of esophageal strictures remains endoscopic dilatation, followed by mitomycin application [2]. When these measures fail, stenting of the stricture is a valuable option. The timing of stenting is uncertain, but there are some indications that early stenting could be beneficial in certain circumstances [26]. A clinical trial comparing early stenting with repeated dilatation could answer this question, but will be extremely difficult to perform in such a rare condition. Likelihood of success seems most dependent on the ability of the patient to tolerate initial placement of the stent without complication and maintaining proper positioning for an adequate period of time before removal [31].

In small children, adult stents with a large diameter cannot be inserted because this causes prolonged pain and nausea. There are some other possibilities, including tracheobronchial and custom-made stents. Tracheobronchial stents have a smaller diameter, but they are stiffer and have a higher radial force. The advantage is that these stents deploy immediately. The disadvantage is that they may be more traumatic and less easy to remove. Custom-made stents are probably a better choice. These stent are made for the individual patient with the diameter and length adapted to the patient. Moreover, the upper and lower part can be made wider, if desired the stent can be partially uncovered and anti-migration flaps can be included; all of these will reduce the migration rate, which remains a major concern in benign disease. Indeed, as dilatation of the stricture is successful, migration rate increases.

Another point of discussion is the duration of treatment. In general, covered stents are removed after 1–4 weeks. It has been shown that results are better when stents are removed after more than 1 week [28]. The longer a stent remains in place, the higher is the risk of migration, the higher the chance of in- or overgrowth, and the more difficult it is to remove. A logical approach

would be replacement of the stent by a stent with a larger diameter (e.g., +2 mm) every 2 weeks until the desired diameter is reached [28].

Removal of a fully covered stent, which is designed to be removed endoscopically, is usually quite easy. Extraction involves using an alligator or rat tooth or biopsy forceps, to pull the purse-string suture into the endoscope channel, thereby collapsing the top of the stent [1, 28]. If impossible to grab the upper string suture, one can grab the lower one and pull the stent into the stomach before extraction. If the stent cannot be pulled into the biopsy channel, an overtube or endotracheal tube can be used [28]. Complications after stent removal are infrequent, but it is advised to remove stent under anesthesia with endotracheal intubation.

Although recommendations cannot be made based on evidence, it seems to the authors that esophageal stenting should be given a chance after failure of dilatations and mitomycin application, but before colon interposition. Knowledge of different types of stents and complications is essential, and stents are preferably inserted in experienced centers. At present, retrievable covered SEMs, if possible custom made, might be preferable, but RCTs are awaited before strong recommendations can be given.

Oesophagogastric Dissociation: When Is It Relevant?

98

A. Bianchi and A. Morabito

Oesophagogastric Dissociation

The Clinical Situation

Even for the otherwise normal child, clinically significant gastro-oesophageal reflux may be a cause of major morbidity and possible mortality and effective treatment difficult to achieve. Despite heavy medical management, the patient's quality of life and indeed that of his family or caregivers is often severely reduced and an outwardly effective conservative approach may not always be acceptable. Failure of conservative management often leads to a surgical antireflux procedure. Of the several varieties of fundoplication, for which the eventual long-term outcomes are not much different, the Nissen 360° moderately loose wrap, undertaken through an open upper abdominal approach or laparoscopically, is still the more common intervention. Fundoplications in this setting have proven generally satisfactory, although for a minority the wrap may loosen and reflux recurs or a hiatal hernia may appear.

For mentally impaired children and particularly those with pharyngeal neuromuscular incoordination, however, a satisfactory result is much more difficult to achieve. They suffer significantly from difficulty with swallowing and are markedly prone to saliva and food aspiration with pneumonitis and frequent hospitalisation for 'chest infections'. In addition the inability to take an adequate oral intake, the significant gastro-oesophageal reflux, and the pronounced retching and vomiting lead to poor nutrition and failure to thrive. The inevitable 'mess around the child' leads to reluctance to physically handle the child, with consequent emotional deprivation both for the unhappy child and for the unfortunate family. The constant attention demanded by these children places a great strain on the parents' relationship and impacts also on the siblings.

Such mentally impaired children often first come to surgical attention at an advanced age with a referral from their paediatrician for a feeding gastrostomy, the presence and repeated passage of a nasogastric feeding tube having become a major problem. Although advocated by some, placement of a gastrostomy tube alone will aggravate the gastro-oesophageal reflux in well over 50 % of children. If the child's overall condition does not allow for a safe concomitant antireflux procedure, then a temporary transgastric jejunal feeding tube/button or a tube jejunostomy is a better prospect. A fundoplication, if the child's condition permits, is a consideration

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_98

although it must be realised that mentally impaired children are prone to a significantly higher incidence of breakdown of the wrap with recurrent reflux (7–35 % within a 2–5-year period). Repeated surgery may be hazardous with increased morbidity and is unwelcomed by the family and also by the medical caregivers who must manage these frail, physically compromised children with impaired respiratory function.

Faced with this situation and asked to express a preference, these concerned and weary families will often ask for a single operative intervention without risk of recurrence of reflux or of further surgery, which will resolve the majority of their feeding and respiratory problems, will allow adequate nutrition and growth and will reduce hospitalisation episodes. Oesophagogastric dissociation [1] (OGD) with gastrostomy is designed to specifically meet these essential needs by eliminating gastro-oesophageal reflux and the possibility of its recurrence and allowing for enteral nutrition without loss. OGD, however, does not alter the pharyngeal incoordination and the potential morbidity from aspiration of saliva, nor does it resolve the troublesome centrally coordinated retching.

Preoperative Evaluation and Preparation

Surgical options for these children are often a later consideration, and by the time of first surgical referral, the child has been fully investigated and the need for help is obvious. Videofluoroscopy, pH studies, radioisotope scans and contrast studies will have confirmed the clinical scenario of a mentally impaired child who is failing to thrive because of inability to swallow, marked vomiting and gastro-oesophageal reflux, with saliva and food aspiration and frequent pneumonitis confirm the severity.

For the perioperative evaluation, delayed gastric emptying, the possible presence of an oesophageal stenosis or ulceration are all pertinent to the surgeon, while lung function is of most concern to the anaesthetist. The services of a paediatric respiratory physician and an intensivist are appropriate to ensure that the child is in the best condition for the planned surgery, and a period of preoperative intensive respiratory management, physiotherapy and parenteral nutrition could be invaluable in reducing the postoperative morbidity. Perhaps the most effective preparation for surgery is the recruitment of a multidisciplinary team to address the specific needs of the individual child and family.

It is the surgeon's specific duty to become personally involved with the family or caregivers through in-depth counselling sessions such that the family's concerns are fully addressed. There should be no doubt as to their clear understanding of the proposed surgery exploring all possible risk, potential postoperative morbidity and *the family's expectations*. The family must be fully aware that OGD is designed to eliminate reflux and food aspiration, to improve lung function and to allow stable nutrition and growth but that it will not address the swallowing difficulty, saliva aspiration and the centrally mediated 'retching' that is often so distressing to the family.

The Operative Procedure

Through an upper abdominal approach, the left lobe of the liver is displaced medially to allow liberal mobilisation of the oesophagus at the hiatus in the diaphragm (Fig. 98.1). The posterior vagus nerve is protected, the oesophagus is detached at the cardio-oesophageal junction and the stomach oversewn, leaving access only through a gastrostomy. The jejunum is divided and the distal end is passed in Roux-en-Y isoperistaltic fashion on a tension-free mesentery through the transverse mesocolon and behind the stomach, to anastomose with the oesophagus at the level of the diaphragm. A 'wide oblique' rather than a circular end-to-end anastomosis will reduce any possibility of stenosis. Bowel continuity is established by end-to-side jejunojejunostomy at a point 40 cm distal to the oesophageal anastomosis. A pyloroplasty is added if there has been a possible pre- or intraoperative

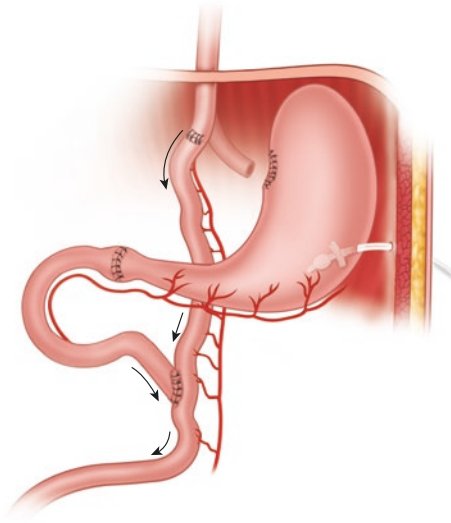

Fig. 98.1 The oesophagus is detached at the oesophagogastric junction and anastomosed to an isoperistaltic jejunal Roux loop. An end-to-side jejunojejunostomy at 40 cm from the oesophageal anastomosis, a gastrostomy and a possible pyloroplasty complete the procedure

injury to the vagus nerves or preoperative evidence of delayed gastric emptying. Operating time varies between 2.5 and 4 h depending on the intra-abdominal conditions following previous surgeries and the type of gastrostomy that is constructed (conventional Stamm tube or a vascularised non-refluxing gastric tube [2]). In view of their often precarious respiratory and physical state, these children benefit from a brief postoperative period of assisted ventilation, physiotherapy and intensive care management. Recovery is usually uneventful and gastrostomy feeds and oral intake commence once bowel function becomes established, commonly within 3–5 days.

Indications

'*Primary OGD with gastrostomy*' should ideally be offered as the single definitive procedure since it meets the family or caregivers' criteria for one safe operation that will eliminate the risk of recurrence of reflux; that will reduce the incidence of aspiration, chest infections and hospitalisation; that will allow better nutrition and growth; and that will improve the quality of life for the child and the family. Primary OGD offers the best prospect of a successful outcome with minimal morbidity. 'First time' surgery offers the surgeon clean unscarred tissues and free natural surgical planes such that dissection is possible with little tissue trauma and bleeding and minimal risk to the lower oesophageal blood supply and to the posterior vagus nerve. Recovery is therefore rapid and the incidence of both short- and long-term complications significantly reduced.

'*Rescue OGD*' is indicated as a salvage procedure following failure of conventional antireflux surgery. Previous intervention/s add to the operative morbidity because of significant adhesions to the liver and to the diaphragm, disruption of the oesophageal hiatus and possible injury to the vagus nerves. It is necessary to unravel the previous fundoplication/s and the attendant scarring and to restore the original anatomy. The condition of the lower oesophagus may be significantly reduced with a poor muscle wall and a reduced blood supply leading to a greater risk of lower oesophageal perforation and breakdown or stricture at the oesophagojejunal anastomosis. It may be necessary to cut back the lower oesophagus to ensure a safe well-vascularised oesophago-jejunal anastomosis. Despite this additional potential morbidity, the long-term benefits far outweigh the risks.

'*Additional indications*' for OGD [3] in otherwise difficult situations are presented in Table 98.1. Experience has shown that OGD can be considered where there has been a need to ensure free oesophageal transit of food to the small bowel and without clinically relevant reflux. It is self-evident that such complex surgery, particularly following on previous operative interventions, carries a greater risk and is best undertaken in a specialist centre well experienced in oesophageal surgery. Potential risks and complications are similar to those associated with rescue OGD; however, once again OGD offers major benefits from effective resolution of the original pathology.

Bleeding remnant after subtotal gastric resection	1
Microgastria	1

Discussion

The majority of otherwise normal children with significant gastro-oesophageal reflux will respond to conservative medical measures (dietary adjustments, proton pump inhibitors, H_2 receptor antagonists) and will further improve or resolve with growth. For those coming to surgery, a conventional fundoplication remains the recommended first-line management providing effective control of symptoms, low morbidity and a relatively low rate of recurrence of reflux. The mentally impaired child is a different surgical proposition, and the high rate of recurrent post-fundoplication reflux requiring additional surgery in these frail and difficult children stimulates consideration of more effective alternatives. Oesophagogastric dissociation [1] was conceived in 1995 for rescue management following recurrence of reflux after multiple failed fundoplication.

Successful outcomes stimulated consideration of primary OGD as the single definitive effective surgery for the mentally impaired child. We believed there was no obvious logical reason for insisting on an initial conventional fundoplication with a high incidence of reflux recurrence within a relatively short time frame. Analysis of published reports [4, 5] suggests that most morbidity associated with OGD relates to operator technique and to poor lower oesophageal quality following on previous surgery. Thus poor tissue handling with trauma and devascularisation will lead to early lower oesophageal perforation and anastomotic dehiscence or late stenosis at the oesophago-jejunal anastomosis. Bleeding and undrained haematoma predispose to a higher risk of sepsis requiring additional surgery. It is relevant particularly after previous surgeries, always to place the oesophago-jejunal anastomosis without tension to a well-vascularised normal oesophagus, necessarily resecting back damaged and weakened oesophageal tissue.

We have continued to build on our published experience [3, 6, 7] and in our own combined series of primary OGD in 40 children and rescue OGD in 14 children; there has been no mortality relating to the operation and the immediate postoperative recovery has been relatively uneventful. Such mortality as there has been has occurred several months later as a consequence of the original condition. There has been no observed instance of recurrence of reflux and other morbidity, although unwelcome and potentially serious has been limited and manageable. Following Primary OGD one child developed a small bowel adhesion obstruction requiring surgery, and two others had an oesophago-jejunal leak that required corrective surgery. One other presented 18 months after OGD with symptoms suggestive of jejunal loop obstruction and was found to have developed a mid-jejunal stricture, presumably of vascular origin, that required resection and anastomosis. A frail 22-year-old adult in poor physical condition and considered virtually terminal developed a left subdiaphragmatic abscess that resolved with antibiotics and drainage without long-term stenosis. Over subsequent years her physical and mental state showed sustained improvement. In the rescue OGD group who had undergone previous operations, one child developed a small oesophago-jejunal leak noted on contrast study that healed with conservative management.

There have been no long-term metabolic or absorptive problems as a consequence of post-OGD anatomy, and specifically anaemia has not occurred. Oesophageal, jejunal loop or intragastric ulceration and bleeding have not been observed. The jejunal Roux loops retained isoperistalsis, and at 40 cm length offered an effective antireflux mechanism such that there has been no evidence of bilious reflux into the jejunal loop and no instance of stenosis at the oesophago-jejunal anastomosis. However one child presented 18 months after surgery with a late

stricture, presumably of vascular origin, at a point half way down the jejunal loop that required resection and anastomosis. It is relevant that oral intake has only been limited by the child's 'swallowing problem' and the discretion of the families or caregivers.

Similar experiences with neurologically impaired children have been published by others [8], and interestingly variations on the original concept are developing with the publication by Fonkalsrud et al. [9] suggesting reconstruction in the form of an isoperistaltic jejunal segment between the dissociated oesophagus and the pyloro-duodenum. OGD is now also finding application within the surgical management of the mentally impaired adult. The initial report by Hazebroek et al. [10] even concludes with the suggestion of 'early OGD as a primary procedure' when the patient is still in good general health and better respiratory condition.

Ongoing follow-up of our patients, presently at 14 years, confirms the well-documented studies reported by Gatti et al. [11] and Dall'Oglio et al. [12] documenting the marked improvement following OGD, in general well-being, physical growth and lung function, with a striking reduction in aspiration episodes and hospitalisation. Just as significant has been the beneficial impact on the parents and caregivers who invariably attested to the major improvement in quality of life for the child, for themselves and for the family.

The encouraging results from OGD led us to consider other possible indications as detailed in Table 98.1. In these otherwise difficult surgical circumstances [3, 6], we were able to provide free oesophageal transit into the small bowel and without reflux, with the children demonstrating renewed growth and improved quality of life. A similar experience published by Lagausie et al. [13] in 2005 further emphasises the safety and versatility inherent to OGD. Based on this experience, we venture to speculate that OGD may even have a role in the management of the dysfunction associated with the dilated megalo-oesophagus and in achalasia following a failed Heller's procedure.

Review of the published literature [14] to 2008 and our own experience leads us to the conclusion that oesophagogastric dissociation is a reasonably safe procedure that indeed meets the criteria set by the families and caregivers. We have been favourably encouraged by their ongoing appreciation and recommendation of the procedure that has been underpinned by the great improvement in well-being and quality of life for the children and their families. Our positive experience with a young adult supported by the published report from Hazebroek et al. [9] suggests that the same is likely to hold true for adults.

Gastrostomy Feeding and Gastroesophageal Reflux

99

Peter B. Sullivan

Several clinical conditions require adjunctive tube feeding in order to maintain a normal nutritional state for the patient. Commonly in clinical practice, a nasogastric tube is used for this purpose, but for longer periods of time, or for indefinite use, this method of delivering enteral feeds is less acceptable than gastrostomy tube feeding [13, 43]. For much of the twentieth century, the Stamm gastrostomy, which requires open surgical laparotomy, was the most commonly accepted insertion technique. This was until 1979 when Ponsky and Gauderer introduced the percutaneous endoscopic gastrostomy (PEG) technique [18]. PEG has the advantage that it is minimally invasive, it can be performed by a gastroenterologist, it is relatively inexpensive, and, if the patient's condition precludes use of a general anesthetic, it can be performed under sedation. A PEG may also be placed with laparoscopic assistance when anatomical variants preclude the conventional PEG insertion technique [17].

Indications for Gastrostomy Tube Feeding

The range of indications for insertion of a PEG is extensive (see Table 99.1). The commonest indication for PEG insertion in pediatrics is to overcome oral-motor impairment and feeding difficulties in children with neurological impairment; the largest single group is children with cerebral palsy. Contraindications to gastrostomy tube insertion are listed in Table 99.2.

In children with neurological impairment gastrostomy, placement has been shown to significantly increase weight, reduce feeding time, and reduce both feed-related choking episodes and frequency of chest infections [27, 54, 57]. Family stress is significantly reduced [27], and quality of life of parents increases after PEG insertion to assist feeding [58]. Severe oral-motor dysfunction is a marker for the severity of degree of neurological dysfunction. Accordingly, children with severe neurological impairment who require gastrostomy feeding have a substantial long-term mortality. This is probably related more to the underlying neurological condition than it is to PEG placement [9].

Table 99.1 Indications for insertion of a gastrostomy feeding tube

Failure of adequate nutritional intake
Oral-motor dysfunction (>50 % the commonest indication)
Craniofacial abnormalities
Head and neck trauma
Supplemental alimentation in those with increased calorie requirements
Malignancy and chemotherapy
Chronic renal failure
Cystic fibrosis
Congenital heart disease
Crohn's disease
Short bowel syndrome
Human immunodeficiency viral infection
Prolonged dependence on nasogastric tube feeding (>6 weeks)
Unsafe airway
Recurrent aspiration
Gastric drainage/decompression
Motility disorders
Short-bowel syndrome

Table 99.2 Contraindications to insertion of a gastrostomy feeding tube

Sick, unstable patient, e.g., in heart failure
Coagulopathy/bleeding disorders
Peritonitis
Severe ascites
Gastric varices
Distorted anatomy
E.g., 2° to severe kyphoscoliosis
Colonic interposition
Oesophageal obstruction
Hepatosplenomegaly
Failed diaphanoscopy

Complications of Gastrostomy Tube Feeding

Insertion of a PEG feeding tube carries with it a relatively low risk of complications. The result from Larson's series, which includes both adults and children, is typical of the published literature and revealed a procedure-related mortality of 1 %, a major complication rate of 3 %, and a minor complication rate of 13 % [35]. The commonest minor complication is infection of the gastrostomy insertion site and overgrowth of granulation tissue. Major complications are rare and include wound infection, cellulitis, oesophageal injury (probably sustained during extraction of the guide wire), abdominal wall abscesses, necrotizing fasciitis, gastrocolic fistula, colocutaneous fistula, duodenal hematoma, complicated pneumoperitoneum, gastric perforation, peritonitis, acute gastric dilatation, and gastroduodenal obstruction caused by the balloon of the gastrostomy catheter. Those patients with multisystem organ failure have an increased rate of complications and a poor response to nutritional support; for this population, the risk of PEG may outweigh its benefit [38].

Many of these complications can be avoided or reduced in likelihood by refinements to the technique of insertion [3]. A further complication and one which produces significant issues in relation to clinical management is symptomatic gastroesophageal reflux (GER) occurring after PEG insertion [27, 56].

Gastroesophageal Reflux

Gastroesophageal reflux (GER) is common in children with cerebral palsy, the largest group in whom a gastrostomy feeding tube is inserted, and occurs in 19–75 % of such cases [21, 48, 53, 59]. Central nervous system dysfunction is the prime cause of this high incidence of GER in children with cerebral palsy. Additional contributory factors include hiatus hernia, adoption of a prolonged supine position, and increased intra-abdominal pressure secondary to spasticity, scoliosis, or seizures [22, 24]. As a result of neuromuscular incoordination in the foregut, the anti-reflux function of the lower esophageal sphincter mechanism and esophageal motility are significantly impaired. Gastric dysmotility and delayed gastric emptying may also predispose toward GER in children with neurological impairment [2, 4, 8, 42], although

this relationship has not been demonstrated in all studies [6, 30, 41, 52].

Insertion of a Stamm gastrostomy has been shown to reduce lower esophageal sphincter (LES) pressure and predispose to GER [7, 32]. Studies following PEG insertion have shown both an increase in LOS pressure [29], and no effect on basal LES pressure unless rapid bolus feeds are delivered via the tube [10].

Similarly, some authors have found no relationship between PEG insertion and GER [37, 47, 49, 56], whereas others have [20, 27]. The reported postoperative prevalence of GER as a complication of PEG insertion varies from 13 % to 28 % [26, 28, 33, 56]. It may be that the site of insertion of the gastrostomy tube has an influence on the development of postoperative GER, and some endoscopists have found that tube placement in the antrum or lesser curve is associated with less subsequent reflux [47, 50].

Given the uncertainty about whether PEG insertion will exacerbate GER in the individual patient, especially those with foregut dysmotility, it would seem prudent to establish whether or not GER exists preoperatively [19]. Unfortunately, no test has been shown reliably to predict which patients will develop clinically significant GER post-PEG insertion. Despite normal clinical history and preoperative radiological and lower esophageal pH studies, GER can become apparent in neurologically impaired children after gastrostomy tube placement [5]. Much of the evidence in the literature is conflicting as a result of relatively small studies in selected cases, but the larger studies have shown no significant difference in GER symptoms or median reflux index on 24-h lower esophageal pH monitoring before and after PEG insertion [33, 37, 47]. Even preoperative histological evidence of esophagitis is poorly predictive of subsequent significant GER [12, 26]. In practice a pragmatic attitude should be adopted which takes into account the extent of clinical symptoms of GER (vomiting, aspiration, etc.) prior to PEG insertion and then selects those patients with significant clinical symptoms for investigation by prolonged lower esophageal pH monitoring and barium or water-soluble contrast studies to determine the need for a surgical anti-reflux procedure or jejunostomy [19].

Surgical Anti-reflux Procedures

The notion of a "prophylactic" anti-reflux procedure following gastrostomy insertion especially in children with neurological impairment was advocated by some [31]. The consensus' view now, however, is that such an approach is not advisable [14, 23, 33, 34, 45, 51, 56, 61, 62]. A major reason for this view is that fundoplication is associated with a higher morbidity and mortality rates in neurologically impaired children, when compared with neurologically normal children [36, 40, 44, 46].

Postoperative morbidity rates of up to 50 % and reoperation rates of up to 20 % and mortality rates up to 50 % are quoted following standard Nissen fundoplication [1, 40]. Major complications can occur both intra- and postoperatively including hepatic vein laceration, bowel perforation, tension pneumothorax, paraesophageal hernia, and small bowel obstruction [44]. Children with neurological impairment have more than twice the complication rate, three times the morbidity rate, and four times the anti-reflux reoperation rate than non-neurologically impaired children [15, 44]. In one study, for instance, more than 30 % of children with neurological impairment had major complications or died within 30 days of surgery, and 25 % had documented operative failure [39]. In another report, nearly one half of neurologically impaired children had documented recurrent GER after surgery [40]. Recurrent GER often leads to a second operation, but these repeats have a failure rate of around 30 % [11, 55, 60].

No single symptom is reliably predictive of recurrent GER so it is necessary to have a high index of suspicion for the development of recurrent GER after anti-reflux procedure in neurologically impaired children and to have a low threshold for proceeding to upper GI contrast study and lower esophageal pH study or endoscopy to investigate this possibility [39].

Medical Management of Gastroesophageal Reflux

The advent of proton-pump inhibitors (PPI) for use in children has had a very significant impact on the treatment of GER. Just as increasing experience of the complications following fundoplication has been shown to raise the threshold for performing this operation in children with neurological impairment [51] so has the efficacy of PPI as medical treatment been associated with a dramatic decrease in the number of surgical antireflux procedures performed in children [25].

In conjunction with PPI therapy, strategies to control reflux include a change from bolus to continuous pump feeding [10] and use of whey-predominant enteral milk formulae which have been shown to be associated with faster gastric emptying and less reflux [16].

Part XVII

Evaluation and Management of the Pediatric Patient with Suspected GERD

Regurgitation in Infants

100

O. Kirmemis

Gastroesophageal reflux (GER) is defined as the involuntary passage of gastric contents from the stomach into the esophagus. *GER disease* (GERD) on the other hand is a condition that develops if GER causes troublesome symptoms and/or complications such as pain, poor growth, and esophagitis [1]. *Regurgitation* is defined as the effortless return of stomach contents into the mouth. *Vomiting* is a coordinated reflex and is defined as expulsion of the refluxed gastric contents from the mouth (Fig. 100.1). However, the difference between regurgitation and vomiting is not always clearcut [1–3].

Regurgitation is a common problem in infancy, affecting about 50 % of all babies at the age of 2 months [1]. Most of the infants do not experience long-term symptoms; however, symptoms can result in significant parental anxiety and infant discomfort [2]. Most reflux episodes are asymptomatic, brief, and limited to the distal esophagus. "Excessive regurgitation" is one of the symptoms of GERD, but the terms regurgitation and GERD should not be used as synonyms.

O. Kirmemis
Division of Paediatric Gastroenterology, Faculty of Medicine, Ondoku Mayis University,
Samsun 55200, Turkey
e-mail: ozlemkirmemis@gmail.com

About 70 % of healthy infants have regurgitation that is physiologic, resolving without intervention in about 95 %, by the age of 12–14 months [4] (Fig. 100.2). Daily regurgitation occurs more frequently in infants during the first 6 months of life than in older infants and children. Frequent regurgitation, defined as more than three times per day, occurs in about 25 % of infants during the first months of life.

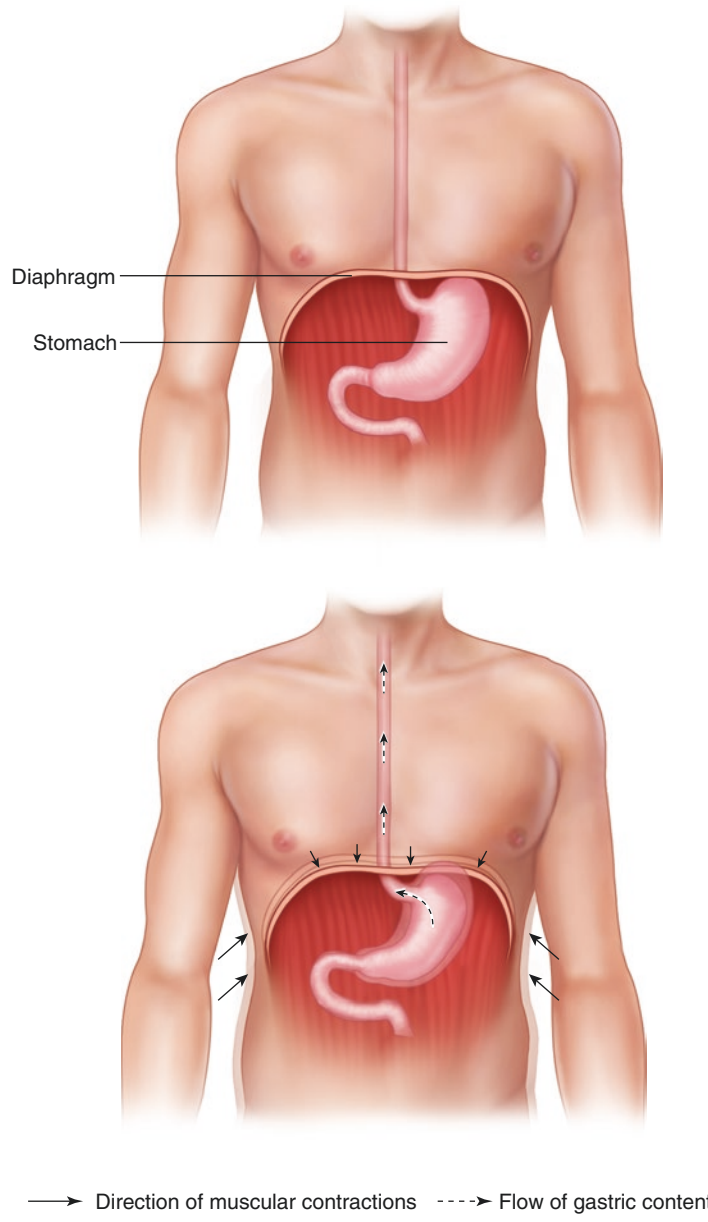
Various studies report a comparable incidence of regurgitation in unselected populations of formula versus breast-fed infants. Exclusively breastfed infants regurgitate less than partially breastfed babies [5]. This observation fits with the knowledge that GER and symptoms of GER (GERD) may be indistinguishable from those of food allergy [6]. Moreover, the association between GERD and cow milk hypersensitivity was observed in both infants and children with severe GERD [7, 8].

The Infant with Uncomplicated Regurgitation

Uncomplicated regurgitation in otherwise healthy infants is not a disease. Common causes include overfeeding and air swallowed during feeding, crying, or coughing. The typical presentation of uncomplicated infant GER is an effortless, painless regurgitation in a healthy-appearing child with normal growth, the so-called happy spitter.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_100

Fig. 100.1 Mechanism of vomiting



Intermittently, an episode of vomiting, even forceful vomiting may occur. Irritability may accompany regurgitation and vomiting; however, in the absence of other warning symptoms, it is not an indication for extensive diagnostic testing. Recurrent regurgitation generally decreases over the first year and disappears about 18 months of age [9]. If there are "warning signs" suggestive of GERD or other pathologic underlying diseases, consultation with a pediatric gastroenterologist is recommended. The same approach is to consider if symptoms persist over the age of 18 months [3].

Uncomplicated regurgitation is a benign condition with a good prognosis, needing no other intervention than parental education and anticipatory guidance (Fig. 100.3). Modification of

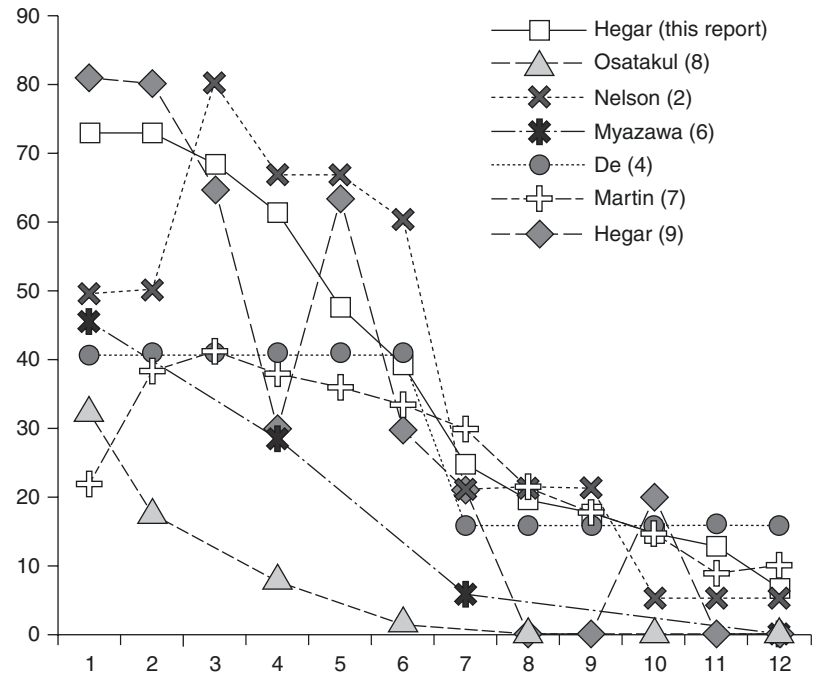


Fig. 100.2 Natural evolution of physiologic regurgitation (Data from Hegar et al. [5])

milk composition (adition of thickening agents), feeding frequency, volume, and sleep position may be indicated [10, 11]. Overfeeding exacerbates recurrent regurgitation.

Thickening of feeding formula has been demonstrated to reduce almost consistently the frequency and volume of regurgitation and result in an increased caloric intake [12–14]. Use of a thickened formula (or commercial anti-regurgitation formulae, if available) may decrease visible regurgitation but does not result in a measurable decrease in the frequency of esophageal reflux episodes.

Prone positioning decreases the amount of acid esophageal exposure measured by pH probe compared with that measured in the supine position. However, prone and lateral positions are associated with an increased incidence of sudden infant death syndrome (SIDS). The risk of SIDS outweighs the benefit of prone or lateral sleep position on GER; therefore, in most infants from birth to 12 months of age, supine positioning during sleep is recommended [3].

There is no evidence that antisecretory or promotility agents improve physiologic infant regurgitation [3].

In infants with persistent uncomplicated regurgitation and no respond to previous management, a 2–4-week trial of protein hydrolysate- or amino acid-based formula or a trial of milk-free diet for the breast-feeding mother is appropriate in order to exclude cow's milk allergy [3, 7, 8].

Regurtitation and Irritability

Reflux is an uncommon cause of irritability or unexplained crying in otherwise healthy infants. However, if irritability persists with no explanation other than suspected GERD, expert opinion suggests the following options. The practitioner may continue anticipatory guidance and training of parents in the management

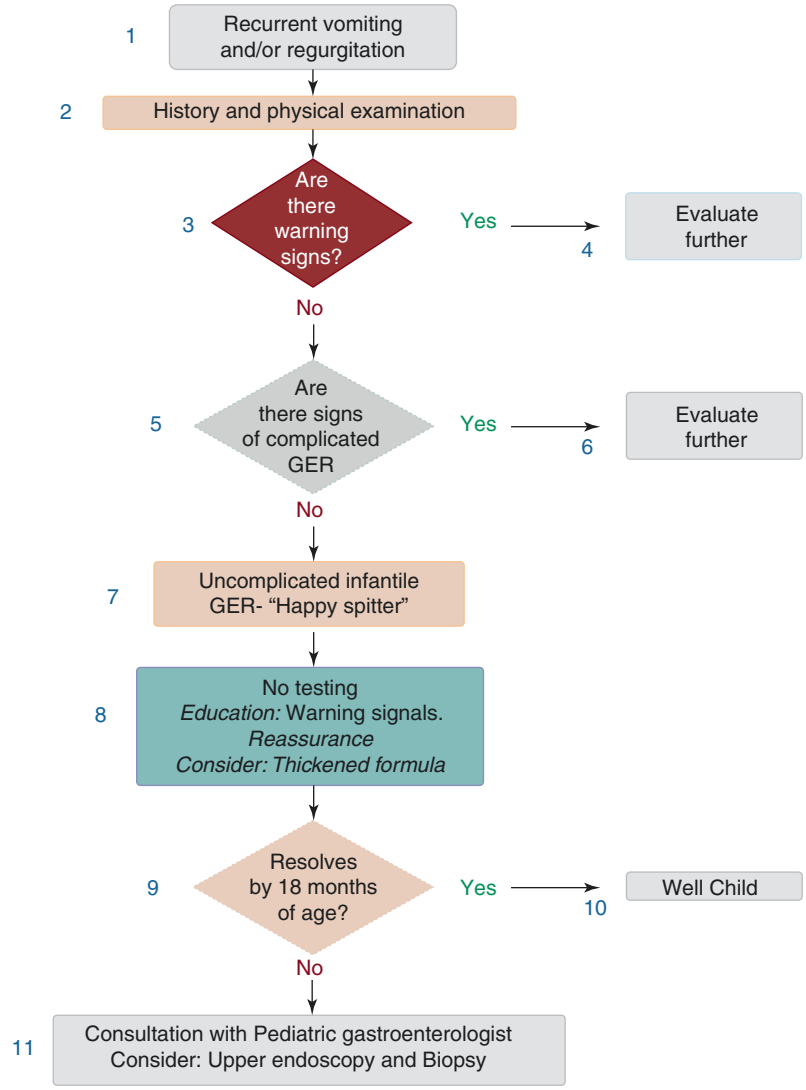

Fig. 100.3 Approach to the infant with uncomplicated recurrent regurgitation (happy spitter) [10]

of such infants with the expectation of improvement with time. Additional investigations to ascertain the relation between reflux episodes and symptoms or to diagnose reflux or other causes of esophagitis may be indicated (pH monitoring, impedance monitoring, endoscopy). A time-limited (2-week) trial of antisecretory therapy may be considered, but there is potential risk of adverse effects and clinical improvement following empiric therapy maybe due to spontaneous symptom resolution or a placebo response. The risk/benefit ratio of these approaches is not clear [3].

The Infant with Recurrent Regurgitation Poor Weight Gain

Poor weight gain is a crucial warning sign that necessitates clinical management. These infants need a complete diagnostic workup, starting with a dietary history to evaluate caloric intake. A feeding history should be obtained that includes an estimate of energy offered and ingested per day, an estimate of energy loss through regurgitation, a description of formula preparation and feeding schedule, an assessment

of breast milk sufficiency, and a description of infant sucking and swallowing behavior. Parents should be advised not to reduce intake to the point of energy deprivation in the attempt to prevent regurgitation. If problems identified by history seem to explain the symptoms and can be addressed, close outpatient monitoring of weight gain will determine whether further evaluation is indicated [3].

If chronic regurgitation and inadequate weight gain persist after observation and despite adequate energy intake, once other causes of vomiting have been ruled out. Infections (especially urinary tract), anatomic abnormalities, neurologic disorders, food allergy, and metabolic disease are among possible etiologies of

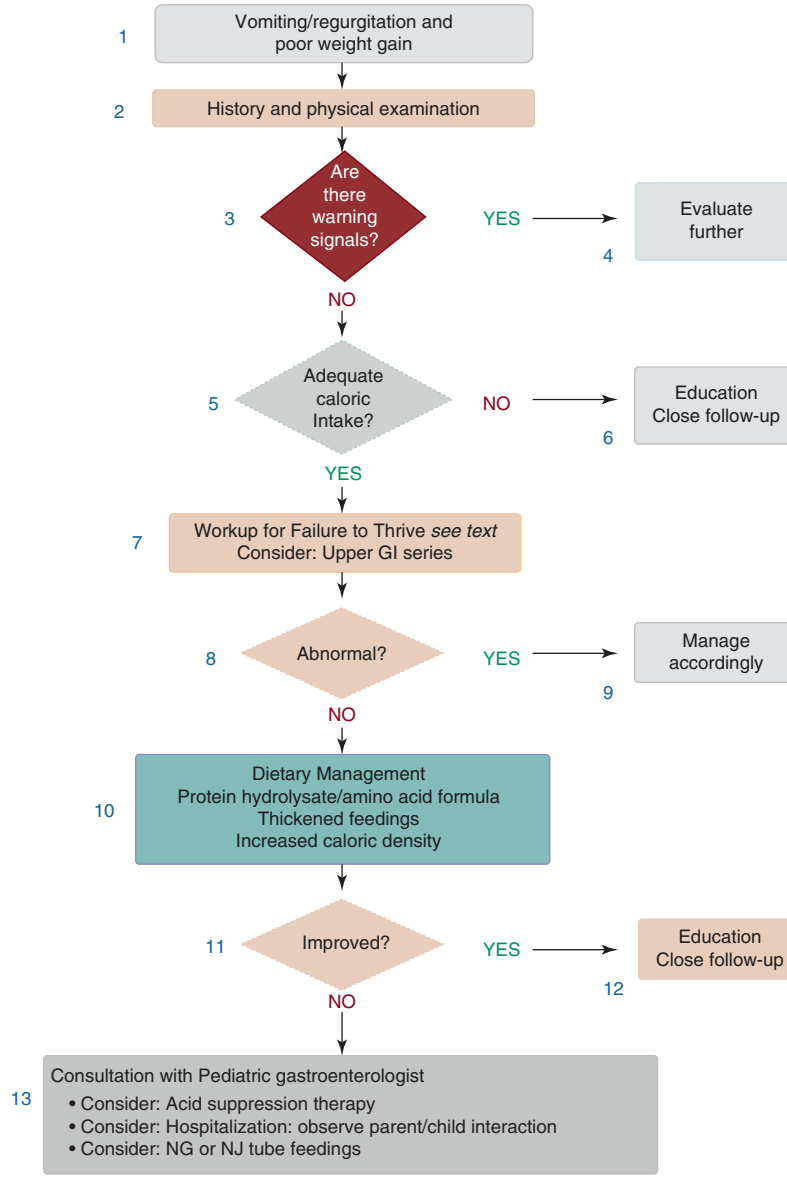

Fig. 100.4 Approach to the infant with recurrent regurgitation and poor weight gain

regurgitation and poor weight gain in infancy (Table 100.1).

A 2–4-week trial of extensively hydrolyzed or amino-acid-based formula is appropriate. Thickening the formula is recommended since it has been shown to help both irritability and weight gain. Depending on the results of investigations and response to dietary management, the infant should be referred to a pediatric specialist (Fig. 100.4). Hospitalization for observation and testing is appropriate in some infants with persistent failure to thrive. Therapy with H2 receptor antagonists and proton pump inhibitors may be suggested in cases with confirmed GERD [11]. Nasogastric or nasojejunal feeding is occasionally necessary to achieve weight gain in the infant with no other clear explanation for poor weight gain [15].

Recurrent Regurgitation and Vomiting in Children

101

Prithviraj Rao and Mike Thomson

Abbreviations

CNS	Central nervous system
CTZ	Chemoreceptor trigger zone
GORD	Gastro-oesophageal reflux disease

Definition

Vomiting is the forceful expulsion of the contents of one's stomach through the mouth and sometimes the nose. Regurgitation (or gastro-oesophageal reflux) differs from vomiting in that it is an involuntary and effortless expulsion of undigested gastric content back up the oesophagus to the mouth, without the force and displeasure associated with vomiting. It's however difficult to make a distinction between the two mechanisms in infants and young children.

Pathophysiology

There may be either or both mechanisms contributing to the symptom of vomiting:

1. The emetic reflex (see Fig. 101.1) [1]
2. The incompetence of the anti-reflux barrier

The emetic reflex is coordinated in an area within the CNS called the 'vomiting centre' where all the afferent stimuli are processed and integrated. The vomiting centre includes the reticular formation of the brain stem, supraoptic and paraventricular nuclei of the hypothalamus and receptors on the floor of the fourth ventricle of the brain known as the area postrema (or CTZ), stimulation of which can lead to vomiting. In a more simplistic way, the process can be divided into 'input' and 'output'.

Input

The various sources of input to the vomiting centre are:

- Vagus nerve, which is activated when the pharynx is irritated, leading to a gag reflex for, e.g. in pharyngitis.
- Vagal and enteric nervous system transmit information regarding the state of the gastrointestinal system. Irritation of the GI mucosa

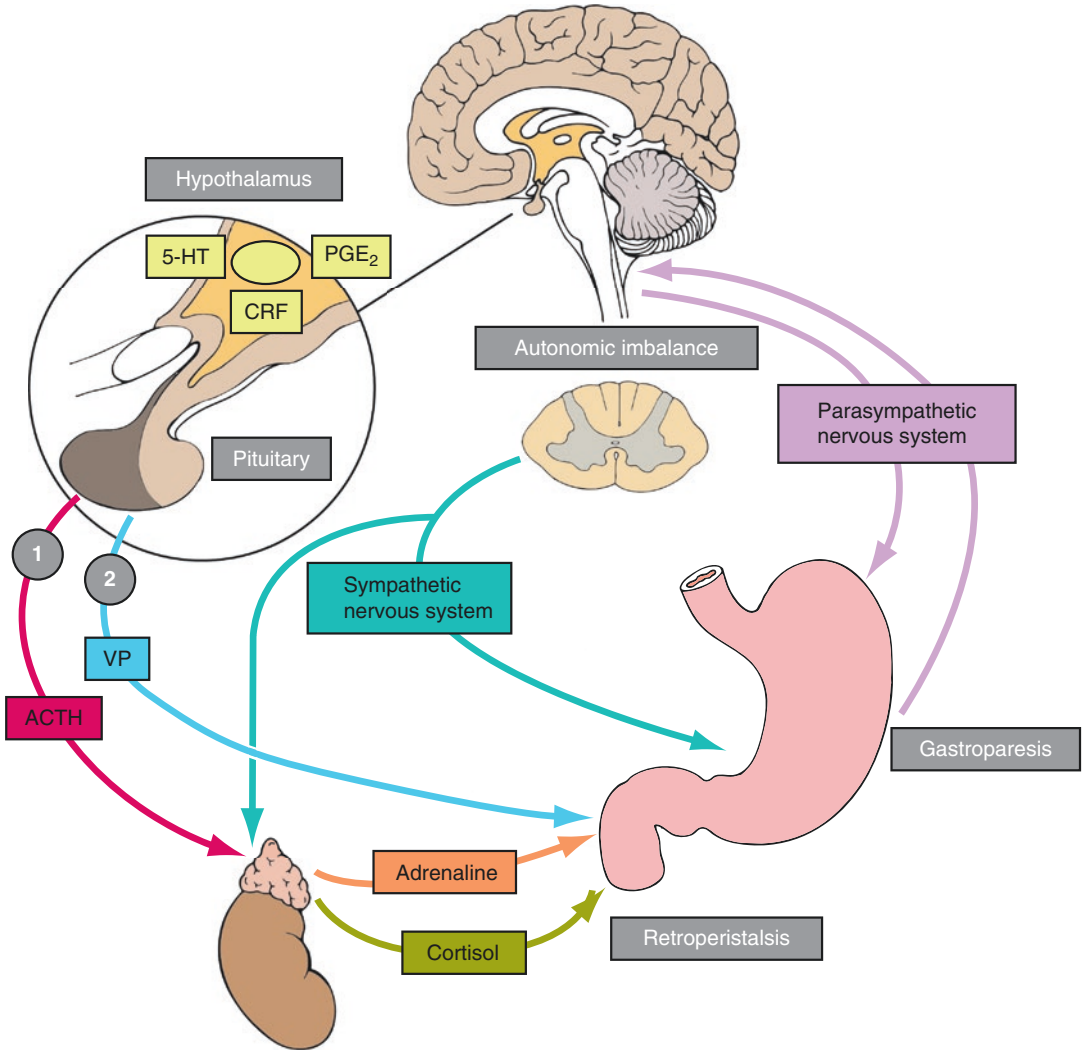

Fig. 101.1 The emetic reflex

by acute infectious gastroenteritis, chemotherapy, radiation or distention activates the 5-HT_3 receptors of these inputs.

- The vestibular system which sends information to the brain via vestibulocochlear nerve. It plays a major role in motion sickness and is rich in muscarinic and histamine H_1 receptors.
- The CNS mediates vomiting arising from psychiatric disorders and stress from higher brain centres, namely, cerebral cortex and limbic system [2].
- The CTZ has serotonin 5-HT_3 receptors, opioid receptors, acetylcholine receptors, dopamine D_2 receptors and receptors for substance P. Stimulation of different receptors is involved in different pathways leading to emesis [3].

Output

The vomiting act encompasses three types of outputs initiated by the chemoreceptor trigger zone: motor, parasympathetic nervous system (PNS)

and sympathetic nervous system (SNS). They are as follows:

Motor output—results in lowering of intrathoracic pressure (by inspiration against a closed glottis) coupled with contraction of the diaphragm, anterior abdominal wall and intercostal muscle, thus propelling stomach contents into the oesophagus. Vomiting is ordinarily preceded by retching.

PNS output—increased salivation to protect the enamel of teeth from stomach acids (excessive vomiting leads to dental erosion).

A deep breath is taken to avoid aspiration of vomit.

Retroperistalsis, starting from the middle of the small intestine, sweeping up the contents of the digestive tract into the stomach, through the relaxed pyloric sphincter.

SNS output—causes both sweating and increased heart rate.

The neurotransmitters that regulate vomiting are poorly understood, but inhibitors of dopamine, histamine and serotonin are all used to suppress vomiting, suggesting that these play a role in the initiation or maintenance of a vomiting cycle. Vasopressin and neurokinin may also participate. The area postrema as such lies outside the blood-brain barrier and can therefore be stimulated by humoral stimuli, cytotoxins, ketones, ammonia and blood-borne drugs that can stimulate vomiting or inhibit it.

Aetiology

The causes of vomiting are listed in the table below with the majority of the organic causes being digestive (gastrointestinal, pancreatic or hepatobiliary) (Table 101.1).

Types of Vomiting

Vomit of Food It's the most frequent type of vomiting and is more often due to primary or secondary GOR. It is thus made of partially digested or undigested food and may occur immediately after a meal or after a few hours.

In an infant with recurrent regurgitation, a thorough history and physical examination with attention to warning signals suggesting other diagnoses (Table 101.2) is generally sufficient to establish a clinical diagnosis.

In infants with uncomplicated GOR, there is no need for extensive diagnostic testing if they demonstrate normal growth and in the absence of other warning symptoms. Recurrent regurgitation due to GOR generally decreases over the first year, resolving at 12–18 months of age [4, 5]. Only parental education, anticipatory guidance and modification of feeding frequency and volume are necessary for the management uncomplicated infant GOR [6, 7]. Overfeeding exacerbates recurrent regurgitation and should be avoided [8]. In some infants with persistent regurgitation, a thickened or commercial anti-regurgitation formula may help control the frequency of regurgitation. Since regurgitation is sometimes the sole manifestation of cow's milk protein allergy in healthy-looking infants, a 2-week trial of protein hydrolysate or amino acid-based formula or a trial of milk-free diet for the breast feeding mother is appropriate. If warning signals are present, further evaluation will be necessary.

The commonest causes of food vomitus in an older child are GOR and cyclical vomiting syndrome which is described later:

'Acid' Vomits The vomitus tends to be mucousy or foamy with a pH of <5.

In infants, it's usually associated with crying and irritability which are nonspecific symptoms associated with a wide range of physiologic and pathologic conditions. Some normal healthy infants cry as much as six hours per day. Likewise there is variation in parental perceptions regarding the severity and duration of crying and its importance. Top on the list of differential diagnosis for pathologic conditions would be GOR.

Table 101.1 Differential diagnosis of vomiting in infants and children

Gastrointestinal obstruction	*Metabolic/endocrine*
Pyloric stenosis	Galactosemia
Malrotation with intermittent volvulus	Hereditary fructose intolerance
Intestinal duplication	Urea cycle defects
Intestinal pseudo-obstruction	Amino and organic acidemias
Hirschsprung disease	Congenital adrenal hyperplasia
Antral/duodenal web	Addison disease
Foreign body	Diabetic ketoacidosis
Incarcerated hernia	Pheochromocytoma
Superior mesenteric artery syndrome	Disorders of fatty acid oxidation
Other gastrointestinal disorders	Mitochondriopathy
Gastro-oesophageal reflux disease (peptic oesophagitis)	Acute intermittent porphyria
Peptic disorders (gastritis, duodenitis, Helicobacter pylori infection)	*Renal*
	Obstructive uropathy
Achalasia	Renal insufficiency
Gastroparesis	Acute hydronephrosis secondary to
Gastroenteritis	Uretero-pelvic junction obstruction
Peptic ulcer	Nephrolithiasis

Food allergy	Lead
Inflammatory bowel disease	Iron
Pancreatitis	Vitamin A and D
Hirschsprung disease	Medications
Cholelithiasis (gallbladder dyskinesia)	*Cardiac*
Choledochal cyst	Congestive heart failure
Chronic appendicitis	Vascular ring
Neurologic	*Psychiatric*
Hydrocephalus	Munchausen syndrome by proxy
Subdural hematoma	Bulimia
Intracranial haemorrhage	Self-induced vomiting
Intracranial mass	*Social*
Migraine	Child neglect
Infectious	Child abuse
Chronic sinusitis	*Others*
Sepsis	Familial dysautonomia (Riley-Day syndrome)
Meningitis	Pregnancy
Urinary tract infection	
Pneumonia	
Otitis media	
Hepatitis	

Incorporated from NASPGHAN–ESPGHAN guidelines

Vomiting associated with GOR is probably a result of the stimulation of pharyngeal sensory afferents by refluxed gastric contents.

The available evidence does not support an empiric trial of acid suppression in infants with irritability or sleep disturbance [5]. A symptom diary [6, 7] or hospital observation [8, 9] may be useful to confirm the history, which is very subject to observation bias. Disorders other than GORD to consider include cow's milk protein allergy [10] and causes as listed in Table 101.1. Allergy to cow's milk protein or other formula intolerance may cause infant irritability, distress and vomiting indistinguishable from GORD. An empiric trial of extensively hydrolyzed protein formula or amino-acid-based formula is reasonable in selected cases.

GORD may present as epigastric pain, heartburn or dysphagia in children and a systematic approach is necessary.

Bilious Vomits Always an ominous sign particularly in infants and suggestive of intestinal obstruction distal to the ampulla of Vater. In

Table 101.2 Warning signals requiring investigation in infants with regurgitation or vomiting

Projectile vomiting
Bilious vomiting
GI bleeding
Haematemesis
Haematochezia
Consistently forceful vomiting
Onset of vomiting after 6 months of life
Failure to thrive
Diarrhoea
Constipation
Fever
Lethargy
Hepatosplenomegaly
Bulging fontanelle
Macro-/microcephaly
Seizures
Abdominal tenderness or distension
Documented or suspected genetic/metabolic syndrome
Associated chronic disease

older children is possibly due to persistent stimulation of the emetic reflex. Diagnostic clue would be within the history of initial expulsion of gastric contents or mucus only, followed by expulsion of bile on subsequent episodes.

Bloody Vomits (Haematemesis) Are a potential emergency and needs evaluation in the hospital setting. Vomits containing bright red blood or coffee-ground material are suggestive of ongoing or recent bleeding from the upper GI tract. Haematemesis is usually a complication of an underlying disease such as peptic disease, coagulopathy, oesophageal varices, etc. A thorough history and examination including an ear, nose and throat assessment is necessary.

Investigations: Barium upper GI series, upper gastrointestinal endoscopy and oesophageal pH/MII both to diagnose GERD and rule out alternative diagnoses.

Cyclical Vomits This condition is described in greater detail in the next section of this chapter.

Cyclical Vomiting Syndrome

Introduction

Cyclic vomiting syndrome (CVS) is an episodic disorder of nausea and vomiting that was first described by Dr. W. Heberden in the French literature in 1806 [11] and then by Dr. Samuel Gee [12] in the English literature in 1882. The syndrome is a functional disorder considered to be a manifestation of migraine diathesis [13, 14] with a characteristic pattern of recurrent episodes of high-intensity nausea and vomiting lasting hours or days, separated by intervals free of symptoms. The pattern has many aetiologies. Patients typically present with six to twelve stereotypic episodes of nausea and vomiting per year that vary in duration and frequently go undiagnosed for years [15]. The diagnosis is primarily based on history and clinical presentation. Treatment focuses on symptom management and prompt measures aimed at aborting or terminating episodes. Anti-migraine medications have been effectively used for prophylaxis in many patients.

Diagnostic Criteria

As per the consensus statement by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) [16] (Table 101.3).

Epidemiology

CVS has been described in all races and ethnicities, although Caucasians appear to be effected to a greater degree. The prevalence of CVS is not known and appears to vary depending on geographical location. In a population-based study performed in Aberdeen, Scotland [17] indicated a prevalence of 1.9 % (though this is likely to be an overestimate), whereas Li and Misiewicz [18] estimated it to be 0.04 % in children of central Ohio. Affected children are more often girls than boys (60:40) of elementary school age (ranging from infants to young adults).

Table 101.3 Diagnostic criteria for cyclical vomiting syndrome

At least 5 attacks in any interval or a minimum of 3 attacks during a 6-month period
Episodic attacks of intense nausea and vomiting lasting 1 h–10 days and occurring at least 1 week apart
Stereotypical pattern and symptoms in the individual patient
Vomiting during attacks occurs at least 4 times/h for at least 1 h
Return to baseline health between episodes
Not attributed to another disorder

CVS occurs in all age groups. Children as young as 6 months and adults as old as 73 years have been described as having CVS. The median age at onset of symptoms ranges from 5.2 to 6.9 years.

Symptoms and Associated Features

CVS usually has four different phases: prodromal, vomiting, recovery and inter-episodic. Understanding of this phasic pattern helps in both diagnosis and management. The inter-episodic phase is more or less symptom-free. The patient senses the approach of an episode during the prodromal phase, but is still able to retain oral medications. The vomiting phase is characterized by intense, persistent nausea, vomiting, retching and other symptoms. The recovery phase begins as soon as nausea remits and ends when the patient has recovered appetite, strength and body weight lost during the vomiting phase.

Grading of severity	
Mild	CVS not interfering with work or school
Moderate	If attendance at work or school in jeopardy
Severe	If disabled

Prodromal symptoms consist of nausea, lethargy, anorexia and pallor. A migraine-like visual aura is rare. The nausea, vomiting, retching and other symptoms of the vomiting phase are overwhelming and completely incapacitating. Their mean duration is 41 h (median, 24 h). The maximum frequency of vomiting may be more than ten times per hour. Forceful vomiting and retching often cause haematemesis due to prolapse gastropathy or Mallory-Weiss tears [19–21]. Peptic oesophagitis and haemorrhagic lesions of the gastric mucosa are typical endoscopic findings that result from, rather than cause, vomiting episodes. Signs and symptoms of an intense stress response are common, including increased heart rate and blood pressure, drenching diaphoresis, minor loose stooling, low-grade fever and neutrophilia. Many children have behaviours during episodes that may puzzle or mislead carers, but remit promptly during the recovery phase. Headache (40 %), photophobia (32 %) and phonophobia (28 %) may occur and cause patients to seek a quiet and dark environment.

Diagnostic Approach

There are no specific laboratory markers to diagnose CVS. A pattern of recurrent, episodic vomiting in children that fulfils the revised historical criteria listed in Table 101.3 is likely (about 90 %) to be ultimately diagnosed as idiopathic CVS [20]. The challenge would be to differentiate individuals with specific and serious underlying causes of vomiting (about 10 %) for which prompt treatment may alter outcomes (see Fig. 101.2).

A thorough history and physical examination at presentation helps identify those children in whom further diagnostic testing is prudent. The diagnostic principles outlined below are intended to help identify those children with a cyclic vomiting pattern between ages 2 and 18 years at the greatest risk for having an organic cause.

Suspicious symptoms and physical findings include the following:
1. Bilious vomiting, abdominal tenderness and/or severe abdominal pain
2. Attacks precipitated by intercurrent illness, fasting and/or high protein meal
3. Abnormalities on neurological examination including severe alteration of mental status, abnormal eye movements, papilloedema, motor asymmetry and/or gait abnormality (ataxia)
4. Progressively worsening episodes or conversion to a continuous or chronic pattern

Depending upon the presenting symptoms and signs other than vomiting, different diagnostic approaches are recommended as illustrated in Fig. 101.2.

Although children younger than 2 years may have CVS, serious underlying metabolic and surgical disorders are more frequent and more difficult to diagnose in that age range.

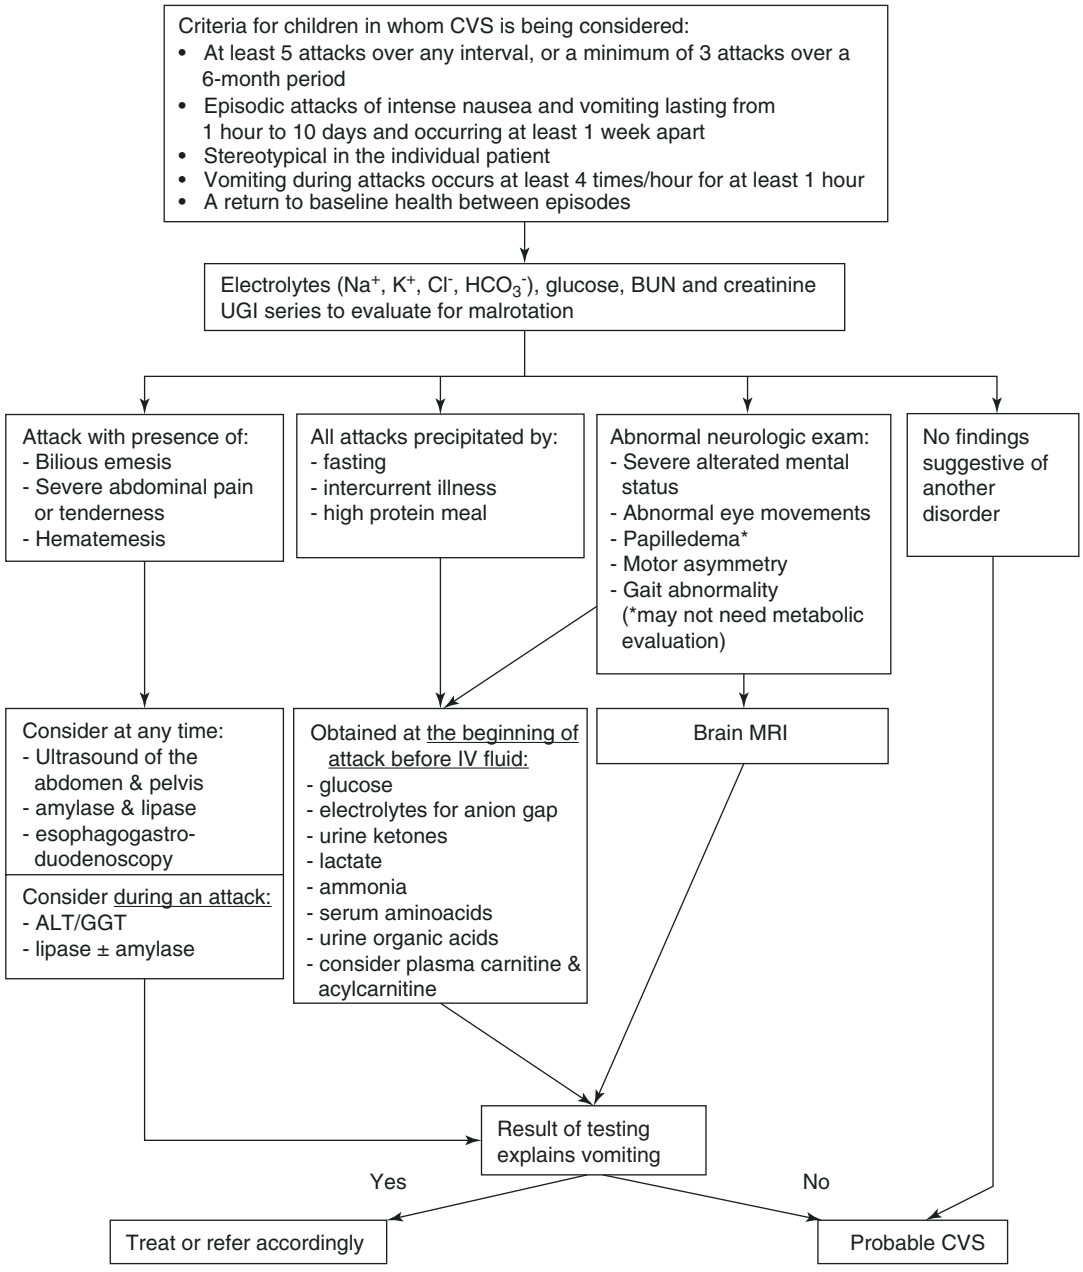

Fig. 101.2 Recommended investigative protocol in children >2 years with cyclical vomiting (Courtesy NASPGHAN: Incorporated from the NASPGHAN consensus statement [16] on CVS)

Children with cyclic vomiting should be evaluated for a possible metabolic or neurological disorder if any of the following conditions are met:

- Presentation under age 2 years (with cyclic vomiting or comorbidities below)
- Vomiting episodes associated with intercurrent illnesses, prior fasting, increased protein intake
- Any neurological finding: ataxia, dystonia or another gait disturbance; mental retardation; seizure
- Disorder or acute encephalopathy (including true lethargy, severe irritability, confusion, psychosis or rapidly changing/unstable mental status)
- Laboratory metabolic findings: hypoglycaemia, substantial anion gap metabolic acidosis, respiratory alkalosis or hyperammonaemia

A referral to a specialist in metabolic disorders and/or a neurologist is suggested for patients with any of the above findings.

Treatment Approach to Recurrent, Episodic Vomiting

The management of CVS requires an individually tailored regimen that takes into consideration the clinical course, frequency and severity of attacks, and resultant disability balanced against the potential side effects of treatment. The clinical course of CVS can be divided into the episode phase and the well phase.

Well Phase During the well phase, lifestyle changes as detailed in Table 101.4 may help reduce episode frequency/intensity.

Because fear and anticipation of future episodes can trigger episodes of CVS, the use of reassurance and anticipatory guidance may help reduce the frequency of attacks. This guidance includes confirming that the attacks are not self-induced and the child will typically improve with age and providing an individualized management protocol.

Table 101.4 Practical therapeutic approach to CVS

Avoid: triggers (vomiting diary to identify potential precipitating factors)
Fasting
Triggering foods (antigenic foods, monosodium glutamate, chocolate, cheese)
Excess energy output (over exercising)
Skipping meals
Sleep deprivation
Provide: fruit juices, other sugar containing drinks
Extra snacks between meals, before exertion or at bedtime
Supplemental carbohydrate for fasting-induced symptoms
Migraine headache life style interventions
Regular aerobic exercise, meal schedules and good sleep hygiene
Recognize that excitement could also be a trigger
Reassurance

Episodic Phase The two key treatment arms are prophylactic (or preventive) measures and medication administered between attacks and acute and supportive interventions given during attacks.

Preventive medications are only indicated if episodes occur frequently (e.g. more than every 1–2 months), are severe enough to cause repeated hospitalisation/school absence and/or fail to respond to abortive therapies.

Recommendations for Prophylaxis

Pizotifen, propranolol or cyproheptadine is the recommended prophylaxis for children 5 years old and younger. In the older child (older than 5 years), pizotifen, amitriptyline or propranolol is recommended, as shown in Table 101.5. The dose can be titrated to effect by increasing it

Table 101.5 Prophylactic or preventive medication in CVS

Children 5 years or younger	
Pizotifen 0.5 mg–1.5 mg/kg/day [first choice]	Side effects: increased appetite, weight gain, sedation
Propranolol 0.25–1.0 mg/kg/day, most often 10 mg bid or tid (second choice). Monitor: resting heart rate maintain 60 bpm	Side effects: lethargy, reduced exercise intolerance
	Contraindications: asthma, diabetes, heart disease, depression
	Discontinuation: tapered for 1–2 weeks
Alternatives	
Cyproheptadine 0.25–0.5 mg/kg/day divided bid or tid b-Blockers:	Side effects: increased appetite, weight gain, sedation
Children older than 5 years	
Tricyclic antidepressants: amitriptyline (first choice)	Side effects: constipation, sedation, arrhythmia, behavioural
Amitriptyline begin at 0.25–0.5 mg/kg qds, increase weekly by 5–10 mg, until 1.0–1.5 mg/kg	
Monitor: (ECG) QTc interval before starting and 10 days after peak dose changes (especially in younger children)	Alternatives: nortriptyline (available in liquid)
b-Blockers: propranolol (second choice)—see above	
Other agents	
Anticonvulsants:	Side effects: sedation, cognitive impairment
Phenobarbital 2 mg/kg qds	Alternatives: topiramate, valproic acid, gabapentin, levetiracetam—consult neurologist
Supplements	
L-carnitine 50–100 mg/kg/day divided bid or tid (max 1 g)	Side effects: diarrhoea, fishy body odour (for L-carnitine)
Coenzyme Q10 10 mg/kg/day divided bid or tid (max 100 mg tid)	

Courtesy NASPGHAN: Incorporated from the NASPGHAN consensus statement [16] on CVS

every 1–4 weeks to achieve at least an average therapeutic dose for two CVS cycles (e.g. if monthly, then for 2 months). If any of the medication causes intolerable side effects and/or proves to be ineffective, then it is appropriate to switch to another medication. The common side effects tend to be dose related and may be addressed by reducing the dosage.

If a patient *does not* respond, consider the following:

- Diagnoses other than CVS and need for additional diagnostic testing
- Whether an adequate trial was administered (e.g. a high-end dose given for at least a two-cycle trial period) or there was lack of adherence
- Combination therapy of two medications (especially amitriptyline with one of the other main drugs)
- Complementary therapy such as carnitine, coenzyme Q, low oestrogen oral contraceptives, acupuncture
- Psychotherapy

Alternate Prophylactic Approaches

L-carnitine (commonly prescribed dose of 50–100 mg/kg/day, max 1 g), a nutrient that serves as a transport cofactor for long-chain fatty acids into mitochondria, may help patients with suspected mitochondrial or metabolic dysfunction and has a benign side effect profile.

There is anecdotal experience with coenzyme Q, low oestrogen oral contraceptives (particularly in menstrual related CVS), acupuncture and psychotherapy, but there's no data to support its use.

Supportive and Abortive Interventions

During the acute episode of vomiting, the supportive measures should be as follows:

- Placing children in less stimulating environments
- Replenishing fluids, electrolytes and energy
- Treating symptomatic nausea, vomiting and severe abdominal pain

Note: Early intervention within the first 2–4 h of onset either at home or at a hospital may be more effective than later intervention.

At all ages, use of intravenous 10 % dextrose and high-dose 5HT3 antagonist anti-emetics (e.g. ondansetron 0.3–0.4 mg/kg/dose every 4–6 h) is recommended to treat energy deficits and vomiting, respectively. If no enteral intake for 3–5 days, then initiate peripheral parenteral nutrition with 1.5 g of amino acids/kg/day and energy units above the catabolic threshold of 55–70 kcal/kg/day.

Only if 5HT3 antagonist anti-emetics are ineffective, then concomitant sedation with lorazepam (0.05–0.1 mg/kg/dose intravenously [IV] every 6 h) or diphenhydramine (1–1.25 mg/kg/dose I.V. every 6 h) is recommended. Severe abdominal pains are treated with parenteral acid suppression and/or nonsteroidal anti-inflammatory drugs or narcotics.

As an abortive approach, intranasal triptans may be used in children age 12 and older with infrequent (<1/month) or milder episodes (<24 h).

Once the vomiting starts, evaluation in an emergency department or direct admission to the hospital ward before dehydration ensues is appropriate in some patients for treatment protocols specifying intravenous fluids, medications and admission criteria.

Providing the patient with a letter that explains CVS and specifies an individualized management protocol can facilitate prompt institution of therapy. A template of such a letter can be found on the following weblink http://www.cvsaonline.org. Some behaviours during episodes may appear to be odd but are in fact common in CVS episodes. Many children become non-communicative and curl into a foetal position because, in their hypersensitive state, any further stimulation heightens their nausea and can trigger more vomiting. At best, the child should not be unnecessarily disturbed. There are other children who drink obsessively to induce vomiting. Reductions in these behavioural responses generally are observed when patients receive adequate symptom relief with antiemetics and sedation. Most patients with CVS will respond partially to one of the regimens discussed above. If a child does not respond, or the episode differs substantially from previous ones by greater severity, longer duration or new or different symptoms, then the clinician should reconsider the possibility of an underlying surgical lesion and the need for new or to repeat diagnostic testing (e.g. abdominal ultrasound, brain MRI).

Reflux Esophagitis and the Child with Heartburn

102

Mike Thomson

Heartburn or substernal burning pain is a symptom of GERD with or without esophagitis [1]. Recent consensus statements suggest that typical heartburn is a reliable indicator for GERD in adolescents and adults if it is the dominant symptom [2, 3]. Recent adult and pediatric consensus guidelines have applied the terms "typical reflux syndrome" or "reflux chest pain syndrome" to this presentation [2, 3]. One study in adults found that dominant heartburn had a positive predictive value of 81 % for GERD determined by pH study [4], but other studies have not confirmed this close association between history and test results [5]. Esophageal pH probe results are normal in one third of adults with chronic heartburn, even those whose heartburn is reproduced by esophageal acid perfusion and those who respond favorably to antacids. Some adults with heartburn and normal pH studies have endoscopically proven esophagitis [6]. In older children and adolescents, the description and localization of heartburn pain are probably reliable. In young children, however, symptom descriptions and localization may be unreliable [7–12].

GERD is often diagnosed clinically in adults based on a history of heartburn defined as substernal, burning chest pain, with or without regurgitation. Based on expert opinion, the diagnosis of GERD can be made in adolescents presenting with typical heartburn symptoms as in adults [3, 13–17]. However, a clinical diagnosis based on a history of heartburn cannot be used in infants, children, or nonverbal adolescents (e.g., those with neurologic impairment) as these individuals cannot reliably communicate the quality and quantity of their symptoms. The verbal child can communicate pain, but descriptions of quality, intensity, location, and severity generally are unreliable until at least 8 and possibly 12 years of age [7–11, 17].

As in adults, individual symptoms in children generally are not highly predictive of findings of GERD by objective studies. For example, in a study of irritable infants under 9 months of age, regurgitation >5 times per day had a sensitivity of 54 % and specificity of 71 % for a reflux index (RI) >10 % by esophageal pH testing, while feeding difficulties had a sensitivity of 75 % and specificity of 46 % [18]. A similar poor correlation of symptoms and esophageal acid exposure was observed during an omeprazole treatment study in irritable infants; similar reductions in crying occurred in both treated and untreated, infants and the extent of reduction crying did not correlate with extent of reduction of the RI in the treated patients [19].

Because individual symptoms do not consistently correlate with objective findings or response to medical treatment, parent or patient-reported questionnaires based on clusters of

symptoms have been developed. Orenstein et al. [3, 20] developed a diagnostic questionnaire for GERD in infants. A score of >7 (of 25 possible) on the initial instrument demonstrated a sensitivity of 0.74 and specificity of 0.94 during primary validation. The questionnaire has undergone several revisions [16]. The questionnaire has been shown to be reliable for documentation and monitoring of reported symptoms. However, when applied to a population in India, it had a sensitivity and specificity of only 43 % and 79 %, respectively, compared to pH monitoring results [14]. In another study of infants referred for symptoms of reflux disease and controls, the questionnaire had sensitivity and specificity of 47 % and 81 % for an RI >10 % and 65 % and 63 % for a reflux index >5 %. The questionnaire score failed to identify 26 % of infants with GERD. The score was positive in 17 of 22 infants with normal biopsies and pH studies and in 14 of 47 infants with normal pH studies. No single symptom was significantly associated with esophagitis [13]. In another study, the questionnaire was unable to identify a group of infants responsive to proton-pump inhibitor therapy [21]. Thus, no symptom or cluster of symptoms has been shown to reliably predict complications of reflux or to predict those infants likely to respond to therapy.

A five-item questionnaire developed for children 7–16 years of age had a sensitivity of 75 % and specificity of 96 % compared to pH monitoring during primary validation [22]. No subsequent independent confirmatory validation has been performed. Other diagnostic questionnaires such as the GERD Symptom Questionnaire [15] have not been compared to objective standards like endoscopy, pH monitoring, or esophageal MII monitoring. Some researchers have used questionnaires to monitor symptoms of children during GERD therapy [23]. Whether this method is preferable to monitoring individual symptoms is uncertain. Although daily symptom diaries are frequently used in adults to monitor the effects of therapy, these have not been validated in children.

No randomized, placebo-controlled studies evaluate lifestyle changes or pharmacologic therapy of heartburn in children or adolescents. Case series have shown that PPI therapy relieves heartburn symptoms in adolescents [17, 23, 24]. Expert opinion suggests using a management approach to heartburn in older children and adolescents similar to that used in adults (Fig. 102.1). Other causes of heartburn-like chest pain including cardiac, respiratory, musculoskeletal, medication-induced, or infectious etiologies should be considered. If GERD is suspected as the most likely cause of symptoms, lifestyle changes, avoidance of precipitating factors, and a 2–4-week trial of PPI are recommended [12, 25–27]. If there is no improvement following empiric therapy, the older child or adolescent should be referred to a pediatric gastroenterologist for diagnostic evaluation. If improvement follows PPI therapy and lifestyle changes, treatment can be continued for 2–3 months. In some patients, abrupt discontinuation of treatment may result in acid rebound that precipitates symptoms; therefore, it is recommended that antisecretory therapy should be weaned slowly [28, 29]. If symptoms recur when therapy is weaned or discontinued, upper endoscopy may be helpful to determine the presence and severity of esophagitis and differentiate reflux-related esophagitis from non-reflux pathologies such as infection or eosinophilic esophagitis that may present with heartburn [30, 31]. Because chronic heartburn can have a substantial negative impact on quality of life, long-term therapy with PPI may be required, even in the absence of esophagitis [32, 33]. Extrapolation from adult data suggests that in older children and adolescents, on-demand or intermittent therapy with antacids, H2RA or PPIs, may be used for occasional symptoms of heartburn [33–36].

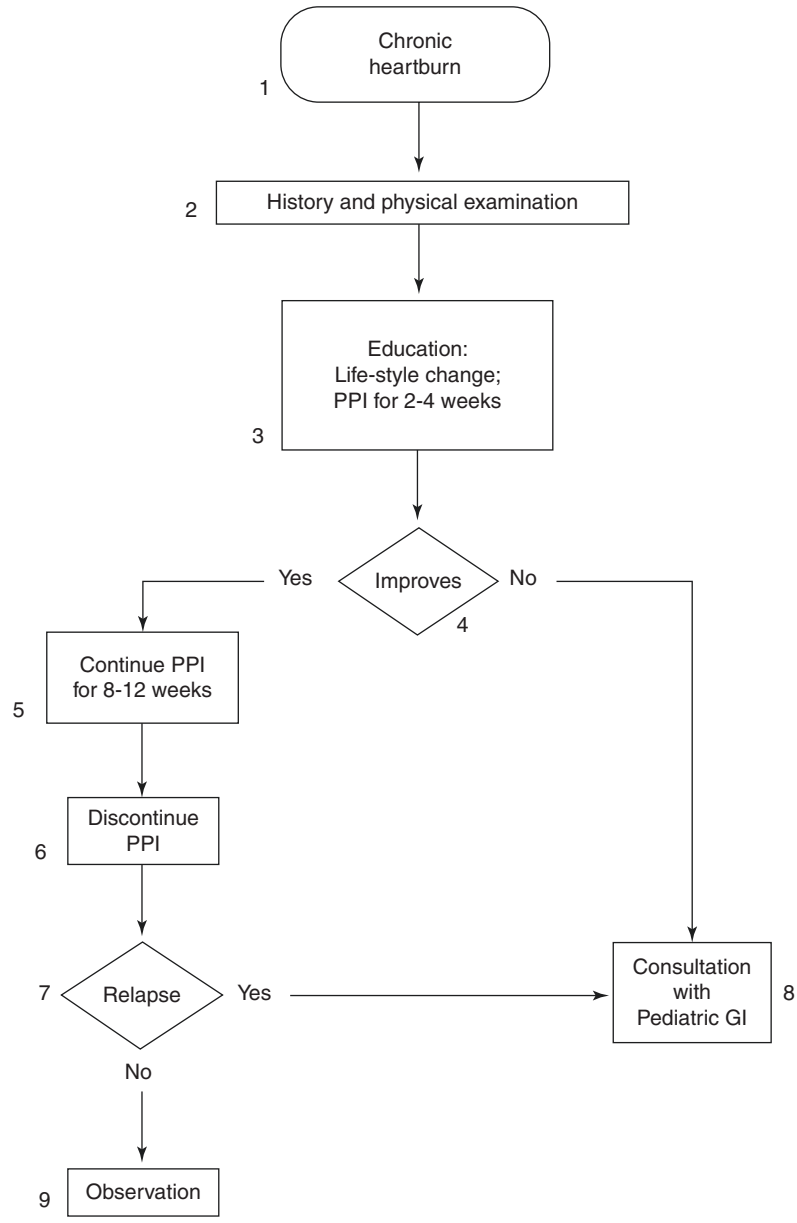

Fig. 102.1 Approach to an older child or adolescent with heartburn

Food Refusal, Dysphagia, and Odynophagia

103

Amy Tsai, Jose Garza, and Ajay Kaul

Introduction

There has been significant advancement in our knowledge of the neurophysiology of swallowing. This fundamental sensorimotor function evolves from the primitive suck-swallow pattern first observed in a fetus to the more complicated adult biting-masticating-swallow pattern. The maturation process occurs in a complex and diverse cortical network which exists in the brainstem and controls the three primary phases of swallowing: oral, pharyngeal, and esophageal. Contribution of the latest neuroimaging techniques in understanding the complex swallowing process has been invaluable. For example, we now know that a normal swallow activates in the mid-lateral primary sensorimotor cortex bilaterally. Sensory input from the tongue and oropharyngeal mucosa is critical in the initiation of swallowing, while proper functioning of the cortical network and the striated muscles of the pharynx and esophagus is crucial for the sequence of motor events that result in a normal swallow. Disorders affecting any site along this pathway can result in dysfunctional swallowing or dysphagia, which in infants and toddlers may manifest as food refusal. Breakdown in the central integration of swallowing and airway protective reflexes can lead to aspiration, which may also present as food refusal.

Pediatric dysphagia may be transient, chronic, or progressive [1] depending on its etiology. It can occur as a result of structural or functional abnormalities in the sensorimotor pathways that control swallowing, behavioral or psychological disorders, or a combination of both. Structural abnormalities of the brain, oropharynx, and esophagus are easily identifiable using radiographic or endoscopic techniques. However, diagnosis of functional abnormalities in the neural pathways affecting swallowing is much more challenging, as there are currently no commercially available diagnostic markers or methods to test them.

Odynophagia or pain during swallowing is most commonly due to an inflammatory process in the oropharynx or esophagus, but occasionally may be related to an impediment in bolus movement. It must be distinguished from heartburn and dysphagia in older children as it may direct the clinician to the correct diagnosis. Although odynophagia may be a symptom of peptic esophagitis, it is more often associated with other conditions such as oropharyngeal inflammation, esophageal ulcer, eosinophilic esophagitis, infectious esophagitis, and pharyngeal or esophageal

motor disorders. Even though it is conceivable that gastroesophageal reflux disease can cause odynophagia, there are no pediatric reports studying their association.

Food Refusal

It is challenging to diagnose dysphagia or odynophagia in infants and toddlers due to an inability to accurately communicate their symptoms. They typically develop behaviors around eating (food refusal) that may be a manifestation of dysphagia or odynophagia. In these younger children, common signs and symptoms of a swallowing problem include vomiting, coughing, choking, aspiration, lack of interest in eating, straining or extension of muscles during feedings, extensive time required to feed (more than 30 min), failure to thrive, choking, coughing or gagging with feeds, and presence of tongue thrusting during swallowing [2]. It has been estimated that 25 % of normal infants and 80 % of young children with developmental disabilities demonstrate infant feeding disorders [3]. Food refusal is considered severe in 1–2 % of infants, resulting in serious deficits in growth and development which persist into childhood in 70 % of the cases [3]. Since the etiology of feeding disorders in young children is usually multifactorial, including neurobehavioral and psychosocial, and has a significant impact on the family, an interdisciplinary approach to address it is warranted. The team should include members from speech and language pathology, occupational therapy, nutrition, child psychology, and a physician with expertise in the field.

Based on a review of 126 children seen at Cincinnati Children's Hospital Medical Center's (CCHMC) Interdisciplinary Feeding Clinic from 2008 to 2009, we found that most children were males and had been of full-term gestational age (see Table 103.1). This may be due to preterm infants being managed at a high-risk clinic during their first year of life. The most common comorbid conditions in the full-term group were gastrointestinal disorders, while in the preterm group was neurodevelopmental disorders. Both groups underwent a variety of diagnostic studies. The top 4 most commonly ordered tests were videofluoroscopic swallow study (VFSS), esophagogastroduodenoscopy (EGD), upper gastrointestinal (UGI) contrast study, and fiberoptic endoscopic evaluation of swallowing (FEES). The average percentage of abnormal results among these studies was 43 % in the preterm children and 55 % in the full-term group. Among the less commonly ordered studies, which include rigid microlaryngobronchoscopy (MLB), flexible bronchoscopy (FB), gastric emptying scan, and brain MRI, the average percentage of abnormal results was 89 % in the preterm group and 68 % in the full-term group. The lower yields of VFSS, EGD, UGI, and FEES may indicate their role as screening tools. The higher percentage of abnormal results among the less commonly ordered studies highlights the importance of choosing the appropriate diagnostic study in the evaluation of pediatric food refusal, so as to reduce the number of unnecessary tests.

Food refusal in infants and toddlers may signify the presence of dysphagia or odynophagia due to a wide spectrum of disorders or disease states. To interpret the clinical manifestations, the clinician needs to consider the age, past medical or surgical history, and a thorough account of the patient's feeding behavior. Table 103.2 depicts a proposed algorithm for the evaluation of food refusal in children.

If the child demonstrates food refusal or unusual feeding behaviors, he should undergo an initial clinical oral motor feeding assessment by a speech language pathologist or occupational therapist. If the initial assessment is suggestive of a purely oral motor dysfunction, then the treatment would proceed to oral motor feeding therapy. Strategies employed during feeding therapy sessions include postural (compensatory) changes, utensils of different shapes and sizes, liquids and solids of different consistencies, and textures and behavioral modifications. Should there be no improvement in the child's feeding refusal after successive therapeutic sessions, then a more in-depth evaluation with an upper endoscopy may be indicated.

If the initial assessment by the therapist is indicative of a swallowing dysfunction, then a VFSS is recommended. This contrast swallow study may demonstrate delayed swallow

Table 103.1 Clinical profile of children evaluated by the interdisciplinary feeding team at CCHMC

	Preterm		*Full term*	
Total 126 (*n*; % of total)	31 (25%)		95 (75%)

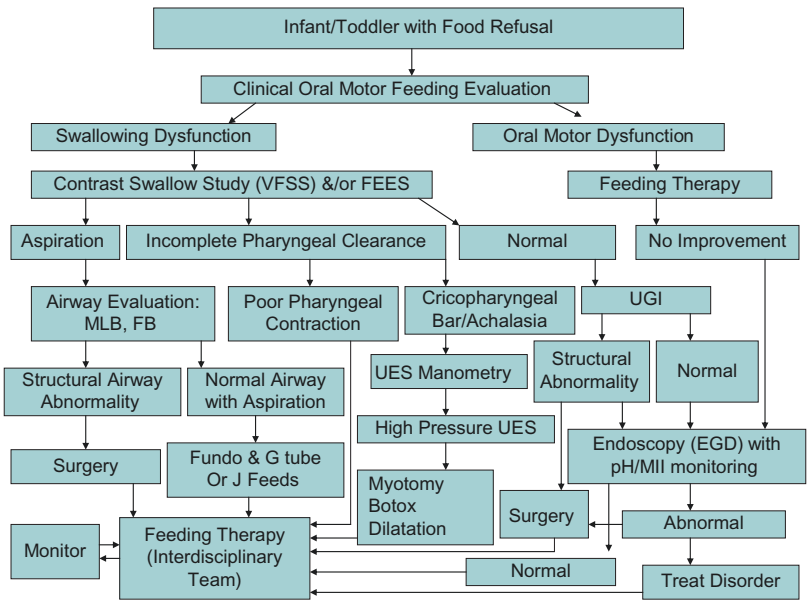
MRI brain	2	100	17	65

Table 103.2 Algorithm for evaluation of food refusal in children



initiation, shallow penetration, deep penetration, aspiration, presence of a protective response, and also if any compensatory strategies are effective in making the swallowing more efficient. If the compensatory strategies alleviate the issue and there is no risk of aspiration, then further airway evaluation with MLB, FB, or FEES is not always necessary. If the contrast swallow study demonstrates incomplete pharyngeal clearance that is not alleviated by compensatory strategies (such as additional swallows, alternating between solid and liquid states, and chin tuck), then this

may be an indication of oral motor weakness and poor pharyngeal contraction. The child subsequently should proceed to feeding therapy. Other causes of incomplete pharyngeal clearance may be upper gastrointestinal motility disorders, including cricopharyngeal achalasia. If the upper esophageal sphincter (UES) manometry study shows a consistently elevated baseline pressure of the UES, then therapy can include esophageal botulinum toxin (Botox) injection, dilatation, or myotomy. If the VFSS is otherwise normal, then the clinician should rule out structural abnormalities that may be causing behaviors of food refusal. An UGI series or endoscopy may reveal an anatomic anomaly such as an esophageal web, stricture, or hiatal hernia that may need surgical intervention. It is well recognized that even after surgical correction or adequate medical treatment of the underlying disorder, children may continue to be orally aversive. Persistence of food refusal despite resolution of the etiologic disorder is believed to be due to a learned response that can be addressed by appropriate therapy and monitoring by an interdisciplinary feeding team.

Aspiration

Aspiration is the entry of foreign material into the airway, below the true vocal folds, and represents a breakdown of the airway protective mechanism (such as esophago-glottal and pharyngo-glottal closure reflexes). It is in contrast to penetration, which involves entry of foreign material into the larynx above the true vocal folds [4]. Aspiration occurs when the airway protective reflexes are compromised as a result of either a structural defect of the laryngeal structures or a functional abnormality. In healthy, awake, and alert individuals, aspiration should result in coughing to expectorate the foreign material. Silent aspiration is aspiration that is not associated with a cough response when an individual is awake and alert [5]. Aspiration of material into the airway can occur from above during swallowing or from below due to refluxed gastric contents. Several studies have shown that oropharyngeal dysfunction with silent aspiration may occur in otherwise healthy children without known risk factors, such as neurodevelopmental delay, gastroesophageal reflux, or overt feeding difficulties [6]. Both forms of aspiration can result from reduced oral control, pharyngeal delay, reduced laryngeal elevation, and esophageal reflux [5]. Many infants who aspirate may not cough [7]. Feeding refusal or unexplained chronic lung disease may be the only symptom of aspiration in an infant or toddler. Aspiration commonly manifests as chronic respiratory symptoms (such as wet cough, choking, gagging, and gurgling noises) during or after feedings [2]. Therefore, early identification and appropriate treatment may reduce the ensuing morbidities associated with swallowing dysfunction and chronic aspiration [8].

Evaluation for aspiration should begin with a detailed medical, developmental, and feeding history [9]. Clinical evaluation should include observation of a typical feeding. Ideally this should be performed by an interdisciplinary team with a speech pathologist, occupational therapist, or nurse with expertise in infant or childhood feeding disorders [1]. The knowledge of the existence and frequency of silent aspiration became evident with the use of videofluoroscopic swallow study (modified barium swallow study). In addition to identifying aspiration, it can also define anatomic or physiologic disorders. Fiberoptic endoscopic evaluation of swallowing (FEES) is another modality for assessing swallows and is performed by an ENT physician while the patient is awake [5]. In addition to visualizing the anatomy and function of the pharynx and larynx with swallows, it can also test for sensation of the region and vocal fold movement. The findings of the two studies often complement each other and give a better understanding of the swallowing process. If a structural laryngeal defect, such as a laryngeal cleft, is suspected, then a rigid microlaryngobronchoscopy may need to be done to confirm the finding before surgical intervention to correct the defect is contemplated. A flexible bronchoscopy with bronchoalveolar lavage (BAL) may be indicated to assess the severity of aspiration by visualizing the mucosal lining of the tracheobronchial tree, secretions, and lipid-laden macrophages in the lung washings. Pepsin

analysis may also be performed on the washings to assess aspiration of gastric contents, as pepsin is exclusively produced in the stomach.

Evaluation and management of a child with aspiration should be done by an interdisciplinary team that includes physicians from otolaryngology, pulmonology and gastroenterology, feeding therapist or speech pathologist, and nutritionist. There are six major issues that need to be addressed by the team including (1) normalization of posture and tone, (2) adaptation of food and feeding equipment, (3) oromotor therapy, (4) feeding therapy, (5) nutritional support, and (6) management of associated disorders [1]. In the event that no surgically correctable structural defect of the upper aerodigestive tract is identified in a child with clinically significant aspiration, oral feedings may need to be withheld and alternative enteral routes for feeding considered. If aspiration occurs only with certain consistencies, then feeds may need to be modified such that the risk for aspiration is minimized. Other strategies such as pacing during feeds and using special feeding utensils are often employed by therapists to avoid aspiration. The team nutritionist should closely follow the child's growth parameters and diet to ensure adequacy of vitamin, mineral, and caloric intake. With time, differential growth of the larynx and oropharyngeal structures reduce the risk for aspiration; and children with milder forms of aspiration and the associated feeding disorder tend to improve.

Causes of Dysphagia and Odynophagia

Older children are more likely to complain of symptoms of dysphagia and odynophagia. The more commonly diagnosed causes are listed in Table 103.3.

Table 103.3 Causes of dysphagia and odynophagia in children

Esophageal causes
1. Eosinophilic esophagitis
2. Gastroesophageal reflux disease (NERD, ulcer, stricture, Barrett's)
3. Pill esophagitis
4. Infectious esophagitis: fungal, viral, bacterial, tuberculosis
5. Foreign body ingestion
6. Rheumatic esophageal disorders: pemphigus, epidermolysis bullosa, dermatomyositis, lupus, systemic sclerosis
7. Esophageal tumors
8. Mucositis (chemotherapy)
9. Congenital esophageal rings and webs
10. Esophageal motor disorders
11. Post operative: fundoplication, cardiac surgery, TEF/EA
Extra-esophageal causes
12. Pharyngitis, laryngitis, tonsillar, or adenoidal hypertrophy or inflammation
13. Vascular compression (dysphagia lusorum)
14. Compression from mediastinal mass
15. Psychogenic
16. Other: hypothyroidism, hyperthyroidism, pellagra, vascular malformation

Eosinophilic Esophagitis

Of the mucosal disorders, eosinophilic esophagitis is now increasingly recognized to be a more common cause of dysphagia and odynophagia than gastroesophageal reflux disease (GERD) [10]. Eosinophilic esophagitis (EE) is defined as a primary clinicopathologic disorder of the esophagus [11]. It is characterized by esophageal and/or upper gastrointestinal tract symptoms, esophageal mucosal biopsy specimens containing greater than or equal to 15 intraepithelial eosinophils per high power field in one or more biopsy specimens, absence of pathologic GERD based on a normal pH monitoring study of the distal esophagus, or lack of response to high-dose PPI medication. Eosinophilic inflammation appears to be chronic, but symptoms may be persistent or relapsing.

Clinical manifestations of EE in pediatric patients vary by age [11]. Younger children often present with feeding refusal because they are unable to convey the feeling of dysphagia [12]. Children may also describe GERD-like symptoms, such as heartburn and regurgitation. Complaints of emesis (occasionally cyclic),

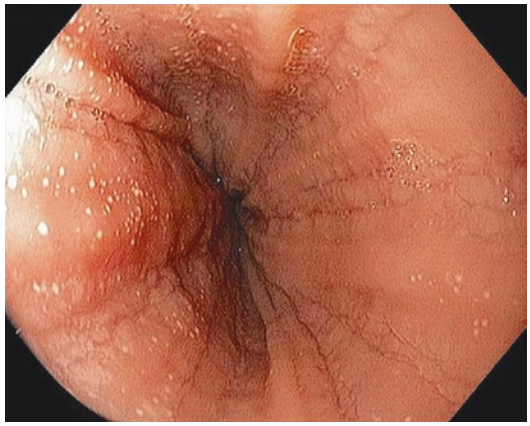


Fig. 103.1 Eosinophilic esophagitis with linear furrowing, edema, longitudinal shearing, raised white specks, whitish exudates, "crepe paper mucosa"

abdominal pain, dysphagia, and food impaction increase with age. Less common manifestations of EE include failure to thrive, weight loss, chest pain, and diarrhea. In the largest longitudinal study consisting of 381 children with EE, Liacouras reported most children presented with GERD symptoms or dysphagia refractory to acid-suppression treatment [13].

There is a higher prevalence of EE in males than females. It has been described in a variety of ethnic backgrounds, including white, African-American, Latin, and Asian; but it remains unclear whether EE has a racial predilection. A higher prevalence of food allergies, asthma, and eczema has also been reported in children with EE [14]. The socioeconomic distribution and seasonal variation of EE has not been systematically studied. This disease has not been shown to decrease life expectancy.

Diagnosis consists of an esophagogastroduodenoscopy (EGD) to identify a number of gross mucosal abnormalities, including longitudinal furrowing, friability, edema, longitudinal shearing, raised white specks, whitish exudates, "crepe paper mucosa," narrow caliber esophagus, Schatzki ring, felinization, and transient or fixed rings [11] (see Fig. 103.1). None of these features are pathognomonic for EE. But in the appropriate clinical context, the presence of more than one of these findings strongly suggests EE. On the other hand, EE patients can also present with grossly normal-appearing mucosa. In Liacouras' study of 381 children with EE, 30 % had an endoscopically normal-appearing mucosa [13]. Therefore, biopsy specimens from the esophagus should be obtained regardless of the gross mucosal appearance. A retrospective analysis of 341 biopsy specimens from 66 adults with EE showed that one biopsy specimen had a sensitivity of 55 %. This was in contrast to a sensitivity of 100 % with five biopsy specimens [15]. Multiple biopsy specimens should therefore be obtained from the proximal, middle, and distal esophagus, in addition to those obtained from the stomach and duodenum to rule out other diseases, such as eosinophilic gastroenteritis and inflammatory bowel disease [11].

Other diagnostic recommendations include an UGI contrast study to identify the presence of an esophageal stricture or other possible anatomic causes for vomiting (e.g., malrotation, hiatal hernia) [11]. The contrast study may also be beneficial in subsequent endoscopies by alerting the endoscopist to use a smaller caliber endoscope or to proceed cautiously in order to avoid a mucosal tear. It also allows the endoscopist to prepare for an esophageal dilatation if indicated [11].

Based on the current diagnostic criteria from the First International Gastrointestinal Eosinophilic Research Symposium Consensus Statement in 2007 for EE, an empiric trial of 6 to 8 weeks of acid-suppression therapy with a proton-pump inhibitor (2 mg/kg/day divided twice a day to a maximum of 40 mg twice a day) is necessary before performing an EGD [16]. Acid from gastroesophageal reflux can also trigger esophageal eosinophilia, but at a much lower degree than that caused by EE [17]. The mainstays of EE treatment are avoidance diets, anti-inflammatory medications, and endoscopic dilatations when strictures are present [17].

Directed elimination diets are often used before considering an elemental diet. They have been shown to be effective in approximately 70 % of EE patients [18, 19]. In a cohort of 35 EE patients, Kagalwalla et al. showed that approximately 74 % responded symptomatically and histologically to the removal of the six most likely foods to cause EE: dairy, soy, egg, wheat, peanut,

and shellfish [20]. Although elimination diets are effective, strict elemental diets have demonstrated a significantly greater response. Case series data in both adults and children support a 92–98 % patient response to amino acid-based elemental formula with both symptomatic and histologic improvement [18, 21]. The elemental formula can be administered either orally or via nasogastric or gastrostomy tube. A repeat EGD is then performed in 4–6 weeks to establish histologic improvement. Foods are then reintroduced sequentially, beginning with the least allergenic [16]. Endoscopic surveillance is repeated after the reintroduction of five to seven new foods. Although dietary therapy is highly effective, the psychosocial impact and quality of life issues on the patient and family must be strongly considered before implementing this mode of therapy.

Topical corticosteroid therapy with swallowed fluticasone is a mainstay of therapy in EE patients. In a randomized placebo-controlled trial of topical therapy with swallowed fluticasone versus oral prednisone [22], each group demonstrated symptomatic and histologic improvement in excess of 90 % of patients. Therefore, high-dose topical, swallowed corticosteroids may be as effective as systemic corticosteroids with less toxicity. Oral viscous budesonide is another steroid preparation that has demonstrated success in pediatric EE patients. Aceves et al. reported an 80 % histologic and symptomatic response in a case series of 20 pediatric EE patients [23]. The disadvantages of using topical steroids are incomplete treatment of the disease, as EE recurs when the treatment is discontinued, and development of side effects, such as esophageal candidiasis [16]. When using topical, swallowed corticosteroids, patients cannot eat, drink, or rinse their mouth for 20–30 min after taking the medication. Other topical therapies, such as cromolyn sodium and leukotriene receptor antagonists, have not been proven to be very successful in the treatment of EE [13]. Currently biologic agents that target the eosinophilic inflammatory cascade, such as anti-IL-5 therapy [24], are in various stages of development and clinical trials.

Although endoscopic esophageal dilatation is indicated for peptic strictures, it should be avoided for most EE patients because of a higher rate of esophageal perforation [25]. Esophageal dilatation is effective for immediate symptomatic improvement for food impaction. It is not recommended as first-line therapy due to concerns of pain, bleeding, perforation, and not addressing the underlying pathogenesis [16]. As a general rule, other modes of therapy should be used before performing dilatation, and an UGI series prior to dilatation may be helpful in identifying the precise location and characteristic of the stricture.

Gastroesophageal Reflux Disease (GERD)

Gastroesophageal reflux (GER) is a physiologic phenomenon that occurs more frequently in infants than older children. Gastroesophageal reflux disease (GERD) in pediatric patients is defined as the reflux of gastric contents into the esophagus that cause troublesome symptoms and/or complications. Symptoms of GERD vary by age. Description of symptom intensity and localization may be unreliable until the age of 8 years or older [26]. The definition of when GER becomes “troublesome” remains challenging in infants and children, who may not manifest an objective complication of GERD clinically. Abnormal crying due to some other cause may be mistaken for GERD. Alarming symptoms include weight loss, dysphagia, bleeding, anemia, choking, failure to thrive, and feeding difficulties [27]. The physiologic basis for most GER episodes is transient lower esophageal sphincter relaxation (TLESR). This brief relaxation of the lower esophageal sphincter (LES) can be triggered by distension of the gastric fundus and is mediated via the vagus nerve [28]. TLESR can result in reflux of air (belch), liquid, solid, or mixed gastric contents into the esophagus.

In the pediatric age group, GER was regarded as the most common organic cause of esophagus-related pain [29] until EE became more prevalent. Reflux decreases the threshold for perception of visceral pain [30]. Risk factors for severe reflux include CNS impairment, esophageal atresia,

chronic lung disease, diaphragmatic hernia, and hiatal hernia. In children, dysphagia may be the presenting symptom of GERD-related esophagitis even in the absence of a history suggestive of gastroesophageal reflux [31]. Dysphagia is a symptom in more than 30 % of adults with GERD [32].

Infants with crying and feeding disorders are perceived as more vulnerable by their parents. Depending upon parental perceptions, experience, coping skills, and psychosocial conditions, these infants are often brought to medical attention. Infants seen in clinic for a complaint of crying and fussiness had more feeding difficulties, were less responsive to treatment, and had more maternal stress [33]. Most infants with physiologic regurgitation (spit-ups) resolve without intervention. A follow-up study showed that infants who regurgitated at 6–12 months of age were no longer doing so a year later [34]. When given a history of "vomiting," it is important to differentiate between regurgitation and vomiting, since the latter is more likely to be pathological and may need to be evaluated more urgently. Unlike vomiting, regurgitation has no CNS emetic reflex, retrograde intestinal contractions, nausea, or retching. However, due to a short esophagus in infants, most reflux episodes tend to project as "vomiting" and are commonly reported as such by parents. A history of regurgitation is neither necessary nor sufficient for a diagnosis of GERD due to lack of sensitivity and specificity [26].

When compared to older children, those less than 5 years of age with GERD tend to present more often with food refusal, regurgitation, vomiting, and abdominal pain [35]. Young children with a history of vomiting after feeding (due to GERD or other reasons) may have difficulty in accepting feeds, despite having no alteration of oral and pharyngeal phases of swallowing [36]. The proposed hypothesis is that initial acid exposure of the mucosal chemoreceptors and nerve endings in the esophagus send afferent signals to the spinal nerves that are transmitted to the brain, which perceives the sensation as pain or discomfort. The neurochemical alterations induced in this pathway appear to persist even after the initial noxious stimulus (vomiting, GERD) has resolved and leaves the child with a hypersensitivity to any bolus movement along the esophagus, including the swallowing of food. Peripheral and central sensitization are believed to be important mechanisms for this ongoing heightened perception of esophageal sensation (visceral hypersensitivity) [4] resulting in food refusal.

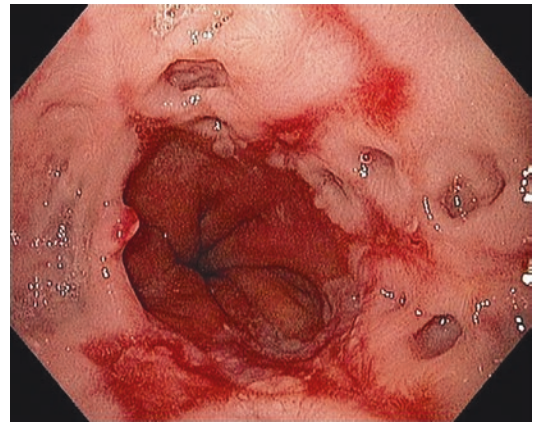

Fig. 103.2 Erosive esophagitis from gastroesophageal reflux disease (GERD)

Older children are able to give an appropriate history of heartburn and regurgitation, thereby making the diagnosis of GERD easier. In adolescents the underlying pathophysiology and symptom presentation of GERD are similar to adults. For unclear reasons, non-erosive reflux disease is more common in symptomatic children with GERD [37]. Complications of GERD such as erosive esophagitis (see Fig. 103.2) and peptic stricture (see Fig. 103.3) are more commonly observed in children with neurodevelopmental delay. A pediatric study showed the prevalence of esophagitis was higher in children with H. pylori as compared to children without H pylori. The prevalence of H pylori was higher in patients over 10 years of age when compared to younger children [38].

In a child with dysphagia or odynophagia, an UGI series is usually the first recommended test. This is not useful for the diagnosis of GERD, but it can evaluate for anatomic abnormalities of the upper gastrointestinal tract which may explain the GERD-like symptoms. If the initial history is suggestive of esophagitis (odynophagia), an upper endoscopy may be performed as the initial diagnostic test [10].

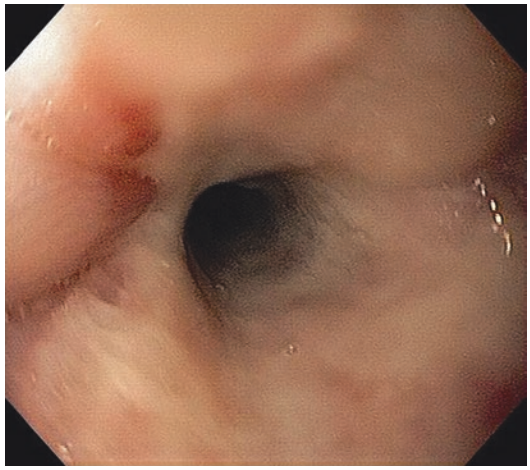

Fig. 103.3 Esophageal stricture from GERD

In infants and children with neurodevelopmental disabilities, a thorough evaluation of the oral, pharyngeal, and esophageal phases of swallowing is imperative when the presenting symptom is dysphagia or food refusal. The VFSS is used to evaluate the oropharyngeal and upper esophageal phases of the swallow. In a study of 186 children with neurologically based dysphagia, aspiration was observed in 48. Of these, 94 % had "silent" aspiration with no objective clinical feature to suggest that these children were at risk for aspiration-related complications [39].

Combined pH/multichannel intraluminal impedance (pH/MII) is being increasingly utilized for the diagnosis of GERD. pH/MII detects bolus movement along the esophagus via multiple impedance measuring sites. It can differentiate between swallowed material and reflux events, and acid and nonacid reflux and detail the mechanism of bolus clearance, acid clearance, proximal extent of a reflux episode, and symptom association [40]. Before pH/MII became available, esophageal pH monitoring was accepted as the gold standard for diagnosis of GER. Although studies have proven the superiority of pH/MII [41], the lack of normative data for children has prevented pH/MII to be widely accepted as the gold standard in the diagnosis of GERD. It is our opinion that pH/MII plays a key role in the evaluation of pediatric patients suspected of having GERD, especially in those less than 8 years of age with atypical symptoms.

An EGD is usually indicated to rule out other causes of esophagitis, such as pill esophagitis, Crohn's esophagitis, eosinophilic esophagitis, and infectious esophagitis. Endoscopy is often necessary in children since there is poor correlation between symptoms and endoscopic esophageal findings [42]. The prevalence of erosive esophagitis has been found to increase with age and is more common in adult males. Additionally, the only endoscopic finding in children that predicts the presence of erosive esophagitis is a hiatal hernia [42]. This is consistent with adult studies which show that lower esophageal sphincter pressure and amount of esophageal exposure to acid are poor predictors for disease severity and that presence of a hiatal hernia exerts a much stronger influence in the severity of erosive reflux esophagitis [34].

No studies have supported empiric therapy for GERD as a valid diagnostic test. Treatment without prior diagnostic evaluation is therefore not recommended in the infant with feeding refusal because it is often multifactorial; and there is no compelling evidence to support a causal relationship between infant feeding difficulties and GERD [10]. Behavioral feeding problems are common in healthy toddlers (9 % reported). These children are often misdiagnosed with GERD and treated with acid-suppression medications. One year follow-up of symptoms of GER during infancy showed no significant difference between cases and controls in feed refusal, irritability with feeding, back arching, choking or gagging, and abdominal pain [43]. Milk protein allergy can sometimes present early with symptoms similar to GERD. An empiric trial with an elemental formula or nursing after the mother has been on a 2-week dairy-free diet can be tried [10]. If feeding evaluation by an interdisciplinary team indicates that food refusal is a result of pain resulting from visceral hyperalgesia or reflux esophagitis, it is imperative to address the acid reflux in order to halt ongoing sensitization of the neural pathways and thereby remove the pain associated with eating [44]. This process of "desensitization" and addressing the learned avoidance response to feedings by an interdisciplinary team often takes time. Histamine-2

blockers and proton-pump inhibitors (PPI) have been prescribed for infants and toddlers even though the FDA has not yet approved PPI use in infants in the USA. Our unpublished data comparing acid reflux episodes using impedance technology in 150 infants either on ranitidine, lansoprazole, or no medications showed a statistically significant decrease in acid reflux events in infants who were on PPI compared to those on ranitidine or no medications. The total number of reflux episodes (acid and nonacid), however, was no different among the three groups.

In an older child with typical reflux symptoms suggestive of GERD, an empiric trial of a proton-pump inhibitor (PPI) for up to 4 weeks is justified. But improvement of heartburn following treatment does not confirm a diagnosis of GERD, as symptoms may improve spontaneously or by placebo effect. When a decision is made to treat GERD, a PPI is usually the treatment of choice. Those currently approved for use in children in the USA are omeprazole, lansoprazole, and esomeprazole. For children with erosive esophagitis, PPIs should be prescribed as initial therapy for 3 months. Pantoprazole has been shown to be effective in reducing endoscopically proven GERD in children [45].

Duodenogastroesophageal (bile) reflux may play a role in the pathophysiology of GERD and esophagitis that is refractory to PPIs [46]. A long-term follow-up study of infants with early feeding refusal showed no increase in disturbing eating habits, lower BMI, or lower self-esteem in adolescence than compared with infants without a history of feeding refusal [47].

Infectious Causes of Dysphagia and Odynophagia

Acute Pharyngitis/Tonsillitis, Retropharyngeal Abscess, and Other Deep Neck Abscesses

An acute onset of dysphagia is highly suggestive of an infectious process. One of the most common examples of this is acute pharyngitis. Typical presentations include severe odynophagia, throat pain, fever, and general malaise. Treatment is directed toward group A beta-hemolytic streptococcus, although viral infections are possible. For recurrent episodes, elective tonsillectomy has been recommended. Despite appropriate antibiotic therapy, acute tonsillitis can progress to a peritonsillar abscess, and surgical intervention may be necessary [48].

An infection of the retropharyngeal space is another cause of acute dysphagia in children. A typical presentation may include fever, irritability, dysphagia, torticollis, and/or drooling. Physical examination often reveals unilateral posterior pharyngeal swelling. Other common areas of infection or abscess are peritonsillar, retropharyngeal, submandibular, buccal, parapharyngeal, and canine space infections. Diagnostic imaging studies to delineate the lesion include lateral neck films, CT, and MR imaging. Treatment should include empiric antibiotic therapy to cover both gram-negative, gram-positive, and anaerobic organisms. Surgical intervention may be indicated as determined by the clinical course [49]. Treatment is surgical drainage of the abscess with paramount care given to the patient's airway [50].

Infectious Esophagitis

Esophageal inflammation could result from fungal (*Candida*), viral (herpes, cytomegalovirus), or bacterial infection. Historic risk factors for *Candida* esophagitis include immunosuppression, chronic inflammatory conditions requiring steroid use, diabetes mellitus, and antibiotic use [51]. In patients with these risk factors and symptoms of dysphagia, this diagnosis should be entertained. Physical examination may reveal white patches in the throat, which is highly suggestive of this etiologic agent. Diagnosis by an endoscopic evaluation may be necessary if risk factors are present. Endoscopic findings include an erythematous mucosa covered with white plaque-like lesions (see Fig. 103.4). Recommended treatment regimens include nystatin, ketoconazole, amphotericin, or fluconazole for at least 3 weeks.

Other causes of acute infectious esophagitis are herpesvirus and cytomegalovirus. Common presentations include fever, odynophagia, and

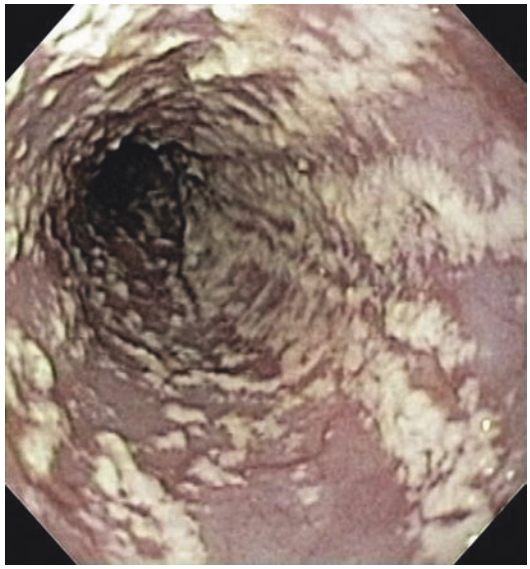

Fig. 103.4 *Candida* esophagitis with an erythematous mucosa covered with white plaque-like lesions

retrosternal pain of acute onset [52]. HSV esophagitis is a common infection in the immunocompromised host, but is also described in the immunocompetent patient. EGD is the diagnostic procedure of choice, since it allows for sampling for histology, culture, and tissue PCR. The endoscopic appearance may reveal vesicles, which are the earliest manifestation. The lesions then coalesce to form ulcers (usually less than 2 cm), frequently with normal-appearing intervening mucosa (see Fig. 103.5). Ulcers are well circumscribed and have a "volcano-like" appearance. In contrast, ulcers in CMV infection tend to be linear or longitudinal and deeper. Erythema, exudates, and erosive esophagitis are also commonly present [53]. Treatment usually involves supportive care in immunocompetent hosts as HSV esophagitis is a self-limited infection [52]. Immunocompromised hosts should be treated with a longer duration of therapy than is typically given for less invasive HSV infection (i.e., genital HSV). Acyclovir (400 mg PO five times a day for 14–21 days) is effective and has few side effects. Parenteral antiviral therapy, pain management, intravenous hydration, and/or nasogastric feeding may be indicated if symptoms of dysphagia and odynophagia are severe.

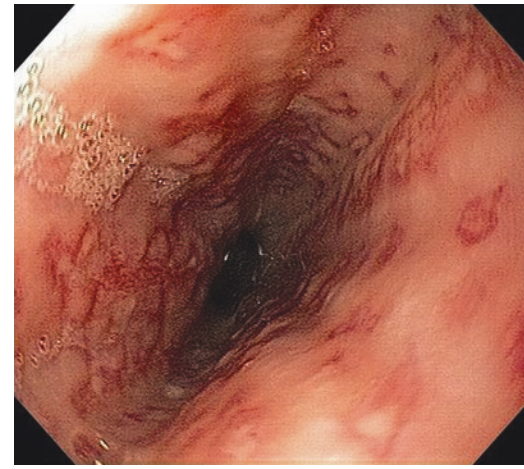

Fig. 103.5 Herpes esophagitis

Pill Esophagitis

Pill-induced injuries or pill esophagitis occur when caustic medicinal pills dissolve in the esophagus rather than passing rapidly into the stomach as intended [54]. The high concentration of active medication in pills is more likely to injure susceptible tissue if delivered to the wrong organ, in particular the esophagus. This type of injury is unfortunately common. Odynophagia is the hallmark of pill esophagitis [54]. The typical patient has no previous history of esophageal disease or symptom and presents with the sudden onset of odynophagia with or without dysphagia. Older patients may perceive that a pill has become lodged [54]. Complaints of retrosternal or substernal chest pain are also common [55]. The physician may elicit clues by careful questioning of whether little or no fluid was taken with the pill or if it was taken at bedtime or while reclining. Less typical symptoms are burning pain, which may suggest GERD, and gradually progressive pain, which may suggest an infectious etiology. Hemorrhage can occur, especially when the esophageal injury is due to nonsteroidal anti-inflammatory drugs (NSAIDS). Cases of hemorrhaging can be life-threatening, as esophageal ulcers have been known to penetrate the left atrium and major vessels. Esophageal perforation and mediastinitis have been attributed to medications such as sustained-release ferrous

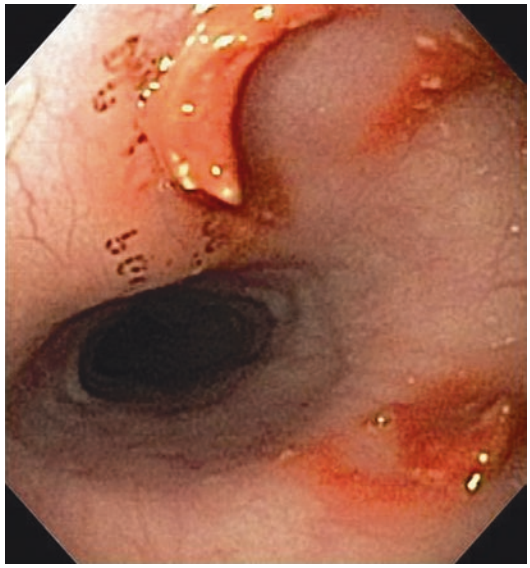

Fig. 103.6 Pill esophagitis with a discrete ulcer with normal surrounding mucosa

sulfate, sodium valproate, and aspirin-caffeine compounds. Other commonly implicated medications include sustained-release potassium preparations, tetracyclines, antivirals, quinidine, and bisphosphonates.

Diagnostic testing may be avoided if the presentation is typical and uncomplicated. A careful history and examination are required to rule out complications of pill esophagitis and to permit planning an alternative to the implicated oral medication. The mainstays of treatment are immediate discontinuation of the offending agent and supportive care. If symptoms progress or persist despite these measures and the diagnosis is in question, then the principle diagnostic modalities are double-contrast barium esophagram and an EGD [55]. An EGD is also indicated when hemorrhaging is involved or the patient is immunocompromised [54]. The typical endoscopic appearance of pill-induced esophageal injury is a discrete ulcer with relatively normal surrounding mucosa [56] (see Fig. 103.6). Endoscopy is much more sensitive than barium esophagram for subtle mucosal lesions. Furthermore, endoscopic biopsy and brushing are more likely than an esophagram to yield definitive alternative diagnoses such as GERD, neoplasia, or infectious esophagitis. The higher yield and accuracy make endoscopy the diagnostic procedure of choice, but it should be reserved for atypical cases as mentioned above [54]. Common sites of injury from pill esophagitis are at the junction of the proximal and middle thirds of the esophagus where the aortic arch compresses the esophagus and the lower esophagus above the LES.

Medical management of moderate to severe cases includes sucralfate to coat, protect, and promote healing of the ulcerated esophageal mucosa and acid-suppression therapy if GERD is felt to have played a role in the pathogenesis of the illness [55]. Rare cases involving hemorrhage or esophageal perforation early in the disease course may require therapeutic endoscopy or surgical intervention. Late complications include esophageal strictures that may require therapeutic endoscopy or bougienage [55].

Foreign Body Ingestion

Ingestion of foreign bodies is a common pediatric problem, with more than 100,000 cases occurring each year [57]. The vast majority of pediatric foreign body ingestions are accidental. In the USA and Europe, coins are the most commonly ingested foreign bodies. Other objects include toys, sharp objects such as needles and pins, batteries, chicken and fish bones, and food. Presenting symptoms vary by foreign body type, size relative to the patient, location of ingestion, and duration of impaction [58]. Children may present with a variety of symptoms, including choking, drooling, dysphagia, odynophagia, chest pain in older children, poor feeding, or respiratory symptoms, especially in younger patients, due to tracheal compression or esophageal erosion [59]. Eighty to 90 % of ingested foreign bodies pass spontaneously. Unsuspecting parents of younger children, who cannot give a history, will oftentimes find a foreign body that has been swallowed and ultimately passed in the diaper. Ten to 20 % of ingested foreign bodies require endoscopic removal; and less than 1 % require surgical intervention [58]. Serious complications, including obstruction and perforation,

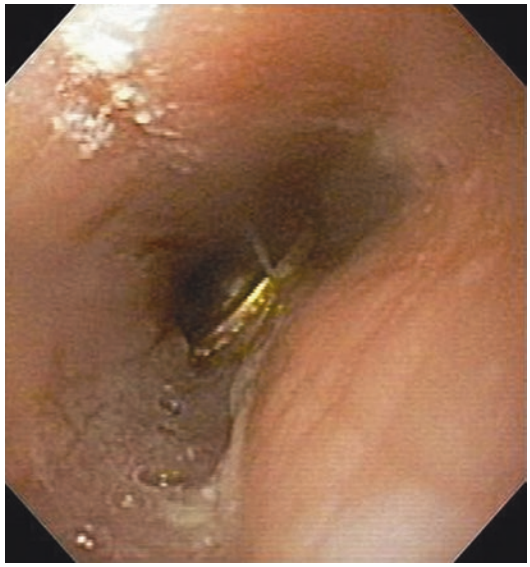

Fig. 103.7 Penny lodged in esophagus

are more likely with large, long, and sharp foreign bodies.

Management strategies are also based on the ingested foreign body type, location, and the patient's size. A radiograph should be obtained in every case of suspected radiopaque foreign body ingestion. When a coin is found in patients with respiratory symptoms lasting more than a few days, the possibility of esophageal erosion by the coin should be suspected. These coins may be difficult to remove endoscopically, require additional diagnostic imaging such as CT, and require the assistance of a pediatric otorhinolaryngologist using rigid instruments for removal. Approximately 60–70 % of esophageal coin impactions occur at the upper esophageal sphincter or thoracic inlet, 10–20 % lodge in the mid-esophagus at the level of the aortic notch, and 20 % sit just above the lower esophageal sphincter (see Fig. 103.7). Patients at increased risk of a retained esophageal coin include those who are small, have underlying esophageal disease such as a stricture (e.g., following previous injury such as a caustic ingestion), have a history of esophageal surgery (e.g., tracheoesophageal fistula repair, esophageal atresia repair, or gastric fundoplication), or have ingested multiple coins at one time [59]. Emergent endoscopic removal of esophageal coins should be performed in symptomatic patients unable to swallow their secretions or experiencing acute respiratory symptoms. Asymptomatic patients or those able to handle their secretions can postpone endoscopy for 12–24 h to allow an appropriate preanesthetic fast. If there is significant delay, the radiograph should be repeated immediately before the procedure to establish that the coin has not passed to the stomach. A retrospective radiologic review of 31 pediatric patients with esophageal coin ingestions reported that 9 of the 11 patients who were asymptomatic had passed the coin upon a 24-h follow-up radiography, thereby avoiding a removal procedure [60]. The other 20 patients were symptomatic (or did not return for follow-up), and one required immediate removal for severe symptoms. Glucagon has not been shown to be effective in facilitating esophageal coin passage in children.

Battery ingestions are also especially common among young children. Management of battery ingestion is significantly different from coin ingestion despite their similar size. Symptoms following battery ingestion are uncommon, occurring in only 3–0 % of cases [61], and correlate poorly with clinical outcome. Batteries of any size lodged in the esophagus cause significant morbidity due to its caustic material and possible discharge of current. Therefore, despite the lack of symptoms, every case of suspected battery ingestion warrants immediate radiography to locate the battery. Leakage of its alkaline contents into the esophagus may result in liquefaction necrosis similar to those following caustic ingestion of lye (sodium hydroxide pH >11.5). Very early complications have included esophageal perforation (within 6 h), tracheoesophageal fistula, esophageal stricture or stenosis (within 10 h), and death. Immediate endoscopic removal of esophageal batteries is warranted, despite the increased risk of aspiration in a patient who has not been fasted [58].

Food impaction is the most common cause of accidental "foreign body ingestion" in adolescents and adults. A previous history of food impaction or of feeling that "food gets stuck" is frequent [62]. In approximately 95 % of meat

impaction cases, there are associated underlying esophageal pathology, such as esophageal narrowing from peptic, caustic, or postoperative strictures or stenosis, eosinophilic esophagitis, or motility disorders [58]. If there is a suspected food impaction, a plain radiograph can be obtained. Contrast administration should be avoided to minimize aspiration of contrast that has pooled above the impaction. Patients unable to handle their secretions require urgent endoscopic disimpaction. Symptomatic patients who are able to handle their secretions should undergo endoscopy within 12 h. In no case should "meat tenderizers" be given, as this may lead to hypernatremia and "tenderization" of the esophagus. At endoscopy, removal of the impaction, rather than blind bougienage into the stomach, is desirable because of the high rate of underlying esophageal pathology [58].

Esophageal Motility Abnormalities

Achalasia is characterized by impaired relaxation of the LES in response to swallowing. It is rare in children, with an incidence of 0.11 cases per 100,000 children. The two most common presenting symptoms are vomiting (85 %) and dysphagia (82 %). Vomiting is more frequent in children less than 5 years of age and dysphagia more common in older children. Achalasia is usually progressive, beginning with solids and frequently progressing to dysphagia for both liquids and solids by the time of diagnosis. Other complaints include weight loss (54 %), chest pain (30 %), and cough (24 %) [63]. Achalasia in younger patients is associated with trisomy 21, triple A syndrome (alacrima, achalasia, adrenal insufficiency), and familial dysautonomia [64]. Treatment options include LES dilation with dilators or endoscopic balloon dilation, botulinum toxin injection in the LES for temporary relief of symptoms, or surgical myotomy with or without a partial fundoplication for more permanent relief.

Nonspecific esophageal motility disorders (NEMDs) are present in up to 50 % of adults with noncardiac chest pain or dysphagia. A study of 154 pediatric patients with at least one of the following symptoms (chest pain, dysphagia, or vomiting) showed that the most common disorder was GERD diagnosed by pH studies in 109 children. The remaining 45 (29 %) children underwent manometric evaluation, and 30 were found to have esophageal motor disorders: 12 achalasia, 3 intestinal pseudo-obstruction, 1 diffuse esophageal spasm, and 1 dysmotility following tracheoesophageal fistula (TEF) repair. NEMDs were diagnosed in 13 of the patients and accounted for 8 % of the diagnoses. Esophagitis itself can sometimes cause a disturbance in the normal contractility and is associated with increased transient LES relaxations facilitating reflux episodes which perpetuate the cycle.

Barium esophagram or UGI series is the most useful initial diagnostic test for suspected esophageal motor disorders, including achalasia. The classic radiographic features of achalasia include bird-beak appearance of the GE junction, dilated distal esophagus, retained food material in the esophageal body, and poor stripping waves (peristalsis). The caveat is that the contrast study may be normal in early achalasia. Manometric confirmation of suspected motor disorders of the esophagus is critical as it has an impact on management. Manometry may reveal abnormal esophageal motility in patients with GERD, with typically a decreased number and abnormal esophageal body contractions [65, 66], and in eosinophilic esophagitis [67]. Manometry may be useful in patients with GERD who have failed acid-suppression therapy and have negative endoscopic findings. Antroduodenal manometry is sometimes useful in neurologically handicapped children because generalized foregut dysmotility may mimic reflux and feeding intolerance [68].

Postsurgical Complications

Fundoplication

Fundoplication is performed with the intent to prevent severe gastroesophageal reflux, its associated symptoms, and long-term sequelae. Sometimes surgery may not resolve the symptoms, or new and troublesome symptoms may

arise. Direct side effects from the surgery include dysphagia, which may be related to edema of the gastroesophageal (GE) junction, transient esophageal hypomotility, excessive tightness of the wrap, obstruction from adhesions, hiatal herniation of the wrap, or paraesophageal hernia. Inadvertent vagal nerve injury during surgery or entrapment of the vagus nerve in a tight wrap may also cause a downstream effect on gastric emptying [69]. The fundoplication wrap creates a relatively fixed high pressure zone at the distal esophagus which prevents reflux but may also impede bolus movement through the GE junction into the stomach. In the presence of underlying esophageal hypomotility, a fundoplication may worsen dysphagia due to ineffective bolus clearance.

There is no reliable method to surgically construct an ideal anti-reflux barrier of appropriate tightness in an individual patient. Patients without any apparent esophageal dysmotility may exhibit symptoms of slow esophageal transit time, such as eating more slowly than their siblings, retching, or dysphagia after a fundoplication [70]. Dysphagia is very common in the immediate postoperative period and sometimes may persist up to 6 months or longer after fundoplication. Dysphagia lasting beyond 6 months warrants further evaluation to rule out other causes such as achalasia, eosinophilic esophagitis, or other esophageal pathology.

Failure of fundoplication to improve preoperative symptoms may be due to an incorrect original diagnosis of GERD. There are many conditions that may mimic GER, such as cyclic vomiting, rumination, gastroparesis, eosinophilic esophagitis, or esophageal dysmotility [69]. A fundoplication can do more harm than good in most of these conditions. Post-fundoplication complications are more prevalent in children with neurologic impairment, chronic lung disease, esophageal atresia, or a generalized motility disorder [69]. These children not only have a challenging physiology, but often are unable to accurately express what is bothering them. Therefore, caution must be exercised before giving a diagnosis of GERD and recommending a fundoplication.

Cardiac Surgery

During open cardiac surgery, the vagus nerves running alongside the esophagus may sustain injury from the surgical retractors. This may lead to vocal cord weakness (from damage to the recurrent laryngeal branch), esophageal dysmotility, and poor gastric emptying (gastroparesis). Infants with a history of cardiac surgery often have feeding problems and/or aspiration in the immediate postoperative period and may need nasogastric feeds until recovery of the vagus nerves. The recovery period depends upon the degree of vagal nerve injury and presence of other comorbid conditions, including malnutrition and hypotonia, which may impact oral motor skills, especially in children with Down syndrome.

Esophageal Atresia and Tracheoesophageal Fistula

Surgical treatment of esophageal atresia (EA) with tracheoesophageal fistula (TEF) is a standard procedure with a spectrum of complications, such as GER, tracheomalacia, disordered esophageal peristalsis, and anastomotic esophageal stricture (see Fig. 103.8). In the neonate with EA, motility disorders of the esophagus have been identified even before surgical intervention [71] and are suggestive of a congenital origin. Morphologically, these patients have abnormalities of the Auerbach's plexus in the esophagus and stomach [72]. Surgical dissection and mobilization of the esophagus during EA repair can damage the motor innervation [73]. Postoperative esophageal dysmotility can certainly be explained by a combination of congenital and acquired factors.

Impaired gastric motility has been demonstrated postoperatively in patients with EA-TEF repair. Delayed gastric emptying was prolonged in the EA group compared with the control group [74]. Manometric studies of gastric motility have shown that peristalsis was abnormal in about 45 % of patients after EA-TEF surgery. This impaired motility often manifests itself as symptoms of dysphagia or feeding difficulties. The reported incidence is about 60 %, when considering both daily and occasional symptoms [75].

Fig. 103.8 Anastomotic esophageal stricture

Another frequently reported symptom is dyspepsia and is related mainly to GER. Motility disorders have been correlated with the onset of GER, and reflux may be responsible for dysphagia when it leads to esophageal stenosis [74].

Extrinsic Esophageal Compression

Symptoms and physical findings produced by vascular rings are primarily those involving airway or esophageal compression. Most patients with a vascular ring present with symptoms in infancy or early childhood. Signs and symptoms include dysphagia, feeding difficulty, stridor, cyanosis, wheezing, respiratory distress, apnea, a characteristic high-pitched, brassy cough, a history of asthma, or recurrent pneumonia. In some cases, airway symptoms are worsened or aggravated by feedings. Symptoms of airway obstruction predominate in patients who present in infancy or within the first few years of life. Symptoms which manifest soon after birth include slow breast or bottle feeding, fatigue with feeding, frequent regurgitation, or aspiration pneumonia. In most cases, workup is initiated when solid foods are introduced, which causes more pronounced dysphagia.

The association of difficulty in swallowing and an aberrant right subclavian artery is termed *dysphagia lusorum*. Martin et al. described four children who had difficulty swallowing and aberrant right subclavian arteries [76]. Esophageal manometry showed high pulsatile pressure in the area of the aberrant right subclavian artery in each child (12–100 mmHg). Three of the four children underwent surgical correction, and their symptoms resolved. Postoperatively, esophageal manometric findings were normal. The authors concluded that dysphagia lusorum occurs in children, and esophageal manometry shows persistently increased intraesophageal pressure, causing a functional partial obstruction in symptomatic children with dysphagia lusorum.

Conclusion

Food refusal and swallowing disorders may represent symptoms of a wide array of underlying anatomical or functional upper aerodigestive disorders along with a behavioral overlay. It is imperative that the specialist has a detailed understanding of the upper aerodigestive tract, as this will facilitate in choosing the appropriate test and treatment modality. The management of younger children presenting with food refusal tends to be more challenging; and an interdisciplinary approach is felt to be most effective in addressing this issue.

The Child with Apnoea or ALTE 104

M.T. Rawat

Apnoea, Apparent Life-Threatening Events and Gastro-oesophageal Reflux Disease

The presentation of gastro-oesophageal reflux disease is variable, is dependent on age but can present in a fairly typical manner in most cases. In adults and adolescents, the cardinal symptoms are thought to be those of heartburn (retrosternal burning sensation) and regurgitation.

However, it is also proposed that GERD can manifest itself in an atypical manner in some patients such that organ systems and structures separate to the oesophagus (extra-oesophageal/supra-oesophageal) are involved producing symptoms and signs that are not seen with classical GERD. This chapter will focus on some of these manifestations, primarily apnoea, but also touch on apparent life-threatening events (ALTEs). Recent guidance on gastro-oesophageal reflux and developments in techniques to detect it will be discussed initially, followed by a review of the evidence for links between GER and apnoea including possible pathophysiological mechanisms involved.

Gastro-oesophageal Reflux Disease: Definitions and Natural History

Defining GER and GERD has been the subject of recent national and international guidelines for both adults (e.g. Montreal classification) [64] as well as children [54, 70]. The summary diagram of the paediatric version of these statements is shown in Fig. 104.1

After a brief discussion of typical oesophageal manifestations of GERD, investigative techniques available and general management in children, the focus will turn to the complex relationship between apnoea and apparent life-threatening events (ALTEs) and GERD, one of the atypical presentations of reflux that have become known as extra-oesophageal and supra-oesophageal reflux.

Extra-oesophageal Reflux

GER is defined as the passage of gastric contents into the oesophagus with or without vomiting. It is stressed that GER itself is a normal physiological event that occurs several times daily in all age groups, is usually short lived (less than 3 min) and occurs mostly in the postprandial period. Regurgitation in paediatrics is defined as the passage of refluxed contents into the pharynx, mouth or from the mouth.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_104

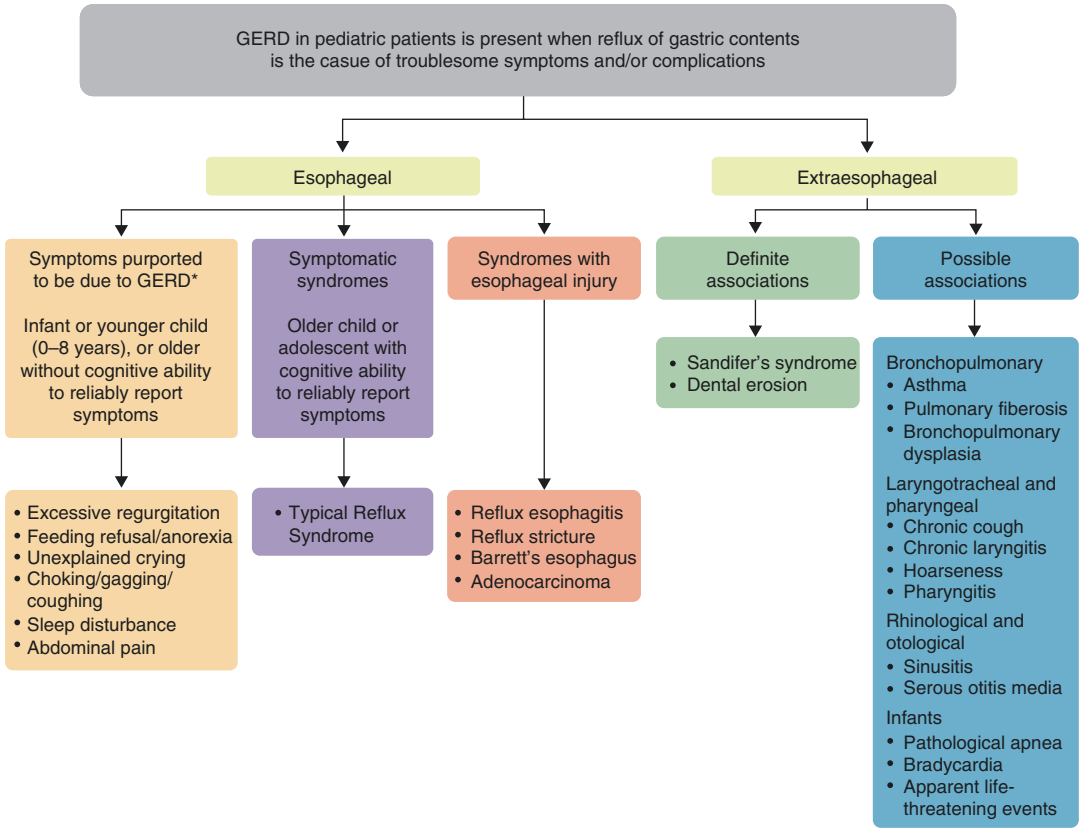

Fig. 104.1 Shows the definition and various manifestations of GERD as in a recent global, evidence-based consensus. Note that apnoea and ALTE are listed as possible associations (From reference [54])

GERD is defined as troublesome symptoms or complications that occur secondary to GER [64].

It is apparent that the diagnosis of GERD has become more patient centred and symptom based.

GERD symptoms vary and are age dependent with adolescents (>12) having similar symptoms to those described by adults, i.e. heartburn with or without regurgitation in the case of typical reflux syndrome.

In children, this definition is used too though some caveats have been recommended. The issue of what is troublesome is complicated in younger patient. Symptom reporting is often dependent on the attentiveness of the parent or main carer particularly in younger age groups or those children without skills to verbalise [4] (e.g. those with neurological impairment). Symptoms should be troublesome to the patient and not just to the carer [54].

Longitudinal studies have shown that GER occurs commonly through infancy with a peak at about 3–4 months of age followed by a decline so that by 14 months less than 5 % of infants are having episodes of regurgitation and by 18 months the numbers affected are negligible [30, 36]. A more recent prospective study that used the Rome 2 Criteria for diagnosis of functional regurgitation in an Italian population showed a lower prevalence (12 %) than previous studies but that it usually resolves by 18 months [7].

Symptoms purported to be due to GERD in infants are nonspecific with regurgitation, irritability, crying, back arching, sleep disturbance and breathing difficulties, food refusal and feeding difficulties being amongst those commonly ascribed to the condition. It can be difficult to differentiate between normal patterns of

regurgitation and crying and troublesome symptoms, and the recent guidelines suggest that a symptom-based diagnosis of GERD in infants is problematic.

Toddlers and pre-school-aged children tend to present with food refusal, regurgitation and abdominal pain, and older children may present with regurgitation or vomiting, cough and epigastric pain or heartburn [18].

To highlight the underappreciated occasional complexity of making a diagnosis of GERD in children, even in adults, the diagnosis can at times be complicated. Accuracy of diagnosis in adults has been questioned recently. The Diamond Study [10], in which a 12-point self-report questionnaire was compared to family doctors and gastroenterologists, showed great accuracy of diagnosis of GERD. In just under half of patients, the main symptoms were those of regurgitation and heartburn, demonstrating the wide spectrum of symptoms that are attributed to GERD in a primary care population of adults.

A condition that could potentially masquerade as GERD in infants is cow's milk protein allergy. It can be the cause of an identical presentation to that of GERD, hence the recommendation that a trial of hydrolysed feed be used when considering the various treatment modalities [66].

Symptom questionnaires have been developed and validated for use in diagnosing GERD. In adults, patient-centred self-assessment questionnaires such as the GERDQ have been developed [22] for use in primary care.

The most thoroughly evaluated such questionnaire for infant symptoms is the Infant Gastroesophageal Reflux Questionnaire Revised (I-GERQ-R) [27]. It is composed of a series of questions from which an I-GERQ-score can be constructed. However, the correlation between results of the questionnaire and findings at endoscopy and histology has been varied between different centres producing perplexing results in clinical trials.

As can be seen, there is a wide spectrum of presentation of GERD in infancy and childhood. Diagnosis is not always straightforward particularly in the younger, non-verbal child.

Pathophysiology of GERD

The oesophagus can usually maintain its preferred empty state by means of upper and lower oesophageal sphincters preventing entry from above and below of unwanted contents (air, noxious refluxate). The LES in particular is relevant to GERD. It acts as a valve preventing backflow of gastric contents into the oesophagus. It is aided in function by the correct anatomical positioning of the oesophagus in relation to the crura of the diaphragm. The intra-abdominal portion of the oesophagus is also angulated such that pressure changes that occur with breathing help to produce a physiological valve effect such that gastric refluxate into the oesophagus is impeded during the normal breathing cycle.

With regards to these barriers, the oesophagus also has clearance mechanisms (secondary peristalsis in response to distension) as well as epithelial defence mechanisms to counter sustained ingress and potentially damaging exposure to acidic fluids [68].

Disturbance of anyone of these can contribute towards damage to the oesophagus.

The underlying pathophysiology of typical GERD involves transient relaxation of the lower oesophageal sphincter known as a TLESR (that is unrelated to swallowing and subsequent oesophageal peristalsis) that permits flow of gastric contents into the oesophagus [25, 68]. This is the mechanism underlying most GER episodes [24, 26] and has been demonstrated in all age groups including preterm infants (Fig. 104.2), thereby refuting the previously held belief of an immature LOS in infants underlying GER in this group [37]. No clear-cut oesophageal motor abnormality has been demonstrated in those with GERD which limits the use of certain techniques such as oesophageal manometry in making a diagnosis (see section below) [65].

Anatomical differences between infants and older children such as a reduced length and straighter (rather than angulated) intra-abdominal portion of the oesophagus, supine positioning, and relatively large volume of feeds (up to 180 ml/kg/day in an infant would equate to 14 L/day in an adult) can explain why infants are naturally predisposed to GER [68].

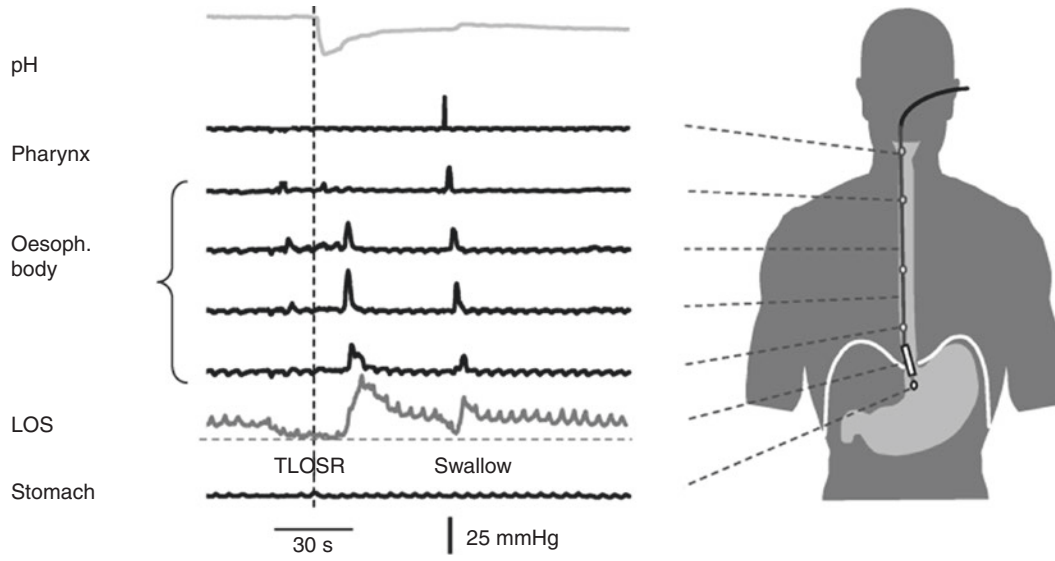

Fig. 104.2 A manometry tracing showing the relationship between a transient lower oesophageal relaxation episode and fall in oesophageal pH measurement, as opposed to a subsequent swallow induced relaxation (From reference [3])

Predisposing Conditions

Certain conditions can predispose patients to severe GER/GERD and its complications. They include underlying neurological impairment secondary to a variety of causes, e.g. cerebral palsy and genetic and chromosomal abnormalities. Chronic respiratory conditions such as cystic fibrosis as well as congenital abnormalities of the oesophagus such as oesophageal atresia or tracheo-oesophageal fistula also contribute to GERD [68, 69].

Otherwise healthy children with hiatus hernia and family history of Barrett's oesophagus also have a higher prevalence of severe GERD and its complications.

Diagnosis and Investigative Techniques

A clinical history can prompt the diagnosis more readily in older children and can be used to look for any warning symptoms and signs indicative of other serious disorders that could be behind a presentation involving crying, irritability, vomiting, poor weight gain and feed refusal in an infant or young child. The range of infections, neurological, cardiac, surgical and gastroenterological conditions that could present in this manner is wide and is well documented in the recent guidelines. The use of questionnaires in the youngest age groups may be of benefit too.

Awareness of other disorders that can mimic features of GERD such as cow's milk protein allergy and eosinophilic oesophagitis is important as treatment is very different [15].

Selected investigations may be useful in the workup of the paediatric patient with GERD as there is no single gold-standard test for GERD.

Contrast studies can confirm that no underlying anatomical abnormality is present but is neither sensitive nor specific enough for diagnosis of GERD as it provides only a snapshot of events at the time of investigation.

Surrogate tests that help to quantify reflux include intra-oesophageal pH monitoring, multichannel intraluminal impedance monitoring and scintigraphy.

Until recently, the 'gold-standard' investigation to assist diagnosing GERD was felt to be the pH study using antimony electrodes on a catheter left in situ in the distal oesophagus to quantify oesophageal acid exposure time [66].

Various parameters can be recorded quantifying or reflecting acid exposure time. It does not however always correlate with symptoms or findings at endoscopy. It is excellent for quantifying acid reflux but not other forms of reflux [39].

The technique can also be used to assess the temporal relationship between reflux events and symptoms, and several methods exist such as the symptom index, symptom sensitivity index and more recently the symptom association probability that expresses the likelihood that the patients' symptoms are related to reflux. It is worth remembering that although the symptom may be found to be associated with reflux, this does not imply causality [6].

However, it has been appreciated for a long time that most reflux that occurs in the postprandial period (particularly in infants) is non-acidic in nature due to the buffering effect of milk feeding and so GERD may be underestimated. Hence, it is difficult to investigate all forms of reflux using a pH-dependent method [37].

pH metry is useful to check on the efficacy of antisecretory therapy in reducing acid exposure time. It is also the monitoring system for which the best clinical data is available that correlates with therapeutic success or failure [47].

Recently the pH study has been supplemented by the technique of measuring intraoesophageal electrical impedance [71, 72]. This technique makes use of an intraluminal catheter with closely spaced electrodes between which the impedance is measured. The latter is similar to electrical resistance as defined by Ohm's law, i.e. the quotient of voltage and electrical current, and depends on the ionic concentration of the luminal contents surrounding the catheter with air having high impedance and liquid low impedance [23, 65]. The principle of the technique is based on a change in electrical impedance during the passage of a bolus through a measuring segment. The use of multiple segments along the catheter along the length of the oesophagus allows for the analysis of the direction of movement of the bolus with a unique pattern being produced with retrograde movement [74] (Fig. 104.3).

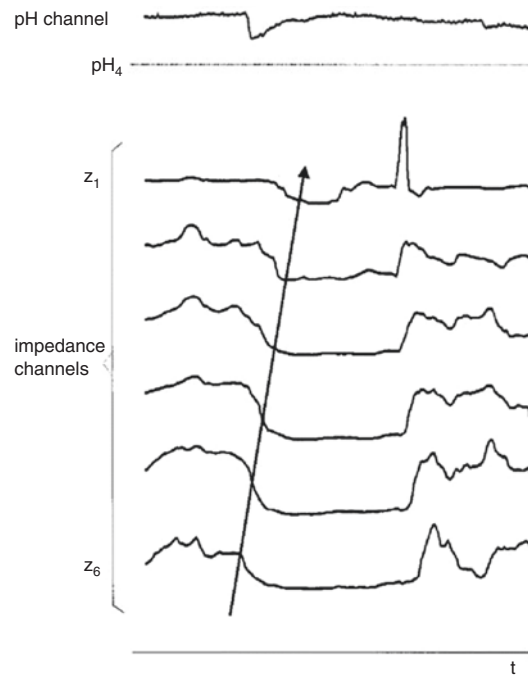

Fig. 104.3 Shows an impedance tracing that demonstrates a drop in impedance in the distal channels (Z6 lowermost tracing)) initially, with a progressive retrograde movement up the catheter to the more proximal channels in mid-upper oesophagus (Z1) with time (*x-axis*), indicating a reflux event of a non-acidic (pH trace not less than 4) nature (From reference [62])

It can be useful in two areas of relevance to reflux: both to aid diagnosis of GERD and in oesophageal function testing.

When impedance monitoring is used in conjunction with pH metry on a combined multichannel catheter, further data can be obtained. This includes qualities such as pH (acid, weakly acid, non-acid) and composition (gas/fluid) of refluxate as well as its direction and the proximal extent of movement, which may be useful when investigating extra-oesophageal symptoms. An example of an impedance tracing showing a non-acid reflux impedance change is illustrated in Fig. 104.3

The technique is sensitive to very small volumes. Temporal associations and relationship of symptoms to reflux can be analysed. Another advantage is that the technique can be used on patients whilst 'on' therapy as it can detect fluid movement independent of pH [5, 6].

Again using the technique in conjunction with polysomnography (sleep studies) has been useful in looking at the temporal relationship between reflux events and postulated atypical or extra-oesophageal symptoms of reflux such as apnoea, ALTE and cough [37].

Oesophageal motility is well studied in adults but data is still lacking in children. A consequence of oesophageal dysmotility may be GERD yet patients with normal motility can experience severe GERD symptoms. Oesophageal manometry can be useful in siting probes close to the lower oesophageal sphincter or diagnosing underlying oesophageal motility disorders rather than diagnosing GERD itself.

The use of MII (impedance testing) together with oesophageal manometry is another area that has been developing recently since the advent of the impedance technique and gives information about the relationship between oesophageal pressures and bolus flow that reflects oesophageal function, for example, bolus clearance, and avoids the use of ionising radiation [65].

Other studies that may be of use include nuclear scintigraphy that can detect reflux as well as complications such as aspiration but can also estimate gastric emptying time.

Management of GERD

The management of GERD in childhood varies with age. In the youngest patient group (infants), conservative measures are initiated and include positional changes at feed times, as well as changes in manner of feeding with thickening of feed, alteration of volume and frequency of feeds and a trial of alternative milks such as hydrolysed formula as cow's milk protein intolerance may be an underlying cause of symptoms identical to those of GERD.

In the older child, altering the volume of intake (avoiding large meals) as well as trigger foods and avoidance of other environmental factors such as cigarettes smoke can be incorporated into the management plan.

Medications such as prokinetics, histamine receptor antagonists, proton pump inhibitors amongst other agents can be used. The data for the effectiveness of most of these agents is limited in children, but documented healing of the uncommon finding of erosive oesophagitis attributed to GERD has been found in those on PPI treatment. This topic is covered in greater detail in recent reviews and guidelines [70] as well as in other areas of this book.

Extra-oesophageal/Supra-oesophageal Reflux

Over the last 25 years, there has been accumulating data to support links between GERD and illnesses and symptoms arising in other organs and structures beside the oesophagus. These are known as extra- or supra-oesophageal reflux syndromes [46, 49, 50].

The respiratory tract – both upper and lower airways – the mouth and the otorhinolaryngological structures are mainly implicated [67]. Studies have shown that up to a third of adults may have some extra-oesophageal symptoms (EES).

It has been postulated for some time that direct contact of acid with respiratory mucosa can result in ulceration as found by Cherry et al. [8] who found improvement of laryngeal ulcers in patients with GERD as demonstrated on barium studies when treated for reflux. Experimentally induced granuloma formation on the true vocal folds in dogs occurred after exposure to gastric juice [9].

Chronic cough, reactive airway disease (asthma), apnoea (of prematurity), bronchopulmonary dysplasia, recurrent pneumonia, subglottic stenosis, laryngitis, hoarseness, laryngopharyngeal reflux, sinusitis, middle ear disorders and dental erosions [11, 12, 14–17, 29, 46, 48, 51, 53, 59] are to name but a few of the disorders proposed to have a link with GERD. Some of these are outlined in Fig. 104.1.

The Montreal definition of GERD in adults [64] described several established extra-oesophageal symptoms associated with GERD. These included cough, laryngitis, asthma and dental erosions. There were also several other disorders that are proposed to have an

association with GERD: sinusitis, pharyngitis, recurrent otitis media and idiopathic pulmonary fibrosis.

Before assuming causality, there should be both epidemiological and temporal association between GERD and the symptom/syndrome in question as well as a feasible pathophysiological concept underlying the link. Treatment of GERD should then result in improvement or elimination of the extra-oesophageal symptoms [28].

The commentary on the statements dealing with extra-oesophageal syndromes emphasised that though the volume of literature dealing with the subject is large, the strength of studies is relatively weak such that a causal link could not be guaranteed with certainty.

In the development of the Montreal statements [64] regarding GERD in adults, it became clear that:

1. The link between GERD and the EES is more likely to be an association rather than a causal relationship as was initially thought to be the case during the development of the statements.
2. It is rare for the EES to present alone without any manifestation of more typical GERD presentations.
3. The conditions involved are likely to have a multifactorial pathogenesis and that GERD is one of the several aggravating factors.
4. The data supporting a beneficial effect of reflux treatments for extra-oesophageal symptoms is weak.

In contrast to GERD in adults where there is more prevalence data available (up to a third of adults with GERD may have EES), there is less data in paediatric patients.

It is easy to understand how diagnostic challenges can arise in infants and children with non-specific (e.g. irritability and apnoea) or extra-oesophageal symptoms such as chronic cough and wheeze/asthma.

A case-control study conducted in Texas looked at the association between GERD and several extra-oesophageal manifestations of GERD in 1980 children older than 2 without neurological deficits or congenital oesophageal abnormalities. Within this cohort, a substantial proportion (one third) had other recognised predisposing factors to GERD such as cystic fibrosis, severe obesity or scleroderma. A significant statistical association between laryngitis, sinusitis, asthma, pneumonia and GERD was found [11, 19–21].

A recent systematic review looked into the prevalence of extra-oesophageal symptoms in children with GERD or the prevalence of GERD in those with extra-oesophageal symptoms as well as the size of the association between the two. A range of symptoms was studied, particularly those highlighted in the Montreal and paediatric definitions of GERD. It concluded that there may be an association between GERD and asthma and possible associations between GERD and a variety of conditions including pneumonia, bronchiectasis, acute life-threatening events (ALTEs), laryngotracheitis and sinusitis [63].

The focus now turns to apnoea and the possible relationship to GERD.

GERD and Apnoea/Apparent Life-Threatening Event (ALTE)

As is apparent from the preceding discussion, GER is a common finding in infancy. It has been proposed to be the cause of several other disorders including apnoea and apparent life-threatening events (ALTEs), which themselves have been implicated in the pathophysiology of the sudden infant death syndrome (SIDS). It is useful to define these disorders in detail according to commonly accepted definitions and then to discuss the anatomical and physiological relationships between the structures involved as this will then ease understanding of the proposed pathophysiological mechanisms underlying any possible links between GERD and apnoea.

Definitions

GER and GERD are defined in previous sections.

Apnoea is usually defined as cessation of breathing for 20 s or for any length of time if accompanied by change in colour, muscle tone or heart rate for a period of time.

ALTE is defined by a National Institute of Health consensus conference as an episode that is frightening to the observer and is composed of a combination of apnoea, a change in colour (usually cyanotic or pallor, but sometimes erythematous/plethoric), muscle tone (mostly limpness), choking or gagging, which requires intervention by a caregiver [35]. After an ALTE, an infant can appear well with no obvious features of illness, and even after a thorough assessment, only 50% of patients will have a diagnosis [52].

Apnoea of infancy occurs in those infants with a gestational age of 37 weeks or more at the onset of apnoea, whilst apnoea of prematurity is defined as the sudden cessation of breathing that lasts for 20 s or is accompanied by bradycardia or oxygen desaturation (cyanosis) in an infant younger than 37 weeks of gestational age [35].

SIDS is defined as the sudden death of an infant under 1 year of age that remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene and review of the clinical history. Since the early 1970s, it has been proposed that apnoea may be the pathophysiological precursor to SIDS, and so home cardiorespiratory monitoring proving this link has never been forthcoming despite intense research [35, 46]

Both apnoea, ALTE and SIDS have a wide variety of possible causes, but all have been associated with GERD. A recent systematic review to determine the causes of ALTE in infants found that the most common diagnoses included GER (the major cause), seizure, lower respiratory tract infection and other unknown causes. The diagnosis of GERD was made using a variety of investigative techniques including pH metry, barium studies, manometry and milk scans in various combinations or solely on clinical grounds in some cases. It was the only diagnosis that appeared in every study analysed [31].

The fact that all occur in the same age range and can occur during sleep or wakefulness lends itself to how one may seemingly imply causality between GERD and these events [40]. However, this relationship is complex and has often been based on circumstantial evidence. Often causality is proposed, yet the literature shows conflicting results and is inconclusive and even shows that there may not even be an association between them.

Upper Airways and Oesophagus

That there is a presumed relationship between apnoea and GERD is unsurprising given the close proximity of the oesophagus to the upper airways. The upper aerodigestive tract consists of the nose, mouth, pharynx, larynx and upper oesophagus and deals with the passage of air and food. A complex neuromuscular apparatus together with fine coordination of its various parts is necessary for normal swallowing, breathing and respiratory control to occur.

The pharynx and oesophagus are both derived embryologically from the foregut, and the development of the oesophagus is discussed in earlier chapters. In normal (nutritive) swallowing that consists of four phases (oral preparatory, oral, pharyngeal and oesophageal), it is the coordination between events during the latter two phases that is of concern when considering the pathophysiology of apnoea and possible links to GERD.

Protection of the airway to prevent ingress of either fluid (amniotic fluid in the foetus, milk/water in the infant) or food is essential during the process of swallowing. This is facilitated by closure of the glottis (laryngeal closure), whilst the bolus of fluid or food passes between the pharynges, propelled by contraction of pharyngeal constrictor muscles, through the relaxed upper oesophageal sphincter into the proximal portion of the oesophagus. The larynx's primary function is to act as a sphincter providing protection to the lower airways from invasion by fluid. This begins in utero, preventing contact between amniotic fluids that is chloride poor and contains potentially noxious substances to the lungs in contrast to the chloride-rich fluid produced by the respiratory epithelium [41, 42, 44].

Swallowing can be either nutritive, essential for food intake and growth or nonnutritive that functions as a means to clear secretions, saliva or gastric refluxate from the pharynx and oesophagus. Nonnutritive swallowing (NNS) begins in the pharynx with the pharyngeal phase and is triggered by messages in the afferent limbs of the reflexes alluded to above [45].

One can see from the above description that there is a need for a physiological apnoea of short duration to occur during the act of nutritive swallowing in order to protect the lower airways.

Pathological apnoea however is more prolonged and is detrimental to the well being of the infant. It is traditionally divided into obstructive or as central dependent on the presence or absence of respiratory effort or as mixed when a combination of the two occurs.

Apnoea of prematurity has been the focus of intense research over several decades, and insights into its pathophysiology have emerged. Premature infants have immature respiratory control patterns with impaired ventilatory responses to hypoxia, hypercapnia and an exaggerated inhibitory response to stimulation of airway receptors [1].

Given the crucial nature of the processes of breathing and swallowing, the interaction between the two is closely controlled. This involves complex neural circuitry and reflexes with afferent limbs using the superior laryngeal nerves, nucleus of the tractus solitarius and second-order neurons, medullary control centres and efferent vagal limbs. These reflexes, the laryngeal chemoreflexes, have been studied in great detail by various groups of researchers and may underpin any potential link between GER events and apnoea [60].

Observations that apnoea often occurs during or after a meal/feed suggest a relationship, yet it is known that this is the time during which GER is most common. Some preterm infants, particularly those with bronchopulmonary dysplasia (also proposed to be associated/caused by GERD by some), develop marked hypoxemia during bottle-feeds.

Several mechanisms have been proposed including immature coordination between suck, swallow and breathing, activation of the laryngeal chemoreflexes, GER, diaphragmatic fatigue or a combination of these [43].

Proposed Pathophysiology Linking GER and Apnoea: Laryngeal Chemoreflexes

Looking at apnoea of prematurity in a critical manner, a recent review found that despite uncertain evidence, premature infants frequently undergo evaluation for reflux and antireflux medications are amongst the most highly prescribed medications in neonatal care, with a significant number of infants discharged on them.

A variety of reflexes can be postulated to link GER and apnoea and include oesophago-glottic closure reflex (oesophageal distension stimulates glottis closure), aryepiglottic closure reflex (misdirected fluid at the posterior margins of the glottis) and laryngeal chemoreceptor reflexes. An afferent limb could be stimulated in any of these areas (oesophagus, upper airway) leading to a common efferent response culminating in glottis closure and obstructive apnoea [56].

Thach has described some of the evidence that has accumulated for laryngeal chemoreflexes and their role in apnoea [60, 61]. It was established that at times of regurgitation of gastric content, the upper airway is protected by reflex behaviour that included anatomical closure of the airway at or above the level of the larynx. There then followed the initiation of swallowing once the bolus of refluxate was in the pharynx, serving to clear the pharyngeal area of potentially damaging material. In some groups of infants, the respiratory pause could be prolonged [33] with repeated swallowing and attempted efforts at breathing being common. Bradycardia also occurred at this time, i.e. pathological apnoea. In this same study, prolonged apnoea was also found to occur at times when pharyngeal pH was unaltered implying no acid reflux to the level of the pharynx and no obvious regurgitation associated with apnoeas. Similar responses were found to fluid infused into the pharyngeal area of sleeping infants via a catheter

that was capable of recording swallows. There then followed swallowing and apnoea with occasional cough. Water was more potent than saline at triggering the response, implying ability to distinguish chemical content of fluid.

It also became apparent that once a volume threshold had been reached, the fluid then flowed out of the pyriform recesses and came into contact with the laryngeal mucosa in the inter-arytenoid space, an entrance point to the larynx (see Fig. 104.4). This area is known to be densely populated with chemoreceptor nerve endings that would act as part of the afferent limb of a reflex [60].

The laryngeal chemoreflexes (LCRs) described are triggered by the contact between liquids (both water-/chloride-poor and acidic solutions) and laryngeal mucosal receptors. The LCR also appears to change with maturation of the infant/animal. Immature responses include laryngospasm, apnoea, oxygen desaturation and bradycardia mediated by a vagal efferent limb as well as a redistribution of blood flow to vital organs and hypertension mediated by a sympathetic efferent limb. An older more mature mammal will respond with arousal and coughing rather than apnoea and swallowing in an attempt to protect the lower airways [61].

The presence of various fluids in the upper airways (either feed/gastric refluxate/water) appears to trigger the LCR and apnoea. The activation of receptors in the laryngeal mucosa is the initial step in the process. Laryngeal taste buds, found in high numbers in the area, are thought to be involved. Other receptors have also been described. Receptors in the laryngeal mucosa have been identified for water and respond to low chloride or hypo-osmolar solutions. Laryngeal c-fibres with vanilloid receptors (TRPV1) that are responsive to changes in acidity are found in adult rats. The precise roles of these receptors in the LCR is not yet fully known but potentially may offer future targets for new therapeutic agents [45].

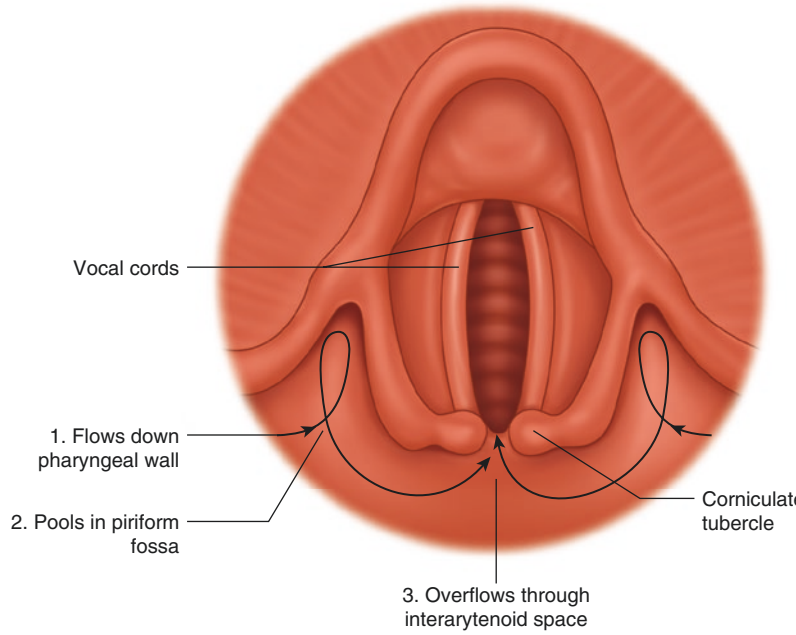

Fig. 104.4 Shows the flow of experimentally placed saline from the pharynx, with pooling in the pyriform fossae, and overspill into the inter-arytenoid space where there is a high density of chemoreceptors at the entrance into the larynx (From reference [60])

The Association Between GER and Apnoea

There have been many studies looking into the relationship between GER events and apnoea given the possibility of a cause and effect relationship between the two that has been discussed above and that could be putatively explained by the mechanisms alluded to in the previous section.

In a study using a combination of pH metry and polysomnography in infants being evaluated after presentation for ALTE in which other causes had been excluded, 21 infants from an initial group of 67 were found to have GER. A group with severe prolonged GER was excluded as the association between the two could not be evaluated. A total of 741 apneic episodes were measured, of which only 140 (19 %) were coupled with GER. Those with GER (pH <4) and those with apnoea (defined as cessation of breathing for at least 6 s or more) associated within 60 s of one another were classified as a coupled event. The majority had apnoea preceding GER, and only in 6.4 % did GER precede the apnoea. The authors concluded that in terms of a cause-effect relationship, the results supported the probability of apnoea as the primary factor with GER secondary to the apnoea. Presumably, the GER is caused by a rise in intra-abdominal pressure associated with the apnoea [2].

As pointed out earlier, apnoea will often occur soon after a feed, the period when GERD is also most likely to occur. Given that recurrent vomiting is a common finding in infants, one may not be surprised that apnoea/ALTE and GER occur together purely coincidentally, such that an association may be present yet causality is not proven. This is a recurrent theme when discussing extra-oesophageal symptoms and GER.

Animal studies show a central or obstructive apnoeic response to infusion of fluid into the oesophagus of a sleeping animal. The apnoeic episode is followed by swallowing and clearance of the bolus [32].

Other studies show acidic GER inducing oxygen desaturation in infants admitted to hospital with an ALTE [13]. Methodological differences between studies (including definitions of apnoea) can make the data hard to compare.

From the data above, it has been postulated that acidic reflux stimulates laryngopharyngeal receptors causing laryngospasm and apnoea. It also appears that only certain episodes of apnoea may be triggered by GERD, such as 'awake apnoea' within 1 h of feeding [57].

Studies using the impedance technique [55] described earlier show an association between 30 % of apnoeic episodes and GER and 70 % of the episodes which reached the pharynx, but only a small proportion of which were acidic in nature [58, 73]. This indicates a role for non-acid reflux in the pathophysiology of these presentations and that would be missed if conventional pH metry were to be used.

More recent studies using the same impedance technique have not supported an association between reflux and apnoea of prematurity [34, 38]; again there are methodological differences between studies. The study by Mousa and colleagues [34] showed little evidence for the association between apnoea and total reflux, acid or non-acid reflux in infants with ALTE or apnoea.

What seems to be more evident from the literature is that the majority of reflux episodes do not cause apnoea and that reflux is not the initiating event. In most studies, there are variable definitions of events, methodology is varied, and the use of older techniques such as pH metry as opposed to the more recently available impedance technique will almost certainly underestimate the role of non-acid reflux in these cases.

As Slocum et al. suggest in their critical review of the subject, one could interpret several of these studies as proving no such link exists. Alternatively, apnoea could occur under certain circumstances in subsets of patients. The proximal extent of reflux or the nature of the refluxate could dictate the response that occurs, and the effect of varying degrees of developmental maturity of different body systems could impact upon the likelihood of the infant being susceptible to GER-induced apnoea [56].

In summary, there may be an association between GERD and physiological apnoea and ALTE; however, a cause and effect relationship

between GERD and pathological apnoea/ALTE has not been conclusively demonstrated. The majority of apneic events do not seem to be caused by GER, yet some reflux may cause some apnoea in certain groups of predisposed patients. Putative mechanisms exist for a link between reflux and apnoea in the form of various reflexes discussed earlier. Studies with similar methodology and definitions are needed in the future to further clarify this controversial area.

Children with Pulmonary Disorders

105

Mark L. Everard and Kostas Priftis

Introduction

The upper gastrointestinal tract and the airways are closely related both anatomically and embryologically. It is therefore not surprising that an abnormality of the normal process of dealing with ingested food substances and liquids may impact on the lungs. For certain conditions such as neurological disorders leading to impaired coordination of the normal swallowing mechanisms or an anatomical abnormality such as a laryngeal cleft which may lead to aspiration of significant quantities of fluid and food material, there is little doubt that there is a causal relationship between the primary condition and the observed pulmonary consequence. At the other end of the spectrum, apparent associations such GER and cough or 'difficult' asthma generate considerable debate as to whether there is simply coexistence of two common conditions or whether there is a causal relationship in one direction or the other. Strong views are often expressed regarding the likelihood of causality despite the absence of convincing data. In large part, these areas of controversies are due to the difficulties of investigating the nature of inflammation within the lower airways, difficulties in clearly identifying aspiration with various imaging modalities and the paucity of well-designed intervention studies. Moreover, the lack of clarity in the use of terms such as 'asthma' compounds the situation.

Children with significant disorders of the oesophagus may present directly to gastroenterologists who may become aware that the child has ongoing respiratory symptoms that may or may not be related to problems in the upper gastrointestinal tract. Similarly the focus of concern may initial focus on respiratory symptoms with the respiratory physician raising concerns that structural or functional problems affecting the upper GI tract are contributing significantly to the pulmonary problems.

Structural problems such as laryngeal clefts and tracheo-oesophageal fistulas will not be discussed further though it should be noted that minor clefts and H fistulae can be very difficult to identify at times even when suspected. The subject of apnoea and acute life-threatening episodes, which if dealt with by a specialist is predominantly dealt with by respiratory physicians, has also been covered in a separate chapter. Therefore, the focus of this chapter will be on the possible adverse effects of GER on the respiratory tract.

Potential Impact of GER on the Respiratory Tract

The enthusiasm for attributing a range or respiratory problems to GER varies widely between and within countries. The wide range of views and practice reflects, in part, the limited evidence base on which to base practice and the tendency for symptoms to vary over time which accounts for a proportion of perceived 'positive' responses to an intervention. Interventions are generally added when symptoms are most troublesome and the natural tendency for many to spontaneously recover over time will lead to perceived positive responses due to 'regress to the mean'. Problems which are frequently attributed to GER include aspiration, chronic cough, 'difficult asthma' and 'recurrent chest infections'.

GER with Aspiration

A variety of conditions place patients at increased risk of aspiration including structural problems such as laryngeal and palatal clefts, tracheo-oesophageal fistulae and mechanical factors such as endotracheal and tracheostomy tubes.

The group of ambulatory patients in whom there is the most robust evidence and the highest prevalence of respiratory problems attributable to GER are those with cerebral palsy and other forms of neuromuscular disease. GER appears to be significantly more common in this patient group compared with the general population, and its potential for inducing pulmonary problems is greatly potentiated by any associated impairment of reflex protective mechanisms designed to protect the airway from aspiration of food and liquid [1, 24, 34, 38]. GER to the laryngeal inlet places such these individuals as risk of both massive life-threatening episodes and, more commonly, chronic pulmonary aspiration.

It has been suggested that in patients with conditions such as cerebral palsy, GER without swallowing dysfunction is not associated with a significant increase in lower respiratory tract infections but even mild GER is associated with such infections in the presence of swallowing dysfunction [34]. Hence, if aspiration is suspected, much of the diagnostic effort is focused on assessing swallowing and excluding structural problems with and assessment of the presence of GER being only one aspect of the pulmonologists assessment [5, 14, 16].

Other patient groups in whom GER with aspiration appears to have a detrimental effect on outcomes include ventilated preterm neonates in whom aspiration appears to be common and to be associated with a less favourable outcome [22, 23]. However, there are no intervention studies in this population. There are concerns that chest physiotherapy may increase reflux and potentially contribute to aspiration in infants with cystic fibrosis [4, 8] though again no intervention studies have been undertaken.

Pulmonary Consequences of Aspiration

The clinical manifestations of aspiration vary considerably depending on the quantity, frequency and composition of the aspirated material. At the most severe end of the spectrum, children can aspirate significant quantities of material during a substantial reflux event or vomit leading to acute aspiration pneumonitis that may be life-threatening. More typically, aspiration secondary to GER is less intense with relatively small quantities of gastric content being aspirated intermittently. This generally leads to more chronic respiratory symptoms. Cough may not be perceived as a major symptom particularly as the cough reflex may be significantly reduced in children with neuromuscular problems resulting in 'silent' aspiration. The manifestations of these events may be:

1. A persistent/recurrent cough
2. Recurrent 'chest infections'
3. Life-threatening bronchopneumonia

The role of GER reflux in the causation of a persistent cough is the cause of much debate. It is probable that most children who aspirate following GER to the laryngeal inlet develop a recurrent/

persistent cough. However, the role of GER in the causation of a recurrent/persistent cough in the absence of aspiration is much less clear and will be discussed below.

For those with GER who are also aspirating material originating from below the oesophagus, the pattern of respiratory symptoms will vary depending on whether there is a primary irritation of the airways due to a chemical bronchitis/pneumonitis [2, 17, 35] immediately after aspiration or ongoing inflammation due to frequent exposure to chemicals in those with frequent aspiration and/or the presence of a secondary bacterial bronchitis [12, 32]. Aspiration of gastric contents will of itself cause irritation within the conducting airways that is likely to induce coughing which is likely to be related closely in time to the event. However, if the impaired mucociliary clearance together with aspiration of organisms from the upper airways leads to the development of chronic bacterial bronchitis [12], the coughing may be largely unrelated to individual aspiration events. Indeed, with a secondary bacterial bronchitis, the primary insult, GER with aspiration, may have resolved prior to the referral for ongoing respiratory symptoms. This secondary pathology effect might explain some of the difficulty in establishing a correlation between coughing and reflux with aspiration events. The organisms responsible are most commonly the pathogens that frequently colonise the upper airway in childhood notably non-typable *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Moraxella* [12, 19]. This condition has been largely neglected for the past few decades, and it is likely that in large part, this has been due to high levels of antibiotic prescribing in young children. However, with the well-intentioned drive to reduce antibiotic prescribing, the condition is becoming far more prevalent. In previously healthy children, the commonest initiating event appears to be a viral lower respiratory tract infection which leads to impaired mucocillary clearance. Aspiration of secretions from the upper airways in those with a neuromuscular problem may well enhance the likelihood of these respiratory pathogens [exactly the same organisms noted in acute and chronic otitis media] reaching the lower airways and establishing biofilms in the conducting airways.

As noted above, a single large aspiration may precipitate a pneumonitis with possible superadded bacterial infection; it seems very likely that the most common cause for recurrent 'chest infections' in those with neuromuscular problems is a true bronchopneumonia. It is often forgotten that the lungs are compartmentalised into the conducting airways [generation 1–16] responsible for conducting air to and from the transitional and respiratory zone [generations 17–23]. A bronchopneumonia represents a pneumonic illness [infection in the respiratory zone] that has its origins in the conducting airways. The organisms noted above behave quite differently under different conditions. In steady state, in the conducting airways, they probably establish biofilms [40] replicating slowly and inducing chronic but ineffectual inflammatory response. Indeed these organisms use material from neutrophils as part of the complex biofilm structure. During exacerbations, they release significantly greater numbers of planktonic forms with the aim of extending their area of colonisation, and if replication takes off in the respiratory zone, this become evident on the chest X-ray as patchy consolidation and labelled 'pneumonia'. Between exacerbations, the CXR may vary from minor bronchial wall thickening with a generally scruffy appearance to persistent areas of opacification due to failure to clear a region effectively. Ultimately the chronic inflammation associated with the persistence of biofilms can lead to 'bronchiectasis' – a radiological sign than a diagnosis identified by CT scans. As such the development of bronchiectasis in many cases represents a failure of medical management due to a lack of appreciation of the importance of chronic bacterial bronchitis and the natural history of the condition. Hence, the opportunity to intervene at an early stage and prevent progression to changes evident on the CT scan is missed. In those with neuromuscular disease and aspiration, it is not sufficient to simply minimise aspiration or eradicate infection – both must be addressed in parallel.

Trying to preserve a healthy airway in a child with neuromuscular disease has major benefits

for the child, the family and the health-care system as admissions due to 'recurrent chest infections' can be prevented. As noted above, this involves both trying to prevent aspiration and treating bacterial bronchitis in order to prevent the recurrent bronchopneumonias and pulmonary damage often observed in these patients.

Investigation of GER with Possible Aspiration

The presence of recurrent of persistent respiratory symptoms in a patient with known neuromuscular disease raises the possibility of aspiration. This may also be amongst the possible factors in an otherwise 'normal' infant with 'recurrent chest infections' or persistent problems such as chronic cough though it is less likely. Amongst 'normal' infants, a history suggestive of aspiration is more likely to be due to rare structural anomalies such as laryngeal clefts or 'H fistulae' or rare neurological problems affecting oropharyngeal co-ordination such as Moebius syndrome.

Centres are increasingly developing multidisciplinary teams to address the many aspects of investigation and treatment. Investigations may include assessment of swallowing attempting to identify swallowing dysfunction which places a child with GER at greater risk of aspiration, investigations such as pH probes with and without multichannel intraluminal impedance monitoring [18, 37, 44] attempting to assess the degree of acidic and non-acidic reflux and attempts to link reflux with aspiration using bronchoalveolar lavage, gastro-oesophageal scintigraphy and barium esophagrams.

Assessment of Swallowing

Videofluoroscopic Swallowing Study [VFSS] and Fibre-Optic Endoscopic Evaluation of Swallowing [FEES]

A videofluoroscopy undertaken with a speak and language therapist or other trained individuals may identify problems with the swallowing mechanisms and occasionally identify aspiration during swallowing. Such a result would suggest that the subject would be at risk of aspiration from GER should this be sufficient to reach the laryngeal inlet. While invaluable in many, this is a relatively labour-intensive form of assessment involving ionising radiation. While a positive result is highly specific, a negative result does not exclude aspiration. Moreover, *inter*subject variation in interpretation is a potential problem. FEES can be complimentary with similar problems in terms of intra-observe variability, expense and limitation in time of assessment [5].

Bronchoscopy

A combination of probable reflux and possible aspiration would in many centres prompt dual procedures with both upper GI endoscopy and bronchoscopy. The purpose of the bronchoscopy is to try and help confirm or refute the presumptive diagnosis of aspiration and to determine whether there are other factors which may be contributing to the pulmonary symptoms.

Determining whether aspiration has taken place is difficult. Occasionally foreign bodies in the form of solid pieces of food may be found, but this is uncommon. More commonly, there is evidence of inflammation with oedematous and collapsible bronchi. This may be due to aspiration or may be due to bacterial bronchitis, and the visual appearance alone is not helpful. Bronchoalveolar lavage samples are routinely sent for microscopy with the lipid-laden macrophage index [LLMI] being the traditional putative marker of aspiration. However, after early enthusiasm, few would place any reliance of this marker alone as elevated levels can be seen in pulmonary disease without any evidence of aspiration and 'normal levels' being observed in children known to aspirate [9, 26, 29, 30]. It is probable that raised LLMI levels in these cases may be due to inflammation due to other causes such as bacterial bronchitis with the lipid membrane of necrotic inflammatory cells being taken up by macrophages, while levels could be low in an older child in whom fluid is generally in the form of water or juice.

It has been proposed that pepsin [22, 23, 31, 41] is a much more discriminatory marker of

aspiration of gastric contents though this has not been taken up widely due to the lack of commercially available assay, but this appears to be changing. Studies have indicated that pepsin may be detected in samples with a normal LLMI while pepsin does not appear in the lungs of 'healthy controls'. Hopes that measuring pepsin in induced sputum may be a noninvasive means of identifying aspiration proved unfounded as it appears that inducing coughing also induces reflux with pepsin being found in induced sputum samples from 'healthy controls' [20].

In addition to attempting to confirm that aspiration is an ongoing problem, the bronchoscopist will also be seeking evidence of either an underlying structural problem or additional/alternative pathologies. In general, fibre-optic bronchoscopy is believed to be less reliable than rigid bronchoscopy in identifying both a laryngeal cleft and tracheo-oesophageal fistulae in large part due to the angle of approach, but certainly the diagnosis of both is made using flexible bronchoscopes and has been missed using rigid scopes. Tracheomalacia/tracheobronchomalacia is both a risk factor for bacterial bronchitis due to impaired mucociliary clearance and will amplify other causes of cough. Identification of this may modify the physiotherapy used.

Contrast Studies and Milk Scintigraphy

Barium swallow and esophagrams again have a relatively low sensitivity but are probably better at identifying aspiration than milk scintigraphy [3] even though the latter potentially has the advantage of being more 'physiological'. It has been suggested that a milk scintigram performed overnight may be more valuable and sensitive [36].

Management of Chronic Aspiration and Its Consequences

In those with neuromuscular disease who are aspirating material regularly with significant impact on the lower airways, a variety of strategies are available. Having confirmed aspiration, it is clearly important to minimise ongoing aspiration to protect the lower airway. Options include limiting oral feeds to those that are perceived to be relatively safe after careful assessment by speech and language specialists or eliminating feeds all together through the use of nasogastic or, in some, nasojejunal tubes [46] though increasingly commonly gastrostomy tubes are sited. Debate continues to surround the use of surgical intervention fundoplication in those with having a gastrostomy inserted for feeding in those with proven aspiration, some arguing that the majority of patients should have a fundoplication to minimise the risk of reflux while others argue that clear evidence of reflux is required before proceeding to a procedure that has a level of associated morbidity [7, 27]. Addressing the issue of salivary aspiration may also be important even when oral feeds are eliminated.

Identification of bacterial bronchitis is challenging and ultimately may require a bronchoscopy. Eradicating biofilms from the conducting airways is much more difficult than treating a pneumonic episode requiring high doses of antibiotics often for prolonged periods. Physiotherapy to aid clearance is clearly an important component but not sufficient on its own.

It is important to realise that other conditions such as asthma may present with a chronic cough in those with cerebral palsy. Being immobile means that wheeze and overt shortness of breath are rarely observed. The exacerbations associated with viral infections are often termed 'chest infections' and treated with antibiotics. The natural tendency for regression to the mean – the natural improvement that occurs in the days and weeks after an exacerbation – can persuade the clinician that the antibiotics provided for the 'chest infection' is responsible for the perceived improvement. Therefore, clinicians should not lose sight of the fact that asthma will be a factor in the respiratory problems of some 10 % of children with neuromuscular disease and that asthma, reflux, aspiration and bacterial bronchitis can coexist each contributing to symptoms directly. Hence, a multifaceted approach is required for many of those with neuromuscular disease and respiratory problems.

Non-aspiration Respiratory Consequences of GER: Chronic/Recurrent Cough and 'Difficult' Asthma

The relationship between chronic or recurrent cough and GER is controversial with opinions ranging from GER being the major cause of chronic cough to those who believe that it is rarely a significant factor in the absence of significant aspiration [32, 47]. In certain countries, chronic cough is an important indication for surgical intervention despite the lack of any objective published evidence to indicate that this practice is appropriate. The cause for such polarised views is in part due to the difficulties surrounding diagnosis. Identifying GER in a child with a cough is not a rare event since GER is common particularly in early childhood and chronic cough is a common but significantly underrecognised problem, affecting some 10 % of the population in Western countries. The coexistence of the two should not imply causation since they are so common. Moreover, coughing per se can increase the frequency of reflux events [48].

The potential mechanisms through which gastro-oesophageal reflux might induce coughing without aspiration are [19, 20, 25]:

- Inflammation and/or stimulation of the vagus through reflux into the lower oesophagus
- Reflux to the upper oesophagus with stimulation of the cough receptors of the larynx

Persistent and Recurrent Cough

A persistent or chronic cough is one that occurs daily to be distinguished from recurrent coughs. A parent will often report that their child 'always' coughs, but closer questioning reveals that they have frequent episodes with, all be it brief, symptom-free interval periods.

In the adult literature, there are many who believe GER is one of the most common causes of a chronic dry cough [25, 43] though this is debated. The data generated in recent studies in childhood has been far from convincing with a number of studies failing to show a correlation between observed reflux episodes and cough [13, 31]. The proposed mechanism is that a vagal reflex is stimulated leading to coughing. A number of studies using both pH studies and impedance have failed to identify a close correlation between a coughing event either in the period prior to or following the cough [13]. Possible confounding factors might include the fact that 'normal children' cough a number of times during the day and the GER may not be the only cause of cough in a particular child. Moreover, it is clear that coughing can induce GER, and while both are common, ascribing a cause and effect is very difficult.

The reported frequency of GER as a cause for a persistent cough varies widely largely along the lines of 'belief' with reports from the USA suggesting that it may be the commonest cause of a persistent cough in childhood [28], while others in Australia and the UK find it infrequently as an isolated cause for a cough [32, 39]. A systematic review found insufficient evidence from high-quality studies to support the concept of using drugs such as PPI for the treatment of cough other than as a trial in those in whom other interventions have failed [11]. The same authors recently published a study in which there was no correlation between reflux episodes and cough either before or after the cough [13].

'Difficult Asthma'

Generally, there are only three causes of 'difficult' or 'severe' asthma:

- It is not asthma.
- It is asthma and something else.
- The patient is not taking the treatment effectively either because they are not taking their 'preventer' therapy according to the recommended regime [poor regimen compliance often referred to as poor adherence] and/or because they do not use their inhaler effectively [poor device compliance] which may be

due to lack of competence [they have not been taught how to use the device] or contrivance [they know how to use the device but choose not to such as not using a spacer].

Many have sought to implicate GER in 'difficult asthma'. While there is no question that GER can coexist with ongoing respiratory symptoms in those with 'difficult' asthma, it has yet to be shown that effective treatment of the reflux leads to a significant improvement in asthma control. A recent large study in adults found no benefit from pharmacological treatment of GER in a group of asthmatics labelled as having 'difficult asthma' and concluded that speculative treatment was not warranted [33]. Other intervention studies have produced similar negative results [42, 45]. Moreover, many of the therapies used to treat 'GERD' are associated with significant morbidity [5], and hence, speculative therapy should be discouraged.

Summary

Recurrent aspiration of gastric contents either acid or non-acid is undesirable with consequences ranging from occasional cough to chronic pulmonary disease and 'recurrent' chest infections. Those at greatest risk are those with neuromuscular disease and structural problems that compromise the normal protective mechanisms. Investigation of possible aspiration can be challenging and requires a multidisciplinary approach.

The role, if any, of GER without aspiration in causing pulmonary symptoms such as chronic cough and 'difficult' asthma remains to be determined. While respiratory symptoms and GER frequently coexist, it is unclear whether there is any causal relationship and if so in which direction.

Gastroesophageal Reflux Disease (GERD) and Dental Erosion (DE)

106

Hanaa Halaby and Mike Thomson

GERD can result in dental injury by dissolving the inorganic material of the teeth (hydroxyapatite crystals in enamel), which occurs below the critical pH level of 5.5 [1]. This is defined as dental erosion, the irreversible loss of tooth substance without bacterial involvement. This is the most predominant oral manifestation of GERD [2].

Endogenous (intrinsic) acid which originate from refluxed gastric juices (Fig. 106.1) and exogenous (extrinsic) sources of acid which originate from usually dietary, medicinal, occupational and recreational sources are both responsible for the increasing incidence and high prevalence of tooth erosion and associated tooth sensitivity observed in many countries in both children and adults [3]. The severity of dental erosions seems to be correlated with the presence of GERD symptoms and in adults with the severity of proximal eosophageal or oral exposure to an acidic pH [4].

The first modern description of DE associated with GERD is in a case report published more than 35 years ago [5]. In recent years, GERD has been described as an important aggravating factor of DE, and DE is now considered a comorbid syndrome with an established epidemiological association with GERD. As an example, the recently published Montreal Criteria, dealing with a global classification of GERD, state: 'The prevalence of DEs, especially on the lingual and

palatal tooth surfaces, is increased in patients with GERD' [6]. This statement (statement no. 48) has been approved with 98 % of agreement among the Montreal Group panellists and, reportedly, is based on a high level of evidence, possibly the highest level of evidence linking GERD with any extra-oesophageal clinical manifestation [6]. Thus, it is not surprising that some authors have advocated that the examination of the oral cavity, in search for 'atypical' DE, should be an integral part of the physical examination of the patient with suspected GERD [7]. On the other hand, other authors have denied, at least in children, that DE may represent a relevant problem in GERD patients [8].

A recent systemic review involving 17 eligible mainly observational and case-control studies of GERD and DE found a strong association between the two conditions [9]. The median prevalence of DE in GERD patients was 24 % and the median prevalence of GERD in adults and in children with DE was 32.5 % and 17 %, respectively. However, there were wide percentage ranges and degrees of tooth tissue loss present among the study populations, and not all studies and evaluations of patients employed oesophageal endoscopy and/or 24-h oesophageal pH metry.

Studies Conducted on Children (See Table 106.1)

A total of five studies were found [8, 10–13]. In the study by Dahshan et al. [10], 37 children undergoing elective upper endoscopy for possible GERD were evaluated for the presence, severity and pattern of erosion and stage of dentition of teeth. It was found that 24 of them had GERD, 20 of whom had DE as well, 10 with mild erosion (tooth score ≤1), 6 with moderate erosion (at least one tooth scored 2) and 4 with severe erosion (at least one tooth scored 3) according to the 4-point score proposed by Aine et al. [12].

In the study by O'Sullivan et al. [8], 53 children with moderate to severe GERD as defined by pH monitoring were examined for DE. No control group was investigated.

Results showed that the prevalence of DE was low when compared with the UK National Survey, with only nine (17 %) of children showing any sign of erosion, and of these, only one had erosion involving dentine.

In the study by Linnett et al. [11], 52 children with a 'definitive' history of GERD underwent a dental examination and were compared on an individual basis with a healthy control sibling without GERD symptoms; the prevalence of teeth erosion was found to be statistically higher in GERD subjects (14 %) than in controls (10 %) ($p < 0.05$). Furthermore, GERD subjects had erosion in more permanent teeth compared with controls (4 % vs. 0.8 %, $p < 0.05$) and more severe erosions.

In the study by Aine et al. [12], 17 children who attended a university hospital paediatric outpatient clinic for GERD and who were found to have pathological reflux at 24-h oesophageal pH monitoring were submitted to dental examination, with teeth erosion scored according to the previously quoted Aine Index (from 0 to 3); no control group was investigated. Overall, two patients had score 0, two patients score 1, six patients score 2 and seven patients score 3, suggesting that only a minority of GERD patients had intact teeth.

Table 106.1 Prevalence of dental erosions in children with GERD

Study (references)	No. patients with GERD	Age (range)	GERD diagnostic method	Prevalence (%)
Dahshan et al. [10]	24/37	2–18 years	Endoscopy	83
O'Sullivan et al. [8]	53	2–16 years	24-h pH metry	17
Linnett et al. [11]	52	17 months–12 years	Symptoms + histology	14
Aine et al. [12]	15	22 months–16 years	Symptoms	87
Ersin et al. [13]	38	6.5 years	Symptoms	NA

NA not applicable

Finally, in the study by Ersin et al. [13], the effects were investigated of GERD on DE vs. caries formation, on salivary function and on salivary microbiological counts. Thirty-eight GERD patients with a mean age of 6.5 years and 42 healthy children of the same age and gender and social background comprised the study group. All subjects answered a detailed frequency questionnaire related to acidic drinks, foods and sugar consumption and underwent a clinical dental examination. The caries experience of the children was recorded according to the World Health Organisation criteria, and erosions were scored according to the Eccles and Jenkins grading scale [14]. The children were also investigated for stimulated salivary flow rate, buffer capacity and salivary mutans streptococci (MS), lactobacilli and yeast colonisation. The results of this rather complicated study are the following: the prevalence of DE and the salivary yeast and MS colonisation was found to be significantly higher in GERD children than in healthy subjects ($p < 0.05$). The caries experience, salivary flow rate, buffering capacities of the children and frequency of acidic drinks, foods and sugar consumption were found to be similar in both groups. The authors concluded that GERD children were at an increased risk of developing erosion and caries compared with the healthy subjects [13].

DE in the intellectually disabled population might be an oral manifestation of GERD, and this group may appear to be at greatest risk [15].

The approach to evaluation and therapy – specifically, the choice of diagnostic tests, duration of therapy, and criteria for cessation of therapy – is unclear. Close consultation with a qualified paediatric dentist is required. The inspection of the oral cavity in search for dental erosions is advisable in patients with known GERD [4].

In conclusion, the fact that dental erosion is a potential risk in children with GERD, whatever the outcome of the studies was, means that paediatricians should be alerted to imply this in their clinical consultation. Children with GERD should routinely be referred to a (paediatric) dentist to quantify the potential erosion risk and, when needed, to intervene and restore the teeth. However, further randomised clinical trials are required to demonstrate that the progression of dental erosion reduces or ceases following gastric acid suppression in patients with confirmed GERD. Collaborative medical and dental management of patients with GERD is strongly advocated [16].

Part XVIII

Children at High Risk for GERD

The Child with Neuromotor Impairment

107

Christopher D.C. Rittey

Introduction

It has long been recognised that children with neuromotor impairment are at high risk of upper gastrointestinal disorders [1–3]. Symptoms such as rumination, dysphagia and vomiting are a frequent cause of diagnostic difficulty, and upper GI problems contribute greatly to the disability that many children with neurological disease experience.

These problems are a source of considerable anxiety and distress, not only for the neurologically impaired child but also for their family. The management of the child with neuromotor impairment involves careful attention to all symptoms which are medically amenable, and there is no doubt that effective management of gastrointestinal disorders, particularly gastro-oesophageal reflux, can have a substantial benefit both in general well-being and in quality of life.

Cerebral palsy is a common neurological condition with an overall prevalence in Western countries of between 1.7 and 2.5/1,000 live births [4, 5]. This incidence has remained constant for at least the last 20 years despite improvements in neonatal care. Improved medical care has led to significant improvements in survival of the most severely disabled people with cerebral palsy [6]. The groups in which the most significant improvement in survival occurred were immobile children who were fed by others and adults who were fed by gastrostomy. Whereas in the past it was considered that poor growth and weight gain were intrinsic components of cerebral palsy, it is now recognised that effective feeding of children with cerebral palsy is not only possible but an important part of their general care, with improvements in spasticity and mood accompanying improvements in nutrition [7, 8].

This review will consider the conditions which commonly occur in children with neuromotor impairment, their clinical presentation, pathophysiology, management – both medical and surgical – and implications for children and families.

Gastro-oesophageal Reflux (GER)

Chief among the gastrointestinal disorders that present in the child with neuromotor impairment is the issue of gastro-oesophageal reflux. The condition is of considerable importance in the child with neuromotor impairment as it is a cause of considerable morbidity including pain, feeding difficulties, recurrent respiratory infection, abnormal movements and behavioural changes.

Incidence

A number of studies have reported the overall incidence of gastro-oesophageal reflux (GER) in population of children with neuromotor impairment. Sondheim and Morris investigated 136 severely impaired children who were institutionalised [1]. Of these children, 20 (15 %) had a history of recurrent vomiting, and, of these, 15 (11 %) had gastro-oesophageal reflux proven by radiological examination and/or by demonstration of acid reflux. Complications of GER were noted in a number including oesophagitis (10/14), anaemia (4/14) and aspiration pneumonia (6/14). When compared to the overall population of impaired children, those with gastro-oesophageal reflux had a lower mental age and higher incidence of scoliosis.

Halpern and colleagues reviewed 613 children referred for diagnosis of gastro-oesophageal reflux and noted a significant increase in incidence in children over 1 year of age with neuromotor impairment compared to those without (69 % vs. 47 % $p=0.14$) [9]. Other reviews have described similar rates of GER in children with cerebral palsy [2, 10–13].

Pathophysiology

Improvements in diagnosis of GER have led to increased recognition of its occurrence in children with neuromotor impairment. The use of impedance studies in addition to pH studies allows detection of both acid and non-acid reflux which may be particularly important in the child with neuromotor impairment.

A number of factors have been identified as contributing to the frequency of GER in these children, and these are outlined in Table 107.1. Although many theories as to the cause of GER have been advanced including raised intra-abdominal pressure secondary to increased muscle tone, persistent supine position, seizures or scoliosis [9], it is likely that the predominant factor is intestinal dysmotility which is likely to affect the entire gut.

Clinical Features

The cardinal clinical feature of gastro-oesophageal reflux is vomiting. However, in the child with neuromotor impairment, other symptoms may be more difficult to determine and a high index of suspicion is required. In a systematic review of symptoms associated with gastro-oesophageal reflux, de Veer and colleagues [16] considered symptoms which they categorised as either gastro-oesophageal reflux disease (GERD) symptoms or behavioural symptoms. The symptoms which were shown to be consistently associated with gastro-oesophageal reflux are shown in Table 107.2. Failure to thrive and pain/irritability were symptoms that had contradictory reporting in different studies.

Food refusal, regurgitation, anaemia, recurrent pneumonia and a variety of respiratory symptoms were found not to be clearly related to

Table 107.1 Factors contributing to gastroesophageal reflux in children with neuromotor impairment

Factors contributing to GER in children with neuromotor impairment
Prolonged supine position
Hiatus hernia
Scoliosis
Spasticity leading to increased intra-abdominal pressure
Seizures
Esophageal dysmotility
Decreased lower esophageal tone [14]
Transient relaxations of lower esophageal sphincter [15]

Table 107.2 Symptoms associated with gastro-oesophageal reflux in children with neuromotor impairment

Symptoms associated with GER in children with neuromotor impairment	
"GERD" symptoms	"Behavioural" symptoms
Vomiting	Depression
Rumination	Changed behaviour
Haematemesis	
Wheezing	
Dental erosion	

gastro-oesophageal reflux in this systematic review nor were behaviour problems, self mutilation, aggression or screaming episodes. However, there is some evidence to suggest that these behavioural problems may be more frequent in children with gastro-oesophageal reflux, particularly those with oesophagitis, and this is certainly borne out by clinical experience.

Symptoms of vomiting usually occur during feeds or within a few hours of feeds. If there are additional symptoms such as coughing, choking or gagging, then the clinician needs to consider the additional possibility of oropharyngeal incoordination leading to difficulties with swallowing or even aspiration. In this situation, careful assessment by the speech and language therapist is essential.

Complications of GER

Persistent gastro-oesophageal reflux leads to prolonged exposure of the lower oesophageal mucosa to gastric acid. This results in peptic oesophagitis. The inflamed mucosa may then bleed, sometimes resulting in iron deficiency anaemia. Occasionally, the bleeding may be sufficiently severe as to present with frank haematemesis. Persistent peptic oesophagitis may lead to chronic inflammation and ultimately to the formation of oesophageal stricture. This may present with feeding or swallowing difficulties.

While early treatment of GER can reverse peptic oesophagitis, in children with neuromotor impairment, the diagnosis of oesophagitis may not be considered until late when long-term sequelae are already present. In some children, the only overt sign of reflux is the appearance of behaviour difficulties including agitation and self-injurious behaviour [17]. Neurologically impaired children with oesophagitis are more likely to present with self-injurious behaviour than children without oesophagitis. A high index of suspicion for gastro-oesophageal reflux in children with neuromotor impairment coupled with appropriate early investigation provides the maximum chance of avoiding long-term complications.

Once oesophageal stricture is present, treatment with repeated dilatation and effective anti-reflux therapy is required. Complications of repeated dilatation include perforation, haemorrhage and infection (mediastinitis).

Another complication of chronic gastro-oesophageal reflux is the development of Barrett's oesophagus. This is a condition in which the squamous epithelium of the oesophagus is replaced by columnar epithelium. The most serious consequence of this is the malignant transformation of the columnar epithelium to adenocarcinoma.

A wide range of extra-oesophageal (mainly respiratory) difficulties are associated with GER. Although there is clear evidence that extra-oesophageal symptoms are common in adults with GERD [18], the evidence in children, especially those with neuromotor impairment, is much weaker [19]. Nevertheless, complications including asthma, aspiration pneumonia, bronchiectasis, apparent life-threatening events (ALTE), laryngotracheitis, sinusitis and dental erosion are reported in children with GERD. Impaired oropharyngeal control in children with neuromotor impairment renders these children at increased risk of aspiration, a risk which may be further compounded by uncontrolled gastro-oesophageal reflux. These respiratory disorders may further contribute to nutritional compromise in children with neuromotor impairment leading to a vicious cycle of deterioration. Effective control of GERD is, therefore, an important component of the respiratory care of these children.

Sandifer Syndrome

The association between vomiting with or without hiatus hernia and abnormal dystonic movements of the head, neck and trunk was first noted by Sandifer and reported by Kinsbourne [20]. Since then, numerous reports confirming the association between these movements and gastro-oesophageal reflux have appeared in the literature

[21–23]. The movements typically comprise odd rotational and extensor posturing of the head and neck which commonly occur during or shortly after feeds. The condition is commonly misdiagnosed as other neurological conditions such as epilepsy, movement disorder or behavioural [24–27].

The precise mechanism for the development of dystonia is unknown. Some authors have suggested that the dystonia occurs as a result of reflex spasm of neck muscles due to common sensory innervation of the neck and diaphragmatic muscles. However, the fact that the condition ceases during sleep tends to argue against this proposed mechanism as gastro-oesophageal reflux is known to continue during sleep and the reflex spasm should be likely to continue irrespective of state of arousal. Kinsbourne suggested that there may be a learned element to the phenomenon with the child discovering by chance that the abnormal posture relieved the discomfort associated with GER. There is some support for this contention from the work of Puntis et al. who described improved oesophageal peristalsis on manometry during the abnormal neck movement [28]. Effective treatment of the underlying GERD is usually effective in controlling the abnormal movements, although the resolution of symptoms may be gradual.

Treatment of GER

Medical

Medical treatment for GERD in children with neuromotor impairment follows the same general principles as in children without neuromotor impairment although it is recognised that there is a higher failure rate of medical management in the former and, hence, a greater probability of proceeding to surgical management. The main aim of treatment is to alleviate pain and other symptoms, to aid nutrition, to allow healing of the oesophageal mucosa and to avoid the development of long-term complications.

Initial management centres around modification of feeding. It is important to avoid overfilling of the stomach, and thus, administration of more frequent lower volumes feeds should be advised. If the child is being fed enterally (either by gastrostomy, jejunostomy or nasogastric feeds), it may be necessary to use continuous feeding regimes rather than bolus feeds to achieve this where GER is severe. Although some people recommend placing children in a supine head-up position to reduce gastro-oesophageal reflux, there are few data to support this recommendation.

Thickening of feeds in infants has long been recommended for the management of gastro-oesophageal reflux. The use of thickening agents in children with neuromotor impairment has not been systematically studied. However, Miyazawa et al. studied the use of pectin as a thickening agent in a crossover study of 18 children with cerebral palsy and GERD. This study demonstrated that pectin liquid partially decreased GER as measured by oesophageal pH monitoring [29] and gives some support to the recommendation for thickening of feeds in management of GERD in children with neuromotor impairment. Concerns have been raised that thickeners may be disadvantageous in some children with GERD due to the osmotic effect of thickeners leading to gastric distension [30].

Simple antacids neutralise gastric acid and can reduce symptoms of dyspepsia and oesophagitis. Their major advantage is a rapid onset of action, but they are limited by their inability to maintain the reduction in acidity in the presence of continued acid secretion. Alginate-containing compounds such as Gaviscon or Peptac have the theoretical advantage of forming a “raft” which lies above the surface of stomach contents and which should provide some protection to the oesophageal mucosa. Although there have been questions regarding efficacy in preventing gastro-oesophageal reflux in infants [31], there are data supporting its use in preterm infants [32]. Efficacy has not been specifically studied in children with neuromotor impairment.

Prokinetics

Prokinetic agents play an important role in the management of severe gastro-oesophageal reflux in children with neuromotor impairment. Prior to

its withdrawal from routine use in children, cisapride had been widely used for the management of GERD in children. Although a Cochrane review questioned its general efficacy for the prevention of GERD in children, studies in children with cerebral palsy [33] and in tube-fed children with severe developmental disabilities [34] demonstrated benefit. Attempts were made to maintain supplies of cisapride following the withdrawal of its licence by the Committee on Safety of Medicines due to risk of prolongation of QT interval but the company ceased production in 2005.

The current mainstays of prokinetic therapy include domperidone and erythromycin. Domperidone is now widely used in children with neuromotor impairment. Domperidone is a peripheral D2 receptor antagonist. It acts by increasing gastric motility and reducing gastric emptying time leading to a reduction in postprandial reflux. A review published in 2005 identified only four randomised controlled studies of domperidone in children, none specifically dealing with children with neuromotor impairment. None of these studies provided any data to support the use of domperidone in children with GERD [35]. However, a small prospective study of 20 infants with gastro-oesophageal reflux compared domperidone with cisapride and concluded that both were efficacious [36] although cisapride was slightly more effective at reducing reflux index. One child taking cisapride had a prolonged QT interval.

Erythromycin is a macrolide which has been shown to act directly on motilin receptors in the GI tract resulting in an increase in gut motility. Although there are a number of observational and controlled studies suggesting benefit in preterm infants [37], there are no data regarding its use in children with neuromotor impairment. Nevertheless, it is a safe and well-tolerated drug and deserves consideration in this group of children.

Metoclopramide is a dopamine agonist which enhances the gut response to acetylcholine thus increasing motility and gastric emptying. It also acts to increase lower oesophageal sphincter tone. However, the evidence available does not demonstrate benefit in the treatment of gastro-oesophageal reflux disease [37], and its side effects, particularly sedation, extrapyramidal effects (acute torsion dystonia and tardive dyskinesia) and irritability, have meant that more effective alternative prokinetic agents have taken over.

H2 Antagonists

H2 receptor antagonists act by blocking the H2 receptors of the gastric parietal cells resulting in the suppression of gastric acid production. The current H2 antagonist of choice is ranitidine due to its greater efficacy and lower incidence of side effects. The duration of action of ranitidine requires twice-daily dosing, with thrice-daily dosing required in infants due to a short duration of action. Although widely used in children with neuromotor impairment, the evidence base for its use is limited [38]. There are concerns about tolerance to the antisecretory effect of ranitidine, and gradual withdrawal is recommended when the drug is discontinued due to the risk of rebound hypersecretion.

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) act by irreversibly blocking the H^+/K^+-ATPase pump in the gastric parietal cells, thus inhibiting gastric acid production. They have largely superseded H2 antagonists as the mainstay of treatment for gastro-oesophageal reflux. The most widely used PPIs in children are omeprazole and lansoprazole, and these are generally well tolerated. Studies reveal that short-term treatment with PPIs is effective in healing reflux oesophagitis and improving symptoms of reflux in children although reviews of the data have cast doubt on whether they are useful in infants [39, 40]. Long-term treatment with PPIs has been shown to be effective in maintaining remission of reflux oesophagitis and reflux symptoms in children [41]. Small nonrandomised studies of omeprazole in children with a variety of neuromotor impairments have demonstrated efficacy, and PPIs are probably the medical treatment of choice for GERD in children with neuromotor impairment [42–45].

The main disadvantage of PPIs in children with neuromotor impairment is the lack of an ideal formulation. Omeprazole tablets cannot be broken and omeprazole MUPS have been shown to block small-bore feeding tubes, although they can be dissolved in sodium bicarbonate which reduces the risk of tube obstruction when administered via nasogastric tube or gastrostomy. Lansoprazole may have an advantage for enterally fed children with neuromotor impairment as there are soluble tablets available which can be placed down a feeding tube and studies have revealed that solutions of other formulations in sodium bicarbonate have been shown to be safe for administration via down feeding tubes [46]. Newer PPIs such as pantoprazole have also been shown to be effective [42].

Other Agents

Baclofen is a $GABA_B$ receptor agonist which is widely used for reduction of spasticity in children with cerebral palsy due to its effect on spinal neurones. In addition to this effect, baclofen has been shown to reduce the incidence of transient lower oesophageal sphincter relaxations and possibly to increase sphincter pressure and increase gastric motility [47]. A small observational study of children with neurological impairment revealed that baclofen was effective in reducing vomiting and in reducing the frequency of acid reflux as assessed by pH monitoring [48]. Optimal dosing regimes have still to be established [49]. Newer peripheral acting $GABA_B$ agonists are being developed and tested, but there is no published experience of these in children [50–53].

Surgical

Fundoplication

Although medical treatment of gastro-oesophageal reflux disease in children with neuromotor impairment is always advised as first line, it is well recognised that this group of children have a high incidence of medically refractory reflux. In the past, surgical options were considered the last resort due to the nature of the surgery. The most widely used surgical procedure for controlling gastro-oesophageal reflux was Nissen fundoplication, and this was shown to be highly effective in controlling symptoms [54–56] although surgical complications are reported in up to 59 % of patients [57]. Many of these children have substantial co-morbidities including recurrent respiratory infection, scoliosis, joint contractures, etc., and major thoracoabdominal surgery carried significant risk. Not surprisingly, the rate of complication of fundoplication has been shown to be higher in children with disability [55, 56, 58–61].

However, surgical advances including the development of laparoscopic and endoscopic procedures have markedly reduced the complications of surgery and shortened admission times such that surgical management of GERD in children with neuromotor impairment is a significantly more viable option and these procedures have been shown to be effective [59, 62].

Complications

The most frequent complication of fundoplication in children with neuromotor impairment is recurrence of symptoms due to failure of the wrap or herniation. In this situation, redo of the fundoplication may be worthwhile, but further recurrences are common. In this situation, more radical surgical options such as oesophagogastric disconnection may be a useful alternative, and benefits from these procedures have been obtained in children with neuromotor impairment [63, 64].

Retching is a common and distressing symptom following fundoplication in children with neuromotor impairment [65–68]. It is recognised that children who retch before surgery are very likely to retch after surgery and post-operative retching is recognised as a significant risk factor for failure of fundoplication [66]. It is suggested that retching is due to an inappropriate activation of the emetic reflex due to failure of central control mechanisms in children with neuromotor impairment and that this may be exacerbated by antireflux surgery [68, 69]. Treatment of retching may be decompression via gastrostomy or nasogastric tube or frequent low volume or continuous feeding

or the use of prokinetic agents. Alimemazine may be useful in this situation [70].

Dumping syndrome can occur in up to 30 % of children after fundoplication and occurs in children without as well as with neuromotor impairment [54, 71, 72]. The mechanism is likely to be multifactorial with factors such as increased post-operative gastric emptying and smaller gastric capacity which results in hyperosmolar food boluses in the small bowel causing rapid movement of water from the intravascular space entering the bowel and reducing plasma volume. Hypoglycaemia follows increased secretion of insulin due to the high carbohydrate load in the duodenum. These result in symptoms such as lethargy, pallor, sweating, abdominal discomfort and distension, diarrhoea, etc. Management is by dietary manipulation [73] and by giving small volume feeds or continuous feeding.

Bloating may occur following fundoplication due to an inability to release wind from the stomach. It may result in acute gastric distension and can be relieved by release of gas by nasogastric tube or gastrostomy.

Motility Disorders

As discussed above, gastrointestinal dysmotility is a common problem in children with neuromotor impairment. The enteric nervous system is an extremely complex system, and it should be no surprise that insults to either the central nervous system or the peripheral nervous system should result in dysfunction of enteric neuronal control. While gastro-oesophageal reflux is a major presenting feature of such gastrointestinal dysmotility, specific motility disorder affecting the oesophagus and stomach is well recognised. Additionally, oropharyngeal dysfunction is a major problem, particularly in relation to nutrition.

Oesophageal Dysmotility

Disorders of oesophageal motility are commonly seen in neuromuscular diseases such as dystrophia myotonica, spinal muscular atrophy, myasthenia (both congenital and myasthenia gravis), congenital myopathies and some neuropathies such as hereditary sensory autonomic neuropathies (HSAN) including Riley-Day syndrome [74–79]. Specific visceral neuropathies are also recognised [80]. These conditions usually present with dysphagia or with gastro-oesophageal reflux. Achalasia of the cardia is a cardinal feature of the AAA syndrome (achalasia, alacrima and adrenal insufficiency).

Management of these conditions includes trial of medical treatment to relax the lower oesophageal sphincter, dietary manipulation and, if necessary, surgical procedures such as oesophagocardiomyotomy [77]. Fundoplication for treatment of gastro-oesophageal reflux in these children has been shown to be effective [76, 81–83].

Delayed Gastric Emptying

Delayed gastric emptying is recognised between 28 and 50 % of children with gastro-oesophageal reflux whether or not they have neurological impairment [84]. However, although some early studies suggested that treatment of delayed gastric emptying might be an important factor in effective treatment of GER [85–87], not all authors agreed with this recommendation [88], and more recent studies have not supported this approach [13, 89–92].

Treatment involves the use of prokinetic agents or surgery (pyloromyotomy). Passage of a feeding tube directly into the jejunum or jejunostomy may be necessary.

Nutritional Issues

Oral-motor dysfunction is common in children with neuromotor impairment, and there is a complex interrelationship between incoordination of tongue and oropharyngeal muscles, temporomandibular joint contractures, vomiting and gastro-oesophageal reflux which contributes to poor nutrition. A clear association between the severity of cerebral palsy and the degree of

oral-motor dysfunction and growth failure has been demonstrated [93, 94], and more recent data support this association in children with a variety of neuromotor impairments (predominantly cerebral palsy) [95]. In the latter study, a validated questionnaire was completed and returned by the parents of 266 children. Feeding problems were extremely common in these children with 89 % reported to require help with feeding and 56 % to have problems with choking. Twenty percent of parents described feeding as stressful and unenjoyable. Prolonged feeding times of greater than 3 h/day were reported by 28 %. This study was not able to document nutritional status as 64 % of the children had never had their feeding or nutrition formally assessed.

There is clear evidence that poor nutrition is directly related to feeding dysfunction [96–98] and that children with neuromotor impairment and poor nutrition are more likely to have other health problems including higher surgical morbidity, pressure sore and death [99]. Indeed feeding status is an important predictor of life expectancy in children with cerebral palsy [6]. However, inadequate intake is not the only cause of growth failure in children with neuromotor impairment and central neurological dysfunction, as well as endocrine factors are important. Nevertheless, to a large degree, nutritional status can be improved by improving calorie intake, either by calorie supplementation or, more effectively, by enteral feeding via nasogastric tube or gastrostomy.

Gastrostomy

Gastrostomy has been used for over a century as a procedure to overcome gastrointestinal dysfunction. More recently, it has become popular as the method of choice to feed children with oral-motor dysfunction. Since the introduction of the technique of percutaneous endoscopic gastrostomy in 1980, this has become the procedure of choice for insertion of gastrostomy (see Chap. **).

Despite the enthusiasm for PEG in children with neuromotor impairment, early studies did not provide clear-cut evidence of benefit [99, 100]. Although weight gain was consistently achieved, there was concern that children fed by gastrostomy had a higher death rate, although this was probably due to differences in the degree of disability in the gastrostomy-fed versus orally fed children. However, subsequent studies have suggested that gastrostomy is both efficacious, safe and cost-effective [101, 102].

Complications

Complications from gastrostomy depend to a large extent on the status of the child before placement. Immediate complications include pneumoperitoneum, oesophageal laceration, colonic perforation and peritonitis. Minor later complications are common and include problems such as leakage from the stoma site leading to skin irritation, formation of granulation tissue and local skin infection. More significant problems include tube blockage, tube removal by the child or migration of the tube from the stomach which can be life-threatening. These are rare but important [102].

An important consequence following gastrostomy is the development of gastro-oesophageal reflux. Initial recommendations were that children having gastrostomy should have routine antireflux surgery. However, this view has been questioned, and there is now evidence that although development of gastro-oesophageal reflux following gastrostomy can occur, it is often effectively managed medically, and surgical treatment should be reserved for those children in whom medical management fails [103]. A Cochrane review of this issue concluded that there is still need for better data to direct clinicians as to whether medical or surgical therapy is optimal for children with GER who undergo gastrostomy [104].

Conclusions

Upper gastrointestinal dysfunction is extremely common in the child with neuromotor impairment. These problems may be seen whether the neuromotor impairment is of central or peripheral aetiology, although the majority of data come from children with central disorder, particularly cerebral palsy. Gut

motility problems result in a wide range of upper gastrointestinal manifestations ranging from oral-motor dysfunction to oesophageal motility disorders and gastro-oesophageal reflux. These all conspire to adversely affect the health, nutrition and quality of life of the child with neuromotor impairment and have a substantial effect on parents and carers.

It is important for the clinician dealing with the child with neuromotor impairment to have a high degree of suspicion for such gastrointestinal problems as the presentation may not always be with overt gastrointestinal symptoms. Effective treatment of gastro-oesophageal reflux is an important factor in improving symptoms, avoiding complications and enhancing nutrition in these children. Additionally, careful attention to nutrition in the child with neuromotor impairment is a key element in maintaining health, enhancing quality of life and improving life expectancy. Management of these problems requires a multidisciplinary approach.

The Obese Child and Reflux

108

Peter Michael Gillett

Abbreviations

BMI	Body mass index
GERD	Gastroesophageal reflux disease
GI	Gastrointestinal
HH	Hiatus hernia
LES	Lower oesophageal sphincter
LESP	Lower oesophageal sphincter pressure
MDP	Minimal distending pressure
MTV	Maximum tolerated volume
OR	Odds ratio
TLESR	Transient lower oesophageal sphincter relaxation

Introduction

The obesity and reflux disease epidemics have paralleled each other in modern times. There are global health consequences that will follow this ever-increasing public health problem – an emerging major issue within the school-age and, in some countries, preschool population. We have clearly not yet seen its major effects. There are ethnic and socioeconomic differences in prevalence within regions and between countries, but overweight and obesity are seen in all industrialised and rapidly developing countries, with prevalence at least doubling (and almost tripling) in larger countries like the USA and Canada, Brazil and Chile, Australia and Japan and in Finland, Germany, Greece, Spain and the UK [77]. There are major difficulties in assessing and comparing studies due to the use of different definitions and methodologies, highlighting the need for collaboration and consensus so we can properly assess the relevance and association between reflux, overweight and obesity in children and adults.

Over the last 40 years, we have seen a worldwide increase in serving size, fast food availability and increased use of ready meals, with a likely decrease in eating at set times and much more eating 'on the go' with a likely increase in calorie (and fat) intake for many, given the trend in weights we are seeing in populations, but the absolute effect it has on GERD in children is unclear. There is clear evidence in adults that obesity and GERD are linked through several mechanisms: low baseline resting LESP, increased TLESR, elevated intragastric pressure and anatomical problems such as hiatus hernia, all culminating in worsening reflux. This chapter explores the current evidence for that causal relationship, the known mechanisms as they relate to obesity,

DOI 10.1007/978-3-642-11202-7_108

what long-term upper GI risks are associated with obesity, what specific paediatric evidence there is and what effects weight reduction and medical or surgical treatment might have on reflux management in children. Most current evidence comes from the adult literature and thus highlights the urgent need for effective studies in children.

Obesity and GERD Mechanisms: What's the Evidence?

Why they are linked is not completely known, but there are a number of likely factors which will all potentially contribute to reflux. Whether all are completely relevant to children is uncertain, as there is a lack of literature, but in adults there are six main aspects to consider:

1. *Lower oesophageal sphincter pressure* (*LESP*) *abnormalities*

   One group showed that basal LES pressure was not different to nonobese patients [58]. The relationship between BMI and LESP, however, has been demonstrated in many other studies in adults. In one study in morbidly obese patients, pre and post lap-band surgery subjects had lower basal LESP, with pressure under 10 mmHg identified as a risk factor for GERD and lower than those obese patients with normal acid exposure [30]. In several other studies, those with highest BMI had the lowest LESP, and the number with severe reflux symptoms was higher in the obese and overweight compared to those with normal BMI [15, 43, 67]. A further study in morbidly obese adults showed that those with lower LESP (18%, 59 of 345) were more likely to have symptoms (and abnormal pH and endoscopic oesophagitis) than those with normal pressure. These patients were also more likely to have a hiatus hernia (see section on HH) [72]. LESP was shown to be no different to normals in another study, but the gastroesophageal pressure gradient to LESP ratio was greater during inspiration and may help promote reflux despite no apparent LESP difference [52].

2. *Transient lower oesophageal sphincter relaxation* (*TLESR*) *and its associations*

   TLESR are integral to acid exposure of the oesophagus and independent of swallowing and resting LESP; the main trigger for TLESR is gastric distension, mediated by stretch receptors in the proximal stomach [27, 36, 82, 83]. In a study of three groups of 28 patients, there was a higher rate of TLESR in the overweight and obese groups within 2 h of a meal, and this was associated with greater acid exposure. LES zone shortening occurs in response to gastric distension, and LESP in normal BMI patients is decreased by fatty meals. TLESR correlate with increased BMI and, importantly in adults, waist circumference [82]. Abdominal obesity causes disruption of the GO junction by increased pressure from extrinsic gastric compression (visceral fat and surrounding adipose tissue) and resulting in an abnormal GO pressure gradient [14, 59]. Others demonstrated increased postprandial reflux in overweight and obese patients and showed that BMI and waist circumference were strongly associated with increased stimulation of stretch and tension receptors in the proximal stomach leading to more postprandial TLESR. There was a BMI dose response relationship [13, 59]. Meals eaten in less than 5 min compared to 30 min will increase that rate of TLESR [78]. We know that any type of meal will increase the frequency of TLESR. We know that LES pressure is decreased by fat; some argue that it is the level of fat in our diet (rather than obesity itself) that may drive reflux, but there is insufficient data to fully corroborate this [2].

3. *Hiatus hernia* (*HH*)

   HH is commonly associated with reflux and GERD and is more common in obese adult subjects. One study demonstrated HH in 181 of 345 obese patients (52.6%) [72]. The presence of endoscopic evidence of oesophagitis and HH was more common in obese patients in other studies [69, 79]. Other studies showed that HH is more common in those considered for bariatric surgery and showed that the hernia migrates upwards in those with raised intragastric pressure [71]. Pressure

studies at the GO junction demonstrated raised intragastric pressure, and the abnormal gradient from stomach to oesophagus was correlated strongly with increased BMI. Obese adults are more likely to have an HH, anatomical separation of the LES and crural diaphragm and a raised intragastric pressure during inspiration affecting the gastric pressure gradient, thus promoting upward movement of a hiatus hernia – again waist circumference was associated and independent of BMI, more in men than women [59, 71]. Anatomical changes were also described in obese patients who had computed tomography imaging for Barrett's and demonstrated a 1.5 times increase in adipose tissue in this area compared to controls; although it is an interesting observation, it has not been further explored [59].

4. *Oesophageal body motor abnormalities*

   Most evidence for this is in patients referred for bariatric surgery. Abnormal motility appears common in adults with obesity. Nonspecific motility and nutcracker changes are mostly described in one study (25.6%, 85 of 345) [14]. Manometry is often abnormal, two studies demonstrating obese patients with either nonspecific changes, nutcracker changes or a hypotensive LES. The majority, despite these results, didn't actually have any symptoms, suggesting abnormal visceral sensation in this group [33, 42]. This is much higher than in nonobese and in non-refluxing patients. Most studies in obese patients with GERD demonstrate nonspecific changes and a lower rate of oesophageal clearance of boluses on manometry [28].

5. *Gastric motor abnormalities*

   Gastric motor function and its contribution to GERD are observed using barostatic balloons. Distending pressure required to elicit symptoms was unsurprisingly higher than in lean healthy controls. This is likely another effect of central (truncal) obesity in that the volume required to reach minimal distending pressure (MDP) is elevated. There was also a difference in perception score in refluxers compared to non-refluxers and showed more sensitivity to proximal gastric distension in those subjects [32]. Gastric volume and emptying have been demonstrated as similar to controls, but it is suggested that appropriate satiety signals do not happen and intestinal absorption is greater, possibly through hormonal and autonomic dysfunction [81]. Others have looked at total gastric capacity by assessing maximum tolerated volume (MTV). Unsurprisingly, obese patients had significantly greater MTV than lean controls [21, 23, 31]. In children, an ultrasound study demonstrated a positive correlation of cross-sectional area of the antrum and higher BMI [3]. Gastric emptying (scintigraphy) evidence is actually very old, and studies are contradictory, with some showing accelerated emptying, others revealing no difference [29, 48]. Other studies suggest that obese patients have less high-volume low pH gastric contents after a prolonged fast, suggesting better emptying [25]. This may be important to look at further, as one might expect obese patients to have reduced emptying, suggesting that a large volume, full stomach under external pressure would lend itself to increased TLESR and increased reflux.

6. *Others potential factors*

   Visceral fat is associated with several disorders including diabetes, ischemic heart disease and malignancies. It is a metabolically active tissue and associated with lower levels of protective and pro-inflammatory cytokines, which are overexpressed in Barrett's and erosive oesophagitis, but further work into its effects on inflammation, or reduction in protection, need to be performed [74]. Oestrogen has also been postulated as a factor in women who are obese with GERD – two studies looked at this, but the results do not explain the sex and race differences we see in populations [55, 56].

What Are the Risks of Such Changes in the Obese Population?

Clearly the risk we face in paediatrics is of obese children becoming obese adults and what effect it has on developing truncal obesity and its consequences for diabetes, heart disease and cancers.

What is important about obesity and its association with the upper GI tract is the risk of reflux or other related symptoms, oesophageal erosions and oesophagitis and Barrett's oesophagus and of upper GI cancer, but is it all directly applicable to children? We actually do not really know and must assess the relationship in adult practice.

Most evidence points to a direct dose-dependent association between BMI and reflux [1, 4, 7, 11, 12, 24, 47, 53]. Although the majority of studies show correlation, some have shown no association of increased reflux symptoms and obesity [19, 46]. Positive studies include the ProGERD study in 6,215 patients which demonstrated higher BMI that was associated with more severe heartburn, regurgitation and erosive oesophagitis. This was more pronounced for regurgitation than heartburn, and, only in women, obesity correlated well with erosive oesophagitis [57]. Obesity and the presence of GERD have been looked at extensively using validated questionnaires, but evidence is of moderate strength. Others have looked at erosive oesophagitis, with the NHANES study amongst others demonstrating a positive association [64]. A review by El-Serag showed that there was a 1.5- to 2-fold increase in the risk of reflux disease and erosive oesophagitis and a 1.5- to 2.5-fold increase in cancer compared to those with normal BMI [11].

Studies looking at Barrett's oesophagus and obesity demonstrated mixed results with either no association or an increase in those with high BMI and reflux symptoms or a risk from those with a high BMI alone [22]. Other studies detail a positive association with abdominal girth (truncal obesity), a measurement that is not relevant to children. Abdominal diameter has been reported (not BMI) as a modest risk for Barrett's [5]. Other studies looking at the association of Barrett's and obesity in adults have been variable, with a high BMI and increased risk, to increased risk with the combination of high BMI and GERD symptoms or no risk [12, 22, 66, 68]. Overall, they seem to favour an association, and abdominal obesity was the key factor [9].

Obesity and adenocarcinoma appear to be the strongest association of all (based on recall of symptoms) within patients who have developed oesophageal adenocarcinoma, as opposed to squamous cancer of oesophagus or gastric cancer. This association, seen within studies looking at all three cancers, argues against recall bias but has certainly demonstrated an increased risk in some population-based studies with cancer case controls [6, 44, 45, 76]. Again, properly designed and powered prospective studies would be invaluable to better answer all these questions.

There appears to be no difference between adult males and females for reflux symptoms, but being male and Caucasian (compared to black and Asian males) appears to be a risk for oesophagitis, for Barrett's oesophagus and for oesophageal adenocarcinoma.

Specific Children's Studies: Obesity and Reflux

There are only a few studies in children looking at the association of obesity and GERD.

Størdal and colleagues looked at 872 Norwegian children (median age 10, 65 % male) with asthma (with 264 non-asthmatic controls, median age 10.5, 48 % male) using a validated GERD questionnaire and a derived symptom score, looking primarily at the relationship of reflux with asthma, but also assessing the relevance of BMI, and with a subgroup of 152 who had a pH probe. More asthmatics (21 %) were overweight compared to controls (10.8 %). Overall, asthma and obesity were significant predictors of reflux, but importantly, after further analysis, a dose effect seems likely for BMI; obese children (BMI over 30) and overweight children (BMI 25–30) were more likely to have positive symptom scores compared to controls (35 %, 22.6 % and 16.2 % in the controls). Of those with a positive pH result, there was significantly higher pH detected reflux rate in overweight children; 58 % were overweight, compared to 22 % of controls (OR 4.9) with or without asthma [70].

Elitsur and colleagues in the Eastern USA showed no evidence of increased reflux oesophagitis in overweight or obese children. This was a retrospective chart review of 738 patients (mean

age 10.6 years, with male-to-female ratio of 1.1:1) who had come for endoscopy, 345 (47 %) of whom were either overweight or obese. They used different definitions from the Norwegian study: those with BMI under the 85th percentile normal, 85–95th overweight and over 95th percentile obese. This study did not look at reported symptoms, only histology. There was no difference in histological findings of acid reflux disease in children who were either normal weight, overweight or obese [10].

Another Eastern American study prospectively recruited 236 obese patients (mean age 12.8 years, 45 % males) and with obese defined as BMI over 95th percentile for age and sex (196 patients) and further defined using z-score to define a group of severely obese children (40 patients with BMI z-score >2.7) from the specialist obesity clinic at their centre. They were evaluated using a standard reflux questionnaire and a derived symptom score and compared to an age- and sex-matched group of 191 children with BMI 5th–95th percentile. Similar to other studies, co-morbidities like neurological impairment, respiratory illness and motility disorders were not recruited. They showed that symptoms of heartburn and regurgitation were more common in severely obese compared to obese children and controls and were independent of other risk factors such as smoking or caffeine. An odds ratio (OR) of 7.4 was much higher than the Norwegian study (OR 1.6) and may have been due to the higher proportion of patients who were severely obese, and the study was of a selected obese population [60].

In another retrospective chart review from California, USA, Patel et al. looked at 230 patients (mean age 11.3 years, with 49.6 % male). Of the total, 67 (29.1 %) were above the 85th percentile for BMI (defined as overweight). The study included 51patients (22.2 %) who were scoped because of reflux symptoms. There was no increased prevalence of oesophagitis in the overweight compared to controls (23.9 % vs. 24.5 % controls), but those who were overweight and on medical therapy had evidence of significant histologic changes of reflux oesophagitis compared to overweight children not on medications (34.1 % vs. 7.7 %) [61].

Another group from the USA looked at children enrolled in a health plan between 2007 and 2008; in a population-based cross-sectional study looking at health records of 690,321 patients aged 2–19 years, they evaluated patients using a random sample of 480 children with ICD-9 code for GERD (530.1) from the clinical diagnosis made by clinicians either from history and symptoms or with additional investigations. BMI was assessed using CDC and WHO definitions. They showed that overall GERD was diagnosed in 1.5 % of boys and 1.8 % of girls. There was a slight increase in diagnosis in the non-Hispanic white population. It was not related to obesity in the 2–5-year-old group, but was in the moderately obese and obese 6–11-year-olds and in 12–19-year-olds with moderate (OR 1.16) and extreme obesity (OR 1.32) relating to a 30–40 % increased risk of GERD compared to those of normal weight. The effect was dose dependent and remained after taking helicobacter status, sex and ethnicity into account [41].

Overall, two prospective paediatric studies demonstrated some correlation of obesity with reflux (one with symptom score and pH, the other with the same symptom scoring methodology). Two further retrospective case note reviews looking at histology showed either no difference or only a difference in those overweight patients taking medications for reflux compared to those on none. It is clear that large well-designed and powered controlled studies are required to further define these issues. Koebnick's paper provides additional evidence that obesity is relevant to GERD. No studies appear to have looked at weight-reduction measures, either medical or surgical, in the detail required to draw any conclusions. Further work is clearly needed!

Clinical Implications: Medical Treatment and Operations for Reflux and Obesity

In a large review, the efficacy of lifestyle change in adults was assessed. They looked at evidence levels from 100 selected studies from a total of 2,039 patients between 1975 and 2004. Tobacco

and alcohol reduction and other factors such as specific caffeine, citrus, late evening meals, chocolate and spicy or fatty meals were not significantly associated with improvement in pH or in symptom improvement [37]. The only significant changes were the use of head of bed elevation and weight LESs [36]. A retrospective review of the use of proton pump inhibitors demonstrated similar healing rates of erosive oesophagitis in overweight compared to those of normal weight, suggesting there was no difference in treatment outcome with higher BMI [75].

Surgical Therapy for Reflux in Obese Patients

Surgical therapy and outcomes of reflux post-fundoplication will be dealt with in detail in the relevant chapter, but evidence in several adult studies suggests that obesity is not an indicator of worse outcome [16, 63, 80]. One group showed a high rate of post-op recurrence, correlating with increasing BMI (31 % in those with BMI ≥30, compared to 8 % with BMI 25–30 and 4.5 % in those under 25) [62]. Others have proposed that those with overweight (BMI under 30) might be candidates for fundoplication alone, those with higher BMI (class I, class II or class III) being considered for fundoplication or an anti-reflux bariatric procedure depending on level of BMI and co-morbidities [39].

What About Obesity Management as a Means of Reducing Reflux?

Some have demonstrated the negative effects on reflux when BMI increased by more than 3.5 from baseline (OR 2.8) [32]. Several studies have detailed the independent positive effect of weight LESs on reflux. One study showed those with BMI over 23 who then had a mean weight LESs of 4 kg had a reduction of 75 % from baseline, with a direct correlation of reduction in symptom score and weight LESs [17]. Others reported decreased upright and postprandial pH results in patients with mean weight LESs of 12.4 kg over 13 weeks [49–51]. Despite these positive studies, others show no symptom difference in those randomised to a low-calorie versus unrestricted diet in 20 patients with reflux oesophagitis who all achieved 10 % reductions in weight after 6 months [40]. Others looking at reflux in response to weight LESs in a gastric balloon study showed that a quarter of obese patients had reflux which seemed to improve with sham balloon treatment but was counteracted by actual balloon distension therapy which worsened LES and pH results despite weight LESs [49]. Because it appears favourable in managing reflux, the promotion of weight LESs in obese children would seem logical, given the health benefits it will bring to other systems. Putting this into practice is the challenge, and, again, proper research is necessary to evaluate such programmes.

Surgical Therapy for Obesity

Despite the apparent logic of weight-reduction programmes for obesity and reflux, there is a bigger literature on operative intervention – studies, however, are limited by lack of randomisation, selection differences and how improvements are assessed [1, 8, 18, 65, 73].

There are several procedures developed in adults for obesity:

- Laparoscopic gastric banding
- Roux-en-Y bypass
- Vertical banded gastroplasty
- Gastric balloon distention

Surgical therapy with Roux-en-Y bypass appears to be the most effective procedure in adults, as there is an anti-reflux component to this operation [34, 35, 67]. The ethical issues in children and adolescents have been discussed in two reviews of the current state of play [38, 73]. There is much controversy about the use of such procedures, and although they have been found to be successful in weight-reduction terms, they are clearly not without risks, and the quality of evidence for promoting surgery has been reviewed [54]. A more recent systematic review looked at

eight studies of lap banding in 345 patients (mean BMI 45.8) and Roux-en-Y bypass in six studies with 131 patients (mean BMI 51.8) with average patient age of 16.8 years (range 9–21 years) [73]. They concluded that there were significant and sustained reductions in BMI with both procedures, but evidence of improvement in diabetes and hypertension was at best moderate to weak and enrolment often poor for longer-term follow-up. Presence or changes in severity of GERD were not documented in any of the research. Complications were not insignificant with both lap banding and Roux-en-Y (the procedures where there is most experience), with significantly more severe problems post-surgery in the latter. The importance of pre- and postoperative psychological management was deemed mandatory, and the selection, centre where it is performed and the timing (after the post-pubertal growth spurt) of such procedures are crucial as are the important ethical issues, particularly in children and adolescents [20, 26, 38]. Clearly, more structured and robust research needs to inform the best practice in adults and children and where surgical options sit for obesity in refractory GERD (or its complications) and for other associated health complications. Other endoscopic techniques are emerging such as the Endo-sleeve which is placed in the duodenal bulb and prevents absorption in the duodenum as barrier of plastic material and can be removed when no longer needed endoscopically.

Conclusions and Recommendations

Most evidence we have is from the adult literature. Extrapolation of conclusions from adult data isn't ideal and may not be completely relevant, given that truncal girth seems to be much more relevant than BMI in adults and not in children. Paediatric evidence is scant and somewhat conflicting but would favour the association of obesity and reflux disease. Clearly many obese children become obese adults, so the issue is pertinent to paediatricians and for those transitioning patients to adult care. The suspicion of GERD in obese children should be investigated and treated appropriately and no differently to the nonobese population, but in the knowledge that it is likely to be more common in this group. Weight reduction is surely indicated, given its preventative benefits for other conditions (diabetes, cardiovascular risk and other malignancies) and almost certainly for reflux-related problems. Concerns about progression of GERD to Barrett's and the increased risk of malignancy in adult studies suggest (although seemingly more related to truncal obesity than BMI), make this an important group of children to study. The use of all available interventions needs to be properly assessed and policed! Operative intervention for what is a lifestyle and public health problem has to be carefully assessed. In many respects, the onus on an individual or family to address weight issues has been overtaken by the ability to operate – this is a significant ethical dilemma. Detailed and co-ordinated work should be considered to assess all aspects of associations and efficacy of treatments in overweight and obese children.

Children at High Risk for GERD: The Premature Infant

109

Taher Omari

Introduction

The functioning of the oesophagogastric junction (EGJ) as an anti-reflux barrier is very important to the developing neonate. Gastresophageal reflux (GER) occurs more frequently in the premature infants and term neonates than older children and is typically recognised as 'physiological GER', or benign feed-related regurgitation, which usually resolves spontaneously over time and is not necessarily symptomatic of GER disease (GERD) unless associated with co-morbidities such as failure to thrive, feeding difficulties, irritability in relation to feeding and respiratory complications, including exacerbation of chronic lung diseases and apnoea. GERD in the neonate is different to GERD in the older child and adults in whom chest pain or frequent 'heart burn' is a more common symptom and where long-term exposure of the oesophagus to acid and pepsin results in oesophagitis, dysmotility (e.g. abnormal peristalsis and poor LES tone) and anatomical changes (e.g. strictures, Barrett's oesophagus). Double-blind placebo-controlled trials have shown that, unlike older children, most infants with symptomatic GERD do not respond to acid suppression therapies [1, 2], suggesting that volume, rather than acidity of GER episodes, is the more problematic feature. Furthermore, typical 'GER-related' symptoms are not specific for GERD and may be due to other causes (e.g. allergy); therefore, the differentiation of symptoms due to GER and symptoms due to other causes is a significant challenge for accurate diagnosis.

The physiological mechanisms underlying triggering GER episodes are now well characterised. Most GER episodes are triggered by one mechanism, transient lower oesophageal sphincter relaxation (TLESR). At the present time, however, there are no safe treatments that directly target inhibition of triggering of TLESR.

Upper GI Motility in Infantile GERD

The occurrence of GER episodes and the exposure of the oesophagus to refluxate following the onset of GER are dependent on the motor mechanisms responsible for EGJ competence and oesophageal volume clearance. Factors that influence GER in the premature infant do so by altering these fundamental mechanisms. In infants, most GER episodes extend into the proximal

oesophagus and often exit the mouth; this is due to the frequent association of abdominal straining with GER and also the higher ratio of gastric volume to oesophageal volume.

Oesophagogastric Junction Competence

The EGJ controls flow of luminal contents between the oesophagus and stomach and comprises the smooth muscle lower oesophageal sphincter (LES) and the crural diaphragm (CD), which functions as an 'external' sphincter supporting the LES (Fig. 109.1a). The EGJ relaxes to allow swallowed food to pass and, in between swallows, is tonically contracted, providing a physical barrier against retrograde flow of gastric contents from the stomach into the oesophagus. The basal EGJ pressure fluctuates over time and during respiration (Fig. 109.1b). The CD is activated during the inspiratory phase of the respiratory cycle and during straining. LES tone varies over time dependent upon fed state and is influenced by many factors: postprandial CCK release, the migratory motor complex (MMC) and methylxanthine therapy to name a few examples. Hence, the measurement of EGJ pressure at a single moment in time may be poorly representative of the 'true' EGJ pressure profile.

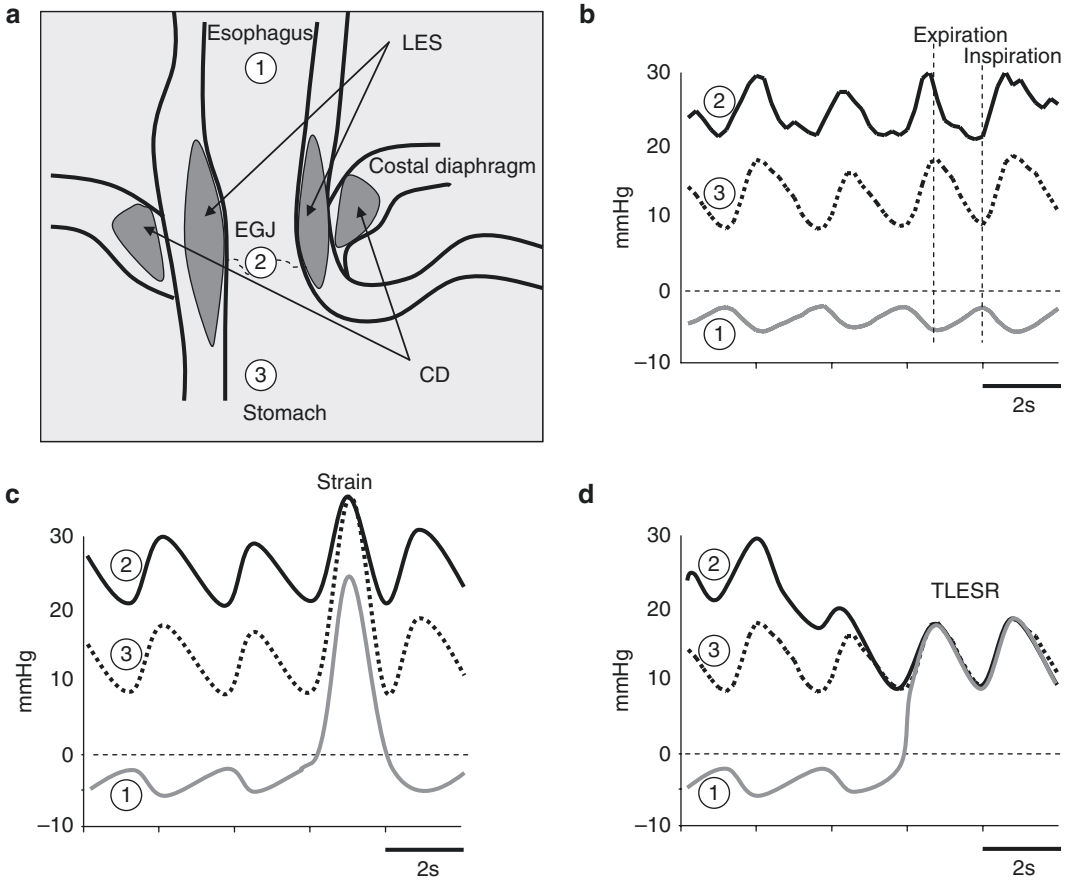

Fig. 109.1 (**a**) Anatomical configuration of the oesohagogastric junction (*EGJ*) and surrounding structures. The EGJ comprises the striated muscle crural diaphragm (*CD*) and smooth muscle lower oesophageal sphincter (*LES*). (**b**) Typical basal pressures across the EGJ. (**c**) Pressure changes typical of abdominal strain-induced reflux. Note that all pressures rise during the strain. (**d**) Pressure changes typical of TLESR-triggered reflux. Note pressures in the LES drop and oesophageal pressures rise, with both equalising to intragastric pressure

As there is a pressure gradient across the EGJ favouring retrograde movement of contents, oesophagogastric 'competence' refers to the ability of the EGJ complex to prevent GER. It is generally thought that an incompetent EGJ is indicated by a low (or poor) basal pressure. The magnitude of the abdominothoracic pressure gradient increases with inspiration and decreases with expiration and is significantly influenced by factors that increase intragastric pressure, such as abdominal staining, or decrease intra-oesophageal pressure, such as increase respiratory effort during airways obstruction. Whilst there is a prevailing view that premature infants have poor EGJ competence, this is in fact incorrect, as prolonged EGJ recordings using the Dentsleeve device have consistently demonstrated resting EGJ pressures in excess of 5 mmHg above intragastric pressure, even in very premature infants.

In the presence of a competent EGJ, GER can therefore only occur in circumstances of elevated intragastric pressure to levels over and above EGJ pressure (e.g. transient abdominal straining) (Fig. 109.1c) or a drop in EJG pressure to levels equal to intragastric pressure (e.g. discrete LES relaxation events) (Fig. 109.1d), the latter being more common.

EGJ Relaxation

Pharyngeal swallowing triggers both LES relaxation and initiates primary peristaltic oesophageal contractions, which can be measured as propagated pressure wave sequences. The onset of EGJ relaxation occurs with pharyngeal swallow, and the EGJ remains relaxed until the oesophageal peristaltic sequence reaches the EGJ, where upon EGJ pressure is reconstituted (Fig. 109.2). In neonates, the period of swallow-related relaxation is comparable to adults, and even very premature infants exhibit a well-developed pattern of swallow-related EJG relaxation [3–5]. Swallow-related EGJ relaxation is

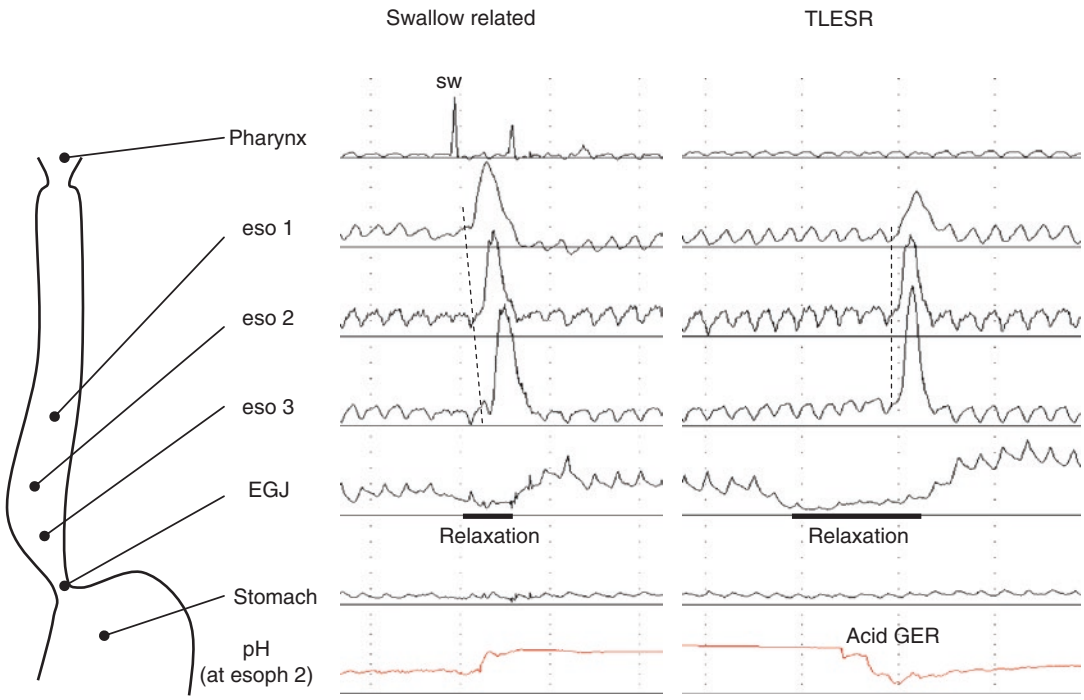

Fig. 109.2 Motility in relation to swallowing and TLESR. Note that the occurrence of pharyngeal swallow (*sw*) initiates primary peristalsis and EGJ relaxation (~3 s duration) triggering acid GER. TLESR is prolonged (~10 s duration), occurs without swallow and in this example triggers acid GER detected by a pH drop

not typically associated with triggering GER, unless associated with failure to initiate peristalsis [4, 6]. Preterm infants often demonstrate a pattern of 'multiple' swallowing, i.e. a sequence of two or more swallows <1 s apart. Such events cause a prolonged more complete relaxation of the EGJ and also inhibition of propagation of oesophageal peristalsis. As such multiple swallowing can be a mechanism of GER triggering.

In addition, the EGJ exhibits transient LES relaxation (TLESR) (Fig. 109.2) which, physiologically, is the mechanism that governs 'belching', venting gas from the stomach to prevent gastrointestinal bloating. TLESR is also the most common mechanism of triggering of reflux. TLESR occurs without pharyngeal swallowing and is prolonged in duration (usually >5 s) and more complete, usually to within 1 mmHg of intragastric pressure. TLESRs have been described in very premature infants and term infants and trigger 50–100 % of GER episodes [4–6].

TLESRs are mediated via a vagovagal pathway initiated by tension receptors located in the proximal stomach [7]. The vagal tension receptors have central terminals in the brain stem (nucleus tractus solitarius) which synapse with neurones of a central programme generator, which is sensitive to a number of other inputs relating to consciousness and body position [8, 9]. Several simultaneous outputs occur following achievement of threshold afferent stimulation of the pattern generator: firstly, the activation of dorsal vagal nucleus motor neurones which project to the LES and lead to smooth muscle relaxation via activation inhibitory motor neurones, and secondly, suppression of excitatory vagal output to the oesophageal body and phrenic nucleus output to the CD, leading to inhibition of peristalsis and inhibition of tonic contraction of the CD [7].

Although this reflex pathway is now well described, the mechanisms that regulate the type of GER (gas, liquid) appear to be more complex than mediated via the single gastric tension receptor reflex. More recent observations suggest that neuroregulatory mechanisms involved can selectively trigger gas over other types of reflux [10], and adult and infant GERD patients with reflux disease appear to selectively trigger more liquid than healthy controls [11, 12]. Also, the rate of gastric emptying, which should affect the degree and duration of gastric distension, does not correlate with triggering of TLESRs [13]. Indeed, recent studies of left/right positioning on gastric emptying and TLESR in infants have shown that right positioning accelerates gastric emptying but paradoxically increases triggering of TLESR [14, 15]. These recent observations, made in preterm infants, suggest that the current accepted model may be too simplistic as it ignores the possibility of secondary mechanisms that contribute to triggering of TLESR in response to luminal contents [16].

Oesophageal Volume Clearance

The motility of the oesophagus, comprising the upper and lower oesophageal sphincters and the oesophageal body, has now been well characterised in premature infants from 26 weeks of gestation to term.

Upper oesophageal sphincter (UES) pressure is generated predominantly by tonic contraction of the cricopharyngeus muscle. With swallowing, the cricopharyngeus muscle is inhibited producing relaxation. The UES is opened by the intrabolus pressure and the superior excursion of the hyoid and larynx [17, 18]. UES function has been investigated in premature infants at gestational ages as young as 33 weeks. In these infants, UES resting tone ranged from 2 to 28 mmHg, and the UES was found to relax appropriately in response to dry swallow [19]. In addition, the magnitude of UES resting pressure is dependent greatly upon the behavioural state with periods of apparent 'comfort' associated with significantly lower UES pressures than periods of activity and apparent 'discomfort' or abdominal straining [19]. Premature infants demonstrate a UES contractile reflex in response to oesophageal distension with air or liquids which demonstrates maturation in terms of stimulus threshold required to initiate the reflex [20–23].

Swallowing initiates primary peristaltic oesophageal contractions, which can be measured as pressure wave sequences propagated in an aboard direction along the length of the oesophageal body. Peristalsis in the premature infants is typically absent in the striated muscle (proximal) oesophagus [24]. However swallow-initiated peristalsis in the smooth muscle (distal) oesophagus has been recorded in the human premature infant down to 26 weeks of gestation [5] and term infants [6]. This peristalsis of the distal oesophagus is essentially *normal* in appearance (propagated following swallow in an abroad direction); however, the rate of propagation of the peristaltic wave is slower in younger premature infants [22]. Premature infants also exhibit spontaneous oesophageal body contractions that occur independently of the usual mechanisms (i.e. swallowing or oesophageal distension). These spontaneous contractions are usually *abnormal* in appearance (i.e. retrograde, synchronous or incomplete propagation) [3, 5, 6] but, being swallow independent, most probably do not appear to impair oesophageal function at least in the healthy infant.

Infusion of fluids and air into the oesophageal lumen triggers reflex secondary peristalsis and reflex swallowing in the premature infants which is volume dependent [20–23]. The mechanisms for clearing refluxate following a GER episode are therefore present and have been shown to effectively clear reflux volume from the oesophagus. Furthermore, the more proximal the reflux episodes, the more likely swallow will be initiated [14] which potentially protects the airway and assists in clearing.

Gastric Emptying

The presence of milk in the fundus stimulates gastric contraction that empties the milk into the duodenum. Gastric emptying is biphasic, i.e. a rapid linear phase which is then followed by a slower exponential phase. Feedback regulation of gastric emptying rate in response the duodenal nutrient infusion is exhibited by infants as young as 32 weeks gestation [25]. As in adults [26], increased caloric density of feeds slows gastric emptying [27, 28]. Studies in premature infants have shown that feed infusion inhibits antral motility and stimulates isolated pyloric pressure waves [29] which serve to regulate fluid flow across through the gastric outlet. The effect of gestational age on gastric emptying rate is not clear.

The relationship between gastric emptying rate and GER is poorly understood. Despite a widely held view that delayed gastric emptying exacerbates GER, there is no evidence of this. Indeed, whilst gastric emptying is most rapid when infants are positioned on the right side (pylorus down), this position is paradoxically associated with *more* GER [14–16], whilst left side positioning markedly delays gastric emptying but decreases GER. The effect of body positioning on GER is directly due to alterations of triggering of TLESR and therefore not simply a function of the location of luminal contents relative to the EGJ outlet (e.g. pooling of contents at the EGJ when positioned right side down). In adults, duodenal infusion of nutrients can trigger TLESR via a mechanism dependent on CCK release [30]. Rapid gastric emptying may therefore exacerbate GER via this mechanism. Alternatively there may be other mechanisms sensitive to the distribution of luminal contents. It has recently been shown that, in right side-positioned infants, TLESRs can be rapidly stimulated with infusion of very small volumes of feed; this interesting observation is difficult to reconcile against known mechanisms of TLESR triggering which rely on gastric distension and/or postprandial release of CCK [16].

Apnoea and Infantile GERD

Apnoea is a major problem in the premature infant, and apnoea is commonly considered to be caused by GERD, particularly if during feeding and/or it is resistant to methylxanthine therapy. Both the distension of the oesophagus during GER and mucosal contact with refluxate have been hypothesised to potentially cause apnoea. The oesophagoglottal closure reflex (initiated by

sensory nerve endings in the body of the oesophagus) is one of a number of reflex responses that can be initiated by oesophageal distension (i.e. GER boluses) that results in adduction of the vocal cords and narrowing of the interarytenoid space and, therefore, whilst providing protection to the airways, may also potentially cause apnoea [31]. An apnoea inducing laryngeal chemoreceptor reflex (LCR) has also been demonstrated in response to laryngeal infusion of water and saline. This is known to exist in human neonates as well as neonatal animal models [32–40] and is proposed as a mechanism of GER-induced apnoea. A direct causal link between GER episodes and apnoea triggering has been explored over many years, and with a variety of methodologies [32–57], the studies are highly inconsistent and, on balance, suggest that, should a causal relationship between apnoea and reflux exist, it is difficult to demonstrate. This is surprising in the light of the fact that the LCR is, in contrast, easily demonstrable in infants with apnoea, and, furthermore, there is clear evidence that as many as 80 % of bolus reflux episodes in infants extend upwards to the proximal oesophagus and pharynx [58].

The effects of stimulation of laryngeal afferent reflexes (such as the LCR) on upper GI tract function have not been studied in detail even though the superior laryngeal nerve (SLN) is the primary afferent neural pathway governing triggering of laryngeal afferent reflexes and the initiation of swallowing, oesophageal body peristalsis and LES relaxation [59]. It has been recently demonstrated that prolonged apnoea episodes (>20 s) in preterm infants are associated with swallowing and LES relaxation, and this appears to bare the hallmarks of LCR stimulation [60] (Fig. 109.3). During such events, the LES pressure preceding apnoea is too high to allow reflux to occur freely (Fig. 109.3). This is potentially clear evidence *against* GER being

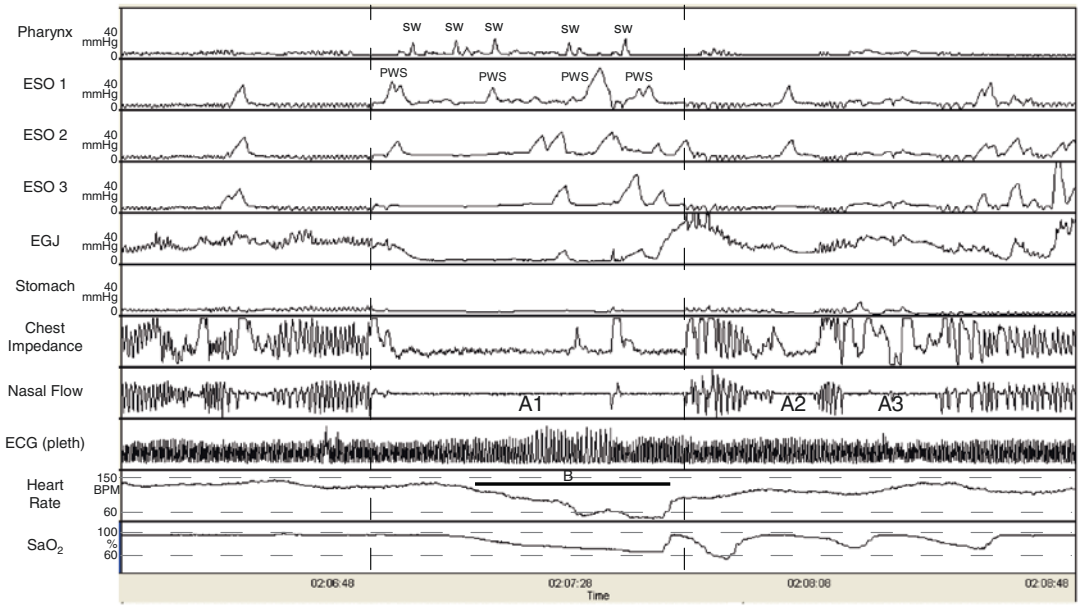

Fig. 109.3 A prolonged mixed apnoea episode (53 s) in a 35-week PMA premature infant. Most probably LCR mediated. The onset and offset of the apnoea episode (*A1*) are marked by *dotted vertical lines*. During the apnoeic period, five pharyngeal swallows (*sw*) occur; initiation of oesophageal PWSs also is apparent. EGJ pressure drops after the onset of apnoea and begins to recover approximately 5 s before the offset of apnoea. Bradycardia (**b**) occurs well after the onset of apnoea. Two additional apnoeic episodes also are apparent (*A2*, 6 s; *A3*, 15 s). Note that these shorter apnoeic episodes, despite causing hypoxia (80 % oxygen saturation), are not associated with swallowing, LES relaxation or bradycardia and thus are unlikely to be LCR mediated (Reproduced with permission Journal of Pediatrics [60])

the predominant trigger stimulus. However, the pattern of LES pressure drop *after* the onset of apnoea may increase the likelihood of reflux occurring in association with straining patterns such as those associated with airways obstruction and cough which are also commonly associated with LCR stimulation. Infants with apnoea unresponsive to methylxanthine therapies are often given anti-reflux therapy. If, however, apnoea is triggering reflux, it is unlikely that anti-reflux therapy will improve apnoea in these patients.

Whilst most studies that directly measure apnoea and reflux have been inconclusive, apnoea and GERD are nevertheless common comorbidities. The pathophysiology of apnoea is clearly complex; however, the main underlying mechanism of apnoea is immaturity or dysfunction of the mechanisms governing control of respiration by the central nervous system. The sites where respiratory and pharyngoesophageal reflexes are processed in the brainstem are very closely related both anatomically and functionally [61]. This neural architecture is essential, for example, for the inhibition of respiration during swallowing (apnoeic pause) to prevent aspiration. Furthermore, the gross neural pathway that regulates the LCR and swallowing involves the same neuroanatomical structures, i.e. involving the superior laryngeal nerve, the nucleus tractus solitarius and vagal efferent neurones (dorsal motor nucleus of the vagus nerve and nucleus ambiguous) [56]. Given the close relationship between neuroregulatory mechanisms governing respiration, apnoea and pharyngoesophageal reflexes, it follows that an immature respiratory pathway (causing apnoea) may correlate with immaturity of the pathways that govern swallowing, reflux triggering and reflux clearing. Hence, the two may be related, due to immaturity of common regulatory mechanisms, however not as 'cause and effect'. It may be possible to test this hypothesis by comparing triggering thresholds for the Santmyer swallowing reflex [62], the oesophageal secondary peristalsis reflex [20–22] and the TLESR reflex [16], in apnoeic infants and age-matched non-apnoeic controls.

Symptom-Based Diagnosis of Infantile GERD

GERD in infants is a complex disorder in terms of the range of clinical presentations, and many patients are diagnosed on 'clinical grounds' alone without further investigations. In most centres, diagnostic testing for GERD is limited to upper GI endoscopy and/or 24-h oesophageal pH monitoring, the former being inappropriate for premature infants, and conclusions based on the latter are heavily weighted on the identification of 'pathological' oesophageal acid exposure (% time oesophageal pH <4). More frequent milk feeding and resultant gastric pH buffering render most bolus reflux episodes 'non-acidic' (pH >4) but does not necessarily reduce TLESRs and reflux bolus overall (Fig. 109.4). Non-acidic reflux is undetectable using standard pH-based reflux detection criteria.

Twenty-four-hour multichannel intraluminal pH-impedance (pH-MII) allows detection of all bolus GER, including gas, mixed liquid-gas or liquid and acidic, weakly acidic or non-acidic GER. The enhanced detection of GER increases the potential for identifying GER as a cause of symptoms such as excessive irritability and crying, feed refusal, cough, apnoea, choking and gagging. Many of these symptoms are not specific to GERD [63] and can be due to other causes, such a food allergies/intolerances, infections or functional gastrointestinal disorders such as infantile colic or constipation [64]. With evidence now emerging that empirical prescription of acid suppression therapy to infants is largely ineffective and potentially harmful [1], more precise diagnostic testing offers the potential for anti-reflux therapy to be better targeted at patients in whom symptoms can be demonstrated to be due to acid GER and/or bolus GER.

Current guidelines from North American Society for Pediatric Gastroenterology, Hepatology and Nutrition and the European Society for Paediatric Gastroenterology, Hepatology and Nutrition [65] advocate the use of pH-MII for the investigation of symptoms such as unexplained crying and/or distressed behaviour, apnoea and apparent life-threatening

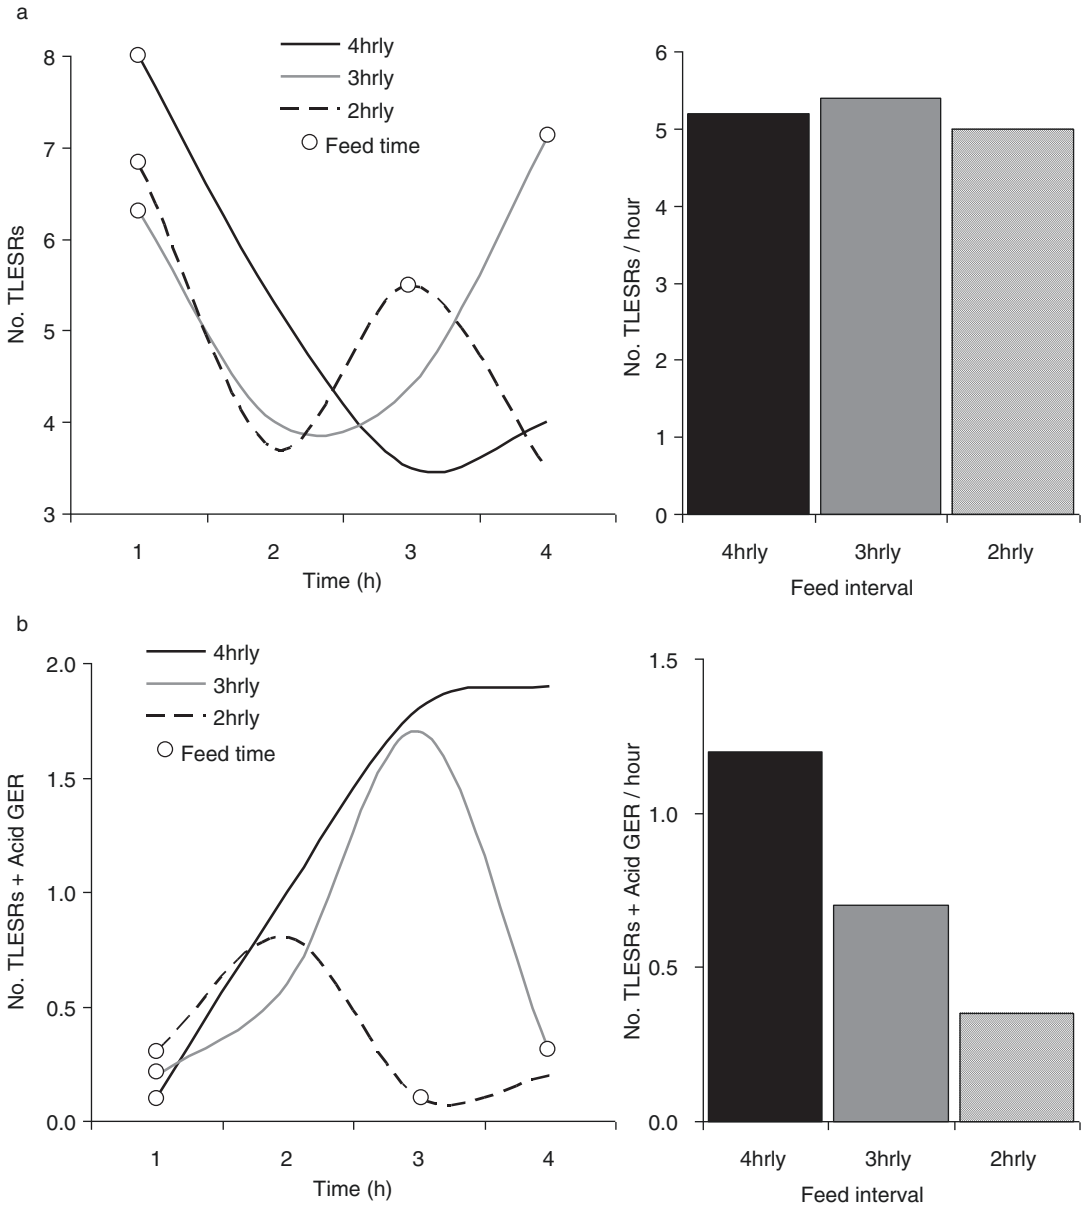

Fig. 109.4 Effect of feeding frequency on the number of TLESRs recorded over a 4 h period. (**a**) As feeding stimulates TLESRs via gastric distension, there is no net effect of more frequent (lower-volume) feeding on the number of TLESRs overall. (**b**) As feeding buffers gastric pH, there is a reduction in the number of TLESRs that trigger GER with refluxate pH in the 'acidic' range (pH <4)

events. Studies in infants, children and adults [5, 6] have characterised the impact of GER episode detection by pH-MII monitoring on diagnosis of GER-symptom associations. When compared with pH-metry alone, pH-MII has been consistently shown to increase the yield of patients in whom a positive GER-symptom association can be demonstrated [66]. The degree of GER-symptom association is best defined using symptom association probability (SAP) which is derived from the statistical probability (P) that GER episodes and symptoms are temporally

related using a Fisher exact test (SAP = [1 – P]*100) [67]. The reported strength of the SAP is that it takes into account the number of time intervals with associations, the number of non-associated intervals (reflux or symptom) and the number of 'empty' intervals (neither reflux nor symptoms). The SAP is therefore less likely to be influenced by the overall number of symptoms/reflux episodes.

Despite what appears to be an improvement in diagnostic methodology, all prolonged 24h reflux monitoring studies need to be interpreted in the context of the vagaries of such tests as currently applied. Firstly, the test assumes that symptoms occurring following reflux are *caused* by reflux; this relationship is yet to be proven by way of outcome studies showing that a high SAP can predict of symptomatic improvement with anti-reflux therapy. Furthermore the tests are far from perfect, and the reliability of the findings are heavily influenced by the diligence of individuals charged with the task of marking symptom episodes when they occur and those responsible for pH-impedance analysis which (in the author's experience) suffers from poor interrater reproducibility across different centres. The standard GER-symptom association interval used is 2 min and was originally based on investigations of heartburn symptoms in adults [67]. However, the optimal time window may be influenced by both the time from reflux to the onset a symptom and the time required to press an event button having noticed the symptom. Some symptoms may be missed entirely or marking significantly delayed due to preoccupying factors. Whilst synchronous video monitoring would enable a more accurate assessment of behaviours associated with onset of GER episodes in infants [68], this approach is unavailable in most centres and is very time consuming in analysis.

Therapy for Infantile GERD

When faced with a premature infant with a reflux-related problem, non-pharmacological therapy can help, and in many cases, symptoms will improve with time and development without intervention. Elevation of the head of the bed, antacids and feed thickeners are usually recommended. Of these measures, feed thickeners have been shown to significantly reduce the incidence of regurgitation and impedance-detected bolus reflux [69, 70]. More frequent lower-volume feeding is a measure that reduces the acidity of bolus reflux; however, it does not reduce bolus reflux overall (Fig. 109.4). The evidence for antacids and cot elevation is largely anecdotal; however in older infants, a range of non-pharmacological therapies in combination (including use of hypoallergenic formulas) does appear to reduce reflux symptoms [71].

In contrast to non-pharmacological approaches, medical therapies for GERD are largely untested in the premature infants. Currently proton pump inhibitor (PPI) therapy is widely used; however, there is little evidence showing that acid suppression reduces reflux-related symptoms, unless use is guided by evidence of extreme levels of oesophageal acid exposure [72]. Other approaches to GERD include pro-motility agents such as cisapride, metoclopramide or erythromycin which improve oesophageal volume clearance, LES pressure and/or gastric emptying, but their effects on reflux are largely unproven and side effects are common and problematic [73–76]. The GABA(B) agonist baclofen has been shown in older children to reduce reflux by inhibiting TLESRs [77]; however, common side effects such as respiratory depression preclude use in premature infants. The compound (R)-(3-amino-2-fluoropropyl) phosphinic acid (Lesogaberan) has recently been described [78]. Lesogaberan is a peripherally acting GABA(B) agonist with an equivalent action to baclofen but potentially with fewer side effects [79, 80]. This therapeutic approach may have significant clinical utility in that it reduces bolus reflux, something that PPI therapy is incapable of doing [72]. The potential to use a combination of PPI and reflux inhibitor therapies, particularly in infants with high oesophageal acid exposure and a positive symptom-reflux association, is tantalising; however, there are no safety data presently available to predict if reflux inhibitor therapies targeting TLESRs will be safe to use in infants.

As previously described, left side body positioning reduces reflux by reducing triggering of TLESRs and moving gastric contents away from the EGJ [81]. Although left-side positioning also slows gastric emptying, there is no evidence of gastric emptying time contributing to infantile GERD [14]; indeed slower emptying may potentially be an *advantage* as it may prolong acid buffering, improve infant satiety and reduce the postprandial release of CCK which may further reduce reflux through reduced TLESR triggering. As this is the case, left-side body positioning may have some therapeutic potential. Whilst the risk of accidental rolling to the prone position when on the left side precludes use of this approach in older infants in the community (due to contraventions of SIDS safe guidelines), this is less of a concern in hospitalised premature infants who are closely monitored as a routine.

Part XIX

The Stomach

Embryology of the Stomach

110

Mike Thomson

Function of the Stomach

The stomach, as a J-shaped dilation of the alimentary canal, is continuous with the oesophagus proximally and the duodenum distally. Its functions primarily include the bulk storage of undigested food, mechanical breakdown of food, disruption of chemical bonds via acids and enzymes (pepsin) and production of intrinsic factor, allied with very little absorption of nutrients.

The stomach releases its contents in a controlled fashion to accommodate the much smaller capacity of the duodenum. The stomach volume ranges from about 30 ml in a neonate to 1.5–2 l in adulthood [1].

Embryology of the Digestive Tract

During the embryological period, the digestive tract is divided into segments based on vascular supply:

- Foregut (oesophagus, stomach, part of duodenum, biliary apparatus) is supplied by the celiac artery.
- Midgut (rest of small and large bowel up almost to the splenic flexure) is supplied by the superior mesenteric artery, and the hindgut (rest of large bowel to superior part of anal canal) gained its blood supply from the inferior mesenteric artery. The foregut derivatives are the pharynx and its derivatives, the lower respiratory tract, the oesophagus, the stomach, the duodenum as far as the entrance of the common bile duct, the liver, the pancreas and the biliary apparatus. All except for the pharynx, respiratory tract and upper oesophagus are supplied by the celiac artery

The foregut extends from the buccopharyngeal membrane to the duodenum. It is initially located in the median sagittal plane and is attached by mesentery to the anterior and posterior abdominal walls [2, 3].

During the solid stage of development, the endoderm of the gut tube proliferates until the gut is a solid tube. A process of recanalization restores the lumen.

Embryology of the Stomach

In the middle of the fourth week, a fusiform dilatation appears in the caudal part of the foregut that indicates the site of future stomach. It links the pharynx to the primitive midgut. The dilatation oriented in the midline enlarges and broadens ventrodorsally (Figs. 110.1 and 110.2). By the fifth and sixth week, the dorsal border grows

DOI 10.1007/978-3-642-11202-7_110

much faster and forms the greater curvature, whereas the ventral border forms the lesser curvature. Two positional shifts bring the stomach to its adult configuration. By the seventh to eighth week and as stomach enlarges, it slowly rotates 90°, clockwise around its longitudinal axis. As a result, the ventral border moves to the right and the dorsal border to the left with the right side becoming the dorsal surface and the left side becoming the ventral surface. Initially the two ends of the stomach lie in the midline. During rotation, the cranial end moves to the left and slightly ventrally, and the caudal end moves to the right and dorsally [4].

The early stomach is suspended from the dorsal body wall by a portion of the dorsal mesentery called the dorsal mesogastrium. It is connected to the ventral body wall by a ventral mesentery that also encloses the developing liver [4].

Since the stomach is attached to the dorsal body wall by the dorsal mesogastrium and to the ventral body wall by the ventral mesogastrium (Fig. 110.3), its rotation and disproportionate growth alter the position of these mesenteries. Rotation about the longitudinal axis pulls the dorsal mesogastrium to the left, creating a space behind the stomach called the omental bursa (lesser peritoneal sac) (Figs. 110.3, 110.4, and 110.5). This rotation also pulls the ventral mesogastrium to the right. As this process continues in the fifth week of development, the spleen primordium appears as a mesodermal proliferation between the two leaves of the dorsal mesogastrium (Figs. 110.3 and 110.4). With continued rotation of the stomach, the dorsal mesogastrium lengthens, and the portion between the spleen and dorsal midline swings to the left and fuses with the peritoneum of the posterior

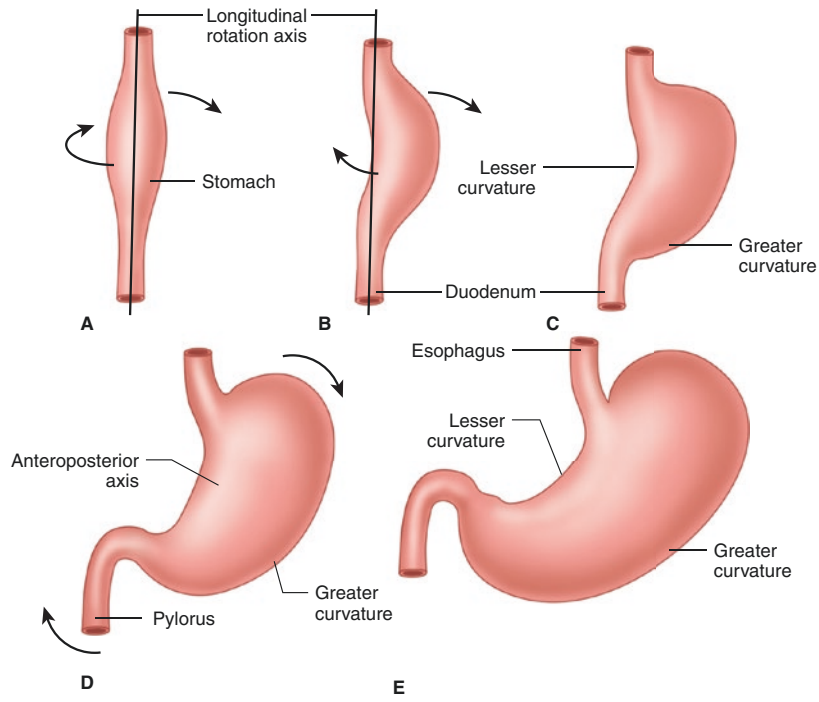

Fig. 110.1 Rotation of the stomach. (**a**–**c**) Rotation of the stomach along its longitudinal axis as seen anteriorly. (**d**, **e**) Rotation of the stomach around the anterior axis. Note the change in position of the pylorus and cardia

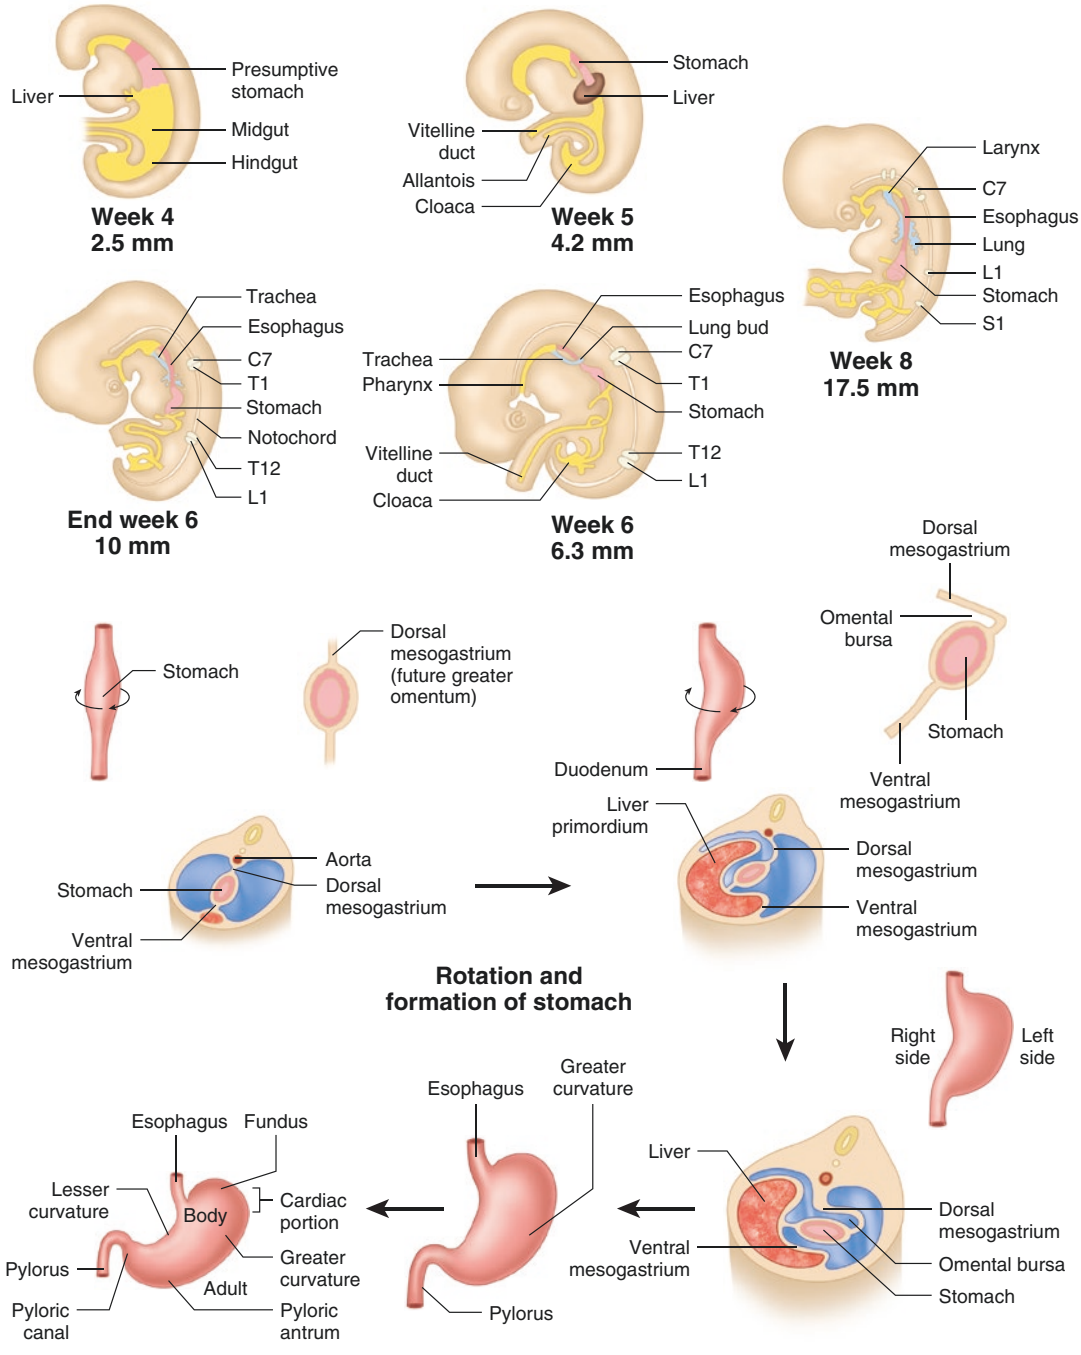

Fig. 110.2 Embryology of stomach

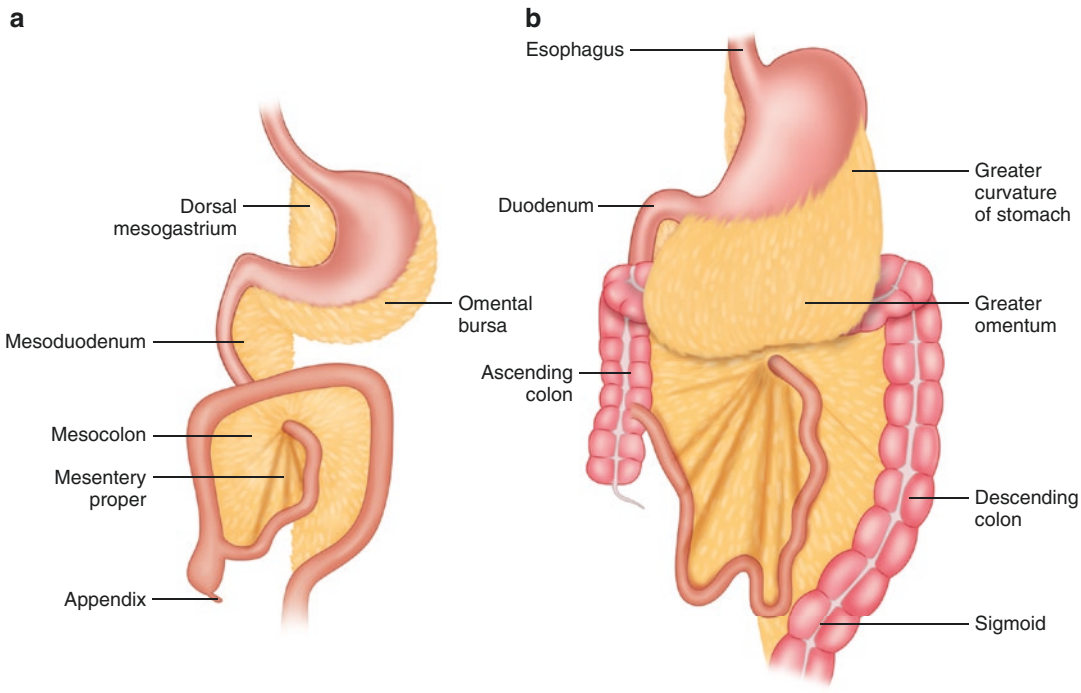

Fig. 110.3 Dorsal mesentery derivatives. (**a**) Derivatives of the dorsal mesentery at the end of the third month. The dorsal mesogastrium bulges out on the left side of the stomach, where it forms part of the border of the omental bursa. (**b**) The greater omentum hangs down from the greater curvature of the stomach in front of the transverse colon

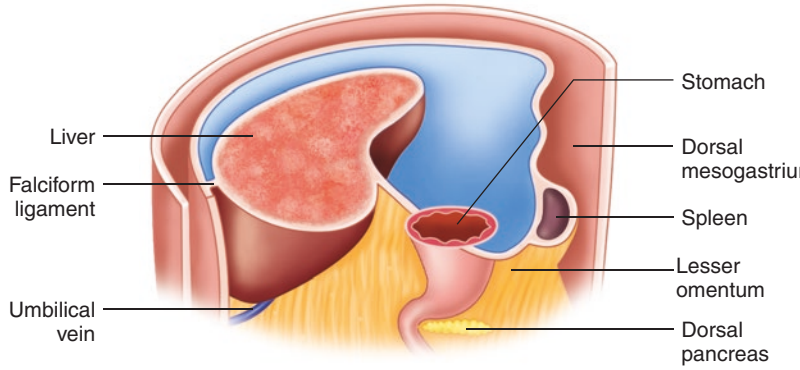

Fig. 110.4 Coronal view through the stomach and mesenteries. Transverse sections through the region of the stomach, liver and spleen, showing formation of the omental bursa (lesser peritoneal sac), rotation of the stomach and position of the spleen and tail of the pancreas between the two leaves of the dorsal mesogastrium. With further development, the pancreas assumes a retroperitoneal position

abdominal wall (Figs. 110.3 and 110.4). The posterior leaf of the dorsal mesogastrium and the peritoneum along this line of fusion degenerate. The spleen, which remains intraperitoneal, is then connected to the body wall in the region of the left kidney by the lienorenal ligament and to the stomach by the gastrolienal ligament [5].

The events also explain the vagal innervations of the stomach: the right vagus nerve innervating

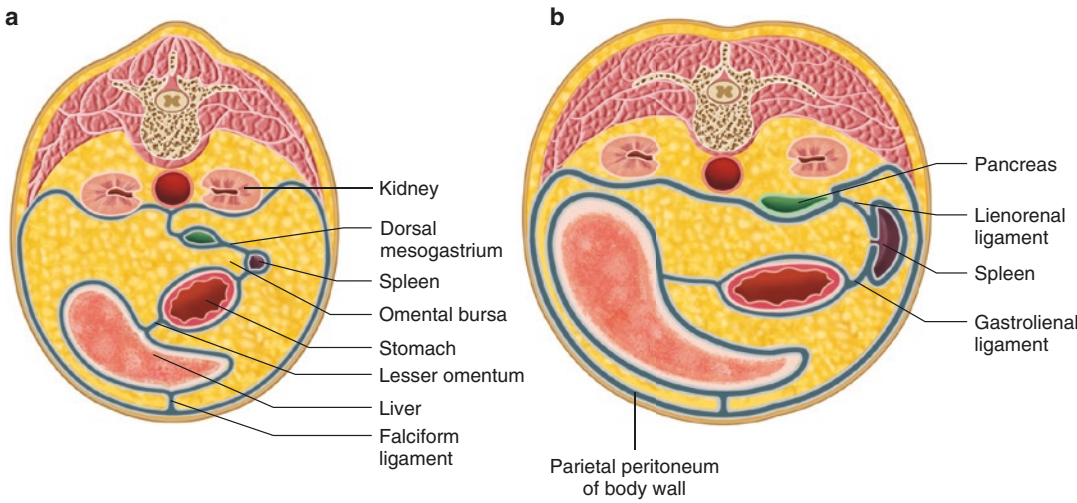

Fig. 110.5 Transverse section through the stomach showing the formation of omental bursa

the posterior stomach wall (the primordial right side) and the left vagus nerve innervating the anterior wall [6].

Position of the Stomach

With the development of the oesophagus, the proximal end of the stomach migrates caudally through the following vertebral levels: C2 (at week 4), T2 (at week 6) and T10 (at week 8). The caudal shifting of the entire foregut comes to an end with the formation of the diaphragm and the resulting fixation of the oesophagus-cardia passage as well as the formation of the vessel-pancreas-stalk at the level of the duodenum. At 12 weeks, the cardia is fixed at the level of T11, and the pylorus is fixed at the level of L1 as a result of the duodenal development and fusion of the posterior peritoneum [7].

The gastroesophageal orifice is the most fixed part of the stomach. The fundus fits into the curve of the left dome of the diaphragm. The pyloric part is very mobile. The greater curvature may even enter the true pelvis and forms the left lower stomach border, whereas the lesser curvature forms the right upper border. Posteriorly, portions of the pancreas, transverse colon, diaphragm, spleen and apex of the left kidney and adrenal gland bound the stomach. The posterior wall of the stomach actually comprises the anterior wall of the omental bursa or lesser peritoneal sac. Anteriorly the liver bounds the stomach, whereas the inner aspect of the anterior abdominal wall bounds the anterior left lower aspect. The stomach lies on a variable visceral bed that includes the diaphragm, pancreas and transverse mesocolon. Posterior gastric ulcers may involve the pancreas and the splenic artery, resulting in severe pain and bleeding.

The stomach is completely invested by peritoneum, except for a small bare area at the gastroesophageal junction. This peritoneum passes as a double layer from the lesser curvature to the liver as the gastrohepatic portion of the lesser omentum and then hangs down from the fundus and greater curvature as the greater omentum, extending to the transverse colon (as the gastrocolic ligament), spleen (as the gastrosplenic ligament) and diaphragm (as the gastrophrenic ligament).

Stomach Parts

The stomach is divided into four regions that can be defined by anatomic or histologic landmarks. Anatomically the cardia is a small ill-defined area of the stomach immediately adjacent to its junction with the oesophagus. The fundus projects upwards, above the cardia and

gastroesophageal junction. This dome-shaped area of the stomach is its most superior portion and is in contact above with the left hemidiaphragm and to the left with the spleen. The body, or corpus, the largest portion of the stomach, is located immediately below and continuous with the fundus. The incisura angularis, a fixed, sharp indentation two thirds of the distance down the lesser curvature, marks the caudal aspect of the gastric body. The gastric antrum extends from its indistinct border with the body to the junction of the pylorus with the duodenum. These gross anatomic landmarks correspond roughly with the mucosal histology because antral mucosa (pyloric gland mucosa) actually extends from an area on the lesser curvature somewhat above the incisura. The caudal end of the stomach is physiologically separated from the small intestine by the muscular pyloric sphincter [8].

The Tissue Layers

The luminal surface of the gastric wall forms thick, longitudinally oriented folds, or rugae, that flatten with distention. Four layers make up the gastric wall: mucosa, submucosa, muscularis propria and serosa (Fig. 110.6).

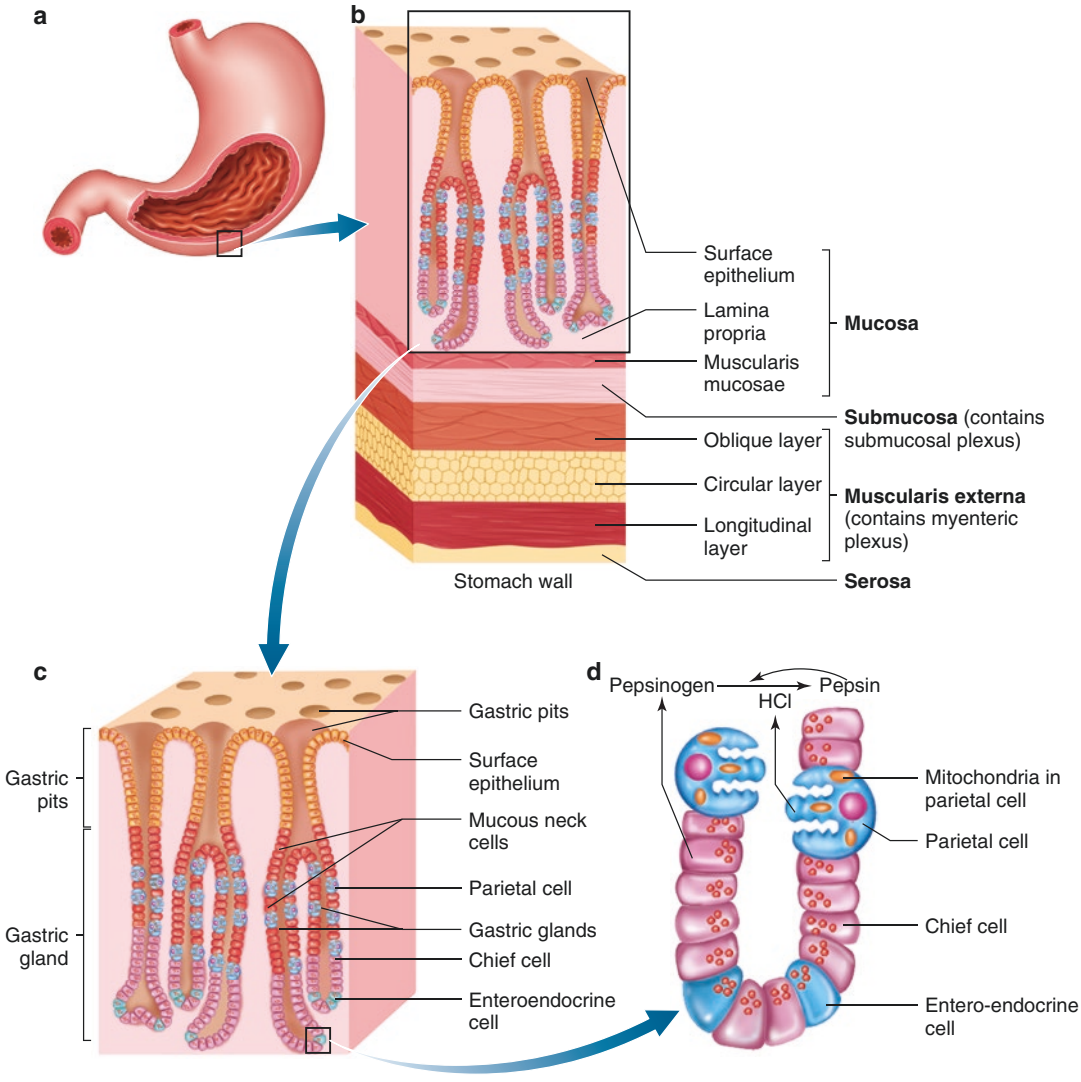

Fig. 110.6 Histology of the gastric gland

Mucosa lines the gastric lumen, appearing as a smooth, velvety blood-filled lining. The mucosa of the cardia, antrum and pylorus is somewhat paler than that of the fundus and body. It is within the gastric mucosa that most of the functional secretory elements of the stomach are located.

The submucosa, immediately deep to the mucosa, provides the dense connective tissue skeleton of collagen and elastin fibres. Lymphocytes, plasma cells, arterioles, venules, lymphatics and the submucosal plexus are also contained within the submucosa.

The third tissue layer, the muscularis propria, is a combination of three muscle layers: inner oblique, middle circular and outer longitudinal. The inner oblique muscle fibres course over the gastric fundus, covering the anterior and posterior aspects of the stomach wall. The middle circular fibres encircle the body of the stomach, thickening distally to become the pyloric sphincter. The outer longitudinal muscle fibres course primarily along the greater and lesser curvatures of the stomach. The final layer of the stomach is the transparent serosa, a continuation of the visceral peritoneum. Connective tissues and smooth muscle are derived from splanchnic mesoderm.

Histological Differentiation of the Stomach

The gastric epithelium including hormone-secreting specialised gastrointestinal cells, gastric pits and gastric glands are derived from the foregut endoderm. The muscular walls of the stomach (lamina propria, muscularis mucosae, submucosa, muscularis externa, adventitia and/or serosa) are derived from splanchnic mesoderm.

At the histological level, development of fetal gastric mucosa occurs very early during fetal life. Between 11 and 17 weeks, the stratified surface of epithelium is replaced by a simple layer of columnar epithelial cells. The surface mucus cells, which are similar throughout the stomach, produce mucus. Mucus, along with bicarbonate, is luminal cytoprotection from acid, pepsin, ingested substances and pathogens.

The first pit/gland structures are observed at 11–12 weeks of gestation. When the surface epithelial lining invaginated by gastric pits, or foveolae, that provide the gastric glands access to the gastric lumen. The gastric mucosa is organised in vertical tubular unit consisting of an apical pit region, and isthmus, and the actual gland region that forms the lower part of the vertical unit (Fig. 110.6). The progenitor cell of the gastric, which is localised in the isthmus, gives rise to all epithelial cells. The mucus-producing pit cells migrate up towards the gastric lumen, and acid-secreting parietal cells (oxyntic migrate downwards to the middle and lower regions of the gland. Chief (zymogenic) cells secrete pepsinogen and predominate at the base of the glands. Neuroendocrine cells, including enterochromaffin cells (serotonin), enterochromaffin-like cells (histamine) and D cells (somatostatin), are also present at the base of the gland [8].

The gastric glands of different anatomic regions of the stomach are lined with different types of specialised epithelial cells, allowing for differentiation of these regions by type of gastric gland.

The stomach's most proximal region, the cardia, is a small transition zone from oesophageal squamous epithelium to gastric columnar epithelium. The cardiac glands are mostly populated by mucus-secreting or endocrine cells. The cardiac pits are irregular and shallow; the ratio of the lengths of pit to gland is approximately 1:1.

There is a gradual transition from cardiac glands to the second region, the acid-secreting segment of the stomach. This region encompasses the gastric fundus and body and contains the oxyntic glands. These glands are long and deep with straight pits. The ratio of the length of pit to glands is approximately 1:4. It has parietal (oxyntic) cells that secrete hydrochloric acid and intrinsic factor, chief (zymogen, peptic) cells that secrete pepsinogen, endocrine cells and mucus neck cells. Of note glands become functional and secrete HCl and enzymes at 8–9 months of gestations.

The final region, corresponding to the antrum and pylorus, contains the pyloric glands, composed of endocrine cells, including gastrin-producing G cells and mucus cells. The glands here are characterised by deep pits but short glands, with a pit to gland ration close to 1:1.

Mucus is also secreted along with bicarbonate, by the surface mucus cells between glands. Surface mucus cells secrete neutral mucus, rather than sulphated mucus separated by mucus neck cells, which reside in close proximity to parietal cells. The surface mucus cells are cytoprotective, whereas the mucus neck cell functions as a stem cell precursor for surface mucus parietal, chief and endocrine cells [9].

Blood Supply

Gastric blood vessels are derived from the splanchnic mesoderm. The arterial blood supply of the stomach is from the celiac trunk: (1) the right gastric (from the hepatic) and left gastric arteries run along the lesser curvature; (2) and the right gastroepiploic (derived from the hepatic) and left gastroepiploic and short gastric (from the splenic) arteries course along the greater curvature. The venous drainage of the stomach generally accompanies the arterial supply. The veins empty directly or indirectly into the portal vein. The connections between the left gastric and oesophageal veins are important portal-systemic anastomoses (Fig. 110.7).

Lymphatic Drainage

Most of the lymphatic drainage of the stomach eventually reaches the celiac nodes after passing through intermediary lymph nodes. Lymphatic plexuses drain into regional nodes that accompany the arteries and end ultimately in the thoracic duct. Hence, carcinoma can spread (1) to the liver (2), to the pelvis by retroperitoneal lymphatics and (3) to the rest of the body by veins and by the thoracic duct.

Innervation

Autonomic nerve plexuses, submucosal and myenteric, differentiate from the neural crest. The stomach receives innervation from several sources: (1) sympathetic fibres are derived from preganglionic

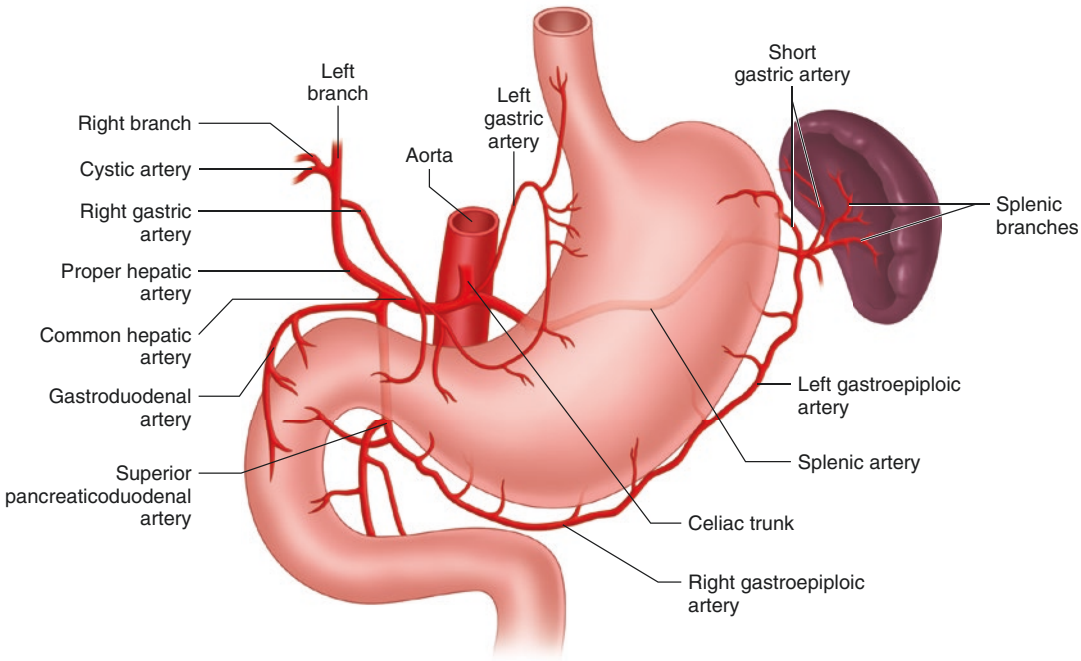

Fig. 110.7 Blood supply to the stomach

fibres arising predominantly from T6 to T8 spinal nerves, via the splanchnic nerves and celiac ganglion (synapse) supply blood vessels and musculature; (2) parasympathetic fibres from the medulla travel in the right and left vagus nerves, which form the distal oesophageal plexus, and (3) sensory vagal fibres include those concerned with gastric secretion. Both vagal nerves give rise to multiple gastric branches to the stomach wall, where the preganglionic fibres synapse with the ganglion cells in the submucosal (Meissner's) and myenteric (Auerbach's) plexuses. From these plexuses, postganglionic fibres are distributed to secretory components including cells and glands and to motor components such as muscle [10].

Normal and Pathologic Mucosa

111

Marta C. Cohen

Normal Mucosa

The four regions of the stomach are the cardia, fundus, body, and antrum. Throughout the stomach, the wall is organized in four layers: mucosa, submucosa, muscularis propria, and serosa.

The gastric mucosa has a superficial layer of columnar mucus-secreting cells that contains foveolae (pits) where deep-seated coiled glands open (Fig. 111.1) [25]. The foveolae, also lined by the superficial columnar mucus-secreting cells, correspond to invaginations of the surface epithelium. They are wider in the antral mucosa (proximal to the pylorus) where at times adopt a slightly villous appearance (Fig. 111.2).

The columnar cells from the superficial mucosa depict basal located nuclei with an inconspicuous nucleoli and clear apical cytoplasm that contain neutral mucins which are positive with periodic acid-Schiff (PAS) stain [13, 14, 25]. The coiled glands are immersed in the loose connective tissue that constitutes the lamina propria, which extends between the muscularis mucosae and the more superficial foveolae.

In the different areas of the stomach, the foveolae show subtle different features, and the deep glands diverge in function and histological appearance:

Cardia

This is the most proximal anatomic region of the stomach. It is situated immediately distal to the esophagus and is characterized by the presence of mucinous surface epithelium with underlying mucus-type or mixed mucus/oxyntic-type glands (Fig. 111.3) [19]. Traditionally, the cardia has been described as a 1–2-cm normal structure present at birth and with no definite anatomical limit with the gastric body [13]. However, it has recently been proposed that while the normal anatomic cardia may be comprised of pure oxyntic-type mucosa, the mucus-type glands develop as a metaplastic event and are an histologic manifestation of gastroesophageal reflux [4–7]. However, studies conducted in pediatric patients and our own experience show that cardia mucosa is frequently present in the proximal stomach with underlying loosely packed pure mucus-type or mixed mucus/oxyntic-type glands [11, 14, 19]. The mucus-type glands occupy approximately one half of the mucosal thickness and secrete predominately neutral mucin with a minimal quantity of sialomucins (Fig. 111.4) [13, 18, 25]. Although the cardia glands can

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,

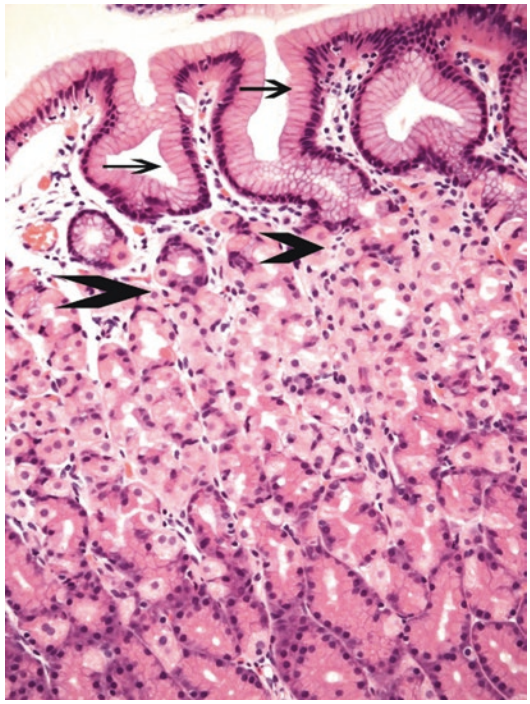

Fig. 111.1 Normal fundic-type gastric mucosa depicting a superficial layer of columnar mucus-secreting cells containing foveolae (*arrow*) where deep-seated glands open (*arrow head*) (H & E × 20)

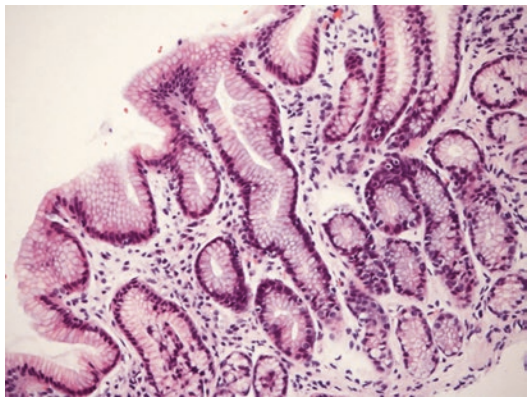

Fig. 111.2 The foveolae (pits) are wider in the antral mucosa (proximal to the pylorus) where at times adopts a slightly villous appearance (H & E × 10)

occasionally contain parietal cells, they do not usually include chief cells [14]. A rather unusual finding is the presence of ectopic intestinal mucosa or pancreatic acinar tissue in the cardia, described in a small percentage of infant postmortem examinations [14].

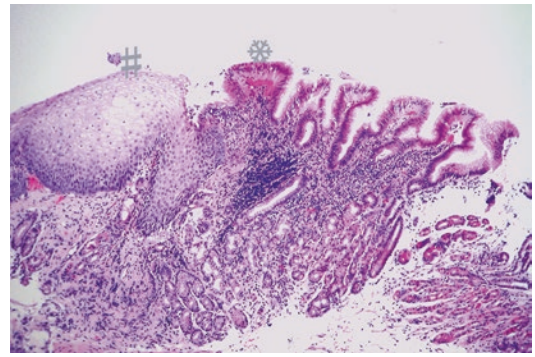

Fig. 111.3 The gastric cardia, situated immediately distal to the nonkeratinizing squamous mucosa of the esophagus (#), is characterized by the presence of mucinous surface epithelium with underlying mucus-type or mixed mucus/oxyntic-type glands (*) (H & E × 10)

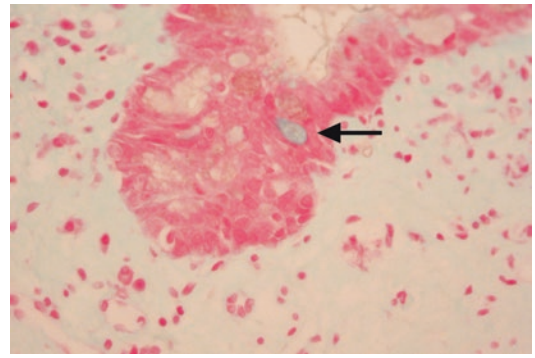

Fig. 111.4 The cardiac mucus glands secrete predominately neutral mucin with a minimal quantity of sialomucins (*arrow*) (Alcian blue pH 2.5 stain, × 40)

The different views expressed by adult and pediatric pathologists regarding the existence or not of the cardia-type mucosa could be explained by the inverse correlation between age and length of cardiac mucosa ($p = 0.005$) [11].

Fundus

The gastric fundus corresponds to that part of the body (corpus) that is adjacent to the cardia and bulges above it [14]. In comparison with the slightly villiform feature of the cardia and antral mucosa In comparison with the slightly villiform features of the cardia (Fig. 111.3 and 4) and antral mucosa (Fig. 111.2), the fundic foveolae (Fig. 111.1) appear, the fundic foveolae appear more flat,

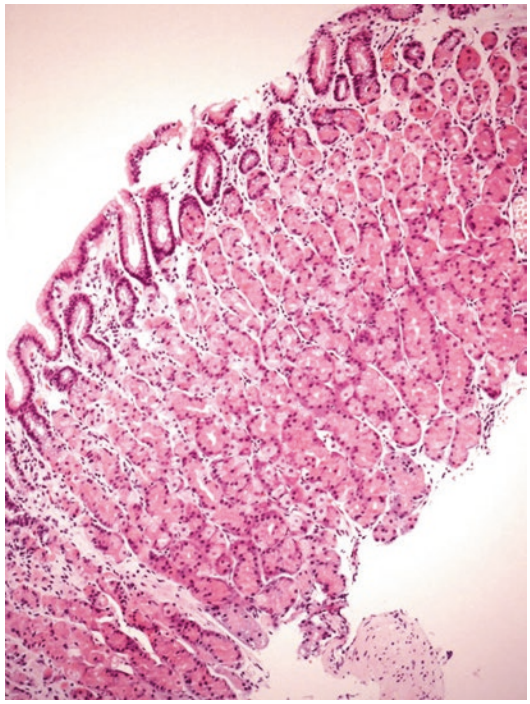

Fig. 111.5 Histology depicting rather flat fundic foveolae covering tightly packed acid-secreting glands (H & E × 10)

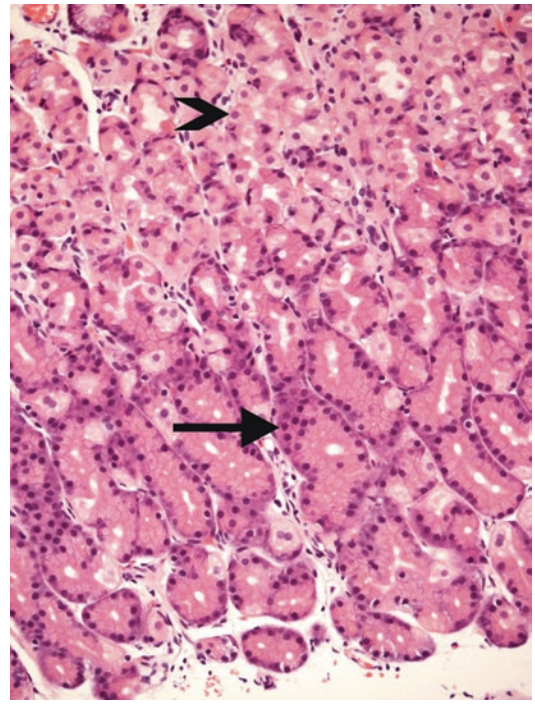

Fig. 111.6 Fundic glands are composed of bluish cuboidal chief cells (*arrow*), mucus cells, and pink parietal cells (*arrow head*) (H & E × 20)

making up less than 25% of the total mucosal thickness. The glands are tightly packed and straight rather than coiled (Fig. 111.5) [25]. They are composed of bluish cuboidal chief cells basally: chief, parietal, and mucus cells in the neck; and pink triangular parietal cells in the area corresponding to the isthmus of the gland (Fig. 111.6) [13]. The cellular products are inherent to each type of cell: chief cells secrete pepsinogen, parietal cells secrete acid, and mucus neck cells produce neutral and acidic mucin (in particular sialomucin) [25].

In addition to the above-described cell types, the fundic mucosa contains a variety of endocrine cells, mainly histamine-secreting enterochromaffin-like cells, although also serotonin enterochromaffin cells are also seen. The neuroendocrine cells are mostly located toward the base of the glands. Special stains (i.e., Grimelius) have now been replaced by immunohistochemical techniques (i.e., chromogranin, synaptophysin) to demonstrate the endocrine cells, not visible with routine hematoxylin and eosin stains. More sophisticated immunohistochemical techniques currently allow to identify specific hormones (i.e., gastrin or somatostatin) [25].

Body

The body or corpus makes up the majority of the stomach [13]. The mucosa of the body is identical to the mucosa of the fundus (see above).

Antrum

The antrum occupies the distal third of the stomach, extending between the incisura angularis and the pylorus. The foveolae (pits) occupy approximately half of the total mucosal thickness and may appear villiform (Fig. 111.2). The glands are mucus secreting, similar to the cardiac zone. Occasional parietal cells, but not chief cells, can be found at the junction with the adjacent body (fundic-type mucosa). As in the

fundus, the prepyloric antral mucosa contains endocrine cells that produce gastrin, enterochromaffin, somatostatin, and serotonin.

Lamina Propria

The collagenous tissue that provides support to the foveolae and glands constitutes the lamina propria. Elastic, reticulin, and occasional smooth muscle fibers as well as capillaries, arterioles, and nonmyelinated nerve fibers also contribute to the structure of the lamina propria [25]. During childhood, the lamina propria contains few lymphocytes, plasma cells, and rare eosinophils that do not expand the interglandular region (Fig. 111.7). B and T cell lymphocytes are scattered through the mucosa, and superficial aggregates are not usually seen. On the contrary, plasma cells (usually IgA-secreting type) often occur in small clusters [13]. Small lymphoid aggregates, devoid of germinal centers, can be rarely identified at the deepest part of the gastric mucosa.

Pathologic Mucosa

A detailed description of the histological characterization of various conditions presenting with an abnormal gastric mucosa is beyond the scope of this chapter.

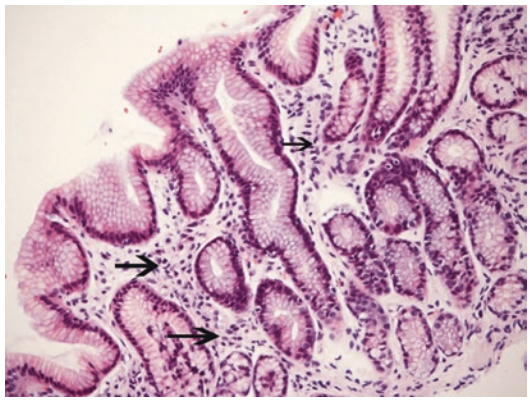

Fig. 111.7 Antral mucosa showing mucus glands immersed in the lamina propria; this contains few lymphocytes and plasma cells (*arrows*) (H & E × 10)

The term gastritis is used to denote inflammation-associated mucosal injury. However, epithelial cell injury and regeneration are not always accompanied by mucosal inflammation (i.e., chemical gastritis). Gastritis has a wide pathologic spectrum and anatomic distribution, as well as an evolving etiology. Different classification systems are in use. Key to the gastroenterologist and pathologist's collaborative work is a mutually understood and agreed classification [13, 14]. The Sydney pathologic classification of gastritis, published in 1990 and revised in 1994, is based on topography, morphology, and etiology of the inflammation [15]. The updated version of the Sydney System retained the general principles and grading of gastritis but provided with a useful visual analogue scale to help in the histological grading of gastritis. Although designed for gastritis in adults, the system has demonstrated that it applies to children as well [9].

According to the inflammatory cell infiltrates present in the gastric mucosa, the gastritis can be classified into acute or chronic forms. Chronic gastritis can further be subclassified as non-atrophic and atrophic and special types as chemical, radiation, lymphocytic, noninfectious, eosinophilic, reactive gastropathy (nonsteroidal anti-inflammatory drugs, bile reflux), etc. See Table 111.1.

The most usual entities encountered by the pediatric pathologist include, but are not limited to:

(a) *Helicobacter pylori* gastritis
(b) Lymphocytic gastritis
(c) Granulomatous gastritis and gastric Crohn's disease
(d) Eosinophilic gastritis
(e) Graft-versus-host disease
(f) Reactive gastropathy
(g) Nonspecific gastritis

Helicobacter pylori Gastritis

H. pylori infections have been associated with chronic gastritis, gastric and duodenal ulcer, and a higher risk of gastric carcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma. Diagnosis of *H. pylori* involves endoscopy with biopsy, culture, urease test, urea breath test, polymerase chain reaction (PCR),

and serologic detection of antibodies. However, the gold standard is the histologic detection of *H. pylori* in biopsy. *H. pylori* gastritis is infrequently biopsied in the acute phase of the infection. If performed, the histology shows mucosal injury with acute inflammatory cell infiltrates constituted by polymorphonuclear neutrophils. More commonly, the biopsy shows a chronic gastritis. *H. pylori* organisms present as coccoid and curved Gram-negative bacillus and are found particularly within the mucous lining of the surface epithelium. *H. pylori* are visible with hematoxylin and eosin (Fig. 111.8). The use of special stains such as silver stains (i.e., Warthin-Starry, Steiner), Giemsa or immunoperoxidase against

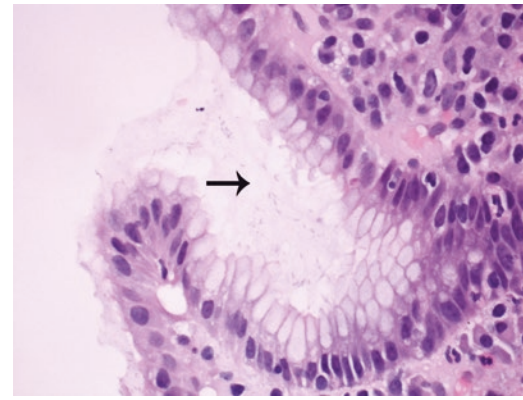

Fig. 111.8 Microphotography showing curved *H. pylori* organisms (*arrow*) of approximately 4 μ embedded within the mucus lining of the surface epithelium (H & E × 40)

Table 111.1 Etiologic-pathogenic classification of pediatric gastritis

Pattern of gastritis	Condition	
Infectious	Bacteria:	*Helicobacter pylori*
		Helicobacter heilmannii
		Streptococcus
		Staphylococcus
		Mycobacterium tuberculosis
		Treponema pallidum
	Fungi	*Candida albicans*
	Parasites	*Giardia lamblia*
	Virus	Cytomegalovirus
		Herpes
Noninfectious immune	Celiac disease	
	Graft-versus-host disease	
	Eosinophilic gastritis	
	Autoimmune gastritis	
	Henoch-Schönlein's disease	
	Polyarteritis nodosa	
Genetic/metabolic disorders	Cobalamin C disease	
	Chronic granulomatous disease	
Chemical/toxin injury	Nonsteroidal anti-inflammatory drugs (NSAIDs)	
	Other drugs	
	Bile reflux	
Physical agent injury	Tubes	
	Radiation	
Vascular	Congestion	
	Portal hypertension	
Unknown/uncertain	Crohn's disease	
	Ulcerative colitis	
	Ménétrier's disease (not associated with cytomegalovirus infection)	
	Non specific chronic gastritis	

From: Dimmick et al. [13, 14]

H. pylori is used when the organisms are difficult to identify with hematoxylin and eosin (Fig. 111.9). In children, *H. pylori* is a pangastritis, although the antrum and the cardia are usually more severely inflamed. Histologically, the lamina propria exhibits lymphoid and plasma cell inflammatory infiltrates which include a variable number of polymorphonuclear neutrophils (Fig. 111.10a) [1, 10, 15]. Usually, the pathologist encounters that the neutrophilic infiltrates involve the germinative area at the necks of the glands, constituting an "active" *H. pylori* chronic gastritis (Fig. 111.10b) [1]. Lymphoid follicles are fairly common at this stage. These are responsible for the nodularity of the gastric mucosa seen at endoscopy (Fig. 111.10c) [28]. Lymphoid hyperplasia and nodular gastritis appear to be more frequent in children than in adults and usually regress following *H. pylori* eradication [30].

Focal loss of glandular units, replaced by dense collagen bundles with scant inflammatory cells, has been described in treated long-standing *H. pylori* chronic gastritis [10]. The fibrous tissue is arranged in a "starry" shape, with a central area of scarring extending into the adjacent interglandular tissue. This feature could represent a very early stage of the atrophic gastritis described in some adult patients with *H. pylori*-associated chronic gastritis [2, 23]. In addition, the presence of isolated cells containing sulfated mucosubstances has been identified in gastric biopsies from pediatric patients with *H. pylori*-associated chronic gastritis.

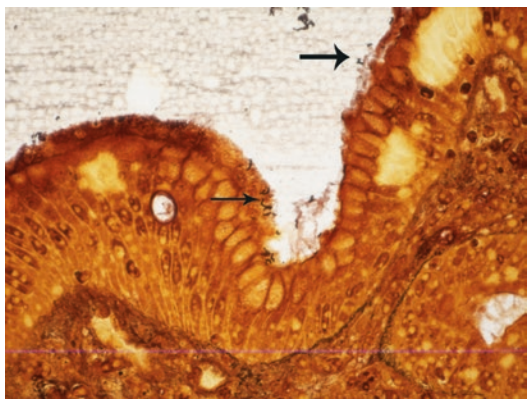

Fig. 111.9 *H. pylori* organisms positive with Warthin-Starry stain (*arrows*) (Warthin-Starry stain × 40

The presence of sulfated mucosubstances in patients with long-standing *H. pylori*-associated chronic gastritis, not present in the normal gastric mucosa, may represent a very early (perhaps reversible) stage of intestinal metaplasia [8].

Lymphocytic Gastritis

Lymphocytic gastritis is associated with *Helicobacter pylori* infection and with celiac disease. Initially described by Haot et al. [21], it is characterized by the presence of increased mucosal T cell lymphocytes both in the lamina propria as well as the surface and foveolar epithelium of the antrum and body with sparing of the deep glandular epithelium (Fig. 111.11a, b) [16, 21]. The number of intraepithelial lymphocytes in lymphocytic gastritis is 25 lymphocytes per 100 epithelial cells, although usually 30–65 lymphocytes per 100 epithelial cells are seen [34]. Children with lymphocytic gastritis and celiac disease had a mean of 40.64 lymphocytes per 100 epithelial cells [12]. There is no correlation between the histologic and clinical severity of lymphocytic gastritis in celiac disease, but the mucosa returns to normal with gluten withdrawal [14, 22]. In addition lymphocytic gastritis characterizes the endoscopic entity chronic varioliform gastritis. Of the patients with lymphocytic gastritis and celiac disease studied by DeGiacomo [12], only one had the endoscopic appearance of varioliform gastritis.

Granulomatous Gastritis and Gastric Crohn's Disease

Granulomatous gastritis may accompany systemic disease, infections, foreign body reaction, malignancy, or vasculitis but may also be an isolated finding [29]. In children, Crohn's disease is the most common type of granulomatous gastritis [13, 29]. Although histologic abnormalities are seen in up to 80 % of children with Crohn's disease, specific features such us giant cells are seen in approximately 30 % of cases [16]. Interestingly, histologic evidence of Crohn's disease may be found in absence of symptoms of inflammatory bowel disease or preceding them [16]. Histologic features of Crohn's disease include nonspecific chronic gastritis, chronic active gastritis, and the

more typical noncaseating giant cells granulomas (Fig. 111.12). A recent investigation conducted in children with inflammatory bowel disease indicated that although the presence of granulomas can support a diagnosis of Crohn's disease, severe inflammation and other abnormalities can occur in the proximal gastrointestinal tract either in Crohn's disease or ulcerative colitis [32].

In addition to the more convincing noncaseating giant cell granulomas, the presence of the so-called focally enhanced gastritis was initially considered to aid in establishing the diagnosis of Crohn's disease [24]. However, a retrospective case-controlled investigation conducted in children with inflammatory bowel disease, *Helicobacter pylori* and controls, showed that focally enhanced gastritis was present in 65.1 % of children with Crohn's disease, 20.8 % with ulcerative gastritis, 2.3 % controls, and 2.6 % children with *H. pylori* infection [31]. Focally enhanced gastritis characterizes by the presence of inflammatory cell

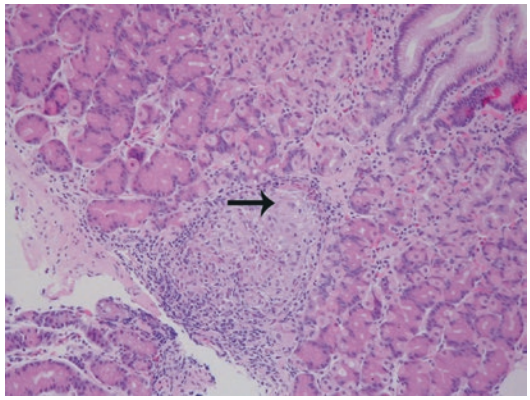

Fig. 111.12 Fundic-type gastric mucosa depicting non-caseating granulomas in a patient with Crohn's disease. The *arrow points* toward a giant cell (H & E × 20)

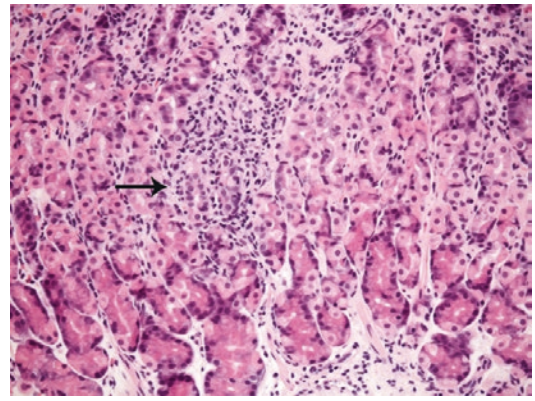

Fig. 111.13 Gastric biopsy in a child with Crohn's disease showing lymphoid inflammatory cell infiltrates surrounding fundic glands, constituting the so-called focally enhanced area of gastritis (*arrow*) (H & E × 20)

infiltrates (lymphocytes, mononuclear cells, and occasional neutrophils) surrounding a gastric foveola/gland or a small group of foveolae/glands (Fig. 111.13) [24].

With the exception of chronic granulomatous disease, other granulomatous gastritides are rare in children. These include sarcoidosis, Whipple disease, and vasculitis-associated and unclassifiable granulomas [13, 17]. Chronic granulomatous disease is an X-linked recessive immunodeficiency disorder occurring in boys, in which granulomatous gastric wall involvement is common [16]. The histological findings include presence of focal, chronic active inflammation in the antrum with granulomata, eosinophils, foci of necrosis, or giant cells. In my limited experience and that of other authors [14], pigmented histiocytes are not visualized.

Eosinophilic Gastritis

This is the gastric component of the eosinophilic gastroenteritis. The inflammatory cell infiltrate is mainly constituted by eosinophils involving the mucosa and submucosa, muscularis propria, and/or serosa of the stomach. Eosinophilic gastritis can be associated to food allergy, collagen vascular diseases, parasites, collagenous colitis, *H. pylori*, and idiopathic etiology [3, 14, 16].

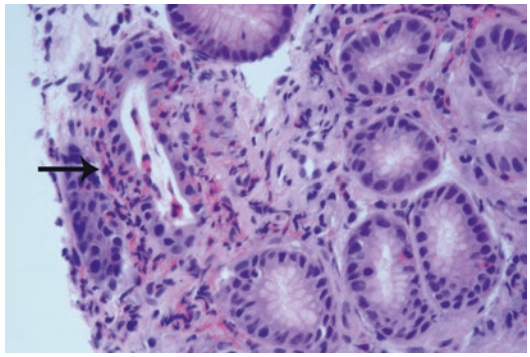

Fig. 111.14 Antral mucosa in a case of eosinophilic gastritis showing numerous eosinophils within the lamina propria and invading the adjacent glandular epithelium (*arrow*). (H & E × 40)

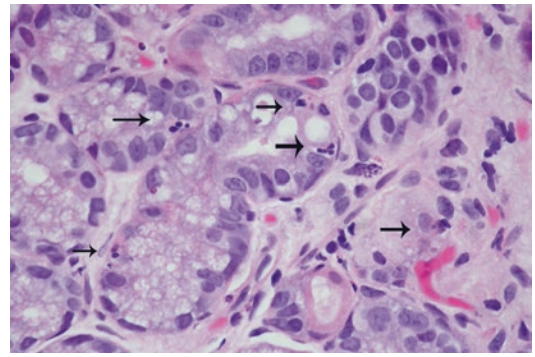

Fig. 111.15 Deep-seated glands in gastric antral mucosa depicting frequent apoptotic cells (*arrows*) in a case of graft-versus-host disease (H & E × 40)

Biopsies depict high number of eosinophils with fewer lymphocytes, plasma cells, and eosinophils within the lamina propria, with variable presence of mucosal necrosis and regenerative changes [14]. In allergic gastritis, the antrum is more commonly affected [20]. The histology depicts prominent infiltration of eosinophils within the lamina propria and invading the surface and foveolar epithelium (Fig. 111.14). Other inflammatory cell types included are lymphocytes, plasma cells, and neutrophils [13].

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD), a common complication of hematopoietic stem cell transplantation, is a clinical syndrome that requires synthesis of clinical, laboratory, and histopathologic findings for diagnosis [33]. Histological features of early GVHD include crypt epithelial apoptosis and dropout and variable lymphocytic infiltrate within the superficial epithelium and lamina propria (Fig. 111.15). The features can be focal and subtle or more diffuse and severe, including crypt necrosis and denudation of areas of the superficial mucosa [27].

Reactive Gastropathy

The mucosal changes that characterize the chemical or reactive gastropathy are the presence of foveolar hyperplasia, reduced secretion of mucins, edema, vascular ectasia, and strands of smooth muscle in the lamina propria associated with minimal or absent inflammatory cells in the antral mucosa (Fig. 111.16) [14, 26]. The most frequent etiologies of reactive gastropathy in children are duodenal-gastric bile reflux and nonsteroidal anti-inflammatory drugs.

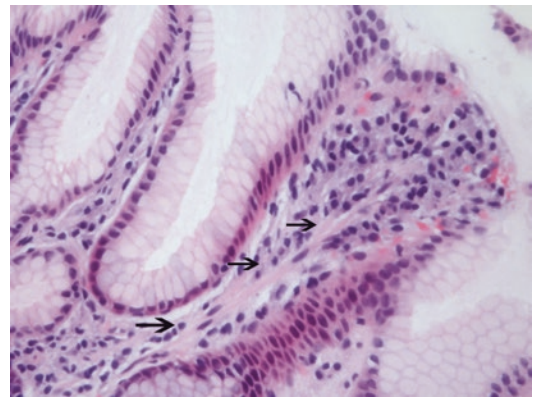

Fig. 111.16 Reactive gastropathy characterizes by foveolar hyperplasia, presence of strands of smooth muscle in the superficial lamina propria (*arrows*), and absence or minimal inflammation in the antral mucosa (H & E × 20)

Nonspecific Gastritis

A significant number of children present with chronic gastritis, usually of mild or moderate severity, for which no cause is identified. The inflammation is chronic with lymphocytes and plasma cells, usually patchy and more superficial than deep [13, 16]

Part XX

Evaluation

Upper GI Endoscopy in the Diagnosis of Gastropathy

112

Mike Thomson

There is clearly no substitute for visual diagnosis reinforced by histological biopsy assessment in the diagnosis of mucosal pathology involving the stomach in children. The inflammatory pathologies which cause symptoms are amenable to diagnosis and differentiation with this tool, and anatomical abnormalities can also be identified. A distinction between "gastropathy," which is the term used for description of visual abnormalities at endoscopy involving the stomach (and encompassing histological pathologies), should be made in contrast to the term "gastritis," which is taken to indicate histological inflammation. In other words "gastritis" is a term that should not be used by the endoscopist to describe their *macroscopic* determination of pathology as this is a *microscopic* diagnosis. This important distinction is elegantly drawn by [1].

More detailed reviews of infant gastropathology and technology can be seen in other texts [2].

This chapter will not deal with histological diagnoses, which are dealt with in detail in Chap. 111. Rather it will describe the process, tools, ideal environment, methodology, and macroscopic diagnoses which are required by, and attributable to, upper GI endoscopy in children. More extensive detailed expositions on pediatric endoscopy in general are available [3, 4].

M. Thomson
Sheffield Children's Hospital, Sheffield, UK

Process

Clearly the first issue is to make a decision that gastroscopy as part of an upper GI endoscopic assessment will be an investigation in an individual child that will actually alter patient management. Symptoms of gastric pathology may be indistinguishable from that arising from the esophagus or duodenum, e.g., dyspepsia, nausea, and regurgitation. In this scenario examination of the upper GI tract may be of advantage in differentiation of the origin of the symptom and hence directing appropriate management. Symptoms and their origin are examined in other parts of this book. Once the decision is made to proceed to EGD, then the child and family should have adequate information made available to them, with the possibility of reflection on the decision to move ahead to EGD available. Leaflets, a web presence, endoscopy unit visits, and face-to-face explanations are obvious ways for these issues to be addressed, and consent from parent and, if needed or desired, child would then be "informed" consent. All parts of this patient's journey should be subject to examination in training.

Ideally the unit would be close to, or part of, a pediatric ward, although not unreasonably endoscopy units may exist within a theater complex; occasionally, although certainly less than ideal, the existence of a unit is within a larger adult endoscopy facility. Recovery facilities may, and probably should, preclude such an arrangement.

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_112

Age-appropriate material with cartoons, videos, and distraction by play therapists and concealment of any potentially scary equipment may make the initial impression less than forbidding for the child. Age-appropriate interaction with the child is the most important strand however. Excessive noise from adjacent rooms, protection of privacy, adjustable temperature, and lighting are all common sense measures which do not need to be reiterated here.

The recovery area would also be child-friendly and equipped with resuscitation equipment.

Clean and dirty areas for scope processing are considered mandatory nowadays with through-the-hatch-type processors, and guidance for setting up such an area is freely available in most countries by visiting websites such as that of the British Society of Gastroenterology (www.bsg.co.uk).

GI endoscopy is an invasive procedure and in almost all children has the potential to cause great distress if performed without adequate sedation or general anesthesia. Unfortunately for some children, pediatric endoscopy is still sometimes performed without any or with minimal so-called conscious (although it rarely is so) sedation. Although there is an obvious need to alleviate distress in infants and children undergoing endoscopic procedures, there is no consensus on the best approach. The choice is between sedation and general anesthesia. The ideal sedative regimen would be effective for every patient, act rapidly, induce an adequate but safe levels of sedation for the duration of the procedure, wear off immediately afterward, and have no adverse effects. No such regimen exists. For this reason, many advocate the use of general anesthesia for pediatric endoscopy. Others disagree, arguing that sedation has an essential role in pediatric practice and that for GI endoscopy it can be both safe and effective. The logistic and financial implications of relying on general anesthesia must also be considered. The true morbidity and mortality rates associated with pediatric endoscopy, whether performed under general anesthesia or sedation, are unknown.

From a practical point of view, it is generally considered possible to distinguish between two distinct levels of CNS depression, referred to as "conscious sedation" and "deep sedation." The distinction between these states is central to the debate about safety and efficacy. The term conscious sedation implies a level of CNS depression in which communication is maintained so that the patient can respond to verbal command. The term deep sedation implies a level of CNS depression in which the patient is essentially unconscious and does not respond to verbal command. Practically it is rare that conscious sedation state is used in pediatric endoscopy, and therefore by any safety standards, it is recommended that one practitioner, usually a pediatric anesthesiologist, is dedicated to the safety of the child and administration of whatever method of deep sedation/GA is used. The mode of this is less important, i.e., safe airway, successful completion of procedure, no distress, timely execution, and ability of the endoscopist to concentrate on their responsibility of carrying out the procedure without having to worry about the child's safety; these are the important considerations [5–7].

Tools

Endoscopy and mucosal biopsy are a cornerstone of modern pediatric gastroenterology practice. The ability to make an accurate tissue diagnosis has been a major factor in the development of pediatric gastroenterology. Endoscopy continues to evolve, and in today's age, pediatric gastroenterologists are using the endoscope not only as a diagnostic device but increasingly as a therapeutic tool and vehicle by which to deliver endoluminal, and even extraluminal intraperitoneal, minimally invasive therapies, although these remain some way off. These are early days, but obvious initial benefits are saving procedure time, hospital admission time, and avoidance of surgical morbidity. In due course therefore the stomach may provide a portal to the peritoneum allowing natural orifice endoluminal therapeutic endoscopic surgery (NOTES) to occur. This is dealt with in Chap. 111, and its value is yet to be fully determined.

Evolution of Endoscopes

Internal examination of the human body dates back to Hippocrates (460–377 BC). He used a speculum for rectal examination, and in his treatise described rectal inflammation, hemorrhoids, and fistula. Abu Al-Qasim Khalaf ibn Abbas az Zahrawi (930–1013 AD), an eminent surgeon in Cordoba, Spain, ingeniously added a light source (reflected light by a glass mirror) for examination of the cervix. In 1806, Philipp Bozzini, a German physician from Frankfurt, invented the "lichtleiter" (light conductor) using the candle as source of illumination [8]. Visualization was limited; the examination was unfortunately painful to the patient. The Vienna Academy of Medicine did not view it kindly and reprimanded him for being "too curious." The French physician Antonin J. Desormeaux in 1858 resurrected Bozzini's invention and developed the "lichtleiter" further, replacing the candle by the much brighter gas flame using alcohol and turpentine as fuels [9].

Kussmaul performed the first esophagogastroscopy on a professional sword swallower. He swallowed a 47 cm long, 13 mm diameter metal tube. Unfortunately the Desormeaux lamp (gas illumination) had inadequate light failing to illuminate. To counter illumination problems, Leiter and Nitze used loops of platinum wire as filaments for electric lamps operated with galvanic batteries [10]. These lamps could get very hot, and in addition they devised a cooling mechanism for the hot light source eventually performing the first successful gastroscopy. They ended up arguing about the resulting credit, and historically they came to blows engaging in vitriolic correspondence. Leiter later collaborated with Johann von Mikulicz, successfully moving the light source to the distal end of the endoscope [11].

The first flexible gastroscope was invented by Dr Rudolph Schindler in 1932 [12]. The gastroscope was 75 cm long and 11 mm in diameter. About one third of the entire length of the tube toward the end could bend by an angle of 34° without distorting the image. A number of short focus lenses were positioned throughout the tube, and the light source was a miniature light bulb. This semiflexible gastroscope remained in popular use until 1957.

The fiberoptic era was born when, in the American gastroscopy society meeting of 1957, Hirschowitz successfully demonstrated the prototype, formulated with the help of a physicist [13]. In 1960 ACMI Ltd produced the first commercial fiberoptic gastroscope. Robert Kemp in 1962 suggested using a controllable directional tip helping to develop it further.

In 1983 the first digital endoscope was produced by Welch Allyn. At the tip was an electronic sensor consisting of packed grid of photocell receptors which electronically transmitted images to a video processor and then to a television monitor. This evolution has particularly accelerated the endoscopist's training, additionally adding to the interest of all present in the theater including the patient (Fig. 112.1).

The use of gastrointestinal endoscopy in the pediatric population was initially driven by the imperative of histological diagnosis in conditions such as celiac disease and the inflammatory bowel diseases. It has superseded such modalities as the Watson-Crosby capsule for obtaining small

Fig. 112.1 A Hirschowitz gastroscope recently (Nov, 2006) sold on eBay for 68.50

bowel mucosa and offers advantages over these methods by way of observation of the whole of the upper GI mucosal surface and anatomy while providing as many biopsies as are needed for diagnosis of esophagogastroduodenal pathology; indeed the duodenal biopsies provided have been shown to be as good as those obtained by capsule without the necessity for screening irradiation and usually occurring in a more controlled airway setting of general anesthetic [14].

The use of diagnostic GI endoscopy in children has followed developments in the adult sphere and is now considered standard practice for all mucosal GI diseases. Indeed modalities such as wireless capsule endoscopy and double balloon enteroscopy added to upper GI endoscopy and ileocolonoscopy now enable the pediatric endoscopist to visualize and biopsy the whole of the gut from mouth to anus [15–17].

The more recent advances of therapeutic intervention have transformed areas such as enteral nutrition support with PEG and PEJ tube insertion, esophageal stricture management, and especially variceal and non-variceal bleeding management and are now considered mandatory for any advanced pediatric endoscopist.

Technique of Endoscopy Involving the Stomach

The instrument will pass down the narrow confines of the esophagus without difficulty. It is important to make any necessary adjustments to keep the esophageal lumen at the center of view (Fig. 112.2). Insufflation of air from time to time will maintain a clear view. The gastroesophageal junction is identified using a number of anatomical features.

First, the z-line, or dentate line, of the gastroesophageal mucosal junction may be visible, the esophageal mucosa appearing pale compared with the salmon-pink gastric mucosa (Fig. 112.3).

Second, the gastric rugae may be seen immediately distal to the esophageal mucosa. Last, there may be an area of relative luminal narrowing at the level of the diaphragm, the "diaphragmatic pinch." Each of these indicators should be evaluated because in individual patients, some may be more reliable than others. A sliding hiatus hernia can be confirmed by noting that the z-line and gastric rugae lie above the diaphragmatic pinch (Fig. 112.4). Similarly, in patients with Barrett's esophagus, the z-line may be proximally displaced (Fig. 112.5). Finally, before advancing through the gastroesophageal junction, aspiration of air reduces the intraesophageal pressure and may reveal small esophageal varices

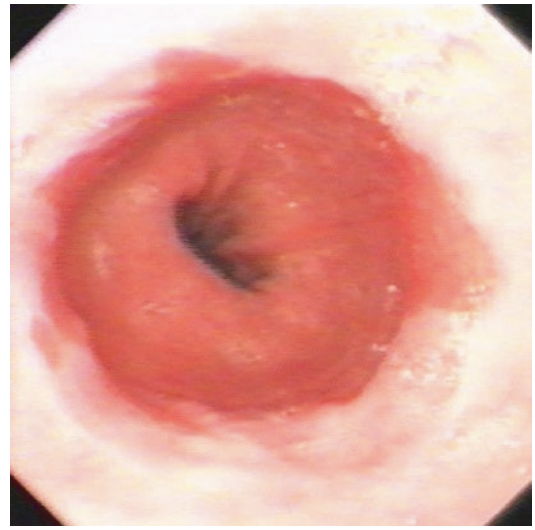

Fig. 112.2 Esophageal lumen

Fig. 112.3 Dentate or z-line, with an inflammatory polyp

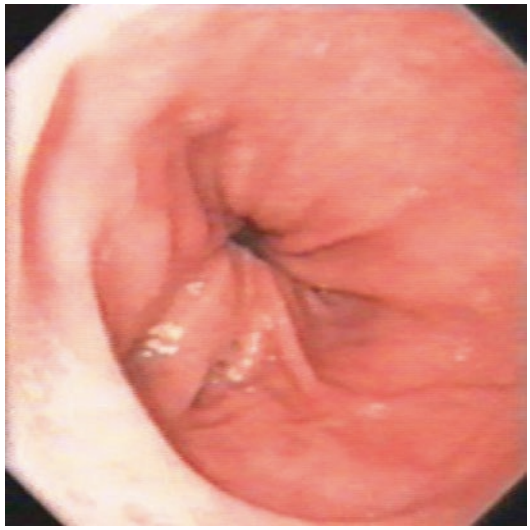

Fig. 112.4 Hiatus hernia showing diaphragmatic "pinch"

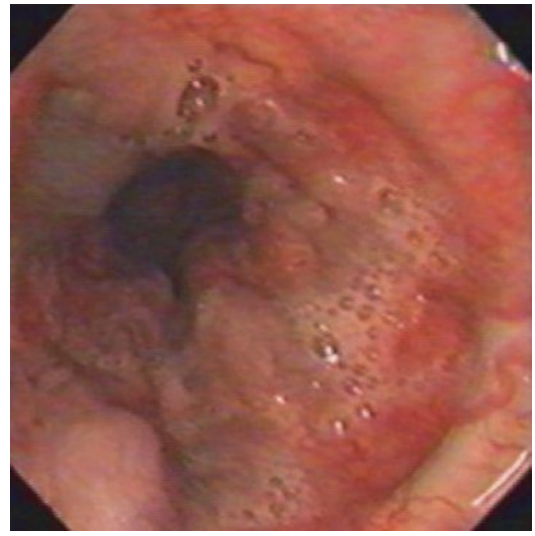

Fig. 112.6 Esophageal varices

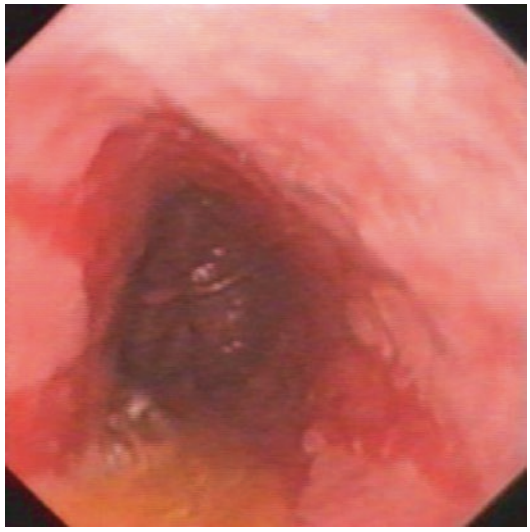

Fig. 112.5 Barrett's esophagus

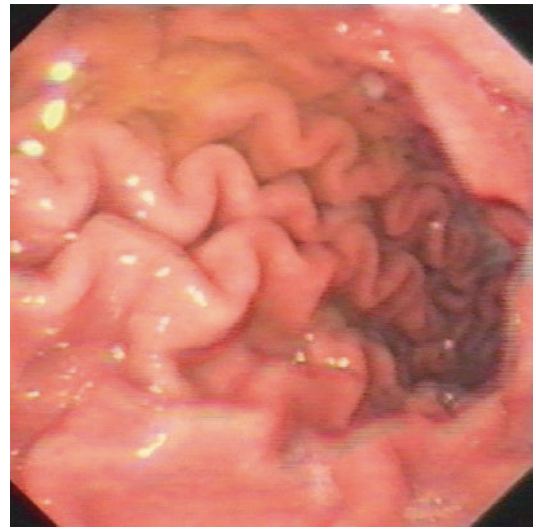

Fig. 112.7 Gastric rugae

that might not otherwise be obvious (Fig. 112.6). The endoscope moves easily through the gastroesophageal junction, but immediately upon entering the stomach, the forward view may be obscured by gastric mucosal folds in the cardia. At this point adequate insufflation of the stomach is necessary to gain a clear view. Aspiration of pooled gastric secretions is critical prior to full distension of the stomach to minimize the risk of aspiration. As air is insufflated, the gastric lumen and the gastric rugae are evident, but with further distention, the rugae gradually flatten (Figs. 112.7 and 112.8). As the endoscope is advanced, it readily slides down along the greater curvature of the stomach to the gastric antrum, facilitated by clockwise torque, advancement, and upward tip deflection. The lesser curvature may be seen on the right, and often the prominence of the area gastricae can be noted (Fig. 112.9). This is a normal mosaic appearance and finding, although

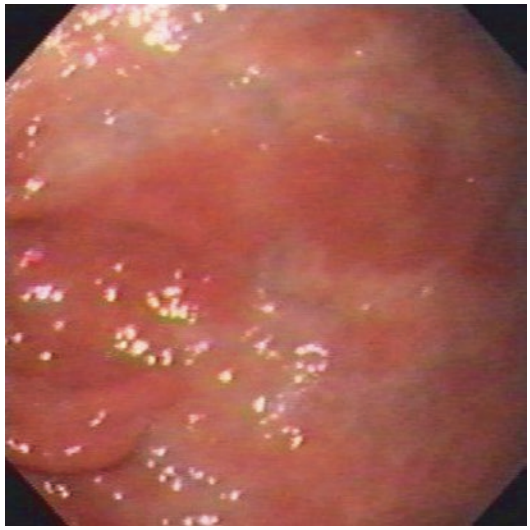

Fig. 112.8 Insufflation expands stomach and therefore rugae disappear

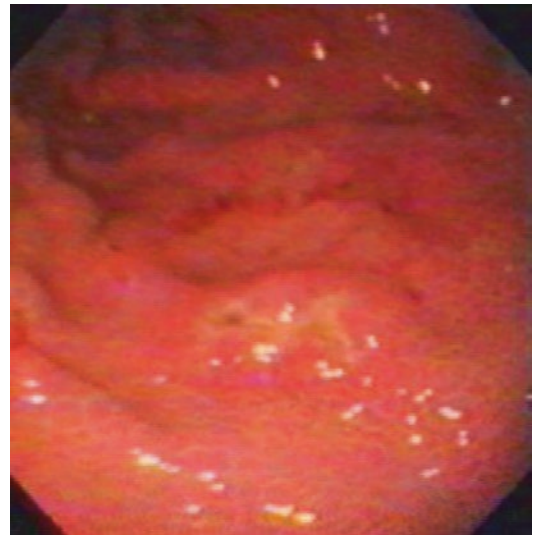

Fig. 112.10 Crohn's of stomach: mosaic appearance of edema

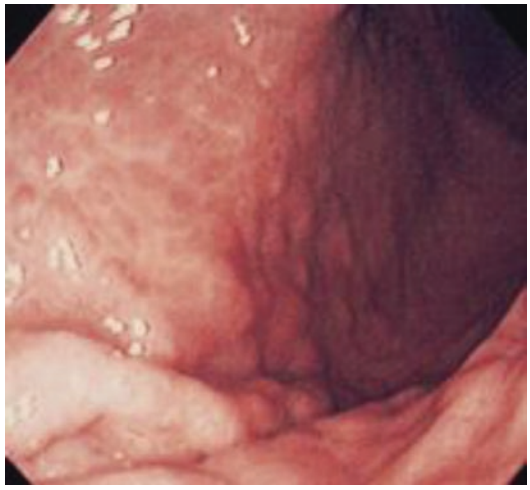

Fig. 112.9 "Area gastricae": prominent area on lesser curvature of stomach which is a normal finding

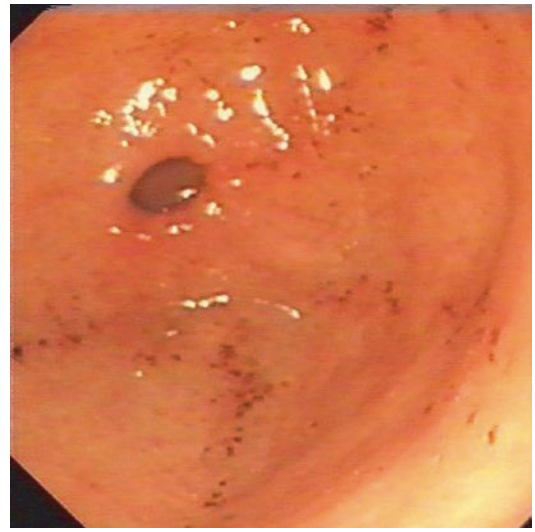

Fig. 112.11 Pylorus

if seen elsewhere in the stomach it can point to the possibility of inflammation such as Crohn's disease [18] (Fig. 112.10). Very often as the endoscope reaches the antrum, the pylorus comes into view (Fig. 112.11). However, in infants and small children, the pylorus is often located very close to the angulus incisura, and the angle of approach is necessarily somewhat acute (Fig. 112.12). In this case it can be very helpful to perform a so-called "J-maneuver" of the endoscope. The endoscope is retroflexed in order to look back up the stomach (thus adopting a "J" configuration). Then with some minor adjustments, it is usually easy to look face-on at the edge of the angulus incisura. The pylorus lies a few centimeters distal to the angulus. Once visualized with this maneuver, the line of approach is

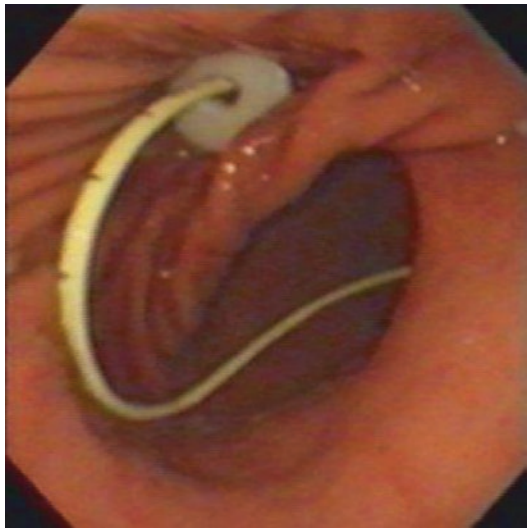

Fig. 112.12 Angula incisura around which a PEGJ tube has been passed into the pylorus

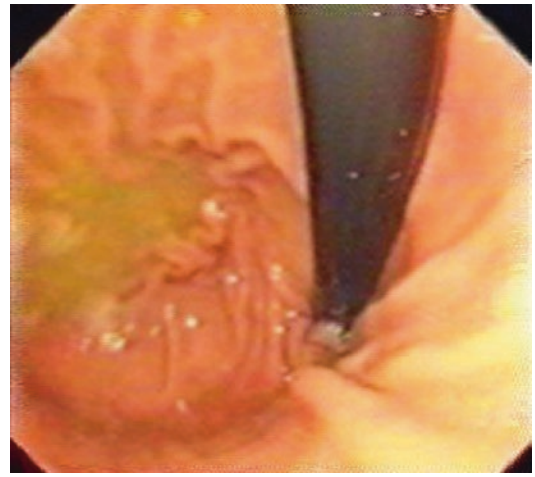

Fig. 112.13 J manuever to see the cardia and fundus

clear. The J-maneuver can also be very helpful in performing a thorough examination of the gastric fundus and cardia (Fig. 112.13). The gastric body lies proximal to the angulus and further proximally is the fundus and the gastroesophageal junction through which the shaft of the endoscope is to be seen passing downward (Fig. 112.13). If the endoscope is carefully withdrawn in the retroflexed position and some lateral and rotational adjustments are made, thorough examination of the entire gastric mucosa is possible.

Once the entrance to the pyloric canal is visualized, intubation is usually straightforward. If the pylorus is closed, it appears as a series of mucosal folds radiating from a central point. With gentle pressure, sometimes assisted by a brief puff of air, the endoscope will usually pass easily into the pylorus.

Biopsies are usually taken from the antrum which can be 2 or 4 in number, and this is the area with highest yield for *Helicobacter pylori*, and the body. A rapid urease test for *H. pylori* is also usually obtained. Some children have *H. pylori* identified in the fundus also. Any lesion should be photographed and if necessary biopsied. Gastric aspiration for identification of TB may be helpful. More recent innovations such as narrow band imaging, autofluorescence, and now confocal endomicroscopy with up to 1,000× magnification (i.e., histology in vivo) allow specific targeting of biopsies to areas likeliest to provide highest diagnostic yield [19] (Figs. 112.14, 112.15, 112.16, 112.17, and 112.18).

Diagnostic Indications

These are varied and are summarized in Table 112.1. Each pathology is identified and examined in more detail in the relevant chapter with description of macroscopic and histological appearances so this will not be undertaken here.

It is clear that the major impact over the last 20 years on identification of mucosal pathology and its potential symptomatic causation has been the endoscopic assessment and biopsy. Each pathology will not be dealt with here, but the reader is directed to the appropriate mucosal and symptom-specific chapter.

Therapeutic Endoscopy of the Stomach

These are summarized in Table 112.2, and as they are not dealt with elsewhere in the text, it will be touched upon here as follows.

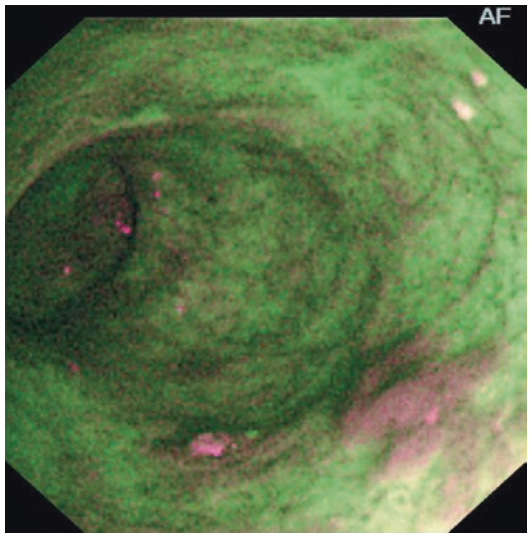

Fig. 112.15 Autofluorescent endoscopic imaging

Fig. 112.16 Tip of confocal endomicroscope revealing laser imaging portal

Gastric Bezoar

The term "bezoar" derives from the Persian word *badzehr*, which means antidote. Some types of trichobezoar are able to precipitate or bind arsenic compounds (a commonly used ingredient in the poison) hence acting as an antidote. In 1575, Ambroise Paré, a French army physician and surgeon, proved this to be wrong, an experiment which costs the cook his life. A cook at Paré's court was caught stealing fine silver cutlery who agreed to be poisoned. Despite using the bezoar stone, he died in agony days after. Paré had proved that the bezoar stone could not cure all poisons as was commonly believed at the time.

Bezoars are of several types with phytobezoars being the commonest type. These are soft and are composed of plant and vegetable fibers [20]. In comparison trichobezoars are composed of hair, undigested fat, and mucus. The hair may come from the patient, other humans, animals, carpet fibers, or blankets. Hair fibers are trapped

Table 112.1 EGD and diagnostic indications involving the stomach

Mucosal injury and inflammatory pathologies	Bleeding lesions	Miscellaneous
Acute (stress) ulceration	Acute (stress) ulceration	Bezoars
H pylori gastritis	Gastric fundal varices	Ectopic pancreas
H pylori gastric ulcer	Portal gastropathy	Adenomatous polyps (e.g., Gardner's and FAP)
NSAID gastritis	Dieulafoy's lesions	Hamartomatous polyps (Peutz-Jeghers polyposis)
Eosinophilic gastritis	*H. pylori* gastric ulceration	Gastric carcinoma, lymphoma, leiomyoma, leiomyosarcoma, mucosal-associated stromal tumor (MAST), GOJ tumors
GVHD	Virus-related hemorrhagic gastritis (esp. Influenza A)	GAVE (gastric-associated vascular ectasia or watermelon stomach)
Autoimmune gastritis	Drug-related gastritis	
Atrophic gastritis	GAVE (gastric antral vascular ectasia or watermelon stomach)	
Crohn's and UC-related gastritis		
Varioliform gastritis		

in gastric folds and resist peristalsis because they are slippery. More hair is added, and a ball forms. The hair protein is denatured by gastric acid, causing the ball to turn black. Fat becomes trapped in the hair fibers and ferments, leading to a putrid smell.

One variant of trichobezoars is the "Rapunzel syndrome." This is a trichobezoar extending from the stomach into the small intestine sometimes even involving entire length of the small intestine. The twisted hairs can become hard like a wire. There are reports in which these can cause compression of the mesenteric wall of the intestine occluding the blood supply resulting in pressure necrosis and perforations [21, 22] (Figs. 112.19, 112.20, and 112.21).

Endoscopy or surgery may be used to remove bezoars. With the help of an endoscope, these are broken into smaller pieces using a polypectomy snare, biopsy forceps, directed water jets [23],

injection of enzymes (papain, cellulose), or mechanical lithotripsy (bazotome, a needle knife device, or bezotriptor, a lithotriptor) [24]. Fifteen patients were treated with mechanical lithotripsy with a 100 % success rate (five patients required two sessions). Gastroscopy re-performed 3 days later showed only four patients with small residual bezoar fragments, which were removed endoscopically. Once the bezoar is broken into smaller pieces, these can then either be removed endoscopically or allowed to pass through the pylorus.

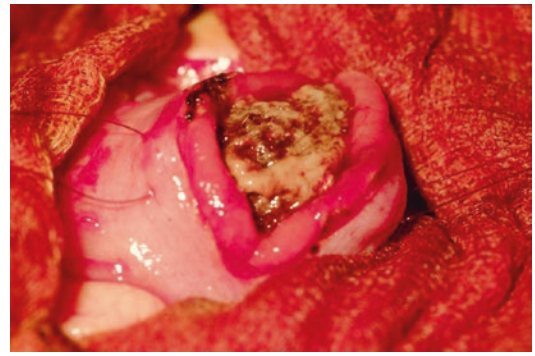

Fig. 112.20 Surgical removal of trichobezoar

Fig. 112.21 Bezoar from an 11-year-old girl with Rapunzel syndrome. The large size (34 cm long and 8 cm in diameter) did not permit endoscopic removal

Another group has reported use of electrohydraulic lithotripsy (EHL) to treat bezoars [25]. After submerging the bezoar in saline, the EHL probe was brought into direct contact with the mass and used to deliver a series of short bursts that fragmented the bezoar into pieces 1–1.5 cm in diameter. Uncomplicated 100 % success (11 patients) was reported. In addition there was no recurrence after 30–68 months follow-up.

A group in China has reported use of a mini-explosive device to treat diospyrobezoars [26]. Hydrazoic acid (trizoic acid) is a colorless, volatile, and extremely explosive liquid at room temperature and pressure. All the salts are explosive and readily interact with the alkyl iodides. The metallic salts all crystallize in the anhydrous form and decompose on heating, leaving a residue of the pure metal. It is a weak acid (pKa 4.6–4.7). In this report trizoic lead was loaded into small steel tubes (0.5 cm thick, 1 cm in length, and 2 mm in

diameter). These were connected to a pulsed neodymium laser. The device was passed through the endoscope and placed in direct contact with the bezoar. The laser was ignited, followed by a mini-explosion and a small hole in the bezoar. After three to five of these explosions, bezoar fragments were then removed with a snare. Gastric mucosa was intact in all patients (except a small erosion in one patient). No discomfort was reported during the procedure, and 21/31 patients were cured in one treatment session. Patients reportedly felt no discomfort. This method with its hazards is unlikely to be adopted worldwide.

Coca-cola [27] was used in a 42-year-old man in four aliquots of 30 mls. Each aliquot was injected into the bezoar with the endoscope being forcefully buried into the bezoar at four different places. Thereafter the diet was restricted for 48 h. A repeat endoscopy showed the bezoar had cleared from the stomach.

Endoscopic Pyloromyotomy for Congenital Pyloric Stenosis

Ramstedt's pyloromyotomy (open and laparoscopic) has been the gold standard operation for treatment of congenital pyloric stenosis for more than 80 years. Recently Ibarguen-Secchia from Texas has reported use of endoscopic pyloromyotomy in a series of ten children [28]. Transendoscopic use of a needle knife or a sphincterotome was used in a quadrantic manner through the mucosa, and division of the internal hypertrophied circular muscle was carried out. Prior endo-ultrasound can help in the decision as to how deep to make the incision, but standard transabdominal ultrasound is sufficient. The route of treatment is somewhat more appropriate than dividing the serosa and outer normal longitudinal muscle as in the standard approach, and it has not seemed to matter that the mucosa is divided. This was performed with a view to achievement of a quicker operation and post-op recovery time. Nine out of ten children had the procedure as a day case, and one out of ten needed electrolyte correction before being treated the next day. All children were fed only after an hour of the procedure compared to the median time of 38 h for laparoscopic pyloromyotomy and 64 h for an open abdominal procedure. Vomiting continued to a lesser degree in two but eventually resolved in all over a 6–18-month follow-up. The results are impressive. However, this is only a one operator-conducted small case series; clearly, one needs to be cautious about bleeding and perforation, which may cause significant morbidity particularly in this younger age group (Figs. 112.22 and 112.23).

Percutaneous Endoscopic Gastrostomy and Gastrojejunostomy

Percutaneous endoscopic gastrostomy tubes are very commonly used since their first development by Ponsky and Gauderer 25 years ago [29]. These were devised to provide hydration and nourishment to the neurologically impaired children unable to swallow. PEG, in particular, was developed to avoid complicated surgery.

PEG tubes may be inserted using a "pull" or a "push" technique. The "pull" technique was pioneered by Ponsky and colleagues [30]. This involves performing a gastroscopy, identifying the anterior stomach wall making sure that there is no organ (particularly the spleen) that is between the wall and the skin. An angiocath is used to puncture the abdominal wall through a small incision, with insertion of a soft guidewire through this. The guidewire is pulled out of the mouth and a feeding tube attached to it and pulled through the mouth out of the incision (Figs. 112.24, 112.25, 112.26, 112.27, 112.28, 112.29, 112.30, and 112.31).

In comparison the "push" technique involves a gastroscopy to identify the anterior abdominal wall, and the wire is placed in the stomach using the Seldinger technique. A series of dilators are then used to increase the size of the gastrostomy with a tube then pushed over the wire. This is rarely performed now in children.

Fig. 112.24 Endoscopic transcutaneous illumination in left hypochondrium

The potential complications of gastrostomy insertion are injury to an organ such as the spleen during insertion of a gastrostomy tube, gastrocolic fistula (diarrhea may occur a short time after feeding), gastric separation, peritonitis, and gastrostomy site cellulitis (Figs. 112.32, 112.33, 112.34, 112.35, and 112.36).

Single-stage insertion of balloon gastrostomies can occur with or without laparoscopic

Fig. 112.25 Trochar placed through skin into gastric cavity. Note: needle with saline-filled syringe used first and inserted with suction in order to determine that the stomach is the first lumen entered, i.e., simultaneous aspiration into the stomach: the tip of needle enters the stomach and not colon. Helpful also in directing trochar insertion

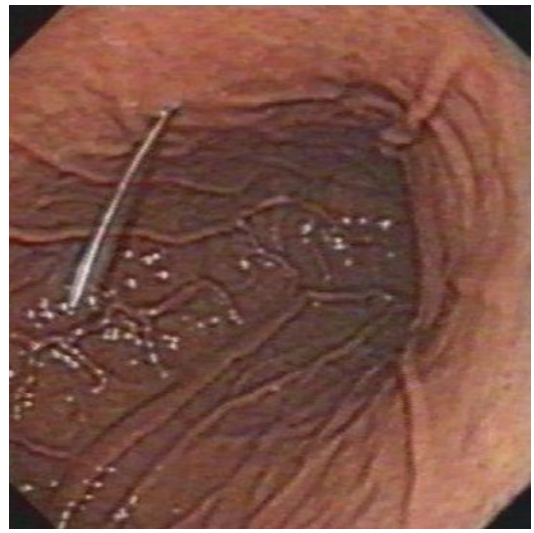

Fig. 112.26 Trochar placed into gastric cavity transcutaneously

assistance, although the blind technique using the endoscope can lead to pneumoperitoneum if not used with care. This technique has not gained wide popularity to date. Generally most operators will place a standard PEG first, allow the track to form over a period of approximately 3 months, and then perform a further endoscopy in order to change this to a correctly sized balloon gastrostomy tube, of which many exist on the market (Figs. 112.37 and 112.38).

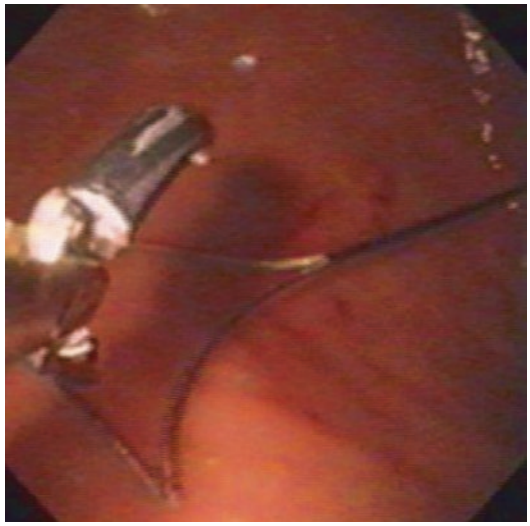

Fig. 112.27 Grasping forceps being employed to grab the wire passed through the trochar (Biopsy forceps or snare can be used)

Fig. 112.36 Contact dermatitis to tape and dressing

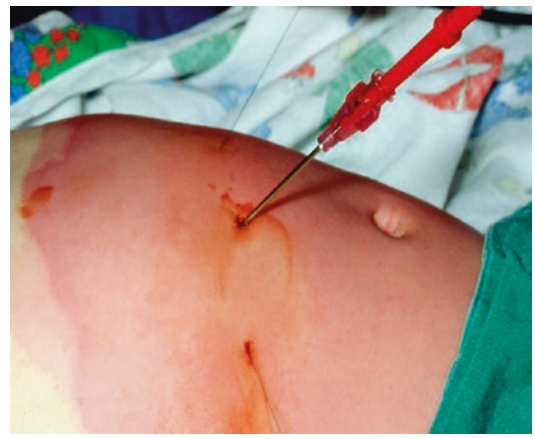

Fig. 112.37 Single-stage balloon PEG insertion. Step 1: apposition of stomach to abdominal wall with cope tags and then trochar-assisted insertion of J-wire

Using the PEG tube, it is also now possible to place a PEGJ tube. This involves placing a short PEG tube in the usual transgastric position. Through the lumen of that PEG tube, a thinner jejunostomy tube is placed. The jejunostomy tube then traverses the pylorus and extends

Fig. 112.38 Single-stage technique with splittable sheath placing one-step balloon gastrostomy

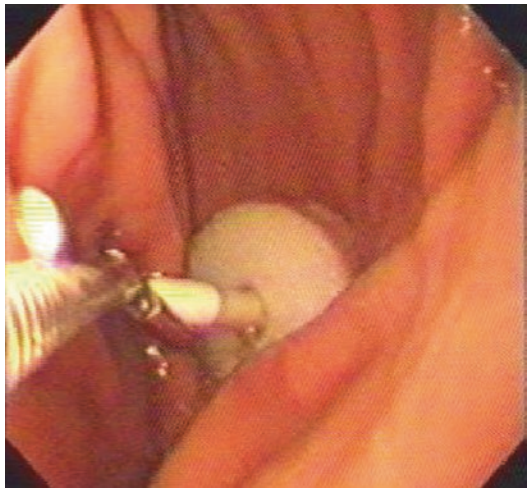

Fig. 112.39 Insertion of PEGJ lead 12FG through PEG 16FG and grabbed by grasping forceps

down beyond the ligament of Treitz. Although non-endoscopic direct placement of a PEJ tube across the abdominal wall into the proximal jejunum has also been reported, in general, jejunal tubes are fraught with problems and tend to get blocked or displaced easily. However more recently it has been possible to place a laparoscopically assisted percutaneous endoscopic PEJ with a similar technique to that employed with the PEG technique (Figs. 11 2.39, 112.40, and 112.41). Specific products and their intricacies are beyond the scope of this text, and the reader is referred to the standard pediatric endoscopic texts by Murphy et al. and Gershman et al. [3, 4].

Fig. 112.40 Use of grasping forceps to place end of PEJ through pylorus

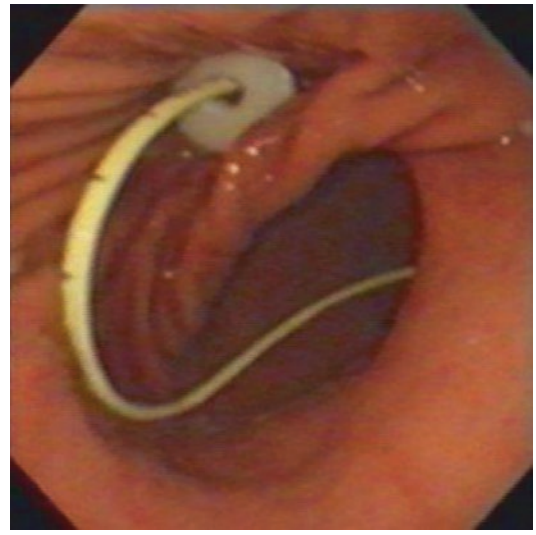

Fig. 112.41 PEJ now in situ from PEG site through pylorus

Gastric Bleeding

Although not popular for variceal treatments, due to ulcerogenic properties especially in the mid esophagus, injection of sclerosing or hemostatic agents is an option for initial treatment of gastric bleeding due to ulcers in the stomach or duodenum. It should be remembered that epinephrine injection via an endo-needle will tend to occasion

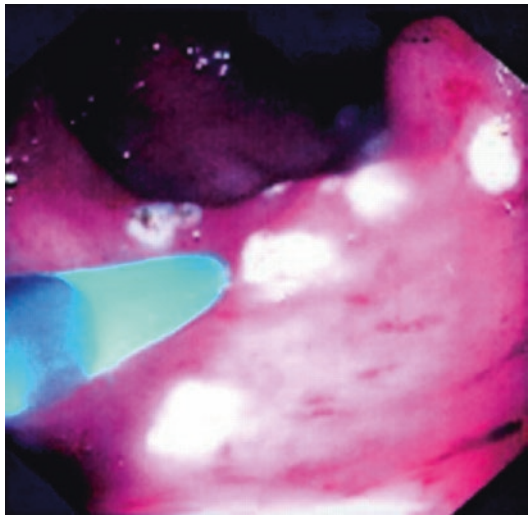

Fig. 112.42 Argon plasma probe and application in gastric bleeding

Fig. 112.43 Monopolar gold-probe electrocautery in gastric bleeding

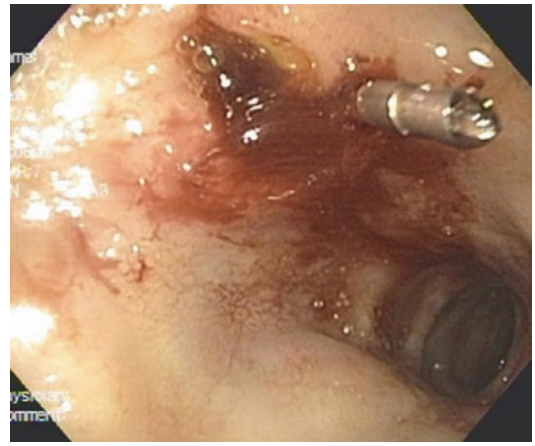

Fig. 112.44 Endoclip and application in gastric bleeding

only temporary vasospasm and bleeding cessation and will lull the operator into a false sense of security as 30 or so minutes later the bleeding may well reoccur as vasospasm resolves. Of course metal clips, referred to as endoclips delivered via the biopsy channel, can be very effective in conjunction with other techniques such as electrocautery and argon plasma coagulation in order to facilitate hemostasis. Gold-probe monopolar electrocautery (Figs. 112.42, 112.43, 112.44, 112.45, 112.46, 112.47, 112.48, 112.49, and 112.50) is also very effective for treatment of bleeding ulcers or preventing rebleeding in a patient with a non-bleeding visible vessel such as the Dieulafoy's lesion [31, 32]. Individual description of technique is beyond the scope of this chapter.

Foreign body removal is best described in the above standard endoscopic texts.

Pancreatic Cystogastrostomy

In the situation of pancreatic pseudocysts, usually the cystic mass produces a bulge into the gastric lumen, classically due to anatomical proximity, on the greater curvature. If noticeable then endo-ultrasound can be used to identify the gastric vessels and hence avoid these when subsequent incision through the gastric wall is made (Figs. 112.51, 112.52, and 112.53). The first step is to inject epinephrine into the gastric wall to prevent excessive hemorrhage following the use of the endo-knife or snare. Secondly, an incision can be made into the area where it is identified that the pseudocyst is juxtaposed to the gastric wall. This can be enlarged with a sphincterotome, and through this larger opening, pigtail cannulas can be introduced allowing drainage of the pseudocyst and subsequently prevention of closure of the fistula thus artificially created. Removal of these is not usually necessary. Symptomatic relief is usually immediate.

Anti-obesity Endotherapy

Balloons

The use of gastric balloons has not yet been properly explored in children or adolescents, but it has potential, especially in the medium-term accession of some weight loss, but may be not more than the initial satiety suppression that goes with gastric distension over the first few months post-insertion. Nevertheless, these devices may provide some initial inroad to weight loss, while other measures take a foothold, e.g., psychological, lifestyle management, dietary, exercise, and drug treatment (Fig. 112.54).

Endosleeve

This clever device is deployed from the duodenal cap endoscopically, and it essentially is anchored there by a self-expanding ring, which also allows subsequent endoscopic removal, and a plastic

Fig. 112.49 Familial adenomatous polyposis in the stomach (FAP): incidental as do not bleed and do not undergo dysplasia

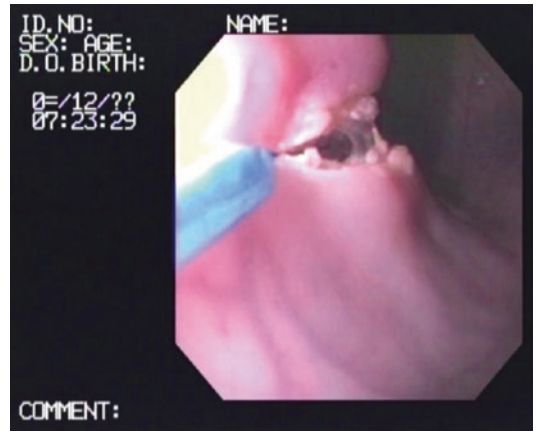

Fig. 112.51 Endo-knife incision through greater curvature of stomach into cyst, having injected adrenaline and employed endo-ultrasound to avoid gastric vessels

"sleeve" then is deployed distally preventing food absorption from the whole of the duodenum. It has been only used in adult studies, and its safety in children is not yet determined (Fig. 112.55).

StomaphyX

This is an endoscopic application which uses a new full-thickness plication technique by endoscopy, also used for creating a fundoplication endoscopically (EsophyX) at the GE junction, and pleats the stomach decreasing its

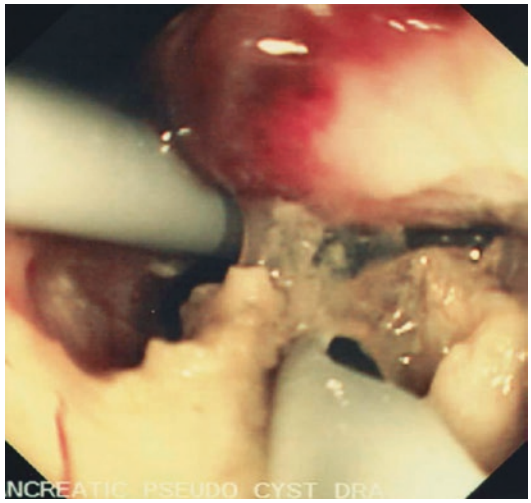

Fig. 112.53 Straight stents in situ into cyst from stomach

Fig. 112.54 Intragastric balloon

volume. It may be an adjunct to formal bariatric surgery, but again has not been applied in the pediatric age group (Fig. 112.56).

Endoscopic treatment of varices and NOTES are described and will not be delineated here.

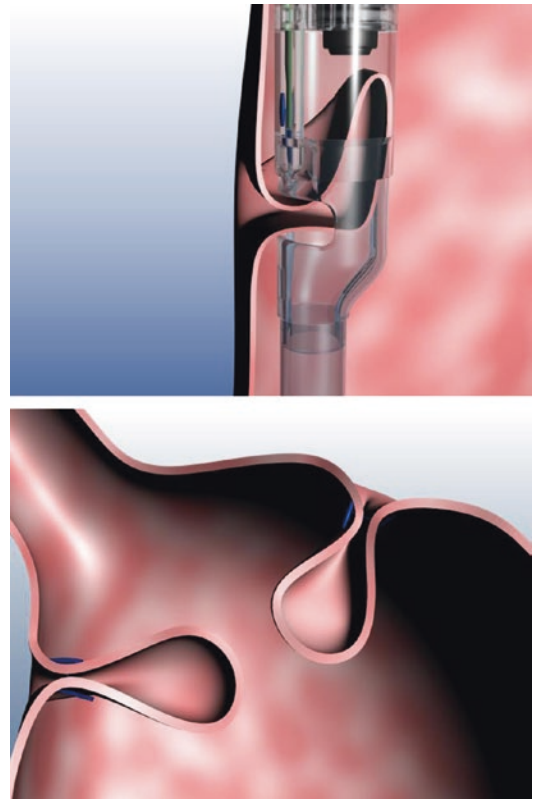

Fig. 112.56 Full-thickness transoral incisionless gastric volume diminution with StomaphyX

Summarizing, one would say that gastric endoscopy has turned the corner from diagnostic to therapeutic over the last few years and that the next decade or so may be viewed in retrospect as the time that gastroscopy came of age, mainly as a portal to natural orifice transendoluminal endoscopic surgery; however, this is still some way off.

List of Abbreviations

99Tcm	Technetium 99m
cm	Centimeters
CT	Computed tomography
GE junction	Gastroesophageal junction
GIST	Gastrointestinal stromal tumor
HSP	Hypertrophic pyloric stenosis
mm	Millimeters
MRI	Magnetic resonance imaging
PET	Positron emission tomography
UGI	Fluoroscopic upper gastrointestinal series
US	Ultrasound

Imaging Evaluation of the Stomach

Imaging Overview

Radiography, fluoroscopy, ultrasound, and scintigraphy are the primary modalities for imaging the stomach in pediatric patients. Computed tomography (CT) and magnetic resonance imaging (MRI) play complimentary roles, primarily for tumor or inflammatory disease follow-up and may discover stomach pathology during the workup of abdominal pain or an unrelated condition. Imaging the stomach in infants and children requires techniques which are age- and patient condition-specific.

Ultrasound

Ultrasound imaging is the most common cross-sectional imaging modality utilized in pediatrics. Unlike CT and fluoroscopy, there is no ionizing radiation used in diagnostic ultrasound, and sedation is not required. The small size of pediatric patients allows for the use of higher-frequency ultrasound transducers, resulting in better imaging quality than is seen in adult patients. For ultrasound of the stomach and bowel, a linear high-frequency transducer is used, often 12 MHz or higher. These probes are widely available in pediatric hospitals, but may not be available in places where primarily adult patients are imaged. These transducers allow for easier discrimination between the hypoechoic muscular bowel wall and hyperechoic mucosa. Pedialyte or other clear oral liquids are often employed to distend the stomach for ultrasound evaluation. Breast milk and formula appear echogenic are not optimal for this purpose.

Fluoroscopic Technique

Thin barium contrast is utilized in most pediatric fluoroscopic studies. Contrast may be administered via bottle, sippy cup, straw, syringe, or an enteric tube. The patient should be Nil Per Oral (=nil by mouth) (NPO) for the procedure. NPO requirements vary by institution but typically are 2 h for neonates, 4 h for infants and young children who eat solid foods, and 6 h for older children. A nasogastric tube can be used to remove liquid stomach contents in emergent cases. These examinations are usually performed with the fluoroscopic table horizontally positioned.

Older pediatric patients may be able to tolerate double-contrast examinations with thick barium contrast and effervescent crystals if fine mucosal detail is the goal of the examination. Air contrast is simulated in crying infants who swallow air. This can also be achieved in older children by puncturing the straw used to drink thin barium with a 20-gauge needle. Near-iso-osmolar nonionic water-soluble contrast is used in patients with suspected postoperative leak and may also be used in premature infants [29]. If aspirated, near-iso-osmolar nonionic water-soluble contrast is less likely to cause pulmonary edema than higher-osmolality water-soluble contrast agents and can enter the intravascular space, mediastinum, pleural space, and peritoneal cavity without complication. These contrast agents are also used intravascularly for CT. Water-soluble contrast that reaches the peritoneal space is absorbed and excreted by the kidneys [29].

The volume of contrast used for UGI depends on patient age. In premature infants and term neonates, evaluation of the stomach may require as little as 5 mL of contrast. The amount of contrast required is usually less than an infant's normal feeding volume. Older children may require 6–8 oz of contrast, depending on gastric motility and body habitus.

The radiation dose for an upper GI study can approach that of an abdominal CT. Decreasing total fluoroscopy time, using low-dose pulsed fluoroscopy, and minimizing the number of fluoroscopic spot images obtained will reduce the total radiation dose to the patient. Many pediatric radiologists have replaced fluoroscopic spot images with fluoroscopic hold images to reduce radiation. These techniques are routine in pediatric imaging facilities, but may not be regularly employed at adult imaging facilities.

Nuclear Medicine

Nuclear medicine offers functional imaging of the stomach and the ability to localize ectopic gastric mucosa and hypermetabolic gastric tumors. Technetium 99m (99Tcm) is the most common radionucleotide used in scintigraphic imaging of the stomach in children. 99Tcm-sulfur colloid-labeled formula or food can be fed to a patient to evaluate gastric emptying, gastroesophageal reflux, and aspiration. 99Tcm pertechnetate can also be given intravenously to show uptake in gastric mucosa. This agent is actively secreted by gastric mucosa and may help localize enteric duplications above or below the diaphragm [20]. The stomach may also show uptake of free 99Tcm pertechnetate if it is present as an unlabeled contaminate in a study which uses technetium bound to another agent. Gastrointestinal bleeding, including that caused by gastritis and enteric duplications, can be localized with a 99Tcm-red blood cell scan or 99Tcm-sulfur colloid-labeled scan [30]. 18Fluorodeoxy-glucose PET-CT demonstrates activity within hypermetabolic tissues and has become a useful tool in assessing response to treatment for gastrointestinal stromal tumors in both the adult and pediatric populations [3]. Similar to MRI studies, patients are required to remain motionless on the nuclear medicine gamma camera or PET scanner for a prolonged period of time, and sedation is often required for younger children. Nuclear medicine studies employ ionizing radiation in the form of gamma rays, X-rays, and emitted positrons (PET). The dose for each examination depends on the amount of radiopharmaceutical given as well as the biological and physical half-life of the radiopharmaceutical and varies by target organ.

Computed Tomography and Magnetic Resonance Imaging

CT and MR are often reserved for cases where ultrasound and fluoroscopy have not been diagnostic or for the follow-up of inflammatory or neoplastic disorders. CT involves a significant amount of radiation and should not be utilized in cases where ultrasound can answer the clinical question. CT scanning during multiple phases of contrast enhancement is common in adult CT imaging, but should be avoided in children due to the greater lifetime risk that radiation poses in children. Patients 8 years of age or older can typically follow breath-holding instructions for MR to decrease artifacts from respiratory motion. Younger patients often require sedation as the imaging time may approach 60 min. A skilled child-family life specialist and the use of video goggles in the MR scanner can reduce the need for general anesthesia in younger children [15]. MR enterography and CT enterography allow for better evaluation of the stomach wall than conventional CT and MRI. Enterography studies utilize a large quantity (e.g., 15 mL per kg) of oral contrast consumed at specific intervals before scanning to distend the stomach and bowel. One agent is a solution made of 0.1 % barium sulfate with sorbitol and guar gum to maintain luminal distention and viscosity (VoLumen, E-Z-EM, Lake Success, NY) [1]. The low CT density and low MR intensity of the enterography contrast allow for better visualization of enhancing mucosa than standard high-density oral contrast. Glucagon can also be given to slow peristalsis and decrease MR motion artifacts.

Congenital Abnormalities of the Stomach

Gastric Duplication

Ultrasound is the initial test of choice in the evaluation of suspected gastric duplications in children and is useful if the duplication is contiguous or discontinuous with the gastric wall. Ultrasound of a gastric duplication will show a thick-walled cystic structure with bowel wall signature. Bowel wall signature is a stratified pattern of echogenicity seen in any type of enteric duplication, with an echogenic central layer of mucosa, hypoechoic muscular wall, and echogenic external layer of serosa (Fig. 113.1) [24]. The internal contents of the cyst may be anechoic or contain echogenic debris. Further evaluation may be performed with CT or MRI if ultrasound is not diagnostic or if the lesion extends above the hemidiaphragm (Fig. 113.2). Fetal MRI is useful in the assessment of suspected gastric duplications discovered on prenatal ultrasound and may help differentiate between other types of abdominal cysts. Duplications which are within the wall of the stomach or that are large and cause obstruction or mass effect can also be identified fluoroscopically. On a fluoroscopic upper gastrointestinal series (UGI), this type of duplication will show extrinsic compression of the stomach with a smooth indentation at the site of the duplication, most commonly along the greater curvature [29]. If the lesion connects directly with the lumen of the stomach, the lesion itself may begin to fill with contrast, similar to a gastric diverticula. Approximately 50 % of gastrointestinal duplications found anywhere in the body contain gastric mucosa [28] and will show scintigraphic uptake of Technetium 99m, the same agent used in Meckel scans [20]. Lesions responsible for gastrointestinal bleeding may also be localized on tagged red blood cell scintigraphy.

Microgastria

Microgastria represents a congenitally small stomach which failed to undergo normal differential growth of the greater and lesser curves of the stomach and subsequent 90° clockwise rotation [22, 29]. Consequently, this appears as a small midline vertically oriented stomach with a distended esophagus and GE reflux on UGI [16, 29]. This may be seen in association with malrotation, heterotaxy syndromes (asplenia), or limb reduction defects [17].

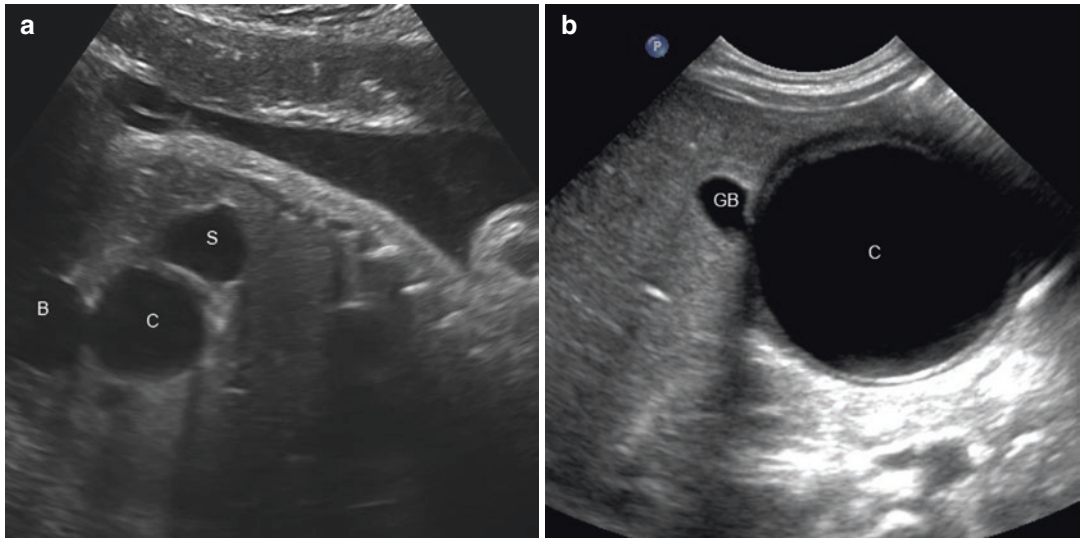

Fig. 113.1 Gastric duplication cyst. (**a**) Prenatal ultrasound image demonstrates a thick-walled cyst (*C*) positioned between the stomach (*S*) and bladder (*B*). (**b**) Postnatal ultrasound demonstrates a thick-walled cyst in the expected location of the pylorus posterior to the gall bladder (*GB*). The cyst wall consists of hyperechoic inner layer of mucosa, surrounded by hypoechoic muscle and echogenic outer layer of serosa, a pattern referred to as "bowel wall signature"

Antropyloric Web

Antropyloric web is thought to represent the consequence of a vascular accident during development and may be seen with ultrasound, UGI, and prenatal imaging [8, 29]. The web may involve the antrum or prepyloric region, and may be thick and persistent or thin and perforate spontaneously. The web creates a pseudo-double-bubble appearance with dilatation of the stomach; the body is separate from a dilated antral region and decompressed duodenal bulb. Decompression of the duodenal bulb differentiates this from the "double bubble" of duodenal atresia. The web is echogenic on ultrasound and produces "knife-like" filling defects on upper GI [8].

Ectopic Pancreatic Tissue

Ectopic pancreatic tissue has a characteristic appearance and can been seen on fluoroscopic imaging as a small round intraluminal filling defect with central umbilication often in the antral region [29]. Given the small size of this lesion, compression images of the stomach or double-contrast UGI may be required. Rarely, ectopic pancreatic tissue can be found in gastric duplications [5].

Developmental, Acquired, and Iatrogenic Conditions

Gastroesophageal Reflux

Gastroesophageal reflux (GER) is commonly present on UGI in early infancy and is considered normal when patients are growing appropriately and are not overtly symptomatic [29]. Fluoroscopically depicted GER does not equate to gastroesophageal reflux disease [6].

Upper GI fluoroscopic studies performed in children with GER are primarily performed to exclude structural reasons for emesis or feeding difficulties and can assess esophageal motility, as well as gastric emptying. Complications of GER which can be identified by UGI include esophageal dysmotility, esophagitis, and mid to distal esophageal stricture [19].

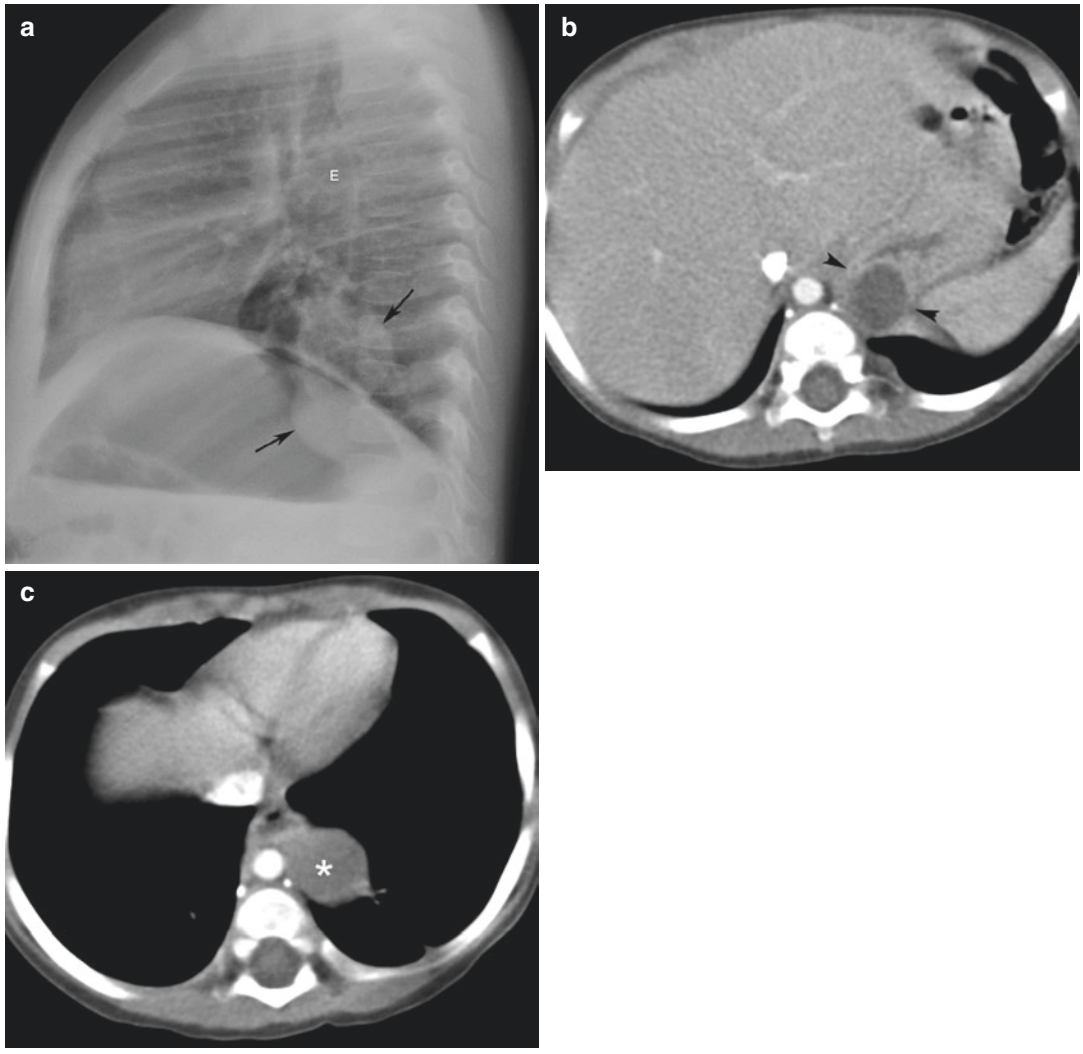

Fig. 113.2 Concurrent gastric and esophageal duplication cysts. (**a**) The lateral chest radiograph depicts a dumbbell-shaped density centered on the hemidiaphragm (*arrows*) with associated gas distention of the entire esophagus (*E*) secondary to mass effect. (**b**) Axial CT image at the level of the subdiaphragmatic portion of the duplication shows the stomach wall extending out along the medial and lateral margins of the cyst (*arrow heads*). This "claw sign" indicates origin of the cyst within the gastric wall. (**c**) Fluid density mass in the left chest (*) is the concurrent esophageal duplication

Intermittent fluoroscopy for 5 min with documentation of the frequency and level of reflux has been described as a method for quantifying GER [29]. However, this increases fluoroscopy time and ionizing radiation dose to the patient unnecessarily and should be avoided. US can be used to documenting episodes of GER, but is not widely available in the United States. Scintigraphy provides quantification of postprandial GER while also quantifying gastric emptying time, but provides little anatomic information.

Gastric Outlet Obstruction

Hypertrophic pyloric stenosis (HPS) is the most common cause of gastric outlet obstruction in early infancy [29]. Ultrasound is the initial

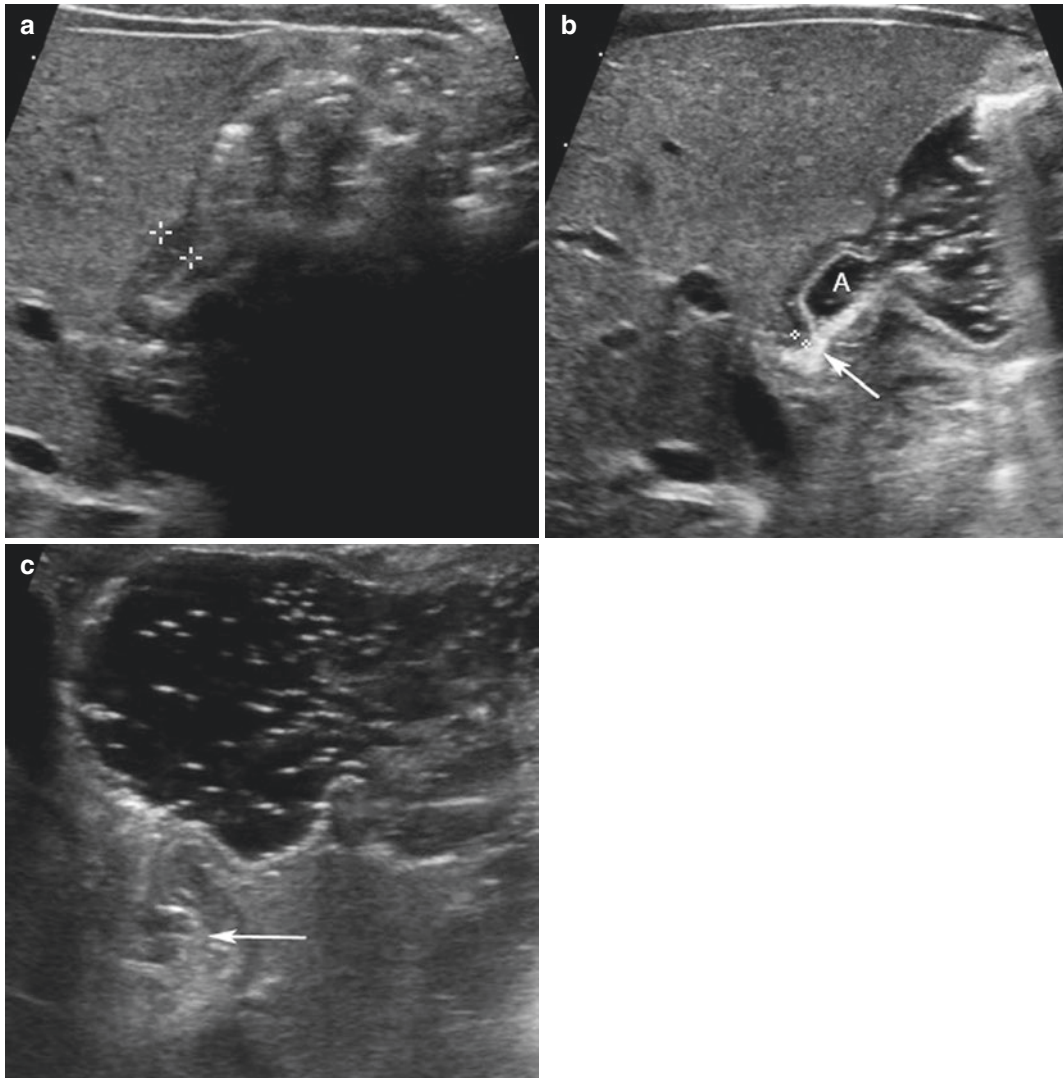

Fig. 113.3 Pylorospasm, normal pylorus, and overdistended stomach in the same patient. (**a**) Antropylorospasm is present; antropyloric wall measured 3.7 mm. (**b**) After feeding there is distention of the antrum (*A*) and a normal pyloric thickness of 1.5 mm. Liquid is passing through the pylorus (*arrow*). (**c**) Overfeeding with clear liquids pushes the pylorus posterior and difficult to assess (*arrow*)

imaging test of choice in infants between 1 week and 3 months of age with gastric outlet obstruction symptoms and nonbilious emesis.

Successful ultrasound imaging of HPS is operator dependent and is difficult if the patient is inconsolable. Feeding the patient a small quantity of clear fluids while in the right lateral decubitus position will distend the stomach and promote gastric emptying. This differentiates the pylorus from the often collapsed or contracted antropyloric region. Antropylorospasm (Fig. 113.3) is a common source of false-positive ultrasound studies for HPS [9]. Overdistention of the stomach leads to posterior displacement of the pylorus, which makes imaging more difficult. A high-frequency linear transducer is placed in oblique-transverse orientation on the right upper quadrant, and the liver is utilized as an imaging window. This will produce a longitudinal image of the pylorus posterior to the gallbladder (Fig. 113.4). Do not accept any images of the "pylorus" that include the heart. Inexperienced ultrasound technologists

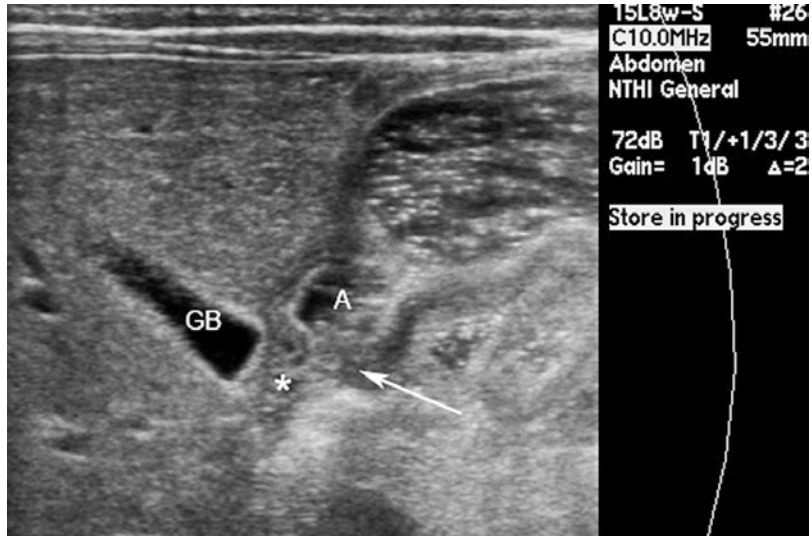

Fig. 113.4 Normal pylorus. The pylorus (*arrow*) is directly posterior and medial to the gallbladder (*GB*) The duodenal bulb is partly distended with fluid and is triangular in shape (*). Fluid distends the gastric antrum (*A*). Scanning was performed at 10 MHz

may mistake the gastroesophageal junction for the pylorus (Fig. 113.5). Pyloric muscular wall thickness can be measured in longitudinal and transverse dimensions. Measurement of a single wall of the pylorus is considered pathologic if greater than 3 mm [24]. The distal end of the pylorus is demarcated by the triangular duodenal bulb which may be filled with either fluid or echogenic gas (Fig. 113.6). Hypertrophic pyloric stenosis should appear mass-like. If no clear shouldering is seen on the antral side of the pylorus, the structure being measured may represent the collapsed gastric antrum.

The length of the pyloric channel is considered pathologic if it measures greater than 16 mm [24]. However, there is overlap between the pyloric channel length in HPS and in normal patients [29]. Haider et al. have found a direct correlation between pyloric length and birth weight in cases of HPS in small and premature infants [14]. Passage of gastric contents through a mass-like pylorus does not exclude HPS. HPS can develop quickly over the course of days, and repeat US imaging should be considered in any patient with persistent symptoms. Keckler et al. showed the pylorus can increase in thickness by up to 0.5 mm per day in HPS [18]. US imaging after pyloromyotomy demonstrates increased thickening of the pylorus in the immediate postoperative period with return to normal thickness at around the fifth postoperative month [31, 32].

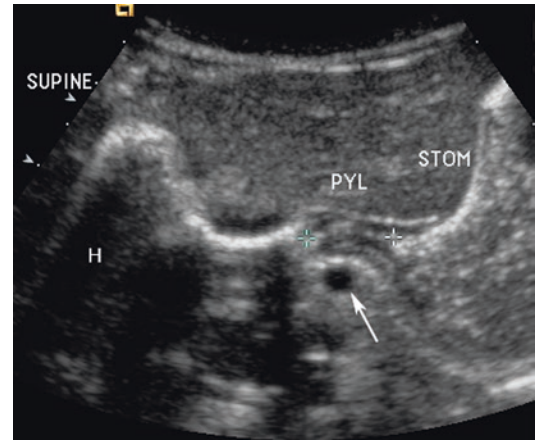

Fig. 113.5 Gastroesophageal junction is mistaken for the pylorus. The GE junction is measured and mislabeled "PYL." The descending thoracic aorta (*arrow*) is directly posterior to the GE junction. The heart is included in the image (*H*). Gallbladder is not included in the image

Documentation of the relationship between the superior mesenteric artery and superior mesenteric vein may be included in ultrasound assessment for HPS. However, a normal relationship between these vessels does not exclude malrotation. An upper GI evaluation is often performed if the pylorus is normal and the clinical picture is concerning for malrotation. This has led some to suggest that an upper GI is a more cost-effective way to evaluate HPS. However, UGI does not give pyloric wall thickness

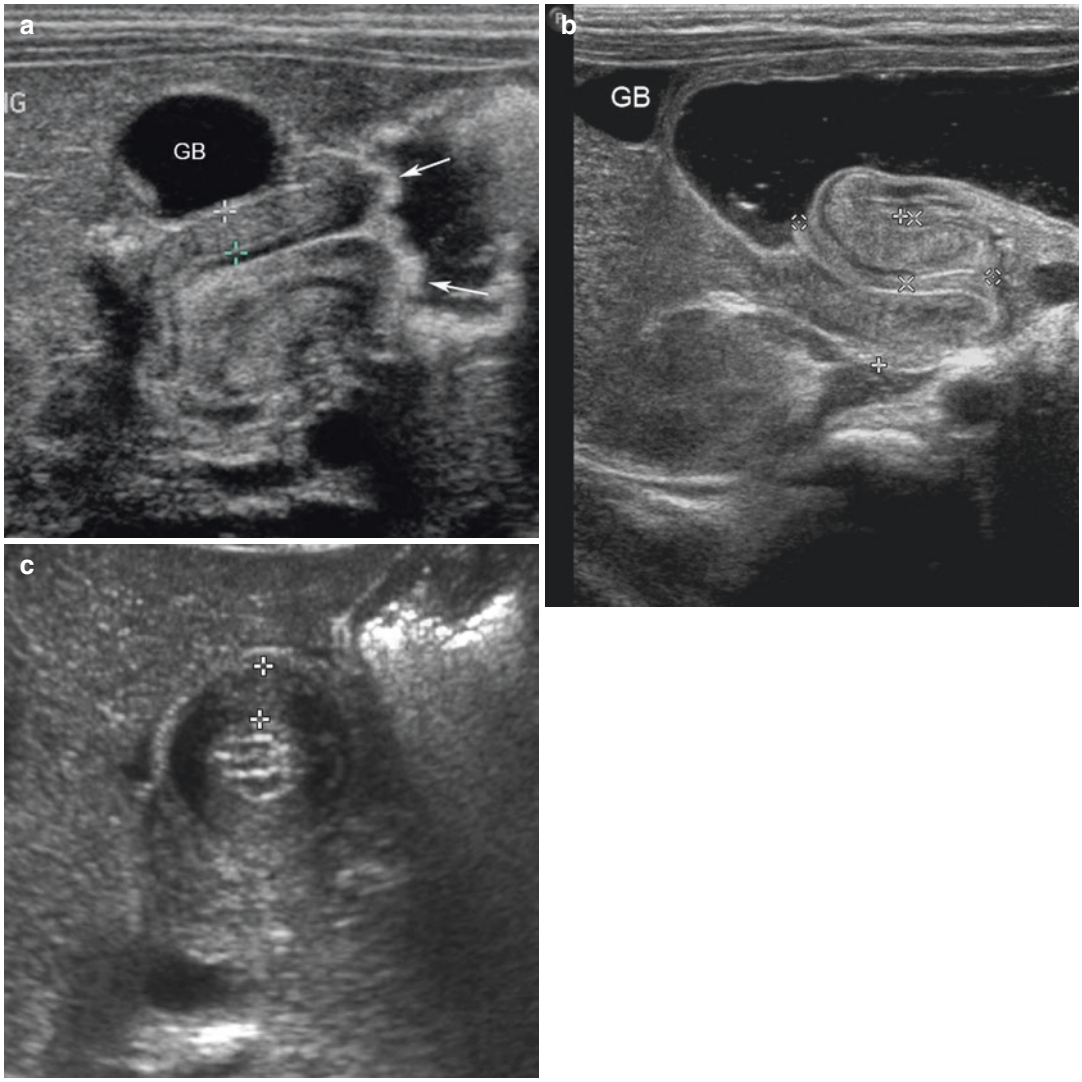

Fig. 113.6 Three patients with hypertrophic pyloric stenosis. (**a**) Pylorus is demonstrated just deep to the gallbladder (*GB*). Pyloric muscular wall thickness is 3 mm, pyloric channel is elongated, and the pylorus is mass-like with shouldering of the pylorus into the gastric antrum (*arrows*). (**b**) Similar finding is seen in a more advanced case of HPS where the pylorus is displaced posteriorly by stomach distention. Pyloric wall measures 5 mm and appears mass-like. (**c**) Transverse image of the pylorus in HPS. Measurement in the transverse plane may exaggerate pyloric thickness if the image is taken off axis

measurements and involves radiation. The fluoroscopic findings for HPS include the caterpillar sign (which represents hyperperistalsis and can also be seen by plain radiography (Fig. 113.7)), shouldering of the hypertrophied pyloric muscle, elongated narrow pyloric channel (Fig. 113.8), and significantly delayed gastric emptying [24]. UGI is also used for the assessment of persistent gastric outlet obstruction postpyloromyotomy (Fig. 113.9). Benign gastric pneumatosis may also be seen on plain radiography in HPS [4, 29].

Congenital and acquired conditions that cause gastric outlet obstruction in infants and children include antropyloric web, gastric duplications, mucosal hypertrophy in long-term prostaglandin therapy (Fig. 113.10), gastric ulcer disease, and, rarely, ectopic pancreatic tissue (Fig. 113.11) [13, 22, 27]. In obstruction due to prostaglandin therapy,

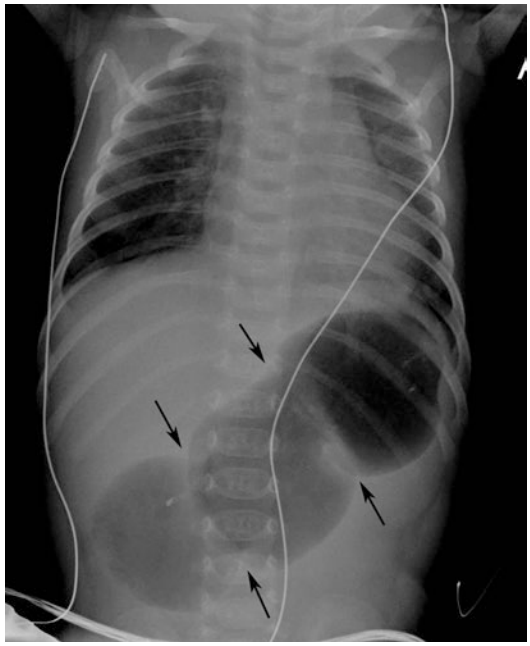

Fig. 113.7 Caterpillar sign of hypertrophic pyloric stenosis. The stomach is massively distended extending into the right lower quadrant with little distal gas. There are two indentations representing hyperperistaltic waves along the gastric contour (*arrows*)

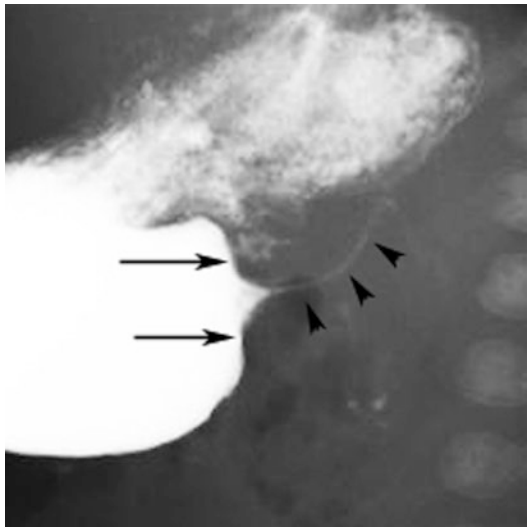

Fig. 113.8 Upper GI findings of HPS. The mass-like pylorus indents the gastric antrum; shouldering (*arrow*) the pyloric channel is elongated and narrow (*arrow heads*), and there is delayed gastric emptying (Courtesy of Dr. Steven Kraus, Cincinnati Children's Hospital and Medical Center, Cincinnati, OH)

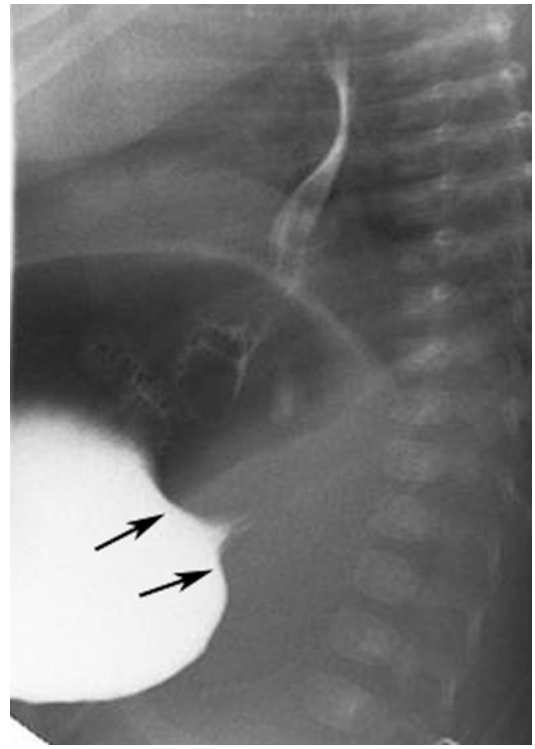

Fig. 113.9 Obstruction postpyloromyotomy. The stomach is massively distended. There is shouldering from the edematous pylorus (*arrows*) and gastric outlet obstruction which resolved spontaneously in this case

the pyloric channel is elongated, but the muscular wall thickness is normal by ultrasound [21]. Antropylorospasm may lead to significant delay in gastric emptying in normal infants during an UGI [29]. Placing the patient in the right anterior oblique or prone position on the fluoroscopy table may promote gastric emptying during the examination.

Inflammatory and Neoplastic Conditions

Stomach pathology may be found in studies performed for other reasons, such as the workup of suspected appendicitis, evaluation for weight loss or malabsorption, neoplasm follow-up, and evaluation of known inflammatory bowel disease [7]. When there is incomplete stomach distention or ingested material in the stomach, on CT or MRI wall thickening cannot reliably be determined.

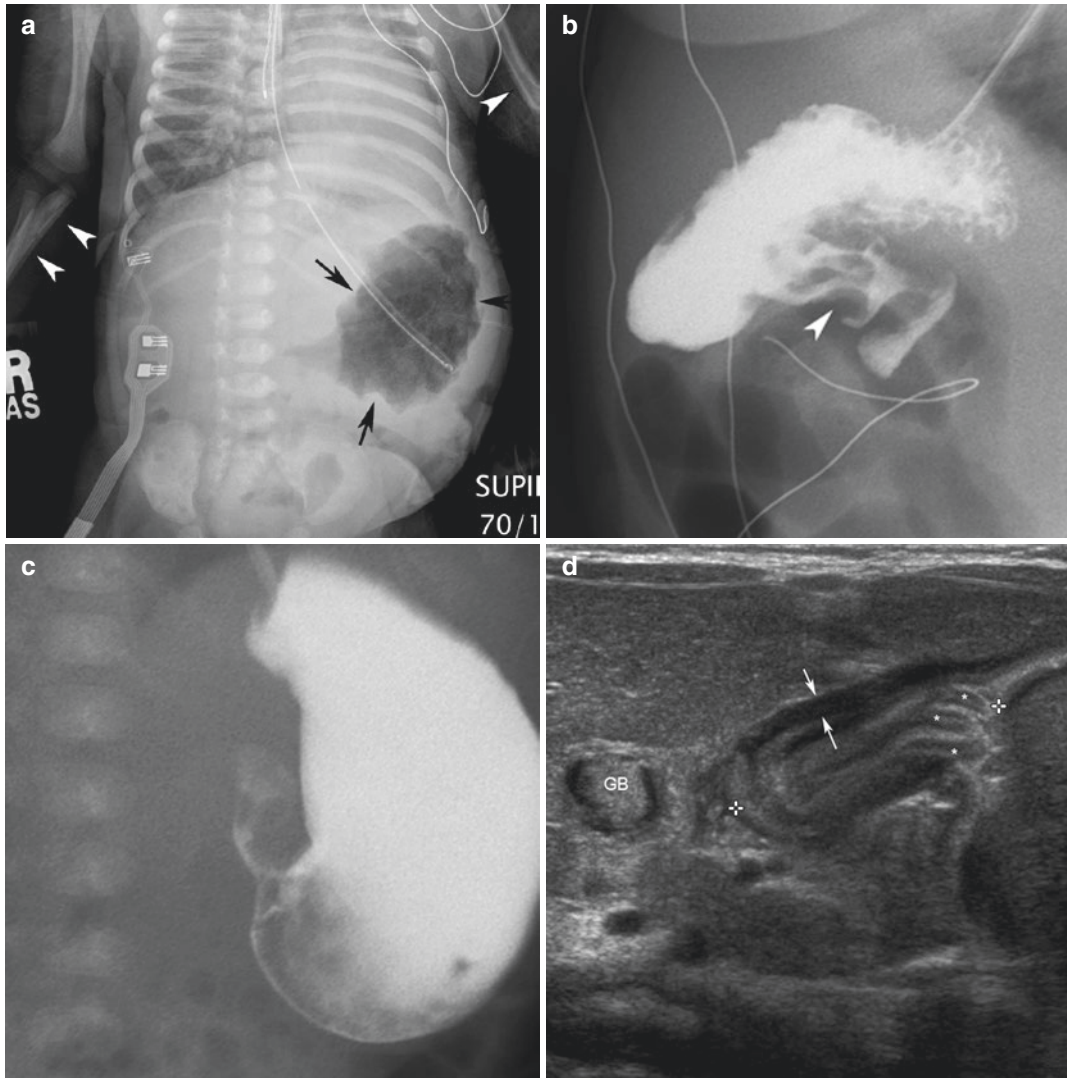

Fig. 113.10 Gastric mucosal hypertrophy in long-term prostaglandin therapy. (**a**) There is thumbprinting of the gastric mucosa (*arrows*) and diffuse long bone periostitis (*arrow heads*) in an infant with interrupted aortic arch and feeding intolerance. (**b**) UGI demonstrated markedly thickened mucosal folds in the gastric antrum (*arrow head*) and mildly delayed gastric emptying. (**c**) Gastric outlet obstruction mimics HPS in this patient with tetralogy of Fallot and pulmonary atresia. (**d**) The pyloric channel is elongated measuring (+ calipers) 25 mm, with normal muscular wall thickness of 2 mm (*arrow heads*). Several mucosal folds are present in the pyloric channel (*). Gallbladder is sludge filled (*GB*)

However, with adequate distention, wall thickening may be identified (Fig. 113.12). Crohn's disease of the stomach is uncommon, especially in children, but may result in chronic narrowing of the antropyloric region on UGI [12]. Tuberculosis of the stomach results in similar findings [23, 24]. CT and MR enterography studies have recently been utilized in the imaging of inflammatory bowel disease. Active Crohn's disease of the stomach is usually seen as wall thickening and hyperenhancement of the distal stomach. The large quantity and type of oral contrast consumed in the enterography protocols produce superior delineation of the stomach wall to that which can be seen on routine abdominal CT or MRI (Fig. 113.13). UGI may also reveal mucosal thickening in gastritis associated with *H. pylori*, chemical ingestion, eosinophilic gastritis, graft-versus-host disease,

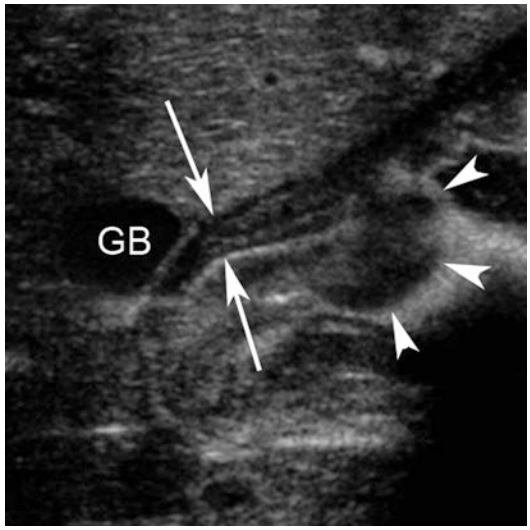

Fig. 113.11 Ectopic pancreatic tissue resulting in gastric outlet obstruction in a 2-day-old infant. Round nodule of ectopic pancreatic tissue (*arrowheads*) is present along the anterior antropyloric wall and mimics the findings of hypertrophic pyloric stenosis. However, the pyloric muscular wall is not thickened (*arrows*). Pylorus is directly adjacent to the gallbladder (*GB*)

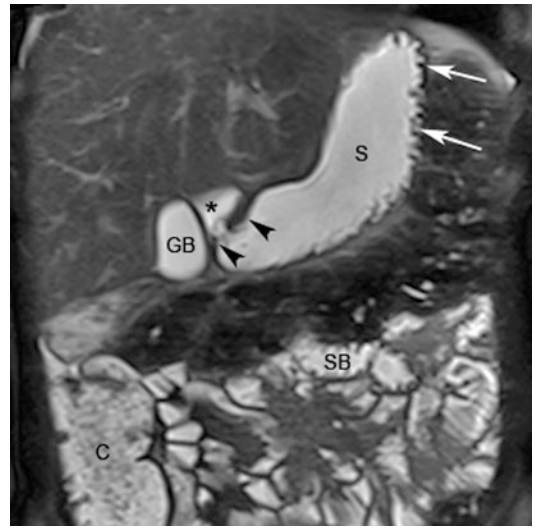

Fig. 113.13 Normal appearance of the stomach, MR enterography. The stomach (S) is well distended by biphasic oral contrast. The pylorus (*arrowheads*) and duodenal bulb (*) are directly medial to the gallbladder (*GB*). Normal rugal folds (*arrows*) are best seen in the fundus. Normal mucosal pattern is also seen in the small bowel (*SB*) and colon (*C*)

Fig. 113.12 Gastric ulcer disease. Coronal CT in an otherwise healthy 12-year-old boy with abdominal pain and nonbilious emesis demonstrates massive thickening of the stomach wall in the gastric antrum (*arrowheads*) and normal wall thickness in the fundus of the stomach (*arrows*) due to large peptic ulcers involving the antrum and pylorus

Fig. 113.14 Gastric lymphoma. CT surveillance in a transplant patient reveals a mass arising from the anterior gastric wall (*arrowheads*) directly adjacent to the patient's gastrostomy tube balloon (*arrow*). The mass is outlined partially by gas, but is also obscured by fluid within the stomach posteriorly (Courtesy of Dr. Brenda Weigel, Minneapolis, MN)

and Menetrier's disease [29]. Childhood gastric tumors are rare [3, 33] and appear as a solid mass contiguous with the stomach wall, best seen when outlined by air or contrast (Fig. 113.14). PET-CT is utilized in the evaluation of gastrointestinal stromal tumors, as described previously [3].

Postoperative Imaging Studies

Gastrostomy tube evaluation is a common pediatric fluoroscopic study. Water-soluble contrast is injected to confirm tube placement within the stomach and to outline the retention balloon. Lateral imaging tangential to the gastrostomy tube skin entry site is essential to show the retention balloon is not inflated within the abdominal wall (Fig. 113.15). Contrast passage into the duodenum and stomach is documented to exclude pyloric obstruction from the retention balloon in the antral region or pylorus (Fig. 113.16). When a gastrostomy tube is malpositioned in the peritoneal space, injected contrast flows dependently and may outline loops of the bowel.

Nissen fundoplication creates a characteristic filling defect just lateral to the gastroesophageal junction on UGI (Fig. 113.17). Contrast may also be seen within the Nissen wrap. However, this does not cause recurrent reflux in all cases [29]. Hiatal hernia or slipped Nissen is identified when the stomach extends above the level of the medial left hemidiaphragm and is best seen on oblique views during UGI. If the patient has no gastroesophageal reflux, a small amount of contrast is given from above to demonstrate the position of the GE junction and differentiate a paraesophageal hernia from a sliding hiatal hernia. The GE junction is below the hemidiaphragm in paraesophageal hernia and above the hemidiaphragm in hiatal hernia

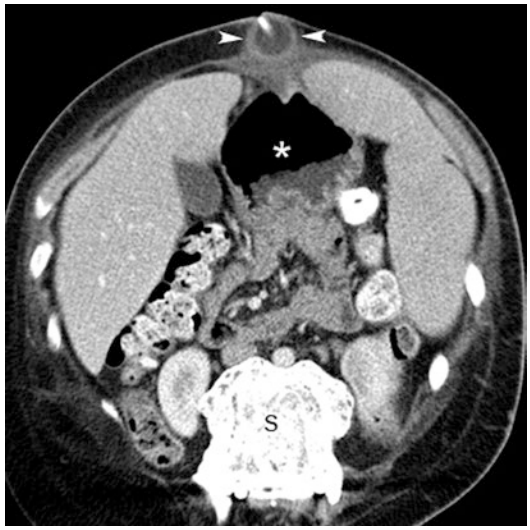

Fig. 113.15 Malpositioned gastrostomy tube. The gastrostomy tube retention balloon (*arrowheads*) is inflated within the anterior abdominal wall, displaced from the stomach antrum (*). The tube was malfunctioning, but the patient was asymptomatic due to decreased sensation from a remote spinal injury (*S*)

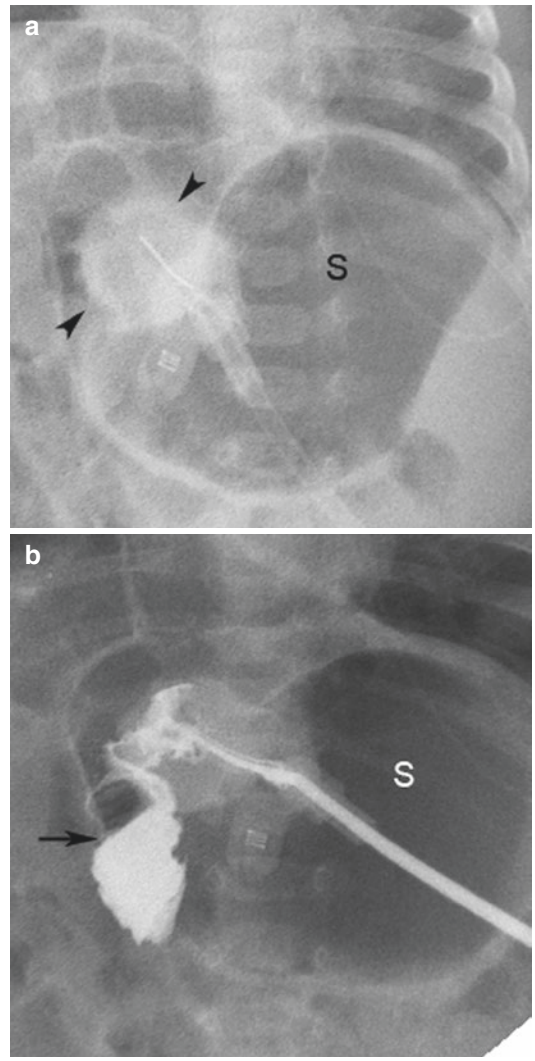

Fig. 113.16 Malpositioned gastrostomy tube. (**a**) The stomach is distended (S) and the retention balloon (*arrowheads*) is at the expected location of the pylorus. (**b**) Injected contrast passes directly into the duodenum (*arrow*) confirming that the retention balloon was inflated at or past the pylorus. (**c**) After deflation and repositioning, the retention balloon (*arrowheads*) is outlined by contrast along the greater curvature of the now decompressed stomach (*S*). Pylorus (*arrows*)

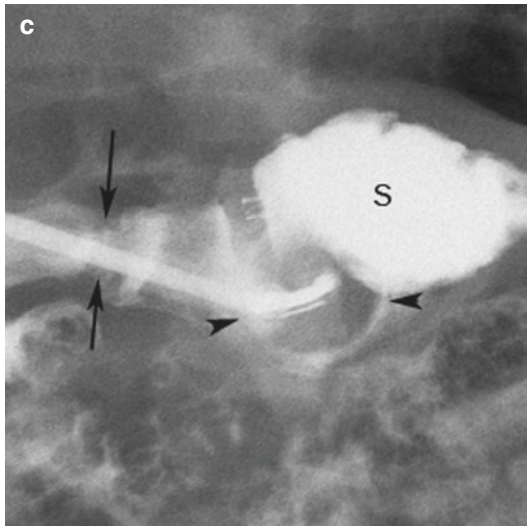

Fig. 113.16 (continued)

Fig. 113.17 Nissen fundoplication defect. Contrast has been injected through the patient's gastrostomy tube. The stomach is well filled and there is no gastroesophageal reflux. There is a small irregular filling defect at the GE junction (*arrows*) which is typical for Nissen fundoplication. The small bowel is malrotated (*arrowheads*)

[19]. If swallowed contrast fails to pass into the stomach in the supine position, it is useful to reassess after the patient has been upright.

Refluxing contrast into the distal esophagus via gastrostomy tube injection is useful in determining the length of the distal esophagus

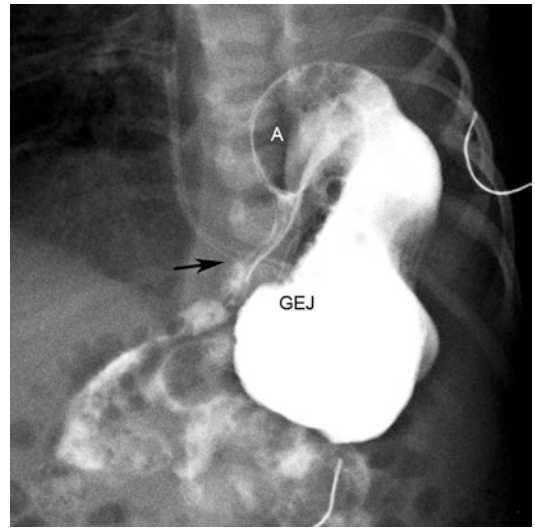

Fig. 113.18 Mesenteroaxial gastric volvulus in an asymptomatic newborn with left lung agenesis and complex spine and chest wall deformities. The stomach is displaced into the left hemithorax due to a congenital diaphragmatic hernia. The gastric antrum (*A*) is positioned superior and anterior to the gastroesophageal junction (*GEJ*). The distal esophagus and elongated antropyloric region cross overlying the spine (*arrow*)

in esophageal atresia and is also useful in finding esophageal leak postesophageal atresia repair.

Emergent Conditions

Gastric Volvulus

Another cause of nonbilious emesis is gastric volvulus. Imaging studies may show an elevated left hemidiaphragm or diaphragmatic hernia both of which are associated with poor ligamentous fixation of the stomach [11]. In acute volvulus radiographs may show a double air-fluid level [19]. On UGI or CT mesenteroaxial volvulus results in the pylorus being positioned superior and anterior to the gastroesophageal junction [19, 29] with an unusually vertical orientation of the stomach (Fig. 113.18). If there is an associated hernia, contrast may remain in the abdominal portion of the stomach due to obstruction at the site of herniation (Fig. 113.19). Organoaxial volvulus

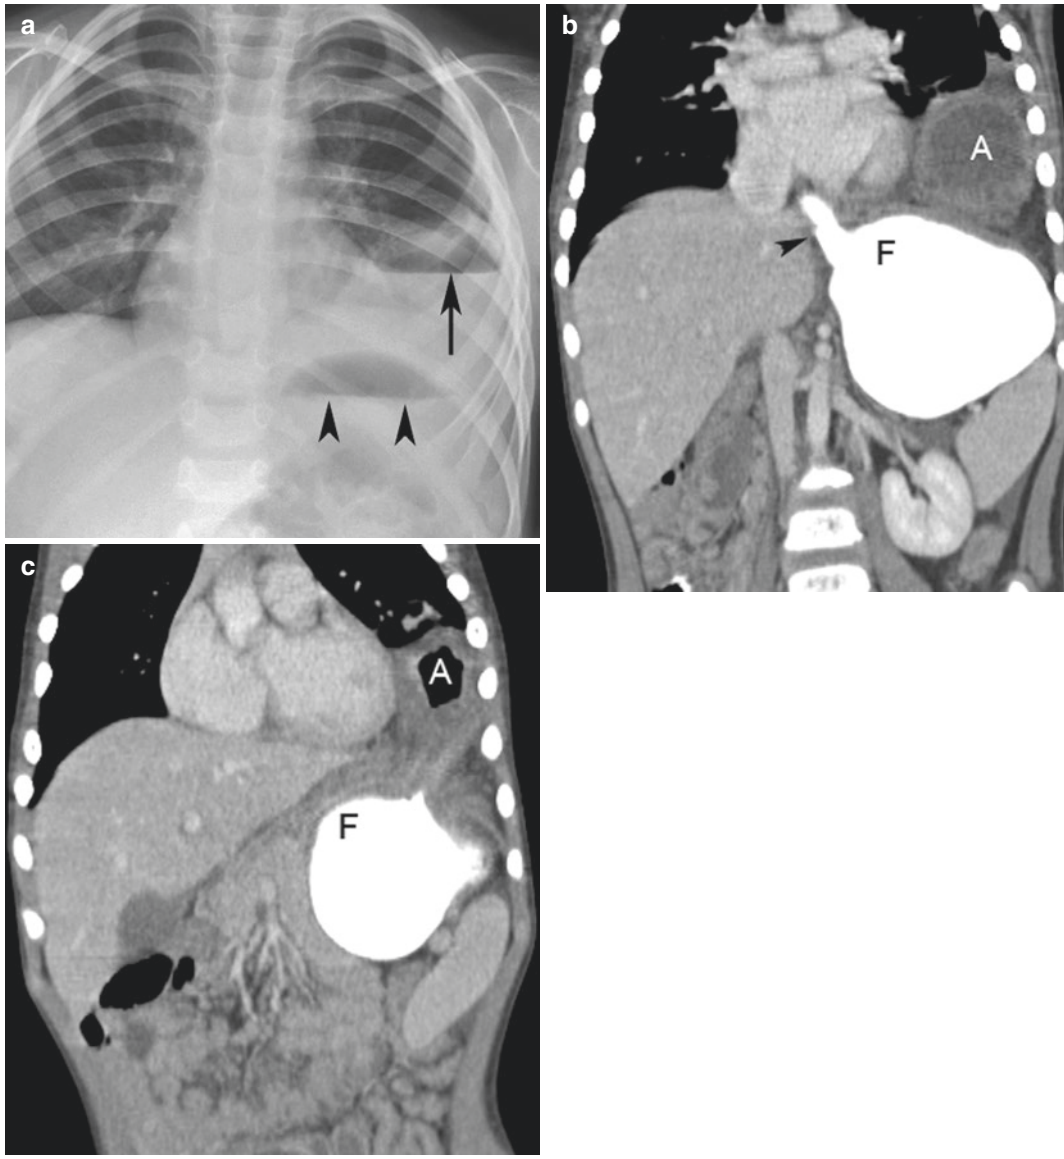

Fig. 113.19 Acute mesenteroaxial gastric volvulus. (**a**) Chest radiograph demonstrates a fluid-gas level in the left hemithorax (*arrow*) and in the expected position of the gastric fundus (*arrowheads*). (**b**, **c**) There are contrasts in the gastric fundus, (*F*) which remains in its expected location, and within the esophagus (*arrowhead*). However, there is no contrast in the stomach antrum (*A*) which has herniated into the left hemithorax (Courtesy of Dr. Eric Hoggard, Minneapolis, MN.)

results in horizontal orientation of the stomach with the greater curvature positioned superior to the gastroesophageal junction. The stomach may assume a similar position in neonates due to circulating maternal hormones and has been described as a "floppy stomach" to differentiate this from a true volvulus [26].

Gastric Perforation

A large amount of free intraperitoneal air in a neonate suggests gastric perforation. This may be seen as a contiguous diaphragm sign, Rigler's sign, outlining of the ligamentum teres by air, or triangular-shaped regions of gas or unusual

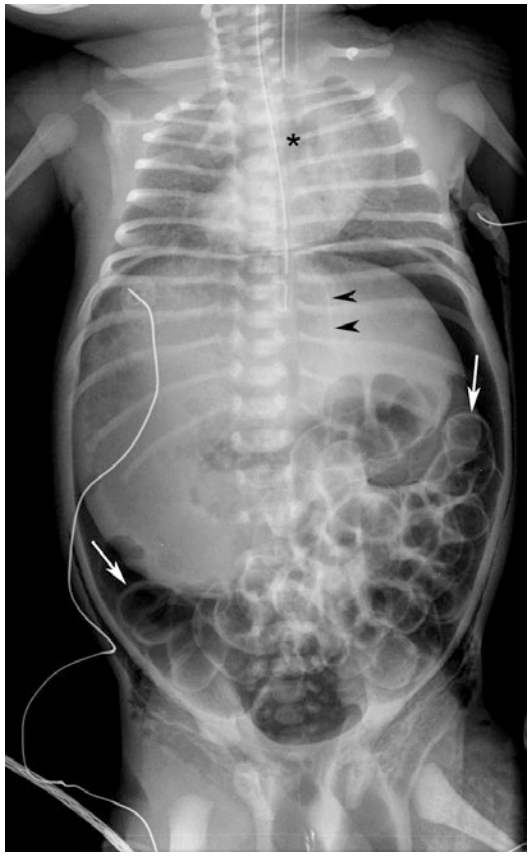

Fig. 113.20 Iatrogenic stomach perforation in a complicated neonate with situs inversus. There is massive free air in the abdomen. Air outlines the ligamentum teres, known as the "football sign" (*arrowheads*). Gas also outlines both sides of the bowel wall, known as the "Rigler's sign" (*arrows*). Gas has tracked into the chest causing pneumomediastinum (*), pelvic subcutaneous tissues, scrotum bilaterally, and the tissue planes of the left thigh

lucent area over the liver on supine images, and can be confirmed by cross-table lateral or lateral decubitus radiographs. Gastric perforation is seen spontaneously in neonates from birth trauma and can be seen in patients of any age due to iatrogenic perforation after enteric intubation or from gastric ulceration (Fig. 113.20).

Foreign Bodies

Ingested foreign bodies such as coins and coin-shaped batteries are likely to pass from the stomach if they are demonstrated below the GE

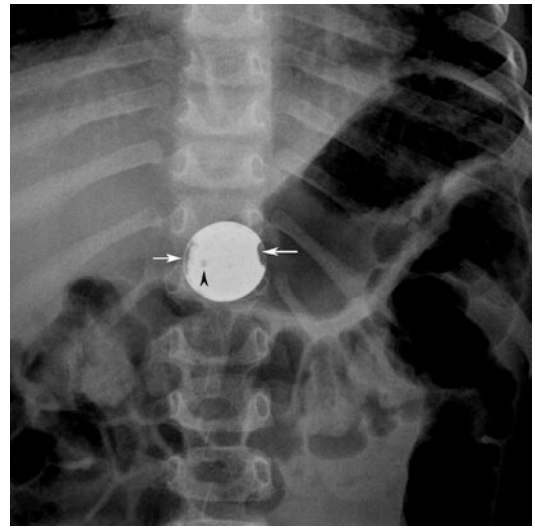

Fig. 113.21 Retained gastric penny. Round metallic foreign body projects over the gastric antrum. The object is eroded at its lateral margins (*arrows*) and centrally (*arrowhead*). Radiographically this cannot be distinguished from an eroded coin-shaped battery

junction on plain radiographs [2, 3]. However, if a penny fails to pass from the stomach, the copper coating erodes, and the underlying zinc is exposed, which may lead to gastric ulcers and anemia (Fig. 113.21). If eroded margins or holes are radiographically evident, the penny should be endoscopically removed [25]. Other radiopaque-ingested hazards include magnets (which can cause enteric perforations), bones, and lead-based objects including jewelry. Many ingested materials are radiolucent and are not detectable by plain radiographs. UGI and CT are imaging options for non-radiopaque stomach foreign bodies including thin metallic objects such as aluminum can tabs.

Hair and high-fiber vegetable matter are common ingested materials seen in childhood bezoar (Fig. 113.22) [29]. Bezoars may be seen as an intraluminal stomach mass on plain radiography, fluoroscopic studies, ultrasound, or CT. However, UGI is the initial test of choice [19]. Trichobezoar is seen as an echogenic mass on ultrasound due to gas trapped within the mass of hair. If a trichobezoar extends into the duodenum and small bowel (Rapunzel syndrome), findings of small bowel obstruction may also be present [10, 31]. Ingested

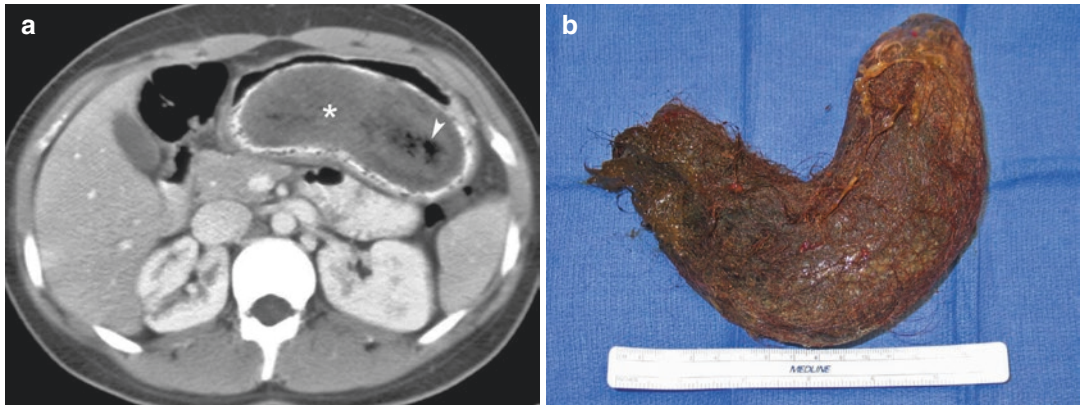

Fig. 113.22 Trichobezoar. (**a**) Axial CT demonstrates a heterogeneous mass of hair (*) and trapped air bubbles (*arrowhead*) distending the stomach, surrounded by contrast posteriorly and air anteriorly. (**b**) The trichobezoar gross specimen conforms to the shape of the stomach (Courtesy of Dr. Hank Baskin, Salt Lake City, UT)

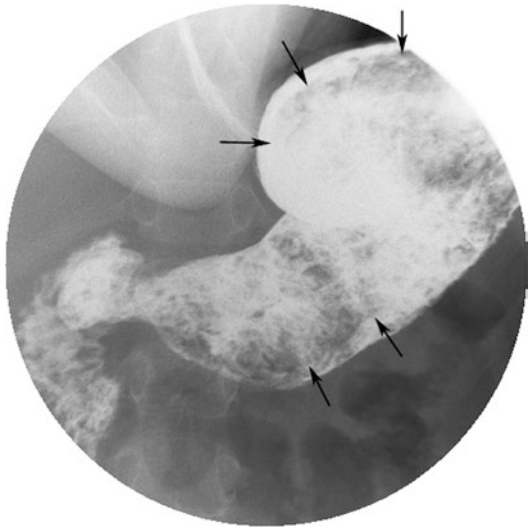

Fig. 113.23 Retained food mimicking bezoar in an autistic child. The stomach is mildly distended with a large immobile filling defect (*arrows*) composed of recently ingested French fries

food may mimic a bezoar if the patient is not appropriately NPO for a fluoroscopic study (Fig. 113.23). Delayed images of the stomach are useful in this circumstance.

Gastric Motility and Electrogastrography (EGG)

114

Alberto Ravelli

Introduction

The physiology and pathophysiology of gastrointestinal motility in the human infant and child are only partially understood. This is largely due to the fact that invasive and unpleasant investigations are usually required to study contractile activity and transit through the gut. In fact, such invasive investigations are less acceptable and on average poorly tolerated by both infants and children, and therefore systematic studies are severely limited. The constraints imposed by such poor acceptability of extensive motility studies in childhood are the main reasons why paediatric gastroenterologists have become increasingly interested in non-invasive means of assessing gastrointestinal motility and transit. Such techniques include radionuclide scan (scintigraphy), ultrasonography, breath test and electrical impedance tomography for the study of gastric emptying and the recording of electrical activity of the gastric antrum by surface electrodes, i.e. electrogastrography or EGG.

Physiology of Gastric Motility and Gastric Emptying

The stomach has a rather sophisticated and diversified motor function (Fig. 114.1). The fundus provides receptive relaxation to accommodate food, and low-frequency tonic contractions provide a pressure gradient that facilitates the aborad progression of the bolus. In the proximal corpus, a specialised region where interstitial cells of Cajal are concentrated acts as a pacemaker originating regular 0.5 Hz (3 cycles/min) electrical activity. This activity sweeps all the way down and around the stomach due to the syncytial structure of the longitudinal, circular and oblique smooth muscle layers of the gastric wall. This pacemaker activity underlies the strong peristaltic contractions of the distal corpus and antrum that are responsible for mixing, grinding and propulsion of food, as well as clearing of gastric residues during phase III of the migrating motor complex. The pyloric region is characterised by coordinated contractions that control gastroduodenal flow. Gastric emptying, however, is not just a mechanical event, since it is modulated by central influences (cephalic phase of digestion) and several intraluminal factors such as the caloric content, osmolarity and composition (medium- or long-chain triglycerides, type of carbohydrates, protein source) of the meal (Figs. 114.2, 114.3, 114.4, 114.5, 114.6 and 114.7).

Electrogastrography (EGG)

History of the EGG

From a historic point of view, EGG is not new in paediatrics. Back in 1926, in fact, 4 years after the first description of a human EGG by Walter Alvarez, I. Harrison Tumpeer, a paediatrician, published an article on the "registration of peristalsis by the Einthoven galvanometer" [1], and a few years later, Tumpeer and Phillips reported the successful recording of an EGG from a 5-week-old infant with pyloric stenosis [2], who was so thin that gastric peristalsis was evident by simply watching the skin over his abdomen. It is noteworthy that this tracing (obtained by using standard ECG limb leads) was described by the authors as looking like an ECG with a slowly changing baseline. The changes in the baseline clearly occurred at approximately 0.05 Hz and closely matched the frequency of gastric contractions that could be observed visually. Therefore Tumpeer and Phillips suggested that such ECG baseline changes, which had often been reported (but not explained) by cardiologists, were in fact due to gastric peristalsis. Since then, there were

no further EGG studies in paediatric patients until 1978, when Telander et al. published a report describing a small infant with severe intractable vomiting and a marked impairment of gastric emptying. These abnormalities were related to a severe dysfunction of gastric smooth muscle, which in turn was due to a derangement of the frequency of gastric electrical control activity from the customary 3 cpm to a "tachygastria" of 4.7 cpm, and to an orad propagation of the electrical activity recorded in the gastric antrum [3]. A similar patient with tachygastria underlying an intractable vomiting and the inability to assume oral feeds was described a few years later by Cucchiara et al. [4]. In both these patients, antrectomy was curative of vomiting and gastroparesis and allowed the children to resume oral feeds.

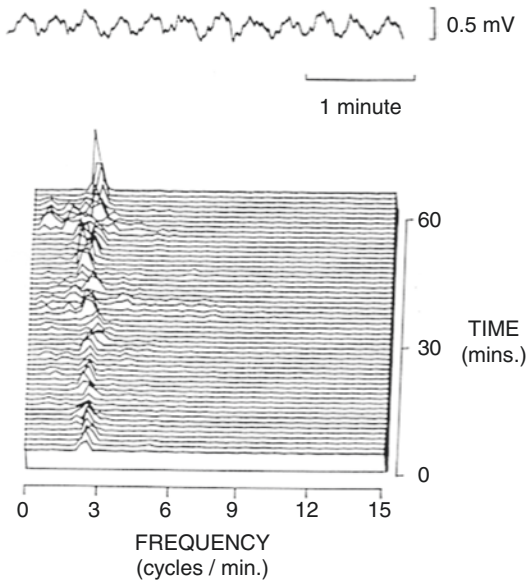

Fig. 114.3 Normal 3 cycles per minute gastric contractions with amplitude on the z axis

Recording and Analysis of the EGG

With time, the technique of recording and evaluation of the gastric electrical activity from surface electrodes has been considerably improved. The use of bipolar electrodes, adequate amplifiers and band-pass filters allows the recording of a much clearer signal. The digital conversion of the raw analogue signal at frequencies of 1–5 Hz provides a mathematical representation of the signal which is suitable for subsequent computerised analysis. The technique of running spectral analysis [5] (by fast Fourier transform, autoregressive modelling or exponential distribution) [6] allows the frequency and power of the signal to be assessed in a more objective fashion than the simple visual inspection. Also, recent developments such as the wavelet analysis [7] can be used to remove artefacts and improve the interpretation of the recording, especially in infants and young children. Such techniques are now customary in modern EGG and were used in a number of paediatric EGG studies that have appeared in the literature over the last 20 years. Essentially, these studies were aimed at either

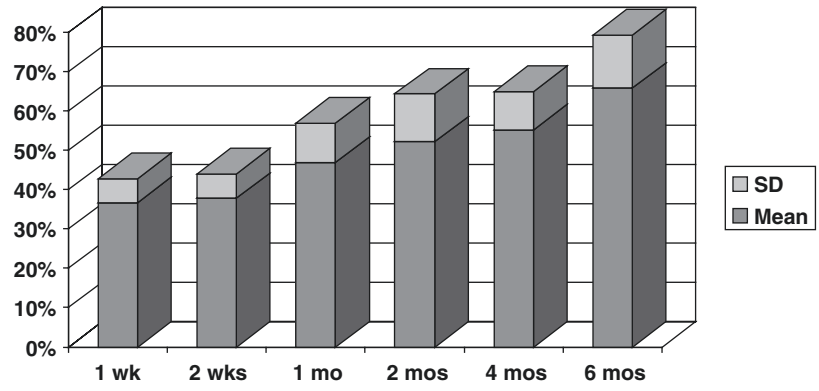

Fig. 114.4 As infants mature the frequency of 2–4 contractions per minute (cpm) increases until at around 4–5 months of age these account for approximately 70 %

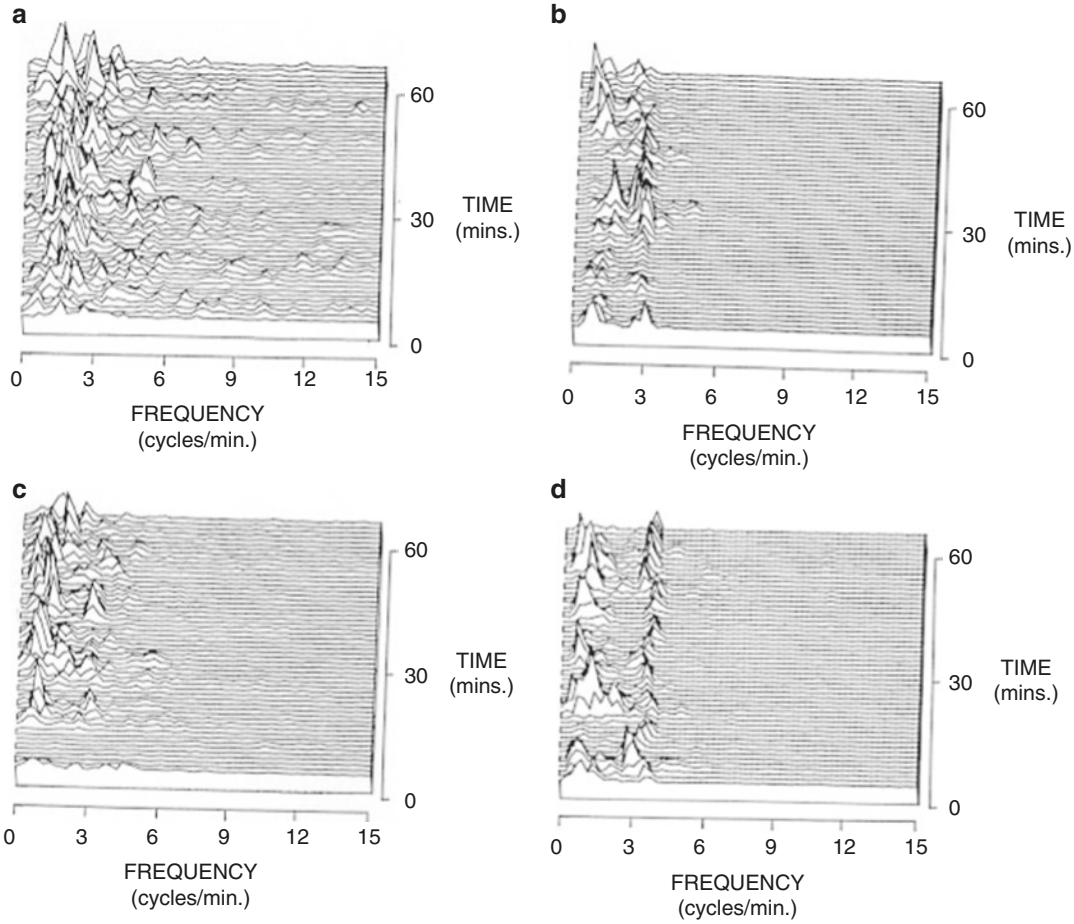

Fig. 114.5 Pre- (*left*) and post- (*right*) prandial gastric EGG both of which can be affected by intra-luminal contents including the caloric content, osmolarity and composition (medium- or long-chain triglycerides, type of carbohydrates, protein source) of the meal

defining the ontogenesis and development of gastric electrical control activity or at investigating the role of gastric antral dysrhythmias in a number of paediatric disorders characterised by nausea, vomiting and feeding problems.

Ontogenesis and Development of Gastric Electrical Activity

Koch et al. found a considerable degree of instability in the postprandial gastric electrical activity of both preterm (28–32 weeks) and term babies, with normal 2.5–3.6 cpm frequency occurring only for 9–34 % of the time and being often overwhelmed by frequencies within the bradygastria or tachygastria range [8]. On the other hand, premature babies did not exhibit any increase in EGG power after gavage feeding of a standard low-birth-weight formula. These findings may reflect an immature response of the gastric neuromusculature (and also of the humoral control system) to formula feeds. Zacchi et al. described cyclic frequency changes of gastric electrical activity in term as well as preterm infants, with faster changes in the latter [9]. Interestingly, Mihailoff et al. reported movement artefacts as a major cause of unusual distribution of frequency and amplitude of the EGG signal in as many as 51 % of infants [10]. This is a common experience for paediatricians involved with gastrointestinal motility testing and should be

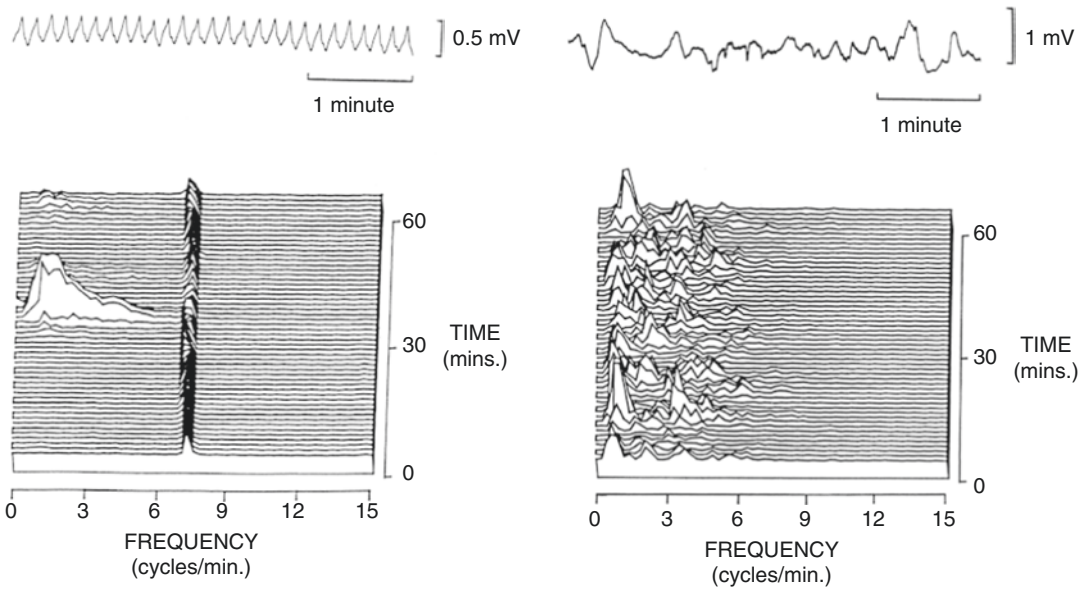

Fig. 114.6 An example of tachygastria (*left*) and disordered gastric contraction frequency (*right*)

taken into account in order to avoid an overestimation of gastric dysrhythmias. By carrying out consecutive measurements of the EGG (at 1 week and 2 months), Liang et al. were able to describe a developmental pattern of gastric electrical activity in preterm infants, which was characterised by a significant increase in the percentage of 2–4 cpm activity and a reduction or normalisation of tachygastria [11]. Furthermore, by the age of 4.5 months, full-term infants showed a significantly higher (70 %) percentage of regular 3 cpm gastric slow waves in comparison with premature babies.

EGG in Clinical Practice

Severe Disorders of Gastrointestinal Motility

A number of EGG studies have been carried out over the years in children with different disorders affecting all the control levels of gastrointestinal motor activity: myogenic, neurogenic (intrinsic and extrinsic) and humoral. Children with chronic intestinal pseudo-obstruction related to a primary neuromuscular disease of the gut may exhibit two distinctive patterns of gastric dysrhythmias: children with an enteric myopathy did have a continuously irregular gastric electrical activity where no dominant frequency could be detected, whereas children with histologically proven neuropathic disease had a persistent tachygastria [12]. Several factors may account for the unstable electrical activity found in patients with myopathy: the inability to maintain a constant frequency or a poor summation of the electrical signal, due to a patchy involvement of smooth muscle cells and/or interstitial cells of Cajal in the disease process, or a marked reduction in signal amplitude and thus in signal-to-noise ratio. On the other hand, the most likely explanation for the tachygastria found in children with enteric neuropathy is a lack of intrinsic inhibitory innervation. Using techniques of chaos analysis, the presence of complex high-dimension interactions in the EGG of children with myopathic pseudo-obstruction was demonstrated, suggesting that gastric myocytes behave like other excitable cells, interacting in a chaotic manner that is increased by disease [13].

Neurological Disorders

Severe recurrent vomiting, often complicated by aspiration and failure to thrive, is common in children with disorders of the central nervous system (CNS) such as cerebral palsy and psychomotor

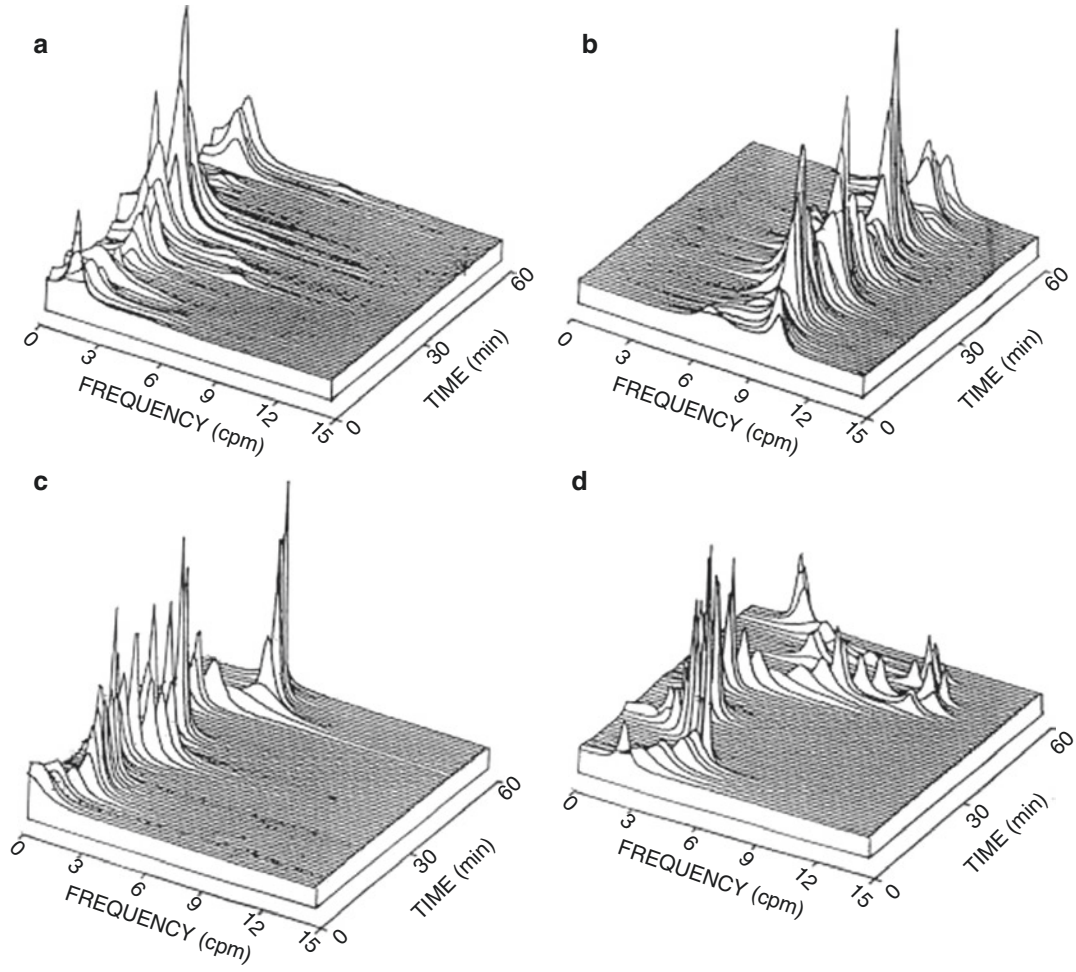

Fig. 114.7 Examples of high amplitude gastric dysrhythmias including abnormal post-prandial tachygastria

retardation. Vomiting is usually ascribed to gastro-oesophageal reflux, which indeed can be found in about 75 % of these patients. In vomiting children with cerebral palsy and neurodevelopmental delay, the majority of whom had gastro-oesophageal reflux, gastric dysrhythmias of different sorts (tachyarrhythmia, bradyarrhythmia, mixed dysrhythmia or unstable electrical activity) were as common as gastro-oesophageal reflux, occurring in 62 % of the patients and were associated with reflux in one-third of them [14]. Furthermore, gastric dysrhythmias were present in most children with disorders of the CNS who had persistent retching and postprandial discomfort following Nissen fundoplication and were already present before the procedure was carried out [15]. Thus it appears that children with CNS disease who suffer from recurrent vomiting often have a widespread disorder of foregut motility, where gastric dysrhythmias (possibly due to persistent activation of the emetic reflex) are as common as – and may contribute to – gastro-oesophageal reflux. In these children gastric dysrhythmias are probably due to abnormal modulation of the enteric nervous system by the CNS, although in some cases an involvement of the enteric nervous system by a process similar to that affecting the brain cannot be excluded.

Postsurgical Nausea and Vomiting

As mentioned above, gastric dysrhythmias were found in children with CNS disorders who had persistent retching following Nissen fundoplication [15, 16], and in the majority of them, dysrhythmias were already present before the procedure was carried out [16]. Since gastric dysrhythmias may be unmasked by Nissen fundoplication, EGG can be useful in detecting which patients are more likely to have retching problems following this operation, so that in these patients alternative therapeutic interventions may be considered [15–17].

Vomiting, retching and feeding difficulties are often present in children who underwent oesophageal replacement for complex oesophageal malformations (e.g. oesophageal atresia with or without tracheo-oesophageal fistula or extensive peptic/caustic stricture) [18]. In a group of 12 such children who had been subjected to gastric transposition, the emptying of the transposed stomach varied – delayed in 7, accelerated in 4 – but in the 4 who had dumping-like symptoms, the EGG looked entirely normal [19].

Disorders of Eating Behaviour

Gastric dysrhythmias have been described in adults with anorexia nervosa [20]. In children with early-onset anorexia nervosa, on the contrary, the frequency of fasting and postprandial electrical activity and the fasting/postprandial amplitude ratio did not significantly differ from that of controls, although patients with longer established disease had a smaller increase in amplitude [21]. It is therefore possible that gastric motility disturbances detected in adult patients with anorexia nervosa are related to a longer duration of the disease and are a consequence, rather than a cause, of malnutrition in these patients.

Functional Gastrointestinal Disorders

Different gastric dysrhythmias and delayed gastric emptying of a mixed solid-liquid meal have been reported in a high proportion of children with non-ulcer dyspepsia [22–24]. In a few patients, these alterations, together with the clinical symptoms, were successfully treated by the prokinetic drug cisapride [23]. It is interesting to note that in many children with non-ulcer dyspepsia, no significant correlation was found between gastric dysrhythmias, gastric emptying and the patients' symptom score [25, 26].

Similarly to other functional GI disorders, gastric dysmotility and the related symptoms of nausea, vomiting and gastric retention can be a consequence of a gastrointestinal infection [27, 28]. Indeed gastric dysrhythmias have been found in patients who developed gastroparesis following a viral gastroenteritis [27, 29] as well as dyspeptic patients with chronic gastritis due to *Helicobacter pylori* [30, 31], with the former condition being self-limiting in most cases and the latter usually resolving after successful eradication therapy [27–31]. Studies in animal models suggest that *H. pylori* infection may induce dyspeptic symptoms via a complex sensory-motor dysfunction of the enteric nervous system [32].

Chronic Renal Failure

A number of neuroamines (e.g. noradrenaline or dopamine) and polypeptide hormones (e.g. gastrin, glucagon, cholecystokinin) have the potential to induce gastric dysrhythmia, delayed gastric emptying, nausea and vomiting in experimental animals as well as in humans [33–35]. The effects of an altered humoral environment on gastrointestinal motility were investigated in children with chronic renal failure, in whom the metabolism of several polypeptide hormones is impaired [36]. Those children who suffered from anorexia, nausea and vomiting were found to have dysmotility of the foregut in the form of gastro-oesophageal reflux, gastric dysrhythmia and/or altered gastric emptying [37, 38]. In most of them, serum levels of gastrin were increased above the upper normal limit [37]. In subsequent studies, vomiting and anorectic children with chronic renal failure were found to have significantly higher fasting and postprandial serum levels of gastrin, cholecystokinin and neurotensin compared to asymptomatic uremic children and children who had undergone renal transplantation [39]. On the other hand, motility tests were

normal in asymptomatic children with renal failure [38]. Following renal transplantation, the gastric dysrhythmias disappeared in all patients in whom renal function and polypeptide hormone levels had normalised [36, 38, 39]. Thus it appears that gastric dysrhythmias (and gastro-oesophageal dysmotility in general) in chronic renal failure are related to an altered humoral environment generated by the impaired renal degradation of these polypeptide hormones.

Food Allergy

Gastric dysmotility and upper gastrointestinal symptoms can be related to food hypersensitivity. Gastric dysfunction in food allergy is described in detail in the next chapter.

Gastric Pacing

Conclusion

In summary, gastric motor function is subjected to complex control mechanisms, and gastric dysmotility is present in a wide variety of paediatric disorders characterised by symptoms of nausea and vomiting where such control mechanisms are deranged. EGG can be safely and effectively used in paediatric patients, from premature babies to children and adolescents, to investigate the ontogenesis of gastric electrical activity and the pathophysiology of gastric dysrhythmias in children with vomiting and feeding disorders. In analogy to other aspects of gastrointestinal motility such as lower oesophageal sphincter pressure and small intestinal motility, gastric antral electrical activity appears to develop from the prenatal period through the first few months of life. In normal healthy children, gastric electrical activity is similar to that in adults in terms of both frequency and response to a meal. Relevant abnormalities (gastric dysrhythmias) have been detected and characterised in several conditions where the different control levels of gastric motor activity are affected, although the correlation between myoelectrical disturbances and gastric motility and emptying is not always clear. Recent developments such as electrical pacing, prolonged ambulatory EGG monitoring, chaos analysis and spatial mapping of gastric frequencies should render the EGG more and more meaningful for the study of gastrointestinal pathophysiology and the assessment of gastrointestinal motility disorders.

Anatomical Gastropathology

Anatomical Gastropathology

115

Basil Bekdash and Sean S. Marven

General

At first glance, the stomach appears to be a simple organ but this belies its functional complexity and importance in normal eating behaviour. In modern societies with abundant calorific foodstuffs, it is arguable that the stomach's adaptability and effectiveness in handling dietary intake permits the increasing prevalence of obesity. Anatomical abnormalities will often produce dramatic and acute but non-specific symptoms.

The stomach is a robust and accessible organ with a rich blood supply from all three main branches of the coeliac artery as well as extra-axial vessels. This affords endoscopists and surgeons multiple options in approaching anatomical pathologies.

As discussed (section "Gastric Volvulus"), the stomach is first discernable as a dorsal foregut expansion in the fourth/fifth week of embryogenesis [55]. Deviations from the typical developmental programme may produce anatomical variants and anomalies that cause symptoms or are detected incidentally during radiological, endoscopic or surgical evaluation. When managing these conditions, caution should be exercised as the majority are rare and variable entities frequently associated with other significant anomalies.

e-mail: basil.bekdash@gmail.com; sean.marven@sch.nhs.uk

Congenital Gastric Abnormalities

The majority of anatomical abnormalities of the stomach are in some sense congenital though many do not present until some time after birth. Occasionally lesions may be suspected antenatally, though the features are non-specific (absent stomach, dilated stomach) and are more likely to be due to commoner anatomical anomalies such as oesophageal atresia and duodenal atresia, respectively.

Outlet Obstruction

The presentation will depend on the degree and frequency (when intermittent) of obstruction and the age at onset for acquired causes. Invariably there will be non-bilious vomiting which may be intermittent if the obstruction is incomplete or intermittent as occurs with some antral webs and duplications. Vomiting secondary to high gastrointestinal obstruction will variably result in failure to thrive, dehydration and the classical hypochloremic hypokalaemic metabolic alkalosis (section "Infantile Hypertrophic Pyloric Stenosis") in severe or chronic cases. Pyloric atresia is the archetypical congenital anatomical cause of gastric outlet obstruction though at least some cases of gastric antral web appear to be congenital, and hypertrophic infantile pyloric stenosis may rarely present at birth [71] (and personal experience).

DOI 10.1007/978-3-642-11202-7_115

Pyloric Atresia

Pyloric atresia is a rare disorder in which there is congenital discontinuity of the gastrointestinal lumen at the level of the pylorus. The quoted incidence of 1/100,000 [40, 48] is based on German studies from the 1970s [2, 18] and a presumption that pyloric atresia represents 1 % of all gastrointestinal atresias. The anomaly has been subdivided based on the morphology of the atresia in a similar manner to other gastrointestinal atresias: type I/A ('membrane') have a thin membrane or web obstructing the lumen. This can result in a so-called windsock deformity, commonly seen in membranous forms of duodenal atresia. In type II/B ('atresia'), the pylorus is in continuity with the duodenum but the lumen is obliterated for a variable distance. In the least common type III/C atresia ('aplasia'), the pylorus is completely dissociated from the distal gastrointestinal tract [48].

The embryopathogenesis is unknown though a first trimester insult is often postulated, largely based on the known associated anomalies rather than any mechanistic hypothesis [2]. There is a well-documented incidence of pyloric atresia with certain forms of epidermolysis [18, 23, 44]. Epidermolysis has been specifically implicated in the coexistence of pyloric and oesophageal atresia and was found in 25 % of 140 cases in the largest (and under cited) series [56]. Epidermolysis associated with pyloric atresia has been described in several syndromic forms and with a variety of other non-cutaneous manifestations (ID #612138, ID#226720) [1, 53]. Gene defects associated with epidermolysis bullosa (simplex)-pyloric atresia (EB(S)-PA) have been identified and affect cell adhesion molecules: plectin 1 (~5 %), integrins α6 (~15 %) and β4 (~80 %). Defects in integrin β4 associated with pyloric atresia and other gastrointestinal manifestations have been found in the absence of cutaneous involvement [57].

Congenital pyloric atresia presents soon after birth with non-bilious vomiting, but the diagnosis is often delayed, allowing fluid and electrolyte disturbances to develop which should, as always, be judiciously corrected. The classical radiographic finding is of a 'single bubble' representing the postnatally gas-filled and distended stomach (Fig. 115.1). The membrane in type I atresia may bulge into the duodenum and can mimic the radiographic 'double bubble' seen in duodenal atresia [50]. Occasionally the newborn will present with gastric perforation secondary to acute gastric distension [7]. Associated anomalies should be excluded by family history (for epidermolysis in particular), general clinical examination and imaging (echocardiogram, renal ultrasound). Malrotation and absent gall bladder have also been associated and can be excluded during the surgical repair of the atresia [2, 44, 48]. Other gastrointestinal atresias occurred in

Fig. 115.1 Typical 'single bubble' radiographic finding in pyloric atresia (Reproduced with permission from Darwish et al. [11])

10 % of the largest series [56] and this possibility should be considered.

Gastrojejunostomy where it has historically been performed has had a poor outcome [28]. Primary restoration of continuity of the stomach and duodenum by excision of the web and pyloroplasty (Finney or Heineke-Mikulicz) in type I atresias and excision with primary gastroduodenal anastomosis in type II and III atresia is currently recommended [2, 23, 40, 48]. The outcome of pyloric atresia in isolation is generally believed to be good, and it is the associated anomalies that determine the longer-term prognosis, producing a relatively high mortality in some series [23]. The relative rarity of the disorder and the common association with other anomalies make further generalisation difficult. Reporting in the literature has been sporadic at best.

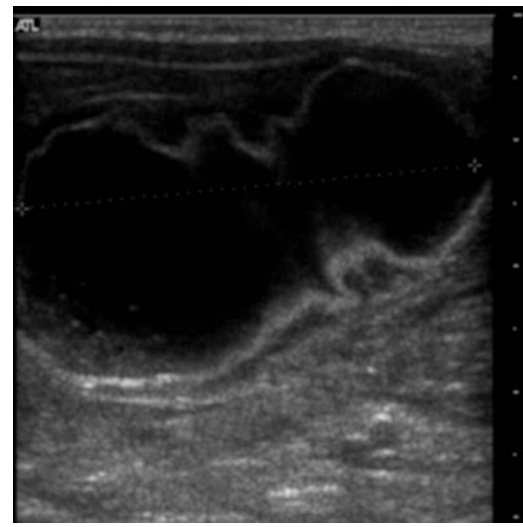
Antral Web

The antral or prepyloric web is an unusual and incompletely defined entity. It has been described in newborns [52], where it must presumably be congenital, as well as in older children and adults where in some cases it was radiologically documented to arise de novo [22]. Whether the two entities are related is unclear, but they show histological similarity, consisting of normal mucosa overlying submucosa and muscularis [42]. This is akin to a similar entity in the small and large intestine (the so-called diaphragm disease [31]) and the normal structure of the plicae circulares. In adults, acquired antral webs and the mucosal diaphragms of diaphragm disease have been postulated to develop in response to mucosal injury and have been related to peptic ulceration [22] and chronic NSAID use [20], respectively.

In infants, the presentation is with incomplete gastric outlet obstruction that may mimic hypertrophic infantile pyloric stenosis (IHPS). The diagnosis may be made on ultrasound but is more likely with an upper gastrointestinal contrast study. Antral web has occasionally been reported in association with IHPS [37]. Treatment in symptomatic cases consists of web excision by endoscopic [36], open [33] or minimally invasive surgery but will depend on the size of the patient, available equipment and expertise. Cases of acquired antral web and diaphragm disease in adults without complete obstruction have been managed medically, directed at the presumed cause of mucosal injury. Empirical removal of risk factors for mucosal injury in either case is sensible after excision to limit recurrence. There have been no long-term studies of outcomes following any intervention owing to the relative rarity of the condition in childhood.

Gastrointestinal Duplications

Gastrointestinal duplications may be cystic or tubular and occur in all parts of the gastrointestinal tract from oesophagus to rectum [61, 62]. They are typically closely related to and share a common wall with the primary gastrointestinal tract, having the same characteristic ultrasonographic appearance (Fig. 115.2). Tubular duplications are more likely to communicate with the primary tract than cystic forms and can be extensive [26]. A few reports of cysts with no direct connection to the primary tract but histological



Fig, 115.2 Sonographic appearance of a pedunculated cystic duplication arising from the posterior gastric wall. Note the characteristic gastrointestinal wall three-layer sonographic signature

features consistent with gastrointestinal duplication have been published [34, 59].

The diagnosis is frequently incidental and may be made late in adulthood [30] typically after imaging (ultrasound or cross-sectional) in the investigation of unrelated symptoms. Symptomatic duplications cause mass effect [51], gastrointestinal bleeding or pain secondary to ulceration caused by ectopic gastric-type mucosa [62] and infection via communication with the primary tract or after bacterial translocation [24]. Gastric duplications represent a minority of all gastrointestinal duplications (5-10% [62]) and typically present incidentally or as a cause of gastric outlet obstruction [51].

Management is determined by the anatomical location, morphology and any symptoms or secondary effects caused by the duplication. Gastric duplications can usually be excised with relative ease by open or minimally invasive approaches [14] occasionally requiring entry to the lesser sac between the transverse colon and greater curve when they arise from the posterior wall of the stomach. Gastric duplications communicating with the pancreatic ductal system [45, 69] require an approach tailored to the individual anatomy to ensure management is safe and effective. This may entail excision of accessory pancreatic tissue or Roux-en-Y drainage [45]. Thorough preoperative planning and intraoperative caution are advised to avoid complications due to unexpected anatomy. Endoscopic resection of predominantly intraluminal lesions has been reported in adults [60] but again requires careful pre- and peri-procedural evaluation to limit the risks of incomplete resection and perforation.

Short-term complications for simple duplications are limited to the general complications of surgery and leak from the suture/staple line (unusual from the stomach). The long-term prognosis is excellent if excision is complete and particularly for asymptomatic simple duplications, a minimally invasive approach is ideal where skills and technology permit. There may be additional sequelae where the lesion is closely related to the pancreas or pylorus and a more complicated reconstruction is performed.

Microgastria

Microgastria is an even rarer entity than pyloric atresia with less than 100 reported cases in the English language literature. There is no strict definition and congenital microgastria is diagnosed when there is the impression of an exceptionally small stomach, often so rudimentary as to be difficult to distinguish from the adjacent normally tubular foregut elements (Fig. 115.3). Small stomachs are a recognised consequence of gastrointestinal obstruction proximal to the stomach most commonly seen in pure oesophageal atresia. This is not usually termed microgastria but is plausibly presumed to be due to the absence of intrauterine gastric filling by swallowed amniotic fluid. The situation is complicated by cases of 'true' microgastria associated with oesophageal atresia and the frequent association of microgastria with conditions that might reasonably be expected to impair swallowing (Pièrre-Robin sequence [17, 32], laryngotracheal clefts [27, 67], severe CNS abnormalities).

The association of microgastria with upper limb reduction defects is perhaps the most formally documented (MIM ID 156810) [1] but is perhaps no stronger than with, for example, splenic malformations and other major foregut

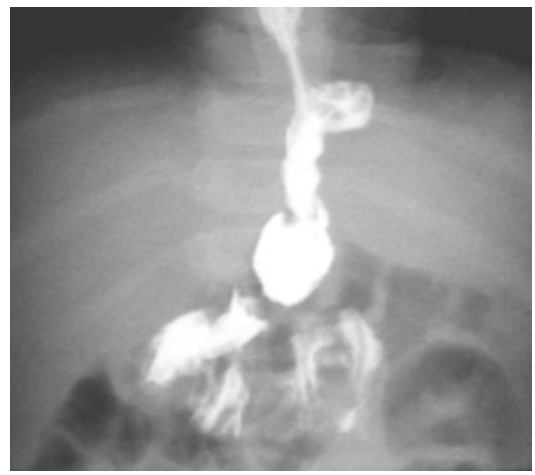


Fig. 115.3 Upper gastrointestinal contrast study demonstrating typical appearance of microgastria (Reproduced with permission from Dr DH Jamieson, Dept Radiology, British Columbia Children's Hospital, Canada)

deformities. The spectrum and severity of anomalies does suggest an early defect in embryogenesis as many have speculated. Apparently isolated microgastria has only been reported in a handful of cases presenting with feed intolerance and failure to thrive though in these cases the patients had reached several months of age [39, 54].

Given the nature of the associations of the condition, surgical reconstruction has only been performed in a minority of cases [25, 39, 54]. Published cases suggest, perhaps surprisingly, that an expectant management approach awaiting feed-related gastric expansion is ineffective and potentially dangerous given the propensity for gastro-oesophageal reflux-associated aspiration in this patient group. There have been no documented cases of attempted staged gastric expansion.

Surgical reconstruction, when performed, has been by augmentation of the micro-stomach with a jejunal J-pouch and Roux-en-Y anastomosis [12, 66], attributed to Hunt and Lawrence who described it for postgastrectomy reconstruction (Fig. 115.4). Long-term results in the survivors have been reportedly good with tolerance of a normal diet [25]. With such small case numbers, generalisations are impossible more so with this complex and varied patient group. Individualised multidisciplinary care is mandatory with careful selection of patients for gastrointestinal reconstruction preceded by thorough preoperative planning and investigation of associated anomalies.

Infantile Hypertrophic Pyloric Stenosis

Infantile hypertrophic pyloric stenosis (IHPS) is the commonest anatomical gastric lesion occurring in childhood, with an estimated incidence of 2–5 per 1,000 live births in Western populations.

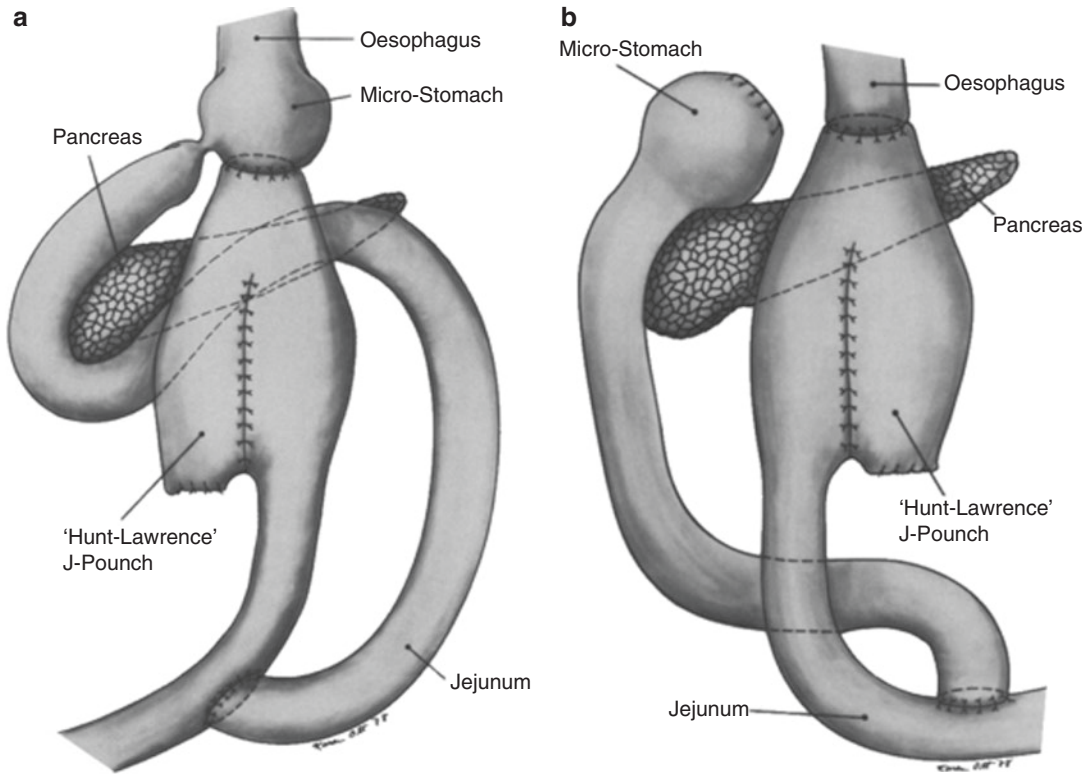

Fig. 115.4 Two options for gastric augmentation ('Hunt-Lawrence' pouch) with stomach in situ (**a**) and with gastric disconnection (**b**) (Reproduced with permission from [66])

The incidence in Afro-Caribbean and Asian populations is generally considered to be lower [35]. For reasons that remain obscure, the pyloric smooth muscle hypertrophies and enters a state of chronic contraction at some time after birth. There is a striking but unexplained male preponderance (consistently 4:1). Maternal risk transmission and familial cases suggest a partly genetic aetiology, though twin and sibling studies contradict this [43]. No single gene defect has been identified to date and work on susceptibility loci as well as candidate susceptibility genes such as nNOS is incomplete [49].

Non-bilious vomiting is invariable and classically becomes projectile, a term that has become synonymous with the condition. The severity of symptoms and biochemical derangement is variable, and it is plausible that 'subclinical' cases may exist. The advent of reliable ultrasound diagnosis is changing the pattern and time of diagnosis but potentially creates new diagnostic challenges [41, 46]. It has long been known that IHPS will clinically resolve with time and histological regression has also been demonstrated [65]. Medical treatment has been advocated particularly in the Far East (principally with atropine [21]) but is incompletely effective, requires longer admission and is not routinely practised in Western healthcare systems as a consequence.

The safe surgical treatment of IHPS is critically dependent on adequate preanaesthetic resuscitation and biochemical normalisation. The persistent and severe vomiting that usually develops produces a classical electrolyte disturbance (common to all causes of high gastrointestinal obstruction) in addition to the features of dehydration (rarely with shock) and under nutrition. In addition to reduced fluid and electrolyte absorption, water, sodium and chloride are all lost directly from the stomach because of vomiting. There is further compensatory renal loss of potassium and hydrogen ions with increasing severity until the classical hypochloraemic, hypokalaemic metabolic alkalosis is fully developed. With earlier presentations, the capillary blood gas may be normal or show only compensatory elevation in the bicarbonate/base excess.

Following resuscitation, the chronic electrolyte and fluid depletion must be corrected at a safe rate for which numerous protocols exist. All follow the basic principle of providing maintenance requirements, replacing the deficit and compensating for any additional ongoing losses. This is continued until biochemical restitution [70] at which point the risks of anaesthesia and thus surgery are minimised. The principle risk, apnoea, is generally held to be related to reduced central respiratory drive secondary to (CSF) alkalosis and can occur spontaneously preoperatively [16].

Surgery for IHPS has been performed for over a century, and the core therapeutic intervention, namely, extramucosal pyloromyotomy, has remained largely unchanged. The mode of access to the pylorus has evolved from laparotomy (typically via a transverse right upper quadrant incision) to a more cosmetic supraumbilical incision [64] and since the 1990s [3] to various laparoscopic approaches. Our preferred approach is via open transumbilical insertion of the primary (camera) port and two 3 mm stab incisions for the (portless) working instruments. The pylorus is superficially incised with an SM69 blade (Swann-Morton, Sheffield, England, UK) and split with a 3 mm laparoscopic pyloric spreader (Fig. 115.5). This simple, reproducible and safe method optimises the utility and cosmesis of the laparoscopic approach. A recent systematic review [58] identified only five studies of level 2 or higher evidence comparing open supraumbilical and laparoscopic approaches and concluded the outcomes were broadly similar with some evidence of benefit in the laparoscopic group in terms of wound-related complications. There was some evidence of quicker time to full feeds; however the small magnitude of the effect, multiple confounders and other statistical irregularities have made this a more contentious finding.

Following uneventful surgery, feeds can be reintroduced as the infant tolerates with close initial monitoring for evidence of undetected perforation. Perforation and incomplete myotomy are the primary specific risks of surgery and occur in <2 % of cases [58]. The reported incidence varies and is biassed by the relatively small sample sizes in published series/studies. Other risks include

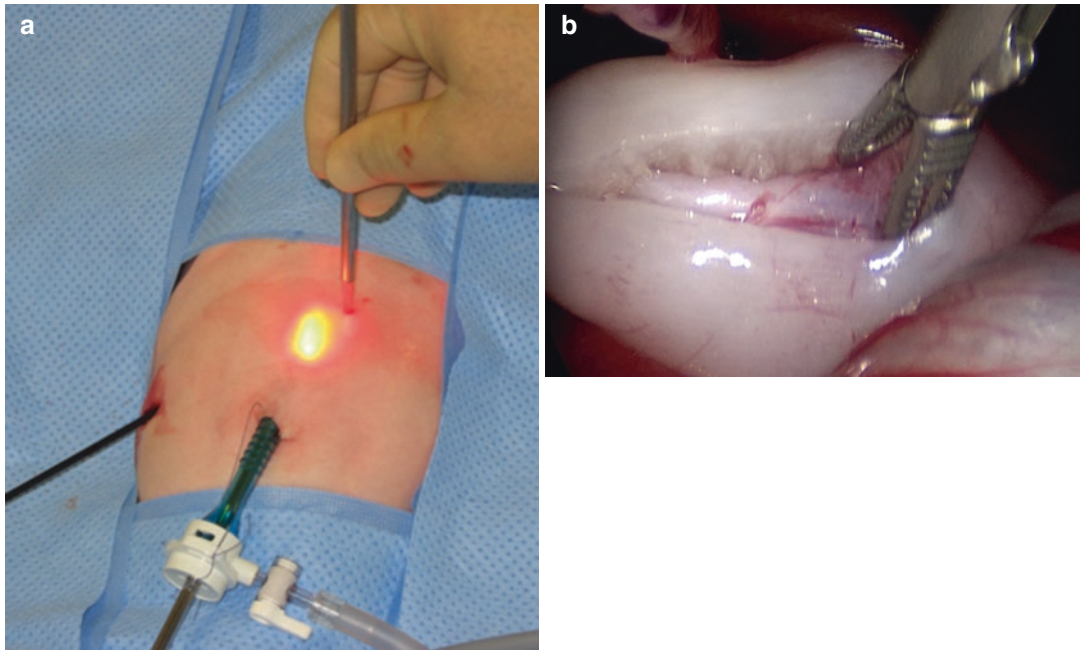

Fig. 115.5 Laparoscopic pyloromyotomy: (**a**) Our institutional intraoperative setup: transumbilical camera port, right lateral (atraumatic grasper) and epigastric (myotomy blade and spreader) portless instruments. Myotomy blade in use. (**b**) Intra-abdominal appearance during pyloric spreading demonstrating split pyloric muscle and bulging mucosa

wound infection, port site herniation and anaesthetic-related events (e.g. apnoea, aspiration).

The long-term outcomes after surgery for IHPS are believed to be excellent but published data is limited in scope. There is some recent and ongoing work suggesting minor adverse effects on neurodevelopmental outcomes compared to matched controls [68]. The origin of this effect is not known but if genuine may be related to general anaesthesia as suggested recently in the anaesthetic literature [63]. This is currently the subject of intense debate and clearly has wider implications.

Gastric Volvulus

Gastric volvulus is defined by both its morphology and clinical time course (acute, acute-on-chronic, chronic). It has been distinguished from gastric torsion by the degree of twisting (volvulus being a rotation of >180°) and the consequent relative symptom severity [9]. Morphological classifications of gastric volvulus inform the radiographic and operative appearances, and the configuration is determined by the specific anatomy in each case. The axis of rotation can be organoaxial, mesenteroaxial or mixed (Fig. 115.6). Historically considered a rare entity [6, 19], a recent review of published cases [9] has suggested gastric volvulus is commoner than suspected. The discrepancy in case numbers identified by reviewers writing at similar times suggests an inconsistency of definition arising from the broad spectrum of predisposing factors.

The normal stomach is fixed at the gastro-oesophageal junction and pylorus at the gastrointestinal tract becomes retroperitoneal. Excess movement is limited by the peritoneal attachments of the stomach derived from the embryonic ventral and dorsal mesentery (gastrohepatic, gastrophrenic, gastrocolic and gastrosplenic 'ligaments'). Primary gastric volvulus occurs in the absence of other gross anatomical anomalies and is attributed to congenital or acquired laxity of

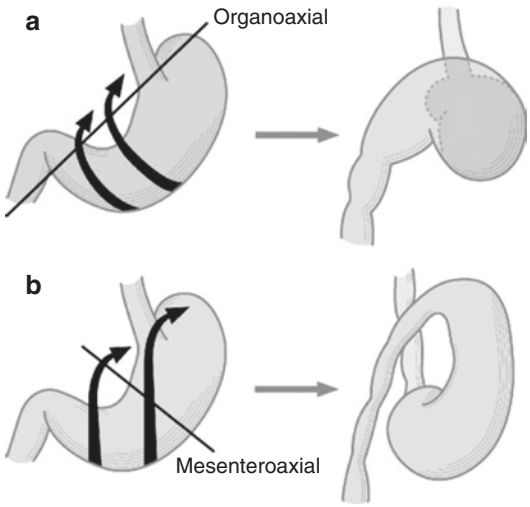

Fig. 115.6 Diagrammatic representation of two axes of gastric volvulus (a = organoaxial and b = mesenteroaxial) and typical configuration of volved stomach (Reproduced with permission from Darani et al. [10])

Fig. 115.7 Characteristic radiographic appearance of acute gastric volvulus. In this case, the distension is mild following insertion of a nasogastric tube. Note the absence of distal gas (Reproduced with permission from Oh et al. [47])

these structures. Secondary volvulus occurs either due to congenital or degenerative anatomical defects altering gastric fixation (diaphragmatic abnormalities, asplenia, abnormal gastrointestinal rotation, oesophageal hiatal defects) [9] or to traumatic and surgical disruption of the same structures (e.g. after Nissen fundoplication [29], liver transplantation [15], diaphragmatic rupture [4]).

Acute gastric volvulus in infants and children presents variably with pain (abdominal, epigastric, retrosternal), retching, vomiting, epigastric distension and gastrointestinal bleeding. The commonest (~75%) reported presenting symptom in children is vomiting with other features occurring much less consistently [9]. Approximately 25% of acute cases present with acute physiological (usually respiratory) embarrassment; however, this may reflect the greater prevalence of secondary volvulus in acute cases with diaphragmatic anomalies being the commonest association. In contrast chronic presentations with feed intolerance, intermittent acute symptoms and failure to thrive were predominantly (75%) of a primary nature [9]. Although chronic volvulus has a slight majority of reported cases, it is likely this is an underestimate of the true incidence.

Diagnosis is the first clinical challenge in all cases, largely due to the typically non-specific features even in acute volvulus. Borchardt in 1904 described a classical clinical triad in gastric volvulus: acute gastric distension, retching and the inability to pass a nasogastric tube. The negative predictive value of the triad is questionable, particularly the inability to pass a nasogastric tube. This is not always prevented by volvulus and has been associated with perforation [13, 38]. A specific diagnosis of gastric volvulus will rarely be made during the early assessment, and it is disingenuous to suggest that special care can specifically be taken when passing a nasogastric tube. In the vomiting child with suspected gastrointestinal obstruction, a large bore nasogastric tube should still be carefully introduced, but caution is advised if resistance is encountered.

Management is initially directed at resuscitation and confirmation of the diagnosis, which requires a high index of suspicion in non-fulminant cases. Plain radiography typically shows massive circular gaseous distension (suggestive of an acute-on-chronic pattern) with relative paucity of distal gas (Fig. 115.7 [47]). This is consistent with a closed loop obstruction caused by a valve mechanism at the gastric inlet and

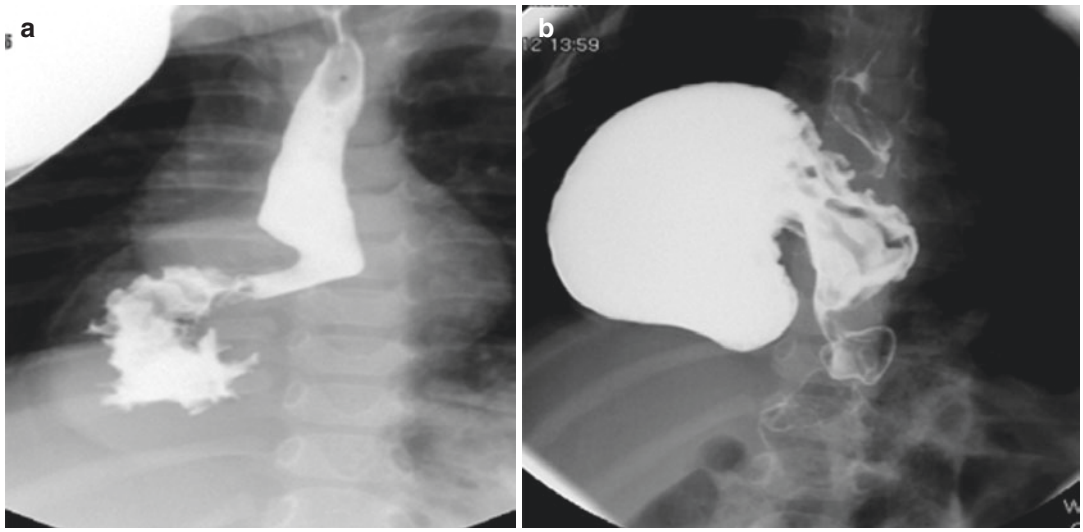

Fig. 115.8 Upper gastrointestinal contrast study demonstrating of organoaxial gastric volvulus during early (**a**) and late (**b**) filling (Reproduced with permission from Dr A Raghavan, Dept Radiology, Sheffield Children's Hospital, UK)

obstruction of the outlet. Upper gastrointestinal contrast studies are the definitive investigation in situations where emergency surgery is not indicated and will demonstrate both the gastric malposition and obstructive effects of volvulus (Fig. 115.8). Gastric volvulus can result in perforation, which can develop rapidly when secondary to massive acute distension or subacutely secondary to ischaemic gastric or distal oesophageal necrosis. In these cases, emergency surgery is indicated and will both confirm the diagnosis and allow for immediate definitive treatment.

There is an incomplete consensus on definitive management, but it is generally agreed that, after derotation and confirmation of viability, any secondary cause should be corrected. This is may be sufficient on its own [5, 9]; however, contrary to this viewpoint, a handful of reports of recurrent volvulus following this approach have been published [8]. Gastropexy can be performed both by open and minimally invasive techniques and by a multitude of techniques. Some authors advocate fixation by gastrostomy tube placement alone; however, gastrostomy tube purely for the purposes of fixation in otherwise healthy patients is probably suboptimal given the possibility of secondary volvulus around a feeding gastrostomy [29]. In keeping with most authorities, we would advocate anterior gastropexy to the anterior abdominal wall as a minimum with additional fixation such as gastrophrenopexy depending on the specific anatomy [5, 9, 10]. With increasing fixation, the consequent distortion of the gastro-oesophageal junction may cause incompetence and additional antireflux procedures may be required [10]. Regardless of the method and adequacy of fixation, recurrence remains a possibility. The true long-term outcomes are not known but are believed to be good in terms of recurrent symptoms or sequelae based on the relatively low frequency of reported complications. Comparison is made difficult by the heterogeneity of the disorder and the complexity of many of the patients' other health and social needs.

There are several unanswered but clinically important questions at this time regarding gastric volvulus. Foremost amongst these is whether gastropexy is mandatory after secondary volvulus noting that this is not routine after, for example, repair of diaphragmatic hernia repair in the neonatal period. Secondly, what is the appropriate threshold for gastropexy in chronic gastric volvulus and even more difficult: is gastropexy appropriate on the incidental finding of risk factors such as diaphragmatic hernia/eventration, asple-

nia, midgut malrotation? Finally, if gastropexy is appropriate, what is the best method in terms of reduced recurrence and side effects such as gastro-oesophageal reflux?

Congenital Gastric Anomalies

116

Brice A. Antao and Victoria A. Lane

Introduction

Stomach is an embryological derivative of the foregut. The foregut, midgut and hindgut are distinguished on the basis of their blood supply from the celiac trunk, superior mesenteric artery and the inferior mesenteric artery, respectively. At the end of the fourth week, almost the entire abdominal gut tube (portion within the peritoneal cavity, from the abdominal oesophagus to the cloaca) hangs suspended on a dorsal mesentery. In the stomach region, the gut tube remains connected to the ventral body wall by the thick septum transversum. By the fifth week, the caudal portion of the septum transversum thins to form the ventral mesentery connecting the stomach and developing liver to the ventral body wall [32]. On day 26, the thoracic foregut elongates rapidly. Over the next couple of days, the presumptive stomach expands into a fusiform structure. During the fifth week of gestation, the dorsal wall of the stomach grows much faster than the ventral wall, resulting in the formation of the greater curvature of the stomach, and deformation of the ventral stomach leads to the formation of the lesser curvature. Continued differential expansion of the stomach leads to the formation of the fundus and cardia by the end of the seventh week. The stomach rotates 90° during the seventh and eighth weeks of gestation around a craniocaudal axis so that the greater curvature lies to the left. At the same time, the right and left vagal plexuses, which originally run through the mesoderm on either side of the gut tube, take up an anterior and posterior position, forming the vagal trunks [32] (Fig. 116.1).

The rotation of the stomach and secondary fusion of the duodenum to the dorsal body wall create the lesser sac of the peritoneal cavity. The final location of the stomach is variable owing in part to its two-point fixation at the gastro-oesophageal junction and gastroduodenal junction, allowing for considerable mobility. The gastro-oesophageal junction generally lies to the left of the tenth thoracic vertebra, with pylorus of the stomach lying on the transpyloric plane, passing through the body of the L1 vertebra.

The stomach is covered in peritoneum except for the 'bare area' at the gastro-oesophageal junction. The peritoneum passes as a double layer from the lesser curvature to the liver as the gastric portion of the lesser omentum and then hangs from the fundus and the greater curvature as the greater omentum, extending to the transverse colon as the gastrocolic ligament, to the spleen as the gastrosplenic ligament and the diaphragm as the gastrophrenic ligament [39] (Fig. 116.2).

During the seventh week (**c**), there is clockwise rotation of the stomach. (**a**–**c** oblique frontal view and **d** direct frontal view)

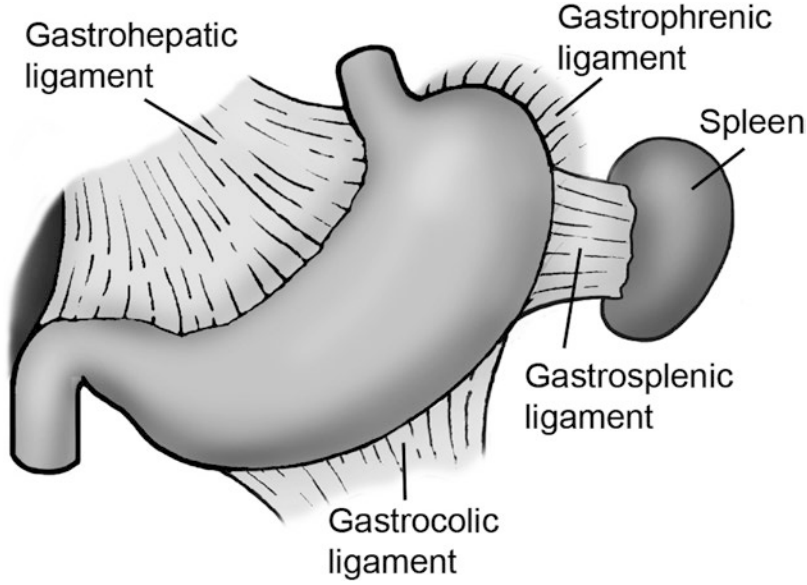

Fig. 116.2 Ligamental attachments of the stomach. Normal ligaments of the stomach include the gastrophrenic, gastrohepatic, gastrocolic and gastrosplenic

The stomach can be divided into five distinct areas, the cardia, fundus, body, antrum and pylorus. The cardia is an ill-defined area near the junction with oesophagus. The fundus is a rounded vault, superior and to the left of the cardia, closely related to the left dome of the diaphragm. The body is the major portion of the stomach, between the fundus and the pyloric antrum. The pyloric part of the stomach is formed from the pyloric antrum (dilated portion) and the pyloric canal (narrow portion). The pylorus itself separates the stomach from the duodenum, the Greek for pylorus being 'gatekeeper'. The stomach has a very rich vascular supply, and

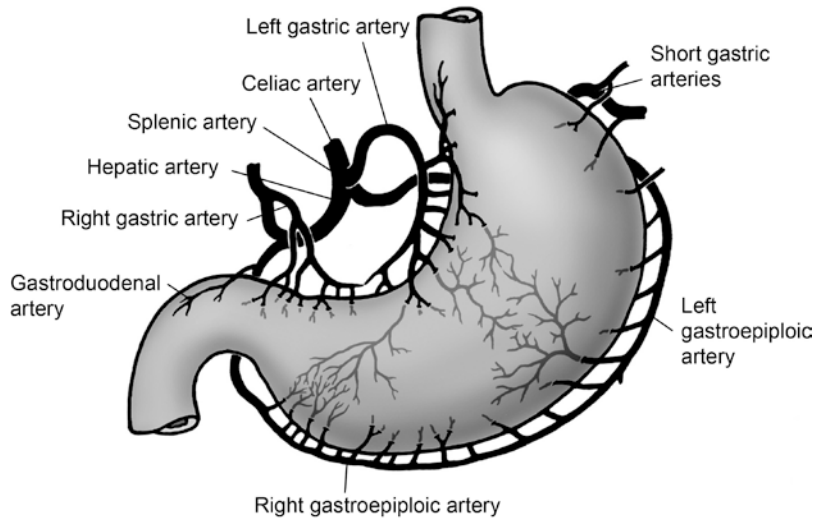

Fig. 116.3 Arterial supply of the stomach

subsequently ischemia of the stomach is very rare. It derives its blood supply from right and left gastric arteries along the lesser curvature, the greater curvature being supplied by the right and left gastroepiploic arteries, together with the short gastric vessels from the spleen. There is also contribution from the posterior branch of the splenic artery and the phrenic arteries (Fig. 116.3).

Venous drainage of the stomach generally accompanies the arterial supply, emptying into the portal vein or tributaries, the splenic or the superior mesenteric veins. Usually the right and left gastric veins drain directly into the portal vein. The right gastroepiploic vein usually drains into the superior mesenteric vein but may enter the portal vein or the splenic vein. The left gastroepiploic vein drains into the splenic vein.

There are four main areas of lymphatic drainage, each of which has its own regional lymph nodes:

1. Lesser curvature drains to the left gastric lymph nodes.
2. Right part of greater curvature drains to the gastroepiploic lymph nodes along the right gastroepiploic vessels.
3. Left part of greater curvature drains into the gastroepiploic lymph nodes along the left gastroepiploic vessels.
4. Lesser curvature of the stomach (related to the pylorus) drains into the right gastric lymph nodes lying along the right gastric artery.

The parasympathetic nerve supply of the stomach is derived from the anterior and posterior vagal trunks and their branches. The sympathetic nerve supply is mainly from the celiac plexus, through the plexuses around the gastric and gastroepiploic arteries. The efferent sympathetic fibres to the stomach arise from T6 to T9 segments of the spinal cord. The anterior vagal trunk usually enters the abdomen as a single branch lying on the anterior surface of the oesophagus. The posterior vagal trunk enters the abdomen on the posterior surface of the oesophagus.

Congenital gastric anomalies are rare. They can have a varied presentation in children, from the neonatal period through to adolescence. The various anomalies in relation to the various anatomical sites in the stomach which are discussed are outlined in Fig. 116.4.

Hypertrophic Pyloric Stenosis (HPS)

HPS is the most common surgical cause of vomiting in infants. It was first described by Hirschsprung in 1888. The pyloric muscle is

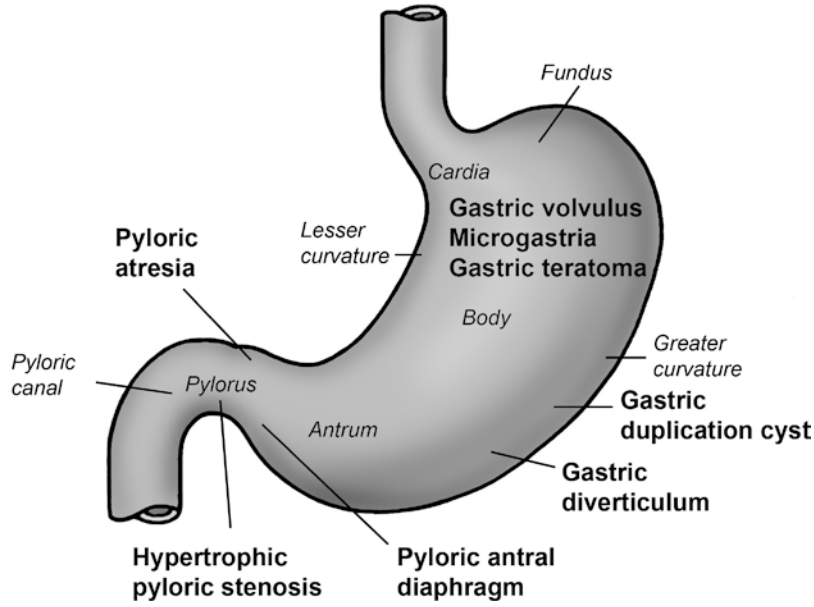

Fig. 116.4 Diagram of stomach showing anatomical areas and the most common sites for congenital anomalies to occur

hypertrophied causing narrowing of the pyloric channel leading to gastric outlet obstruction [50]. The peak incidence of onset is 3–5 weeks of age [48]. It is seen at a rate of 1–4 per 1,000 live births [52, 53, 61, 65]. Males are affected more commonly than female infants at a ratio of 4:1 [23]. Risk factors for HPS include a positive family history, gender, younger maternal age, being the first born infant and maternal feeding patterns [29, 61, 70].

The aetiology of HPS is poorly understood although there have been numerous hypotheses published in the literature including genetic, extrinsic and hormonal factors. Furthermore, abnormalities of various components of the pyloric muscle have been reported including smooth muscle cells, extracellular matrix elements, nerve cells and neurotransmitters. More recently genetic studies have identified susceptible loci for HPS, and molecular studies have concluded that smooth muscle cells are not properly innervated [50].

The classic presentation of HPS is that of non-bilious, projectile vomiting in the full-term infant. Initially the emesis may be infrequent and be mistaken for gastro-oesophageal reflux, but this then progresses to projectile vomiting. On examination, the child may be dehydrated depending on the length of the history, and visible peristaltic waves may be present across the abdomen.

Typically the infant develops a hallmark metabolic derangement of hypokalaemic, hypochloraemic metabolic alkalosis, due to the excessive loss of gastric fluids rich in hydrogen and chloride, and to a lesser extent sodium and potassium. Initially alkaline urine is excreted to compensate for metabolic alkalosis; however as the vomiting and dehydration worsen, maintenance of the extracellular volume through sodium conservation becomes more important, resulting in increased sodium resorption by the renal tubules resulting in potassium loss which is compensated by hydrogen excretion, and a paradoxical aciduria develops, worsening the alkalosis further.

There are various techniques described for palpating the ‘pyloric tumour’ but whichever technique is used requires patience and an optimal examination setting. Ultrasound had become the standard investigation for the diagnosis of pyloric stenosis (Fig. 116.5). The diagnostic criteria for HPS is a muscle thickness of greater

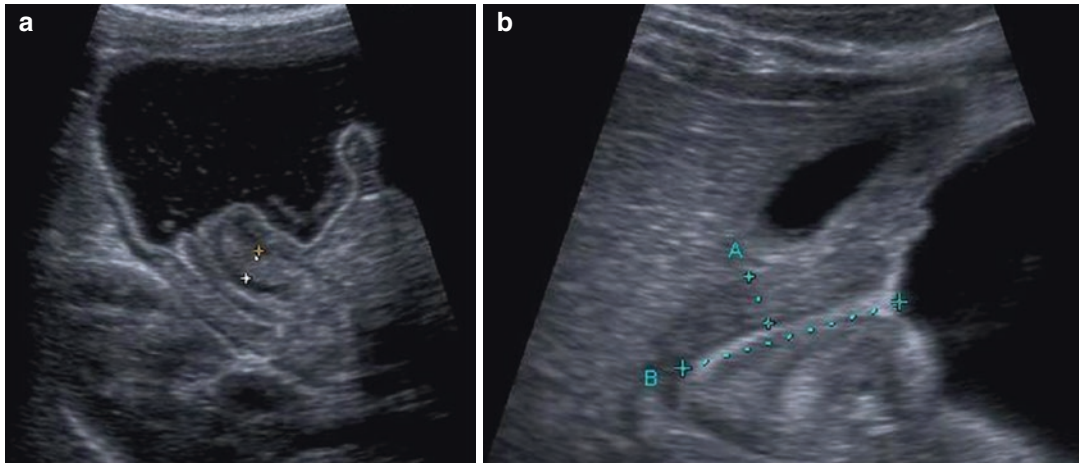

Fig. 116.5 Ultrasound images of hypertrophic pyloric stenosis measuring the width (a) and both diameters (b)

than or equal to 4 mm and a length greater than or equal to 16 mm [29]. In a neonate <30 days, a thickness of 3 mm is diagnostic [31].

The first successful surgical procedure for HPS was performed by Ramstedt in 1912.

Several incisions have been described for the open approach including an incision in the right upper quadrant. A more cosmetic incision is a supraumbilical incision, followed by division of the linea alba or a muscle sparing split of the anterior and posterior rectus sheath, transversely. The pylorus is then delivered through the wound and a longitudinal serosal incision is made, and blunt dissection is used to split the pyloric muscle fibres until the submucosal layer is seen (Fig. 116.6).

The laparoscopic approach is a well-recognised technique, and randomised prospective control trials have not shown any difference in complication rates compared to the open procedure [35, 67]. After establishing the pneumoperitoneum, two further paramedial stab incisions are made in the left and right side of the abdomen for the introduction of the laparoscopic instruments (atraumatic bowel grasper and the pyloromyotomy knife). The pyloric fibres are then incised in a similar method to that described above.

The major postoperative complications of pyloromyotomy include mucosal perforation occurring in 1–2 % of cases [34, 67], incisional

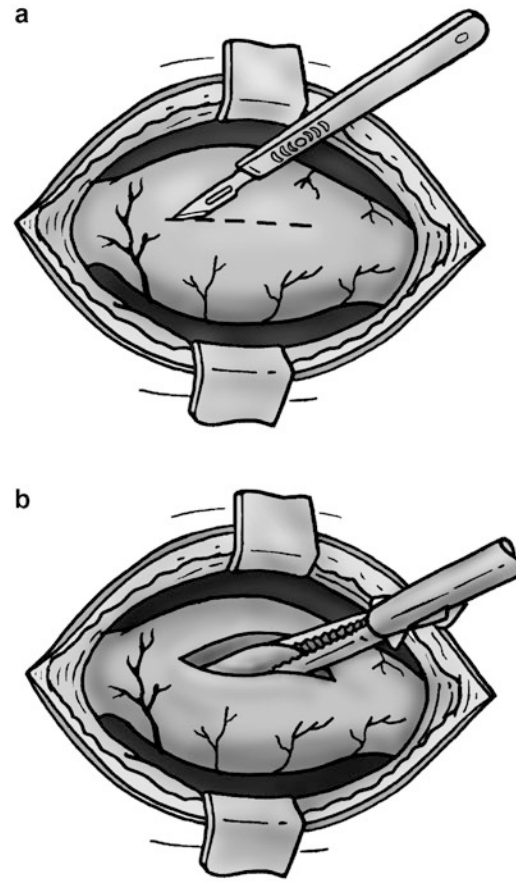

Fig. 116.6 Diagram of open pyloromyotomy. (**a**) The incision is made along the length of the pyloric tumour in the relatively avascular anterosuperior aspect. (**b**) The fibres are slit to expose the bulging mucosa

hernia in 1 % [67], prolonged postoperative emesis and incomplete myotomy. Wound infection occurs in 1–2 % [34, 67]; however there is no evidence to support the use prophylactic antibiotics.

There have been case reports of successful balloon dilatation for HPS in an infant where it was felt that gaining entry to the peritoneal cavity would place the infant at significant risk. Initial reports were unsuccessful, and concerns were raised with regard to the full thickness split of the pylorus. However, Ogawa et al. have reported a successful case in an infant who had previously undergone a staged repair for a giant omphalocele [47]. A pilot, single-centre study of endoscopic pyloromyotomy using a needle knife or standard sphincterotome has been described [24]. Short- to medium-term results showed it to be a safe and effective treatment option in a small cohort of ten infants. However there are no long-term and randomised control trials to support the results for endoscopic pyloromyotomy.

Prepyloric Antral Diaphragm

A prepyloric antral diaphragm is a rare anomaly consisting of a submucosal web of gastric tissue covered by gastric mucosa, found in the distal gastric antrum. Significant associated anomalies (gastrointestinal and cardiovascular) are seen in about 30 % of children with an antral web [6].

In the neonatal period, infants will present with non-bilious vomiting and may have associated respiratory problems and poor weight gain. The diagnosis is made on upper gastrointestinal contrast study in 90 % of patients [6]. The typical appearance of the web is a thin membranous septum projecting into the antral lumen, perpendicular to the longitudinal axis 1–2 cm proximal to the pylorus (Fig. 116.7).

Gastroscopy has been used to accurately identify the pyloric web in older infants and children [68]. Features include:

1. A small fixed central aperture surrounded by gastric mucosa that is smooth and devoid of folds.

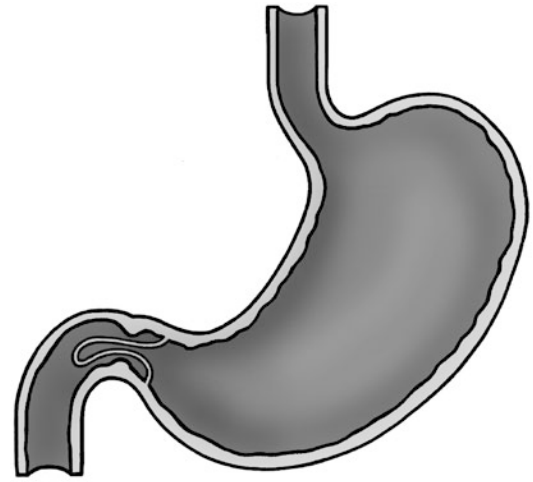

Fig. 116.7 Diagram of prepyloric antral diaphragm

2. No change in the opening size of the web with peristalsis.
3. The gastric wall proximal and distal to the web is seen to contract normally [3].

Surgical correction of the pyloric web involves excision of the web, combined with pyloroplasty as described under the section of ‘pyloric atresia’.

Pyloric Atresia

Pyloric atresia is a rare pathology and constitutes about 1 % of all intestinal atresias. Its incidence is about 1 in 100,000 live births [59], with an equal male/female ratio [25]. It was first described by Calder in 1749 [44, 60], and Touroff et al. presented the first successful operation for the correction of pyloric atresia [44] nearly 200 years later, in 1940.

Pyloric atresia varies from a membranous diaphragm to complete dysfunction at the pyloric level [62] and has three anatomical variants (Fig. 116.8):

1. Type A, pyloric membrane or web occluding the lumen

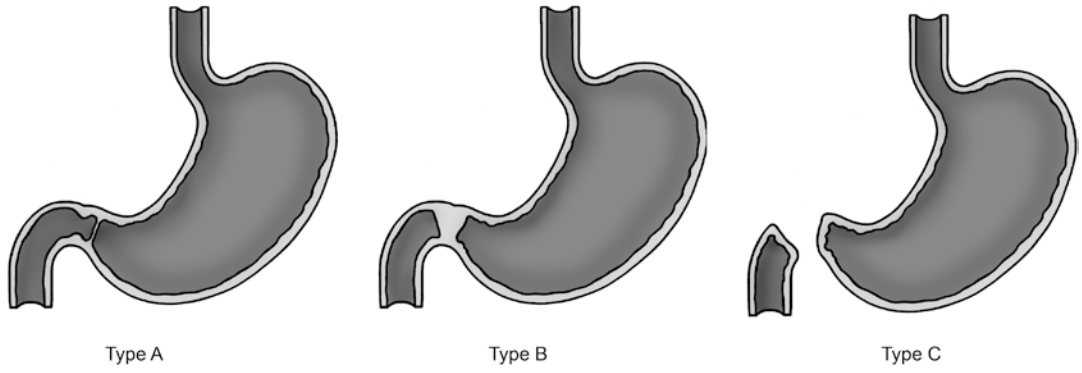

Fig. 116.8 Diagram showing the different types of pyloric atresia

2. Type B, pyloric channel is a solid cord/longitudinal segmental atresia
3. Type C, gap between the stomach and the duodenum/gap atresia [25]

The distribution of anatomical variants in a 15-year review from a single institution was:

- Type A – 57 %
- Type B – 34 %
- Type C – 9 % [25]

The cause of these lesions remains unknown, but embryologically it is thought to result from developmental arrest between the 5th and 12th weeks of gestation. If there is fusion of redundant endoderm before 8 weeks gestation, then discontinuity of gastric wall musculature would result in a segmental defect (type B/C). If the redundancy occurs after 8 weeks gestation, when the muscle layers are complete, then a simple membrane develops (type A) [17].

Congenital pyloric atresia tends to occur as an isolated lesion, which has an excellent prognosis. It is seen in association with other malformations in 30–50 % [15, 19, 27] which can give a negative impact on final outcome. Associated malformations include malrotation, atrial septal defects, vaginal agenesis and tracheo-oesophageal anomalies. Familial occurrence is reported and there is suggestion of autosomal recessive transmission [20, 27]. Eighteen percent of children with pyloric atresia have epidermolysis bullosa (EB) which is a cutaneous genetic disease of variable severity [25]. There are three main types:

1. EB simplex
2. Junctional EB
3. Dystrophic EB

These distinct types are recognised by determining the exact level at which the split responsible for blistering occurs. All three types have been reported to occur with pyloric atresia; however the junctional variant is most common [57, 69]. The distribution of blisters may be localised or generalised and may be present at birth or take up to 48 h to develop after birth. It should be noted that the blistering can affect the gastrointestinal tract, respiratory system and the genitourinary tracts [46]. Evidence suggests that the PA-EB association is a distinct clinical entity and is now referred as the PA-EB syndrome, first described by Swinbourne and Kohler in 1968 [59]. In 1989, Moore [38] reported 125 cases of pyloric atresia and 18 of these were associated with EB [50]. This association is usually fatal within the few months of life, despite surgical correction of the intestinal obstruction [55].

The typical presentation of pyloric atresia is that of non-bilious vomiting, with the absence of generalised abdominal distension (Table 116.1). The epigastrium may be distended if the stomach is large and respiratory problems are not uncommon. Dyspnoea, tachypnoea and excessive salivation may be seen. There may be an antenatal

Table 116.1 Symptoms and sign of pyloric atresia

Symptoms and signs	Occurrence (%)
Non-bilious vomiting	100
Single gastric bubble on radiograph	98
Passage of meconium	69
Polyhydramnios	63

Data from Muller et al. [42] and Lorenzet and Morger [35]

history of polyhydramnios. A delay in diagnosis can lead to severe metabolic acidosis and dehydration, and if the gastric distension is gross, gastric perforation can result.

Abdominal radiographs characteristically show a single gas bubble representing the distended stomach, with no distal gas (Fig. 116.9). Upper gastrointestinal studies although often unnecessary show complete obstruction of the stomach generally at the level of the antrum or pylorus.

Following adequate resuscitation and correction of electrolyte disturbance and protein losses (exacerbated by EB), the surgical treatment of pyloric atresia varies depending on the type of atresia. The options available include:

- Type A: Excision of pyloric web in combination with pyloroplasty
- Type B: Finney or Heineke-Mikulicz pyloroplasty if the solid pyloric atresia is short
- Type C: Excision of the atretic segment and gastroduodenostomy [4, 19, 46, 56]

After identifying the pylorus, a longitudinal incision is made from the gastric side of the pylorus to the duodenum (length 1.5–2 cm) midway between the greater and lesser curvatures of the stomach. The membrane is then excised circumferentially and the mucosa is approximated. After establishing patency of the remaining bowel, the longitudinal incision is closed transversely in two layers [55].

Congenital Microgastria

Congenital microgastria is a rare anomaly. Its clinical manifestation depends on the stage at which embryological development of the stomach is arrested during the fifth week, when differentiation of the greater curvature occurs; neither rotation nor fusiform dilatation of the stomach occurs [17]. In most cases the stomach is represented by a small, saccular or tubular structure with minimal reservoir capacity and is often associated with a megaoesophagus. This anatomical finding leads to postprandial vomiting, gastro-oesophageal reflux and malnutrition [71].

It is frequently associated with other congenital defects including the VACTERL association [22], asplenia (embryologically the spleen is derived from the dorsal mesogastrium which has an intimate relation with the developing stomach), intestinal malrotation and duodenal atresia and renal, limb, central nervous system and cardiopulmonary malformations [71]. It has been suggested that microgastria with limb defects, including radial, ulnar and thenar hypoplasia, and central nervous system anomalies [27, 36, 64] has a genetic basis with an autosomal recessive pattern of inheritance [26].

The clinical presentation is typically of an infant with postprandial vomiting and malnutrition. Diarrhoea due to rapid gastric emptying may also be apparent. The diagnosis of microgastria is easily made with upper gastrointestinal studies showing a small tubular or saccular midline structure which is frequently associated with an incompetent lower oesophageal sphincter and as mentioned, in some cases, a dilated oesophagus.

Before the description of gastric augmentation, congenital microgastria was managed conservatively with generally poor outcome including reduced somatic growth, sexual underdevelopment, delays in cognitive milestones and dumping syndrome [2, 7, 21, 28], although positive outcomes have been reported in less severe forms [2].

The creation of a food reservoir (Hunt-Lawrence pouch) was initially described as a procedure to restore continuity of the bowel in patients who had undergone total gastrectomy for gastric cancer [23, 33]. Its use as a gastric augmentation in children with microgastria was first described by Neifeld et al. in 1980 [45]. This procedure, as originally described, includes a

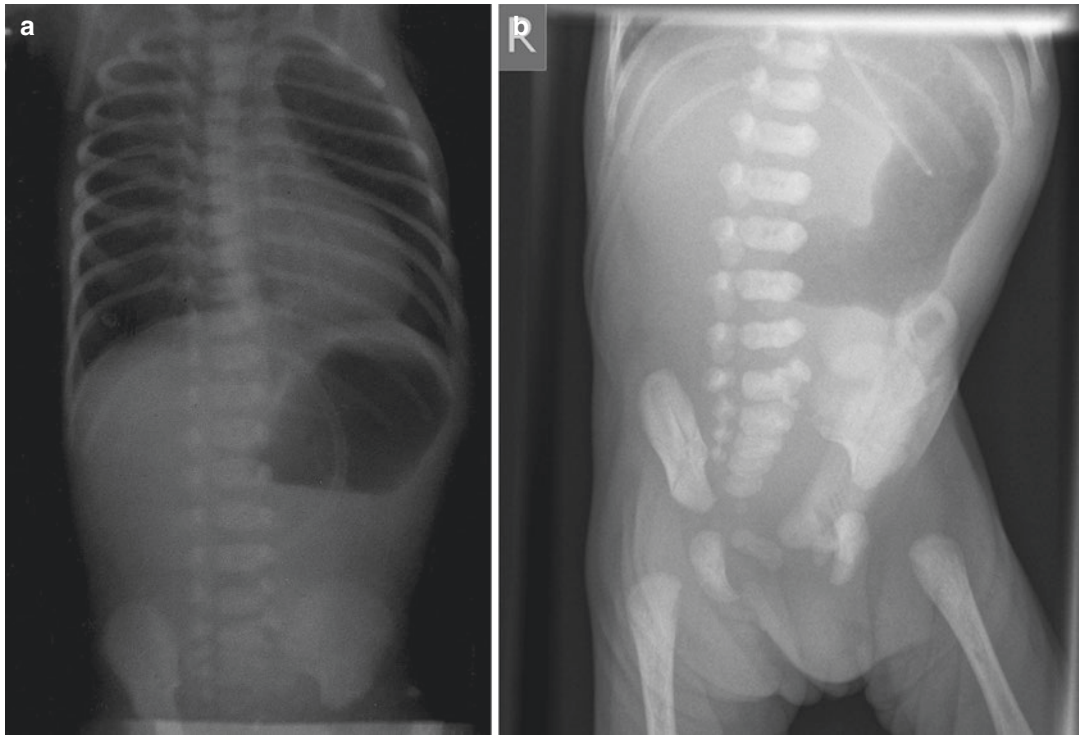

Fig. 116.9 Plain abdominal radiographs showing distended gastric bubble in pyloric atresia

Roux-en-Y from a proximal loop of jejunum to prevent alkaline reflux and a food pouch made by anastomosing, in a side to side fashion, a proportion of the distal jejunal segment (Fig. 116.10). This procedure provides an adequate pouch for food intake and lessens the requirements for frequent feeding. It also facilitates drainage of duodenal contents, decreasing the incidence of alkaline reflux oesophagitis [71].

Postoperatively the patient requires careful follow-up and the regular administration of vitamin B12, and naturally those with asplenia need appropriate penicillin prophylaxis and vaccinations [41].

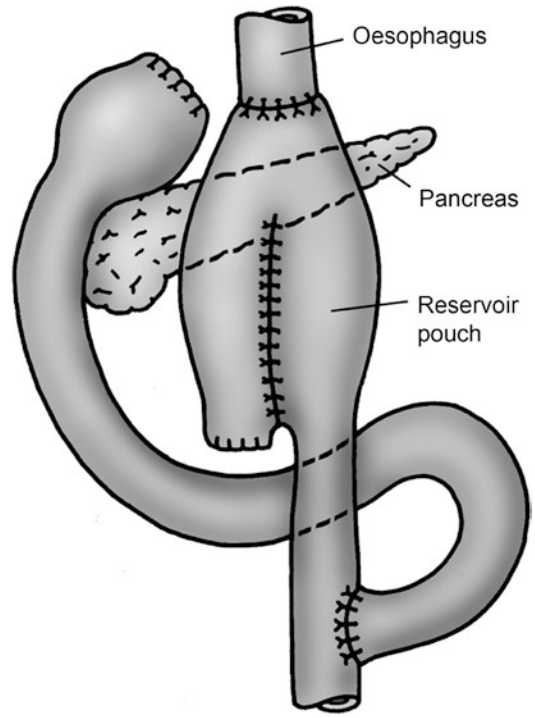

Fig. 116.10 Diagram of Hunt-Lawrence pouch

Gastric Duplication Cyst

Duplications of the stomach are extremely rare and represent 3.8 % of all duplications of the gastrointestinal tract [30, 54]. Most (80 %) are diagnosed in infancy and may be seen on antenatal scans and 65 % occur in females [17]. The majority of gastric duplications tend to occur along the

greater curvature [22] or the posterior wall of the stomach and contain all layers of the gastric wall. They do not usually communicate with the gastric lumen and tend to form a tubular, fusiform or spherical cystic mass [17]. Occasionally there may be a connection to other organs and these can be congenital or acquired. Acquired fistulae can develop due to peptic ulceration, and there are reports of communication to the lung, colon, umbilicus, Meckel's diverticulum [5, 66] and pancreas [40].

Common clinical features include failure to thrive, gastro-oesophageal reflux, abdominal swelling, vomiting and a palpable mass. The cysts may rupture producing peritonitis or may be associated with peptic ulceration and haemorrhage. Fifty percent of patients will have associated anomalies including duplication of the oesophagus and vertebral anomalies [72], and there are published case reports of patients being diagnosed in adulthood with associated pancreatic duct abnormalities [9, 43].

Gastric duplications can be excised by a limited gastrectomy, but on occasions a more extensive resection may be required. There have been reports of creating a window in a dividing septum to form a common lumen; however this is considered to be inferior to excisional surgery. With associated pancreatic duct abnormalities, care must be taken not to injure normal pancreas, and it may be necessary to resect an accessory pancreas [22].

Gastric Diverticulum

Gastrointestinal diverticulae are rare and can occur anywhere along the gastrointestinal tract. Gastric diverticulae have been observed in 0.03–0.1 % of upper gastrointestinal contrast studies and 0.3 % of post-mortem examinations [49, 63]. They can be found at all ages but typically present in the second to fourth decade of life. Seventy-five percent are found on the posterior stomach wall. The majority are congenital (70 %) [58] and solitary, consisting of all layers of the stomach wall. The remaining diverticulae are seen at the pylorus and antrum of the stomach. The finding of ectopic pancreatic tissue suggests a congenital origin, but the majority diagnosed are acquired and secondary to peptic ulcer disease and malignancy, for example [12].

The clinical signs and symptoms of a gastric diverticulum depend on the location, size and presence of ectopic pancreatic tissue. Common presenting features are vomiting, abdominal pain, weight loss, fatigue and anaemia. More serious complications include obstruction, gastro-oesophageal reflux and perforation.

The diagnosis of a gastric diverticulum can be made on endoscopy and upper gastrointestinal contrast studies. The diverticulum appears as a well-circumscribed, smooth, rounded projection from the gastric lumen. The patient must be repositioned in all directions to increase the diagnostic yield of the contrast study. If the lumen of the diverticulum is very narrow, contrast may not enter diverticulum, resulting in the lesion being missed.

In the case of an incidental finding of gastric diverticulum, treatment may not be necessary. If symptoms are thought to be secondary to the diverticulum, then the lesion may be invaginated or amputated. There is a risk of malignancy associated with distal diverticulae and resection has therefore been recommended [17].

Gastric Teratoma

Gastric teratomas are rare benign lesions that occur almost exclusively in males [17]. They account for 1 % of all teratomas [18]. These tumours may have their origins in pluripotent cells and contain all three embryonic germ cell layers. The tumours are often large and multicystic usually on the lesser curvature or posterior wall of the stomach, but the whole stomach may be involved [17].

Clinically the tumours present with haematemesis or non-bilious vomiting due to gastric outlet obstruction with the mean age being 3 months. Antenatal polyhydramnios may be apparent due to gastric obstruction.

Radiographic examination may show calcification and USS may demonstrate solid and cystic

areas within the mass. Upper gastrointestinal studies often delineate the relationship of the tumour to the stomach, but CT/MRI is used to evaluate regional infiltration.

Tumour excision with primary gastric repair is the preferred treatment and is curative. Partial or total gastrectomy is required for intramural tumour extension. Malignant transformation to adenocarcinoma has been reported [8].

Gastric Volvulus

Gastric volvulus is rare but is an important differential diagnosis in those presenting with features suggestive of gastric outlet obstruction. Volvulus results in progressive distension of the stomach with air and fluid which aggravates the obstruction and eventually leads to ischemic necrosis and perforation [14].

The normal stomach is prevented from twisting by its mesenteric attachments (gastrocolic, gastrosplenic, gastrohepatic and gastrophrenic ligaments) as shown in Fig. 116.2. Two further points of fixation include the peritoneal fixation of the pylorus and the cardia. Together these structures anchor the stomach in position and help to prevent excessive movement. Degrees of ligamentous laxity, agenesis and disruption, together with over distension of the stomach and diaphragmatic herniation of the stomach, can lead to abnormal rotation of one part of the stomach around another, resulting in gastric volvulus with complete gastric outlet obstruction.

Gastric volvulus is classified according to the axis around which the stomach rotates (Fig. 116.11). The stomach may rotate on a longitudinal axis that extends from the gastro-oesophageal junction to the pylorus, and this is termed 'organoaxial' volvulus and occurs in two-thirds of patients. Rotation about this axis results in the greater curvature of the stomach resting superiorly to the lesser curvature, giving the suggestion of an upside-down stomach.

The other axis around which the stomach may rotate is around an imaginary line passing from the greater curvature to the lesser curvature. This form is known as 'mesenteroaxial' volvulus. Here the stomach tends to lie in a more vertical plane with the antrum and pylorus rotated anterior and superior to the gastro-oesophageal junction. Also recognised is a 'combined' type of volvulus which is a combination of organoaxial and mesenteroaxial volvulus.

In 1904, Borchadt described a triad of features that were present in an adult who died of acute gastric volvulus and necrosis. These were:

1. Inability to vomit (retching)
2. Severe epigastric distension
3. Inability to pass a nasogastric tube

It has been recognised that these features are not always present in the paediatric population and only 70% of patients have all three symptoms. Other features include chest pain, dysphagia, dyspnoea, dyspepsia and borborygmi [37]. The clinical symptoms often depend on the extent or degree of rotation and obstruction [11].

Symptoms in the paediatric population can range from a chronic history of non-specific abdominal pain to a major intraabdominal catastrophe. Children with neurological impairment have numerous causes for retching and this may lead to difficulty in making the correct diagnosis.

A distended stomach in an abnormal position should raise the suspicion of gastric volvulus, and a single radiograph is usually diagnostic [16]. In contrast to the clinical presentation, the radiological features of gastric volvulus are usually characteristic. The primary radiological sign is viscus containing air. The concomitant pyloric obstruction results in a massively dilated stomach and usually paucity of gas within the remainder of the gastrointestinal tract. On a plain radiograph, any associated diaphragmatic anomalies will also be seen.

Acute mesenteroaxial volvulus can be diagnosed on an abdominal radiograph by identifying the pylorus/antrum being higher than gastro-oesophageal junction, with a distended stomach appearing spherical in supine radiographs. In erect radiographs, there is a double air fluid level seen; one bubble in the fundus and one in antrum. It is important to perform the

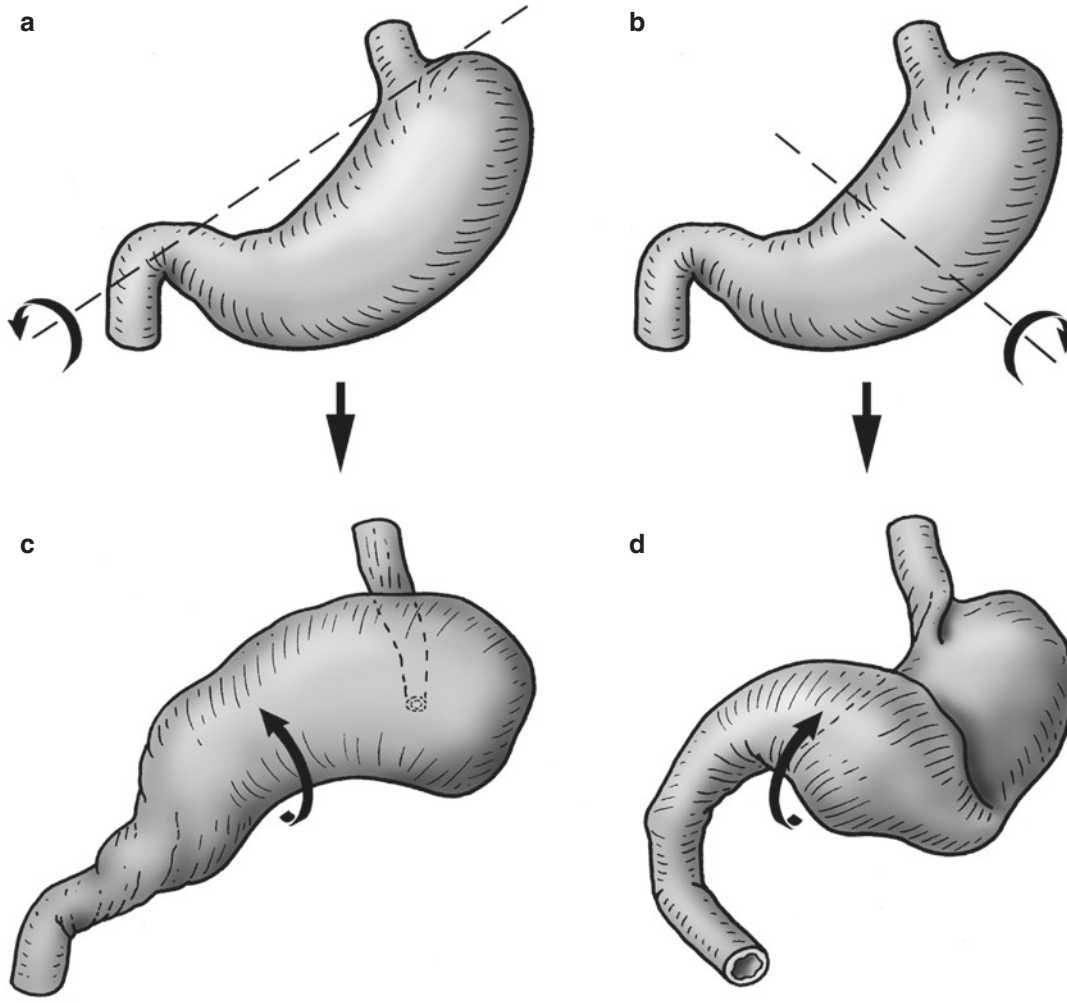

Fig. 116.11 Gastric volvulus. (**a**) Organoaxial axis. (**b**) Mesenteroaxial axis. (**c**) Organoaxial volvulus and 'upside-down stomach'. (**d**) Mesenteroaxial volvulus

radiographs in the erect and supine positions because the extent of rotation is less significant in chronic gastric volvulus than in acute gastric volvulus.

In the organoaxial type, the stomach lies rather horizontally on the plain film with a single fluid level. In organoaxial volvulus, the body of the stomach is inverted, and the greater curvature lies at a higher level than the lesser curvature with the pyloric canal crossing the distal oesophagus. The pylorus usually points downwards and is often near the level of the gastro-oesophageal junction. A single long air fluid level is usually noted on the erect plain film when the volvulus is complete.

Barium examination shows the stomach upside down and documents the obstruction in mesenteroaxial volvulus, while in organoaxial volvulus the gastro-oesophageal junction appears lower than normal and the antrum and pylorus are distended. These radiological findings are virtually diagnostic of gastric volvulus. Endoscopy has been reported as being useful in the diagnosis of intermittent gastric volvulus. Intraoperative gastroscopy demonstrates spontaneous organoaxial volvulus only when the stomach is distended with air [10].

The treatment of gastric volvulus is variable depending on the type. Acute gastric volvulus requires emergency surgery. Chronic gastric volvulus, on the other hand, can be treated conservatively, unless symptoms are severe [1]. Effective treatment for acute gastric volvulus in children requires immediate surgical intervention after appropriate resuscitation. Initially gastric decompression may be required to facilitate reduction of the stomach and prevent impending gastric ischemia [37]. In adults, a nasogastric tube is routinely used; however there are risks of perforation in children; therefore, intraoperative decompression may be required and a gastrostomy serves this purpose well. Earlier reports have advocated the use of trocar decompression, but mortality (33 %) curtailed its use [13]. Endoscopic decompression has also been used in adults but again, perforation risks are high in the paediatric population [51]. Mechanically, only three points of fixation are required to prevent twisting or turning, and the treatment of gastric volvulus works on this simple principle [68].

Surgical correction should include reduction, primary repair of associated anatomical defects and fixation of the stomach. An abdominal approach is recommended even in the presence of an intrathoracic stomach to ensure identification of all associated anatomical defects and to facilitate reduction of the dilated stomach. Gastric fixation is required to prevent recurrence. There have been reports of patients with simple reduction having a recurrence of gastric volvulus [37]. Miller et al. [37] in their review reported no recurrence in children who had undergone gastrostomy fixation. However Cribbs et al. [72] in their review of the literature found nine acute cases in children with a previous history of gastric surgery.

Chronic gastric volvulus is being diagnosed with increased frequency, and this is thought to be due to the increasing use of barium in the evaluation of infants with repeated episodes of vomiting and chest infections. The treatment for chronic gastric volvulus should depend on the severity of the symptoms. Those with mild to moderate symptoms should be treated conservatively [1].

Congenital Pyloric Stenosis, Webs and Strictures

117

H. Till

Congenital gastric outlet anomalies (CGOA) are extremely rare and represent only about 1 % of all gastrointestinal atresias [1]. Embryologically, these malformations are most likely caused by a developmental disturbance of the distal foregut, which forms the antrum and the first, supraampullary portion of the duodenum [2]. In pathological nomenclature, the term represents several different entities like congenital pyloric atresia (CPA), a congenital pyloric stenosis (not to be interchanged with a hypertrophic pyloric stenosis) and intraluminal mucosal webs with or without a central hole (windsock anomaly) [2]. Even a non-folded stenotic ring separating two gastric chambers has been described [3]. Associated anomalies are common [4]. Especially hereditary multiple intestinal atresias (HMIA) are of major clinical importance [5], because these patients often suffer from severe forms of immunodeficiency [5, 6]. Today it remains unclear, whether such immunological defects occur primarily or secondary to the intestinal dysfunction [4]. Finally, an association of the CPA with an epidermolysis hereditaria bullosa (EHB) [2, 7] is well known.

H. Till
Department of Paediatric and Adolescent Surgery, Auenbruggerplatz 34, 8036 Graz, Austria
e-mail: holger.till@medunigraz.at

The first suspicion of a gastric outlet obstruction is raised during prenatal ultrasound investigations. Detection of polyhydramnion, presence of an extremely distended stomach or absence of intestinal filling and motility offer clues towards an impaired gastrointestinal (GI) passage in the foetus. Postnatally the clinical symptoms vary considerably in terms of onset, severity (acute versus chronic), tolerance of feedings and vomiting. A neonate with a complete obstruction (e.g. due to a CPA) usually presents with low birth weight, a small abdominal cavity and non-bilious vomiting. Older children (e.g. those with gastric webs) may complain about chronic and unspecific abdominal pain for some time, non-bilious vomiting and failure to thrive.

Most CGOA can be diagnosed by an upper GI study and an endoscopy. Plain abdominal films possibly demonstrate a “single bubble” and the absence of gas in the distal gut. Even webs, membranes and windsock deformities should be detected on fluoroscopic investigations. Endoscopy has an added advantage that it not only confirms the diagnosis but also enables the possibility for immediate treatment by laser coagulation or sharp dissection of webs. Recently Lin et al. [3] reported about their experience with congenital outlet obstructions of the GI tract. In 37 cases they found 12 gastric, 22 duodenal and 3 jejunal obstructions. Ten of the 12 gastric anomalies underwent an

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_117

endoscopy and a detection of the lesion was possible in every case. Three of these anomalies were webs and could be resected concomitantly. The remaining nine gastric obstructions comprised of non-folded rings or atresias, which were resected. Al-Sahem [1] published a similar experience with 11 cases of gastric outlet obstructions. Intraoperatively, five had a pyloric diaphragm, three had a CPA with a gap between the two segments and two had a CPA without a gap. The pyloric diaphragms were excised during a Heineke-Mikulicz pyloroplasty. The CPAs received a gastroduodenostomy. Although most of his patients did well after the procedures, there was a late 45 % mortality due to sepsis that resulted from an associated immune deficiency.

In summary, children with isolated gastric outlet obstructions have a good prognosis. Prompt endoscopic confirmation and surgical treatment are recommended. However, the associations of EHB or HMIA imply a high mortality due to sepsis and severe immunodeficiencies. These patients require a multimodal therapy beyond surgery.

Gastric Volvulus

118

Tamara Caldaro, Filippo Torroni,
Erminia Romeo, Giovanni Federici di Abriola,
and Luigi Dall'Oglio

Introduction

Gastric volvulus (GV) is a rare cause of partial or total foregut obstruction in paediatric age. This potentially life-threatening condition is characterised by a twisting of the stomach more than 180° on its longitudinal or transversal axis with probable gastric ischemia and perforation. If the rotation is less than 180°, a gastric torsion is present. Delay in diagnosis can result in a high rate of morbidity and mortality.

Historical Background

The term "volvulus" derives from Latin "volvere", which means to turn or roll. Historically, the first reference to a GV dates back to Ambrose Paré (1579) who talked about a complete twist of the stomach due to a sword injury in the left diaphragm. In 1866, Berti anatomically described a case of acute GV based on an autopsy of a 61-year-old woman [6]. In 1895, Berg performed the first surgical procedure to resolve a GV in a 41-year-old man; he reduced the bulky gastric distension using a trocar before derotating the stomach; 12 days after, the patient was discharged in good health conditions [5]. In 1904, Borchardt reported the triad of symptoms and signs of GV: severe epigastric pain, retching without vomiting and failure to pass a nasogastric tube [7]. In 1899, Oltmann illustrated the first paediatric case of GV, and, until 2008, there have been less than 600 reported cases of GV in children [9].

Epidemiology

GV in infants, children and adolescents is a rare pathological condition. Cribbs and colleagues identified 581 paediatric cases of GV published in the English literature between 1929 and 2007. Of these cases, 252 children (43 %) had an acute onset, of which 136 (54 %) with organoaxial volvulus, 103 (41 %) with mesenteroaxial volvulus, 5 (2 %) with combined volvulus and 8 (3 %) with not characterised volvulus [9]. A minimal predominance in male patients was observed [18]. The acute form of GV is frequently described in the first year of life, generally associated to congenital diaphragmatic abnormalities and intestinal malrotation. In older paediatric patients, other predisposing factors are identified, such as paraoesophageal hernia, hiatal hernia, wandering spleen or asplenism. In untreated acute GV, the mortality rate is more than 80 % [13], while in

DOI 10.1007/978-3-642-11202-7_118

patients promptly operated the prognosis significantly improves (mortality: 6.7 %) [9].

Classification

GV may be classified according to its causes and axis of rotation. Depending on aetiology, GV is recognised as idiopathic or acquired. The primary or idiopathic subtype is less common (35 %) [17], and it occurs as a result of hyperlaxity, elongation or absence in the attachments of the stomach that is normally held in place by the oesophageal hiatus, retroperitoneal fixation of duodenum, short gastric vessels and four ligaments: the gastrocolic, gastrohepatic, gastrophrenic and gastrosplenic. Together these structures anchor the stomach and prevent malrotation. The secondary GV is more common (65 %) [17], and it may be related to disorders of gastric anatomy (peptic ulcer, tumours) or function (gastric hypomotility, acute or chronic distension typical in children with neurological impairment), abnormalities of adjacent organs such as the diaphragm (eventration, hiatal or paraoesophageal hernia, congenital diaphragmatic hernia, phrenic nerve palsy) (Fig. 118.1a, b) or spleen (asplenism, wandering spleen) [23] and foregut malrotation. Previous abdominal surgery with interruption of gastric ligaments, as in liver transplantation [12] and fundoplication, can predispose to volvulus. In 1940 Singleton [27] identified three types of GV according to the axis of rotation:

1. Organoaxial GV (Fig. 118.2): the stomach rolls around the longitudinal axis, extending from the gastro-oesophageal junction to the pylorus. The antrum rotates in opposite direction to the fundus of the stomach. It is the most common entity usually associated to diaphragmatic defects, wandering spleen, asplenic or polysplenic syndrome. Recurrently this form manifests as an acute event [19].
2. Mesenterico-axial GV (Fig. 118.3): the stomach twists around a horizontal axis passing through the greater and lesser curvatures. The antrum rolls superiorly and anteriorly and the posterior surface of the stomach lies anteriorly. Generally this is an idiopathic condition with chronic or intermittent symptoms [19].
3. Mixed GV: it is an extremely rare entity due to the combination of organoaxial and mesenterico-axial types.

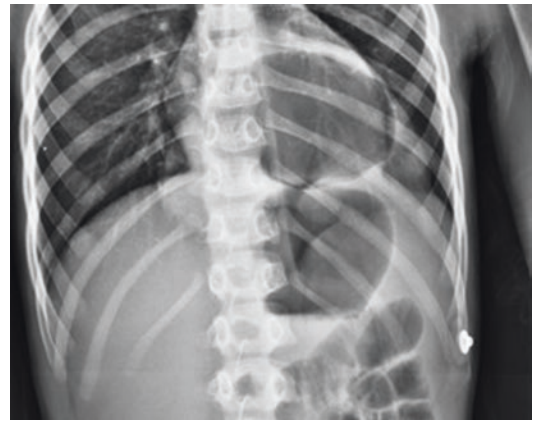

Fig. 118.1 Radiological finding of paraoesophageal hernia after Nissen fundoplication (frontal view)

Clinical Presentation

The onset of GV varies depending on aetiology and degree of the rotation of the stomach and resulting obstruction. In the acute form, the triad of Borchardt (severe epigastric distension, intractable retching and inability to pass a nasogastric tube) is diagnostic in 70 % of adult patients, whereas in the majority of children is usually absent or incomplete. In paediatric population severe symptoms could include most frequently vomiting, dysphagia, dyspepsia and, in case of diaphragmatic defect with cardiopulmonary impairment, chest pain and acute respiratory distress. Hematemesis may also be present, due to mucosal sloughing as a result of ischemia or a mucosal tear for retching. The secondary complications of acute GV consist of gastric ileus, pyloric ischemia and subsequent gastric outlet obstruction, gastric necrosis with perforation and even death. In idiopathic volvulus, the upper abdomen may be distended and severe pain localised in epigastric region; in secondary GV, when related to diaphragmatic anomalies, the abdomen

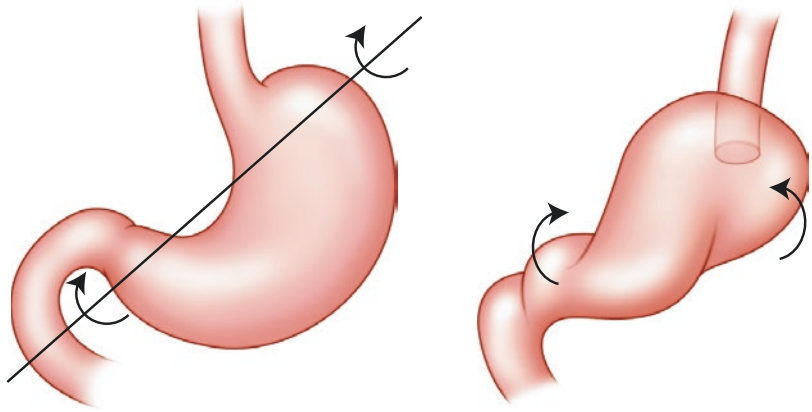

Fig. 118.2 Organoaxial volvulus: the stomach rolls around its longitudinal axis

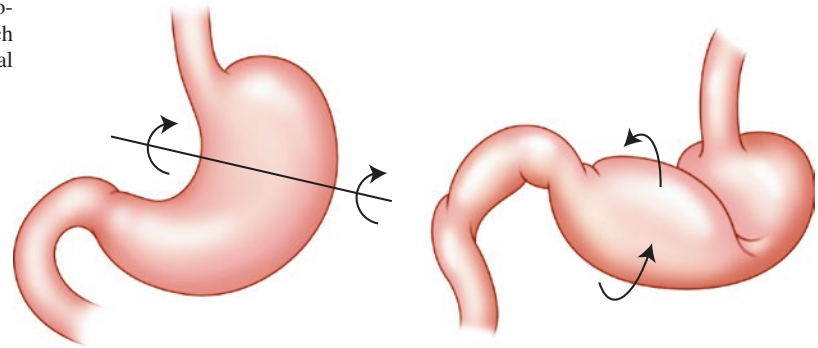

Fig. 118.3 Mesentericoaxial volvulus: the stomach twists around its horizontal axis

may be soft and flat, whereas anomalies could be detected in chest. Patients affected by chronic GV may present mild and non-specific symptoms such as intermittent epigastric pain, early satiety, nausea, recurrent vomiting, sporadic dysphagia, irritability and failure to thrive. These clinical manifestations could appear irregularly for weeks to years and may go underdiagnosed [17]. It must be emphasised that there is a high probability for the chronic form to become acute [13].

Diagnosis

The recognition of GV is often difficult and non-specific. Radiological investigations play an important role in diagnosis and especially in surgical strategies. Traditional X-ray exam is significant to detect gastric dilatation with scarcity of gas in the remaining part of foregut; if GV is secondary to a diaphragmatic defect, retrocardiac air bubble or air-fluid level can be found in the chest. Particularly, in mesenterico-axial form the gastric shadow shows double air-fluid levels in an erect position, whereas in the organoaxial one the stomach is positioned more horizontally with a single fluid level. On the other side, upper gastrointestinal series (UGIS) is considered more specific than traditional X-ray; UGIS reveals obstruction of the stomach at the site of volvulus and its distension at the level of the diaphragm, lying in a horizontal (organoaxial volvulus) or vertical (mesenteroaxial volvulus) plane. Computed tomography scan (CTS) confirms the diagnosis with anatomical details and ascertains possible associated conditions (paraoesophageal or hiatal or congenital diaphragmatic hernias, diaphragmatic eventration) [1, 20, 22, 29, 30].

Treatment

To ensure a good outcome for patients with GV and to reduce the rate of complications and mortality, early diagnosis is required. The treatment can be conservative or surgical: it depends on

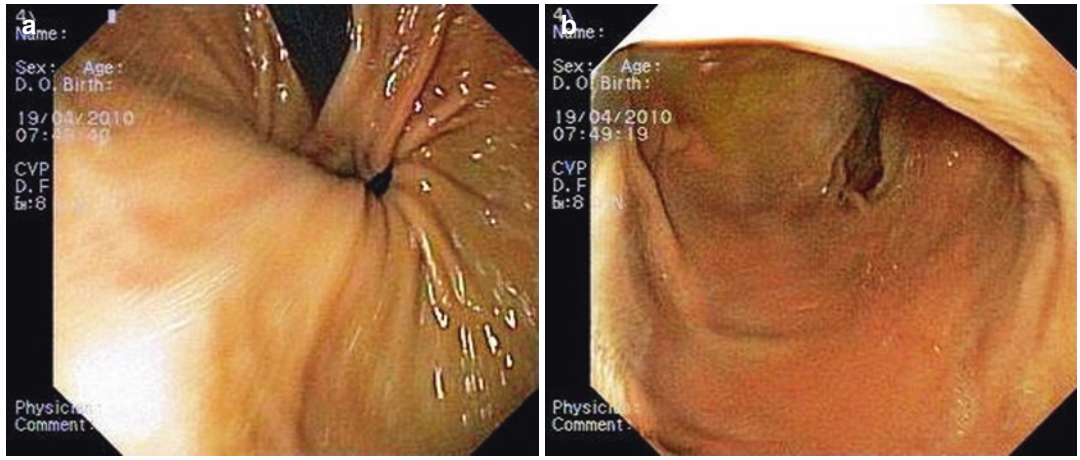

Fig. 118.4 (**a**) Endoscopical view: giant paraoesophageal hernia. (**b**) Endoscopical view: paraoesophageal cavity

the acute or chronic clinical presentation and on potential connected anomalies. Whereas the acute onset must be treated with an emergent surgical intervention, there are no clear guidelines about the management of the chronic one.

Acute GV

In case of acute symptoms, the surgical approach consists of decompression, derotation, fixation of the stomach and handling of associated anomalies. In paediatric age, gastric decompression with a nasogastric tube or with endoscopy is controversial for known risk of perforation [11]. An alternative approach is a trocar placement or an intraoperative decompression with a gastrostomy tube. After gastric derotation, a fixation of the stomach is advised to prevent recurrence [14]. Darani and colleagues proposed a triple gastropexy: anterior gastropexy, phrenofundopexy and esophagocardiopexy. The latter is performed to avoid the opening of His angle, which is due to the two previous steps of the treatment and could favour gastro-oesophageal reflux disease (GERD) [10]. On the contrary, some authors fixed the stomach only with a gastrostomy [16], but cases of recurrent volvulus were reported with a torsion of the stomach around an axis extending from the gastro-oesophageal junction to the gastrostomy site [3]. For this reason, Mayo and colleagues add an anterior gastropexy to a Stamm gastrostomy in all patients treated [17]. A combined laparoscopic and endoscopic approach to create an anterior gastropexy has been reported in children with intermittent primary gastric volvulus. With the gastroscope in place and under laparoscopic guidance, it is possible to fix the stomach at the abdominal wall with percutaneous sutures and in nonrotated position [8]. Fundoplication is often advocated by some surgeons who attribute the increased incidence of reflux to dissection and mobilisation of lower sphincter [4] or to anomaly of diaphragmatic hiatus or to gastropexy. In presence of localised gastric necrosis, limited resection can be performed in order to maintain gastric continuity; if a complete necrosis is found, a gastrectomy could be necessary [15]. In secondary acute GV, the treatment aims to cure any predisposing factors (diaphragmatic defects, intestinal malrotations, wandering spleen, asplenism, paraoesophageal hernia and large hiatal hernia). The large paraoesophageal hernia (Fig. 118.4a, b) could be repaired with a mesh or with direct crural closure depending on the width of the diaphragmatic hiatus. In case of wandering spleen, splenopexy with a mesh or natural tissue or with the placement of the spleen in a "pouch" and associated gastropexy are recommended [28]. When the GV is originated by a diaphragmatic hernia, it could be useful to decompress the stomach before derotating it. With growing use of

laparoscopy, several authors prefer this minimally invasive technique to resolve GV [24]. Bawahab et al. developed an algorithm to define when the laparoscopic method should be attempted. After the first procedures to resuscitate the patient and decompress the stomach with a nasogastric tube, the clinical status must be evaluated; if the patient conditions are unstable and a gastric leak or gastric ischemia is, respectively, documented with a UGIS or an endoscopical exam, urgent open surgery is indicated. If patient's clinical conditions are stable, the contrast study reveals good flow of contrast into the stomach or gastroscopy visualises a normal gastric mucosa, a laparoscopic operation could be performed. This algorithm, used for adult patients with GV by giant paraoesophageal hernia, is useful to avoid emergent surgery and plan the operation in laparoscopy by a surgeon with advanced laparoscopic expertise [4]. To decrease intraoperative complications, Palanivelu et al. advise to maintain a pneumoperitoneum pressure between 10 and 12 mmHg to ease the reduction of hernial contents, if the procedure is performed laparoscopically; to avoid traction on the stomach to prevent serosal lesions; to divide the sac from the pleura carefully to keep away from pneumothorax; and to pay attention when dissecting the right crus, as the left gastric vessel may herniate with the stomach across the edge of the crus [21]. Trocars must be placed high on the abdominal wall to allow instruments to reach into the chest.

Chronic GV

The intermittent chronic neonatal GV is a specific entity, which should be an asymptomatic or poor symptomatic form caused by lax ligamentous attachments because of maternal hormones. Generally this condition is suggestive of an organoaxial partial volvulus, called "floppy stomach", with a spontaneous resolution, diagnosed occasionally during a UGIS performed for other diseases [25]. When the chronic GV is characterised by mild to moderate symptoms, the conservative management should be effective. This onset is typical in children with neurological impairment and is related to a chronic gastric distension due to aerophagia [31]. In these cases, patient undergoes gastric decompression and is maintained in the prone position with slight head up rather than the supine position. Al Salem AH proposed to add prokinetics (metoclopramide) to improve the oesophageal and gastric emptying and H2-blockers to avoid oesophageal ulcers [2]. At the refeeding, small volume meals are suggested [26]. The surgical approach for chronic GV is still controversial, but it is recommended if the conservative treatment fails. The procedure could be performed laparoscopically or via laparotomy, and, just as in the acute form, it consists of derotation of the stomach, anterior or fundal gastropexy, with or without a gastrostomy, and correction of coexisting anomalies. If GERD is diagnosed, fundoplication may be required.

Mucosa-Related Gastropathology

Helicobacter-Related Gastritis and Ulceration and Investigation of *Helicobacter pylori*

119

Priya Narula

Introduction

Helicobacter pylori (*H. pylori*) infection occurs worldwide. Infection occurs most often in poor socioeconomic conditions and has been consistently linked to residential crowding and migration from high prevalence areas. Onset of infection occurs most frequently in childhood [1]. The mode of transmission of *H. pylori* has not been clearly identified. Evidence suggests that direct person-to-person transmission occurs, but the relative importance of the faecal-oral route or oral-oral route is not fully determined nor has the relevance of waterborne and zoonotic pathways been established [1]. Little is known regarding host factors that influence susceptibility to acquisition or persistence of infection.

H. pylori colonisation is the most common cause of chronic gastritis and is etiologically linked to gastric ulcer, duodenal ulcer, gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma. Gastroduodenal diseases associated with *H. pylori* are typically manifested in adults but the infection is usually acquired in childhood, and it is possible that mucosal and humoral responses at this time may affect the course of natural infection.

The Bacterium and Its Pathogenicity

H. pylori is a gram-negative spiral-shaped bacterium that colonises the human gastric mucosa and is consistently associated with the development of chronic gastritis [2]. Several genes of *H. pylori* have been identified as being virulence associated and may have clinical and epidemiological implications. The cytotoxin-associated (cagA) and the vacuolating cytotoxin (vacA) genes appear to be the most extensively studied. The cagA gene is present in some strains (50–60% of *H. pylori* isolates from Western countries and in >90% isolates from East Asian countries) and may have resulted from acquisition of DNA from other bacteria [3]. The vacA gene is present in a majority of strains and comprises two variable parts [4]. *H. pylori* vacA s1, vacA m1 and cagA positive genotypes have been associated with higher degrees of inflammation, atrophy and intestinal metaplasia and epithelial damage in adults [5]. Day et al. [6] demonstrated that cagE is an important virulence factor associated with duodenal ulcers in *H. pylori*-infected children. Rick et al. confirmed the association between gastric mucosal *H. pylori* cagA expressions and paediatric gastroduodenal ulcer disease using in situ hybridisation techniques [7]. However, in a study from China, cagA was not shown to influence the disease phenotype in children, and they had a higher prevalence of cagA+ strains compared to adults [8]. The impact of virulence factors, however, is only

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_119

one of many factors including environment and genetic characteristics of the host that influence the clinical manifestations of infection.

Epidemiology

H. pylori infection is usually acquired in early childhood in both developing and developed countries [9, 10]. Prevalence rates vary and are higher in the developing countries. Sykora et al. [11] estimated a prevalence of 7.1 % in asymptomatic children in the Czech Republic, among the lowest reported in Europe. They found a positive association with increasing age, number of children in the household, lack of formal education of the father and institutionalisation. These findings are consistent with improving trends in living and housing conditions in recent years with decreasing family size.

While the prevalence is decreasing globally and is low in Western Europe and North America, prevalence remains relatively high in most Asian, South American, African and aboriginal populations [12–14]. In a study from Pakistan, a seroprevalence of 47 % was reported with the father's educational status, crowding and increasing age influencing seropositivity [15].

Intrafamilial spread by direct person to person contact is an important aspect or transmission [1, 16]. A recent study suggested that the older sibling may be an important source of *H. pylori* transmission when siblings are close in age [17]. The role of external reservoirs in *H. pylori* transmission has not been ruled out particularly in rural and developing areas [18]. Moderate support for potential waterborne transmission of *H. pylori* has been reported by Travis et al. [19] in a cohort study of 472 children from Mexico and Texas using UBT testing at 6-month intervals from birth to 24 months to describe possible waterborne transmission of *H. pylori*.

Clinical Manifestations

H. pylori infection in children is mostly asymptomatic and not associated with specific gastrointestinal symptoms.

Gastrointestinal Manifestations

Recurrent Abdominal Pain

The association between recurrent abdominal pain, epigastric pain, unspecified abdominal pain and *H. pylori* infection is not established. Whether *H. pylori* gastritis causes abdominal pain in the absence of peptic ulcer is not clear. Several studies have applied different non-invasive tests for *H. pylori* infection and compared the prevalence of positive results in children with recurrent abdominal pain and controls and found no significant difference in infection rates between cases and controls [20, 21]. A meta-analysis of 45 studies also concluded that *H. pylori* infection is not associated with abdominal pain [22]. More recently Tindberg et al. [23] reported no significant association of recurrent abdominal pain with *H. pylori* infection in 695 schoolchildren between 10 and 12 years of age. In fact an inverse association was noted, while recurrent abdominal pain was found unrelated to *H. pylori* infection when adjusted for age, gender and family background variables. And in another meta-analysis, Spee et al. [24] found no association between recurrent abdominal pain and *H. pylori* infection in children, conflicting evidence between epigastric pain and *H. pylori* infection and limited evidence for an association between unspecified abdominal pain and *H. pylori* infection in referred but not in primary care patients.

Several uncontrolled intervention studies show improvement in abdominal pain after *H. pylori* treatment. But in some studies, treatment success was not monitored and eradication of bacteria was assumed in cases of symptomatic improvement [25, 26]. And in other studies, follow-up period was a few weeks only [27]. In a small double-blind randomised placebo-controlled trial in 20 symptomatic children with *H. pylori* (excluding cases of peptic ulcer) followed up for 12 months, bacterial eradication and healing of gastric inflammation did not lead to symptomatic relief of chronic abdominal pain [28].

Therefore, in the absence of ulcer disease, there is inadequate evidence supporting a causal relationship between *H. pylori* gastritis and recurrent abdominal pain.

Peptic Ulcer

Compared to adults, peptic ulcer disease is found less often in infected children undergoing upper endoscopy. In a European multicentric study including 1,233 symptomatic children with *H. pylori* infection, peptic ulcer disease was diagnosed in less than 5 % of children under the age of 12 years and in about 10 % of teenagers [29]. However, *H. pylori* infection is an important cause of duodenal ulcers in children.

A causal relationship between *H. pylori* and duodenal ulcer disease in children has been demonstrated [30]. However, *H. pylori* is not the only aetiological factor as shown in a series of 37 children with gastric or duodenal ulcers, where *H. pylori* was detected in only 15 children [31]. Other aetiological factors were identified in 21 of remaining 22 children including Crohn's disease, coeliac and treatment with ulcerogenic drugs [31].

Rick et al. [7] investigated 51 children of whom 8 had gastric ulcers (6 *H. pylori* positive) and 11 had duodenal ulcers (10 *H. pylori* positive) and found expression of 16S rRNA and cagA was significantly higher in children with ulcer compared with normal children. A strong relationship between gastrointestinal bleeding because of duodenal ulcer disease and *H. pylori* infection in childhood has also been reported [32].

Gastro-oesophageal Reflux Disease

The role of *H. pylori* in gastro-oesophageal disease remains controversial, limited by sufficient published data in children. Recent studies do not report a consistent association between *H. pylori* infection and gastro-oesophageal disease [33, 34]. A retrospective analysis of 420 patients reported that there was a significantly higher prevalence of reflux oesophagitis in an *H. pylori*-infected cohort independent of age or sex suggesting that *H. pylori* infection in children is positively associated with reflux oesophagitis [33]. However, another retrospective analysis of 206 children did not show an increased prevalence of *H. pylori* infection in patients with gastro-oesophageal disease. A negative significant association was not found either between prevalence of *H. pylori* and erosive oesophagitis [34].

Gastric Cancer

Various epidemiological and intervention studies support a causal relationship between *H. pylori* infection and risk of gastric cancer and gastric mucosa-associated lymphoid tissue (MALT) lymphoma [35–37]. Meta-analysis estimates the risk of gastric cancer associated with *H. pylori* infection to be two- to sixfold [38, 39]. A meta-analysis also observed that infection with cagA-positive strains further increase risk for non-cardia gastric cancers by twofold over and above the risk associated with *H. pylori* infection alone [38]. Other factors such as genetic make-up of the host and environmental influences such as dietary salt intake also influence the risk of gastric cancer [40].

Both of these cancer types are extremely rare in children although there are a few case reports in literature [41, 42]. The risk of gastric cancer may be high in *H. pylori*-infected children in whom a parent has gastric cancer. This higher risk may be due to the child sharing similar genetic and environmental factors with the affected parent and may also have the same bacterial strain [43].

About 70 % of gastric MALT lymphomas can be successfully treated with *H. pylori* eradication. In patients with the translocation t (11;18) (q21;q21), a marker of *H. pylori* independency, chemotherapy can be considered in addition to *H. pylori* eradication [44].

Extraintestinal Manifestations

There is uncertainty whether *H. pylori* infection has a role in extraintestinal diseases, although such a role has not been ruled out. There is some evidence to support that treatment of *H. pylori* infection may lead to improvement in iron deficiency anaemia, but there is insufficient evidence supporting a causal relationship of *H. pylori* infection to otitis media, food allergy, idiopathic thrombocytopenic purpura and short stature [45].

Iron Deficiency Anaemia

H. pylori infection may be the cause of iron deficiency anaemia even in the absence of erosions or

ulceration [46, 47] or gastrointestinal symptoms [48]. Studies have shown an association between low iron status and *H. pylori* infection [49, 50] reporting enhanced iron absorption following eradication treatment for *H. pylori* [50]. In a randomised placebo-controlled study of 22 *H. pylori*-infected children and adolescents randomised into three treatment arms – iron only, eradication therapy only or both [50] – eradication therapy increased haemoglobin levels even without iron substitution, while iron therapy alone did not. In another study of 140 children between 6 and 16 years, recovery in iron deficiency and iron deficiency anaemia were achieved with *H. pylori* eradication without iron supplementation [51]. However, this beneficial effect was not confirmed in an intervention study in a high prevalence population, which did not show improvement in isolated iron deficiency or mild anaemia following treatment and resolution of *H. pylori* infection up to 14 months after treatment initiation [52].

No association between *H. pylori* infection and iron deficiency anaemia has also been reported [53, 54]. It can be difficult to distinguish between anaemia due to *H. pylori* infection and due to other confounding factors such as poor nutritional status or other underlying disease. Confounding by mutual risk factors may explain the observed association in the absence of a causal link.

Growth Failure

The link between *H. pylori* and poor growth remains weak. A cross-sectional study of Mexican school children from a low socioeconomic background found a negative association between *H. pylori* infection (based on 13C urea breath test) and height compared to uninfected matched controls and suggested the risk was greater in children above the age of 7 years [55]. However, an Australian cross-sectional study of refugee children from Africa failed to find an association between *H. pylori* infection and growth restriction [56]. Sood et al. compared height, weight and body mass index of 97 *H. pylori*-positive children with dyspeptic symptoms to 160 children with dyspepsia without infection. After adjusting for socioeconomic deprivation and ethnic difference, they found no significant difference between mean weight and height standard deviation scores in infected and noninfected group [57].

Diagnosis

Diagnostic tests for detection of *H. pylori* are classified as invasive and non-invasive tests. Invasive tests require gastric tissue for detecting *H. pylori* and therefore require performing an endoscopy and include histopathology, rapid urease tests, culture, PCR and fluorescence in situ hybridisation (FISH). Non-invasive tests include different methods of detecting *H. pylori* antigen in stool; detection of antibodies against *H. pylori* in serum, urine and salivary samples; and ^{13}C urea breath tests.

Invasive Tests

Histopathology (Figs. 119.1 and 119.2)

Performing an upper GI endoscopy in symptomatic children provides gastric biopsy tissue samples for testing for *H. pylori*. An endoscopy with histopathology not only detects *H. pylori* but also any lesions associated with the infection and any other possible causes for the patient's symptoms.

Samples sent for histology are usually formalin fixed and paraffin embedded, and a variety of stains including haematoxylin and eosin, special stains and immunohistochemistry have been used to detect *H. pylori*. The sensitivity ranges from 66 to 100% and specificity 94–100% in published series from children [58]. The density of *H. pylori* may be patchy and therefore sensitivity increases with the number of biopsies taken. The highest bacterial count is usually in the antrum but in patients on acid-suppressing agents, the bacteria may be found in the corpus. Adult studies recommend discontinuing acid suppressive agents such as proton pump inhibitors for at least 2 weeks prior to testing as bacterial density may be reduced [59].

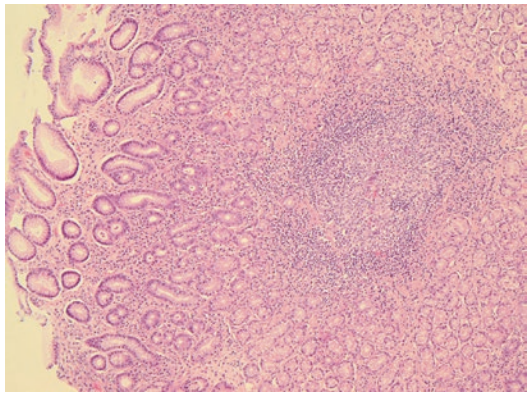

Fig. 119.1 *H. pylori* gastritis – active chronic inflammation in the antrum

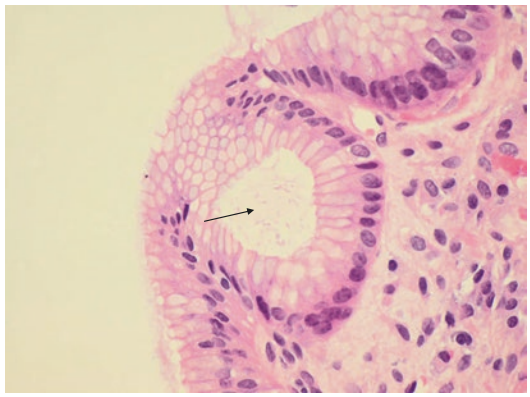

Fig. 119.2 *H. pylori* organisms in the mucous surface

Rapid Urease Test

Rapid urease test can be performed in gastric biopsy specimens using a wide variety of commercially available reagents. This test is based on the activity of *H. pylori* urease enzyme, which splits the urea reagent to form ammonia. Ammonia increases the pH, which is detected by the indicator phenol red. False-negative urease tests can be obtained in patients on proton pump inhibitors and adult studies recommend acid suppressants such as proton pump inhibitors for at least 2 weeks [59, 60].

A significant association between density of *H. pylori* organisms on histology and a positive rapid urease test has been noted [61]. The sensitivity of the rapid urease test varies from 75 to 100 % and specificity 84–100 % in published series in children [58].

Fluorescent In Situ Hybridisation (FISH) or Polymerase Chain Reaction (PCR)

An advantage of fluorescent in situ hybridisation and PCR is the ability of determining clarithromycin resistance in frozen or formalin-fixed paraffin-embedded tissues and does not depend on bacterial growth [62]. However, their use is currently limited as a research tool as it is technically demanding and expensive.

Culture

H. pylori can be cultured from gastric biopsies. The colonies are gram negative, urease positive, oxidase positive and catalase positive. This test has a 100 % specificity and is a reference standard but sensitivities can vary [63, 64]. Variable sensitivities may be due to insufficient number of biopsies, delay in transport, exposure to aerobic environment and also depend on laboratory experience.

Non-invasive Tests

Antibodies to *H. pylori* in Blood, Urine and Saliva

Due to a wide variability in the sensitivity and specificity for detection of antibodies (IgG and IgA) to *H. pylori* in serum, whole blood, urine and saliva in children, these assays cannot be used on their own in children and adolescents for either diagnosis of *H. pylori* infection or to monitor the success of therapy [45]. In addition, they do not distinguish between an active infection and a previous exposure to *H. pylori*. A positive IgG serology test can occur several months or years after infection and therefore cannot be used reliably for diagnosis or to confirm eradication [58].

^{13}C-Urea Breath Test

H. pylori produce urease, an enzyme that splits urea into ammonia and carbon dioxide. The urea breath test is based on the principle that urease activity is present in the stomach of infected individuals. Patients ingest urea labelled with ^{13}C. Hydrolysis of urea occurs within the mucus layer and results in the production of labelled CO_2. The CO_2 diffuses into the epithelial blood

vessels and soon appears in the subject's breath. Labelled urea is usually given to the patient with a test meal to delay gastric emptying and increase contact time with mucosa. After ingestion of urea, breath samples are collected for analysis.

^{13}C-Urea breath test is a simple and safe non-invasive test for detection of *H. pylori* in children older than 6 years of age before and after treatment (at least 4 weeks after stopping antibiotics and 2 weeks off proton pump inhibitors). The reported sensitivities of this test in published series in children range from 75 to 100 % before treatment and 94.1–100 % after treatment, while specificity ranges from 77.5 to 100 % before treatment and 92.3–100 % after treatment [58]. Several protocols can be used to perform this test though optimal conditions of this test in children less than 6 years of age require further evaluation [58].

Stool Antigen Detection

This is a simple, safe and convenient non-invasive test wherein samples can be easily obtained. Several methods are available for detection of *H. pylori* antigen in stool including enzyme immunoassay (EIA) based on polyclonal and monoclonal antibodies and immunochromatographic tests (rapid or quick tests).

A meta-analysis (including adult and paediatric studies) of stool *H. pylori* antigen detection using EIA with monoclonal and polyclonal antibodies demonstrated higher pooled sensitivity with monoclonal antibodies compared with polyclonal antibodies both before treatment (95 % versus 83 %) and after treatment (91 % versus 76 %) of *H. pylori*, thereby concluding that monoclonal EIA stool antigen tests were an accurate non-invasive test for initial diagnosis and confirmation of *H. pylori* eradication [65]. Sensitivities of the EIA monoclonal tests published in paediatric studies range from 96.6 to 98 % before treatment of *H. pylori* and 100 % after treatment while specificities range from 94.7 to 100 % before treatment and 96.2–100% after treatment [58]. An additional advantage is that the diagnostic accuracy of the EIA stool test does not appear to be age dependent [66].

Rapid faecal tests based on immunochromatography using monoclonal antibodies have a lower sensitivity compared to EIA with monoclonal antibodies, along with the disadvantage of interobserver variability and equivocal results [67, 68].

Indications for Treatment

A meta-analysis of studies looking at adult patients with peptic ulcer disease and *H. pylori* infection indicate that relapse rate of ulcers is high without treatment of *H. pylori* infection [69]. Recently published paediatric guidelines in line with this recommend eradication of the organism in *H. pylori* infection and peptic ulcer disease, healed ulcers and history of peptic ulcer disease [45].

If *H. pylori* is detected using biopsy-based methods in the absence of peptic ulcer disease, then treatment can be considered after evaluating the risks and potential benefits for the patient [45].

In the rare child with pathological evidence of MALT lymphoma or atrophic gastritis with intestinal metaplasia, who has coexisting *H. pylori* infection should be treated with eradication therapy [70]. Treatment can also be offered to children infected with *H. pylori* who have a first-degree relative with gastric cancer [45].

Treatment

Choosing an appropriate eradication regimen will not only ensure eradication of *H. pylori* but may also prevent the development of antibiotic resistance and subsequent spread of resistant strains.

A combination of proton pump inhibitors and two antibiotics (usually clarithromycin or metronidazole in conjunction with amoxicillin) has been recommended as first-line eradication for *H. pylori* in treatment in various paediatric guidelines [70, 71]. A prospective randomised double-blind trial comparing dual therapy of amoxicillin and clarithromycin with triple therapy including omeprazole demonstrated that triple therapy

achieved higher eradication rates of 74.2 % compared to 9.4 % with dual therapy [72].

A meta-analysis of randomised controlled trials that compared duration of eradication therapy concluded that extending triple therapy beyond 7 days was unlikely to be clinically useful [73]. Bismuth-based triple therapy is an alternate first-line therapy. A study by the European paediatric treatment registry reported bismuth-containing triple therapies were more effective than proton pump inhibitor containing ones (77 % versus 64 %). However bismuth's palatability affecting adherence is a concern [74].

A meta-analysis of *H. pylori* eradication treatment efficacy in children concluded that overall the methodological qualities of the studies was poor with small sample sizes and few randomised controlled trials and highlighted the need for additional well-designed randomised trials in children [75]. Therefore most evidence is obtained from adult studies.

Development of antibiotic resistance may adversely affect the eradication rates. Non-adherence to treatment is also a well-recognised factor in failed eradication but is difficult to measure in clinical trials. *H. pylori* resistance to antimicrobials can be either primary (i.e. existing before *H. pylori* treatment) or secondary (i.e. developing as a result of failed therapy). Wide use of these antibiotics has led to a significant increase in resistance to clarithromycin and metronidazole and is reported in several studies with overall rates as high as 24 % in Europe [29, 76, 77]. The use of antibiotics for other indications appeared to be a major risk factor for development of primary resistance. Overall resistance to clarithromycin was found in 24 % (mean primary resistance 20 %, mean secondary resistance 42 %) and overall resistance to metronidazole was 25 % (primary resistance 23 %, secondary resistance 35 %). While resistance to both antibiotics was noted in 6.9 % (primary resistance 5.3 %, secondary resistance 15.3 %) and resistance to amoxicillin was only 0.6 % [29].

Clarithromycin resistance is highly predictive of treatment failure if clarithromycin is part of the treatment regime [78], and therefore clarithromycin-based triple therapy should be used as first line guided by susceptibility testing or if clarithromycin resistance rates are low. Treatment directed by antibiotic susceptibility testing results in highly effective eradication rates [79].

Antimicrobial drug resistance therefore is a major cause of failure of *H. pylori* eradication and is responsible for a decline in eradication rate. Declining eradication rates with standard triple regimens have led to the development of alternate treatment options. Sequential therapy is a promising alternative for eradication of *H. pylori*. Sequential therapy involves dual therapy with proton pump inhibitors and amoxicillin for 5 days followed sequentially by 5 days of triple therapy (a proton pump inhibitor with clarithromycin and metronidazole/tinidazole). The mechanism of action of sequential therapy is unclear but the initial therapy with amoxicillin might reduce the bacterial load in the stomach, and this in turn may improve the efficacy of the subsequently administered triple therapy. It has been suggested that sequential therapy may be more effective than standard triple therapy because it involves the administration of four drugs (i.e. proton pump inhibitor and three antimicrobials) with an additional antimicrobial compared to triple therapy. Although, most of this data is from Italian studies and therefore further assessment across a broad range of patients is required before sequential therapy could replace standard treatment regimens. In addition, it is not clear whether it is necessary to give the drugs sequentially or if the four components can be given concurrently as quadruple therapy as that would be less complex for the patient [80].

A meta-analysis of randomised controlled trials (most trials carried out in Italy) in adults and children concluded that sequential therapy was better than triple therapy in eradication of *H. pylori*. It highlighted the need for further trials in other European countries and North America before it can be recommended as first line [81]. Another meta-analysis had similar results showing sequential therapy was superior to standard triple therapy for eradication in treatment-naive patients even when there was evidence of clarithromycin resistance [82].

A prospective randomised trial in adults concluded that in geographical areas with high (>15 %) prevalence of *H. pylori* strains resistant to clarithromycin, a levofloxacin-containing sequential therapy is more effective (96 % eradication rate compared to 80.8 %), equally safe and cost saving compared to a clarithromycin-containing sequential therapy [83]. There has however been a rapid emergence of resistance to levofloxacin, and in some parts of Europe, high prevalence of levofloxacin-resistant strains has been described [84].

In an open multicentric trial involving 62 children with metronidazole- and clarithromycin-resistant *H. pylori*, eradication was achieved in 66 % with high-dose amoxicillin, metronidazole and esomeprazole for 2 weeks [85].

In recently published paediatric guidelines [45], triple therapy or sequential therapy is recommended as first-line eradication regime. In addition, antibiotic susceptibility is recommended for clarithromycin prior to initial clarithromycin-based triple therapy in populations with high rates of *H. pylori*-resistant strains (>20 %). Post treatment a reliable non-invasive test (^{13}C-urea breath test or monoclonal EIA faecal antigen test) is recommended at least 4–8 weeks following completion of eradication treatment.

In cases of treatment failure, repeat endoscopy with culture and antibiotic sensitivity testing can be performed to guide second-line therapy, or FISH can be used to detect primary clarithromycin resistance in previously obtained biopsies. If not possible then, treatment can be modified by adding an antibiotic or bismuth (quadruple therapy) or using antibiotics not used in initial regime (including levofloxacin in triple therapy) and/or giving a larger dose and/or longer duration of eradication treatment up to 14 days [45].

Conclusion

Helicobacter pylori is the most common cause of chronic gastritis and an important cause of gastric and duodenal ulcers. It is usually acquired in early childhood and intrafamilial spread is an important aspect of transmission. Diagnosis is made by biopsy-based tests. *H. pylori* is eradicated using triple therapy or sequential therapy and eradication is confirmed with a reliable non-invasive test. In cases of treatment failure, antibiotic susceptibility testing may be helpful.

Acknowledgements I would like to thank Dr K Venkatesh for his help with the literature search and Dr M Al-Adnani for the histological images of *H. pylori*.

Non-*Helicobacter pylori* Gastritis, Ulceration, and Drug-Related Gastropathies

120

Arun Nanjundaraje Urs

Introduction

Helicobacter pylori infection is the most common cause of gastritis in children and associated with duodenal ulcer [1]. Due to improved socioeconomic conditions, widespread use of effective treatment and pervasive use of antibiotics for unrelated conditions may be some reasons for steady decline in prevalence of *H. pylori* infections [2]. This has led to increasing reports of *H. pylori*-negative gastritis and other causes of gastritis [3]. Although gastritis is a frequent endoscopic or histopathologic finding in children, peptic ulceration of the stomach or duodenum is very uncommon [4].

In this chapter, we aim to provide a structured approach for evaluation of non-*Helicobacter pylori* gastritis, ulceration, and drug-related gastropathies. The aspects of *H. pylori* infection, associated ulcer disease, and systemic diseases affecting the stomach are discussed elsewhere.

Gastritis refers to the presence of inflammatory cells in the gastric mucosa and precludes mucosal ulceration. Gastritis is mostly a histological term that needs biopsy to be confirmed and often appears normal at endoscopy. The epithelial cell damage and regeneration with minimal or no associated inflammation are referred to as "gastropathy" with typical endoscopic features as described by some authors [5]. There is no universally accepted classification, which can provide a satisfactory description of all types of gastritis or gastropathy and also due to different objectives. The upgraded Sydney systems have been widely adopted in adults however and have little broad application to children [6, 7]. The etiology-based classification provides an understanding of natural history of lesion and a practical approach for further investigation and management [8] Table 120.1.

Classification of Gastritis (Table 120.1)

Non-*Helicobacter pylori*-Negative Gastritis

H. pylori has been regarded as the main cause of chronic active gastritis [9] for nearly three decades. True *H. pylori*-negative gastritis is a chronic active inflammation of gastric mucosa with no detectable *H. pylori* organisms. There is perceived belief among the pathologists in the Western world that "*H. pylori*-negative chronic active gastritis" is increasing. Genta et al. performed a database review on 102,497 gastric biopsies of which 10,517 had a diagnosis of chronic active gastritis. In 1,933 cases (18.6%), no *H. pylori* organisms were visualized and of which <10% of cases remain apparently

Uremic gastropathy
Hyperplastic

unexplained [10]. The prevalence and severity of chronic gastritis in *H. pylori*-negative patients with gastrointestinal disorders are more common than previously appreciated and called for better characterization of gastric mucosal histology [11]. Although the etiology of chronic gastric inflammation in the absence of *H. pylori* infection remains unknown, it is believed that "incidental antibiotic treatments" are one of the most common causes of *H. pylori*-negative gastritis along with masking effect of proton pump inhibitors (PPIs) and inadequate sampling or suboptimal staining techniques. A meticulous search for *H. pylori* is merited before a diagnosis of *H. pylori*-negative chronic active gastritis.

Helicobacter heilmannii Gastritis

Dent et al. [12] and McNulty et al. [13] reported the presence of a new spiral bacterium, *Helicobacter heilmannii*, formerly known as *Gastrospirillum hominis*, in the gastric mucosa of three adults with chronic gastritis. *H. heilmannii* infection has since been reported, although rarely, in children [14]. *H. heilmannii* microorganisms are gram-negative bacilli, measuring up to 1.0 μm wide and 5.0–10.0 μm long as opposed to smaller, curved, and less spiral *H. pylori*. Most species possess strong ureolytic ability, particularly those associated with gastric mucosa [4]; this is the basis of identifying the organisms by rapid urease test. *Helicobacter heilmannii* (previously *Gastrospirillum hominis*) is probably transmitted from cats and dogs [15, 16] and may cause chronic active gastritis similar to that of *H. pylori* but with less severe inflammation [17, 18]. However, as yet, a definite association between *H. heilmannii* infection and ulcer disease has not been established [19]. In populations living in North America and Europe, the prevalence of infection is between 0.3 and 1.1 % of the general population [17, 20–22]. In populations living in Southeast Asia, the infection rate may be as high as 6 % [23]. *H. heilmannii* appears to be acquired by human contact with farm animals and household pets [24]. The characteristic spiral organisms are readily identified by the same range of special staining techniques employed for identification of *H. pylori* [23]. Some patients benefit symptomatically from antibiotic treatment [20]. Persistence of *H. heilmannii* has been recorded in children after successful eradication of *H. pylori* and has necessitated further antibiotic therapy [7, 8]. Rarely, other helicobacter species have been isolated from the stomach.

Other Bacterial Causes of Gastritis

Gastric Tuberculosis

The gastric tract is an uncommon site of extrapulmonary tuberculosis infection, even in parts of the world where intestinal tuberculosis is common. The incidence of gastric tuberculosis is 0.03–0.21 % of all routine autopsies [25]. The rarity of gastric tuberculosis is due to gastric acid, continuous motor activity of the stomach, and the scarcity of lymphatic follicles in the gastric wall [26]. Gastric tuberculosis usually develops secondary to other tuberculous lesions, most commonly pulmonary [27]; nonetheless, sporadic cases of primary gastric tuberculosis have been reported worldwide [9–14]. The possible routes of infection include direct infection of the mucosa, hematogenous spread, or extension from a neighboring tuberculous lesion [26]. Gastric tuberculosis is usually associated with an immune-deficient state [27]; many cases reported in developed countries are in immunodepressed patients, particularly those with HIV infection. But such relationships have not been well described in cases reported from developing countries. The clinical manifestations of this type of infection are nonspecific. Consequently, diagnosis is often missed. There are reports of isolated gastric tuberculosis presenting as pyrexia of unknown origin [28]. Other presentations include gastric carcinoma [17], gastric outlet obstruction [18], benign peptic ulcer [19], and, rarely, stomach perforation [20]. Based on endoscopy, lesions may be described as single or multiple ulcers and hypertrophic nodular lesions surrounding a stenotic pyloric channel [29]. The antrum and prepyloric regions are the most common sites of tuberculous lesions in the stomach [25]. The diagnosis of gastric tuberculosis can only be made by histological study of the resected stomach or of a biopsy specimen of this organ. Endoscopic brush cytology and biopsy are only occasionally successful in diagnosis [30]. Submucosal location of the lesion has been cited as a reason for failure of endoscopic biopsies [28, 31]. On biopsy, granulomas are either caseous or non-caseous. Staining for acid-fast bacilli is frequently negative, and the diagnosis is either by culture or finding of confirmed tuberculosis elsewhere [32].

Viral Gastritis

Several viruses infect the stomach; most importantly CMV and others that are isolated include EBV, herpes virus, hepatitis C, measles, varicella, human herpes virus 6, and influenza; and the latter can be associated with severe hemorrhagic gastritis [33].

Cytomegalovirus (CMV) and Gastritis

CMV gastritis occurs mainly in immunocompromised children and adults, such as those with malignancies, immunosuppression (steroids), posttransplant, or AIDS [34] and who are at risk of disseminated and or symptomatic CMV disease. Less commonly, CMV infection occurs in immunocompetent patients [35]. CMV is associated with childhood Ménétrier disease (associated with protein losing enteropathy), which causes significant morbidity in infants/children. Most children recover spontaneously or with supportive care. However rarely, antiviral-specific therapy is required [36–38]. Endoscopically, the mucosa is commonly congested and swollen rugal folds with multiple erosions and ulcerations [39] in the gastric fundus and body. The diagnosis may be established by immunohistochemical detection of CMV early nuclear antigen in gastric biopsy [36]. Detection of CMV DNA in a gastric biopsy sample by PCR is a more sensitive assay than antigenemia and serology tests, as it detects a disease localized to the gastrointestinal tract [40]. The examination of biopsies reveals mixed inflammatory infiltrate and characteristically enlarged endothelial, stromal, or epithelial cells with owl's-eye intranuclear inclusions. However, this highly specific appearance may be difficult to identify. Instead, granular

basophilic cytoplasmic inclusions may be seen. The inclusions in the endothelial cells are best observed when the mucosa is not ulcerated. Alternatively, they are commonly noted in the mesenchymal cells (endothelial and stromal) when the mucosa is ulcerated [41, 42]. The early detection of CMV infection and the early initiation of antiviral therapy for those patients at high risk for CMV infection are very important to reduce the risk for CMV disease and CMV-associated death [43], but otherwise spontaneous recovery usually occurs within 1–2 months [37].

Epstein-Barr Virus and Gastritis

EBV gastritis is rarely recognized with only five reported cases in the literature. The endoscopy revealed several ulcerative lesions and diffuse gastritis [44–47] with dense and diffuse lymphoid infiltrate with atypical lymphocytes. Clinical correlation is required to exclude malignant lymphoma. The in situ hybridization techniques are very useful in diagnosing EBV-associated gastritis and spontaneously resolve with symptomatic management.

Parasitic Gastritis

Anisakiasis

Parasitic disease that affects the stomach is acquired by ingestion of raw or inadequately cooked fish that contains larval nematodes. Once the parasite is ingested, it can migrate back to the esophagus and be expectorated, invade the mucosa of the stomach or intestine, or be excreted in the stools. In the stomach, the parasite can cause severe epigastric pain, nausea, vomiting, and diarrhea within 1–24 h after eating raw fish or can cause chronic intermittent abdominal pain, nausea, and vomiting that can be present for weeks or months [33]. In some patients with anisakiasis, an acute allergic reaction can occur, with urticaria, angioedema, erythema, bronchospasm, and anaphylaxis [48]. Removal of the parasite through endoscopy is curative and is associated with eosinophilic gastritis.

Gastric Giardiasis

Giardia is a flagellated, binucleated protozoan and is one of the most common small intestinal parasites and is found worldwide. GG is uncommon and fewer than 90 cases have been reported in literature [49]. GG is usually seen in the antrum, probably as a result of biliary reflux, and is usually associated with *H. pylori* infection. Conditions of increased gastric pH such as hypochlorhydria (primary or secondary to medications), partial gastrectomy, atrophic gastritis, or biliary reflux can result in *Giardia* colonization of the gastric epithelium. It has been reported that GG can be induced by the use of PPI therapy, and the infection can disappear within 4 weeks of stopping PPI therapy without any specific therapy for GG [50]

Other Parasitic Gastritis

Cryptosporidiosis [51], toxoplasmosis [52], and visceral leishmaniasis [53] are isolated from the stomach, particularly in AIDS patients. These common opportunistic infections have a wide variety of endoscopic appearances and only histologic examinations of biopsy specimens allows for specific diagnosis. The stomach is also rarely affected by *Strongyloides stercoralis*.

Fungal Gastritis

Candida, *Aspergillus*, *Histoplasma*, and *Mucor* may occur in children with burns, malnourishment, and in those who are immunocompromised. Candida species are frequent pathogen demonstrated frequently from gastric ulcers of both immunocompetent and immunosuppressed patients [54]. Invasion of the gastric mucosa by organisms can define whether there is colonization or infection [33]. Gastric phycomycosis is another rare condition, highly lethal in its invasive

form, and characterized by deeper invasion of the gastric wall and blood vessels [55]

Phlegmonous Gastritis and Emphysematous Gastritis

Phlegmonous (suppurative) gastritis is a rare rapidly progressive condition characterized by bacterial infection of the gastric submucosa resulting in necrosis and gangrene [56]. Phlegmonous gastritis is a rare disease with only few reported cases in adult literature occurring in a background of preexisting disease conditions such as alcoholic liver disease, acquired immune deficiency syndrome, and other immunocompromised states [57, 58]. It is most commonly associated with alpha- or beta-hemolytic streptococci (70%), but pneumococci, *E. coli*, *Staphylococcus aureus*, *Proteus*, and *Clostridium welchii* are also isolated [56]. There are reports associated with *Helicobacter heilmannii* in children [59] and in an infant [60]. Endoscopically, the stomach appears edematous with multiple perforations, and the mucosa tends to have a granular green-black exudate. Histologically, an intense neutrophilic collection consistent with pus is seen. The treatment includes surgical resection and drainage of stomach with systemic antibiotics. The mortality rate is still greater than 60% despite aggressive use of antibiotics due to delay in diagnosis and initiation of management (Mittleman and Suarez [57]).

Emphysematous gastritis is a rare but severe form of phlegmonous gastritis, characterized by intramural gas of the stomach due to invasion by gas-forming microorganisms. It is extremely uncommon in stomach compared to other hollow organs [61]. The condition is often lethal, and early recognition and treatment offer the best chance of survival (Huang and Liao 2009).

Reactive Gastropathy

Also described as chemical or reactive or reflux or and type C gastritis. It is one of the most common diagnoses on gastric biopsies in North America [62]. It is a well-described histopathologic entity in adults characterized by foveolar hyperplasia with edema, smooth muscle hyperplasia, and congestion of superficial capillaries in the lamina propria in the absence of significant inflammation [63, 64]. This distinctive histological picture seen in reactive gastropathy is considered to be a nonspecific response to variety of gastric irritants, including bile [65]. The endoscopic features of this entity are vague and may include erythema and ulcerations. Reactive gastropathy is most often associated with either medications (especially NSAIDs) or bile reflux. The prevalence of reactive gastropathy in patients taking NSAIDs is estimated between 35 and 45%. A nationwide database review was performed during a 12 months period in American patients, who had a gastric biopsy with a histologic diagnosis of reactive gastropathy. All patients were stratified by age. The prevalence of reactive gastropathy was 10.5% in children and dyspepsia was the most common indication. Despite its known association with NSAIDs and bile reflux, highlights of the possibility of other factors capable of evolving into reactive gastropathy need to be explored [66]. Pashankar et al. reported the risk factors in their survey of 21 children over a 3-year period were gastroesophageal reflux disease and intake of multiple medications, including nonsteroidal anti-inflammatory drugs [67].

Drug-Induced Gastropathies

There are number of drugs implicated to cause erosions or ulcers or reactive gastropathy of the stomach. Although it is not uncommon, it is generally underreported. They generally cause nonspecific injury pattern, but some of the drugs produce specific injury patterns to be recognized on histology. One of the earliest agents reported is potassium chloride, which causes ulcers and strictures throughout the GI tract [68, 69]

NSAIDs

NSAIDs are one of the most widely available and invaluable drugs for treatment of many disorders

in children and adults. The pathogenesis of NSAID-induced gastroduodenal mucosal injury is complex [72, 73]. The dual-injury hypothesis suggests that both NSAID-mediated direct acidic damage and the suppression of prostaglandin synthesis are necessary to induce gastric damage [72]. The topical irritant effects on stomach and prostaglandin suppression play a role in the pathogenesis of NSAID toxicity [70]. Even a single dose of aspirin may cause petechial hemorrhages in the stomach within a few hours and erosions within 24 h [71]. NSAIDs inhibit COX, especially COX1, which is constitutively expressed in normal GI mucosa decreasing the synthesis of mucosal prostaglandins and thereby interfering with mucosal blood flow. Initially, the acidic properties of NSAIDs induce topical mucosal injury to the gastroduodenum. The active hepatic metabolites of NSAIDs and the NSAID-related decrease in gastric mucosal prostaglandins indirectly contribute to cause gastroduodenal mucosal injury [72, 73]. When the hepatic metabolites in the bile are secreted into the duodenum, they cause mucosal damage to the stomach by duodenogastric reflux and to the small intestine by antegrade passage through the GI tract (Wolfe et al. [73]). Up to 45 % of patients who consume NSAIDs will develop chemical gastritis or reactive gastropathy [74, 75]. NSAID erosions are usually in the gastric body and heal within days, whether or not the NSAID is continued, whereas NSAID ulcers are often large and multiple, more commonly in the gastric antrum than in the duodenum, and painless [76, 77]. In children, hemorrhagic antral gastropathy and ulceration of the incisura are the typical NSAID lesions. Occasionally, more extensive gastric involvement occurs, as does duodenal ulceration. Bleeding from such lesions after ingestion of NSAIDs in children has been well documented [78–81].

Other Common Drugs

Iron: Characteristic brown crystalline material can be found in the lamina propria, in surface exudates, and, less often, in thrombosed vessels; the deposits are highlighted by Perl's Prussian blue stain [82–85]. In most cases, the iron is associated with erosions or ulcers. A pattern of reactive gastropathy or chronic gastritis may be noted in some cases [85, 86].

Many other drugs have been implicated to cause erosions, ulcer, and hemorrhagic gastritis such as colchicine, steroids, valproic acid, alcohol, and chemotherapeutic agents.

Stress Gastritis/Ulceration

Stress-induced gastritis, also referred to as stress-related erosive syndrome, stress ulcer syndrome, and stress-related mucosal disease, can cause mucosal erosions and superficial hemorrhages in patients who are critically ill or in those who are under extreme physiological stress, resulting in minimal-to-severe gastrointestinal blood loss and leading to blood transfusion if not addressed. Patients who may have an increased risk of stress gastritis are those with massive burn injury, head injury associated with raised intracranial pressure, sepsis, and positive blood culture results, severe trauma, and multiple system organ failure. A cohort of 1,006 consecutive admissions enrolled in a pediatric ICU reported that 10.2 % of pediatric participants had UGI bleeding and 1.6 % had clinically significant UGI bleeding [87]. A number of risk factors have been described, but respiratory failure, coagulopathy, and a Pediatric Risk of Mortality Score of $\geq$10 are independently associated with clinically significant upper GI bleeding [87–90]. Based on those findings, authors recommended that prophylaxis to prevent UGI bleeding may be limited to patients who present with at least two risk factors [87]. A guideline on stress ulcer prophylaxis published in 2006 recommended pharmacologic intervention in adults admitted to the ICU who have coagulopathy, require mechanical ventilation for >48 h, have a history of gastrointestinal ulceration or bleeding within 1 year before admission, or have at least two of the following risk factors: sepsis, ICU stay of >1 week, occult bleeding lasting ≥6 days, and use of >250 mg of hydrocortisone or the equivalent [91].

Unfortunately, there is still conflicting evidence concerning prophylaxis for stress ulcers in children with no systematic review on this topic [92].

Corrosive Gastropathy

Accidental corrosive ingestion is one of the common problems in children worldwide [93]. In teenagers and adults, alkali poisoning is more likely to occur as a form of deliberate self-harm and is associated with a higher mortality [94]. Caustic ingestion is seen most often in young children between 1 and 3 years of age [95], with boys accounting for 50–62 % of cases [96, 97]. Early signs and/or symptoms may not correlate with the severity and extent of tissue injury. In a review in which flexible endoscopes were used to evaluate 156 children with caustic ingestion, 17 (11 %) had esophageal and gastric burns, and 14 (9 %) had gastric burns only [98]. Gastric injury often is most severe with acids, such as sulfuric acid, which (because of pooling in the antrum and antral spasm) may cause severe burns in the prepyloric area, potentially leading to pyloric obstruction [99]. Acids generally cause coagulation necrosis, with eschar formation that may limit substance penetration to superficial layer of the esophagus [100]. Alkalis in contrast combined with tissue proteins cause liquefactive necrosis and saponification and are thought to penetrate deeper into tissues [101]. Alkali causes more damage to the esophagus, while acid ingestion tends to result in more severe gastric injury. However, deliberate ingestion of large quantities of alkali may injure the stomach and even the small intestine. Gastric injury is more likely to follow ingestion of a liquid than solid alkali [94].

Bile Gastropathy

Duodenogastric reflux results from retrograde flow of duodenal secretions through the pylorus into the stomach. Duodenogastric reflux (DGR) can be classified to two types, primary DGR or secondary DGR. The pathogenesis of primary DGR is not totally understood; possible hypotheses are disorders of gastric or duodenal motility, incompetent pyloric sphincter, and the gut hormone secretion. Secondary DGR is due to the operative stoma of the stomach, duodenum, and gall bladder [102]. Duodenogastric reflux (bile reflux) can cause gastric mucosal inflammation and/or ulceration [103], intestinal metaplasia in the stomach [104], and increased risk of gastric cancer [105]. DGR could cause hyperemia and erosions of gastric antral mucosa under endoscopy and gastric antral intestinal metaplasia histologically in children [106]. DGR is difficult to diagnose as the clinical symptomatology and endoscopic and histological features are nonspecific. The other different investigative methodologies such as measuring the concentrations of bile acids [107] and sodium in gastric contents [108], pH-metry [109], Doppler ultrasonography [110, 111], and dynamic cholescintigraphy are however helpful but not easily available in children.

Radiation Gastropathy

This is rare but has been associated with massive abdominal irradiation given to patients with malignancy, causing erosions or ulcers particularly in the gastric antrum and prepyloric regions.

121 Long-Term Effects of Achlorhydria on the Stomach (*Helicobacter pylori* and PPI Therapy)

Marta Tavares and Jorge Amil Dias

The stomach has had an increasing importance in the GI tract pathology due to the multiple consequences of acid production that go well beyond the nutritional functions.

Processing ingested food is a major function of the stomach through mechanical physiology using kinetic tridimensional muscular structure and also through secretion of hydrochloric acid with pH between 1.0 and 3.5. Extreme acidity is produced by oxyntic cells located in the stomach fundus and body. These cells actively transport chloride and hydrogen ions into the glandular lumen in a mixture with pH 0.8 allowing persisting maintenance of acidity in gastric lumen with various consequences:

1. Activation of a proenzyme, pepsinogen, secreted by pyloric glands located in the antrum thus transforming it into an active enzyme that catalyses the hydrolysis of protein macromolecules.
2. Optimisation of enteric absorption of vitamins and minerals like vitamin B12 which requires intrinsic factor (IF) to promote absorption. IF is produced in antrum cells when the pH is low. Acidity of the stomach is very important for transformation of ingested iron from ferrous to ferric form and maintenance of chemical stability allowing subsequent intestinal absorption. Active secretion of ascorbic acid from plasma into gastric juice enhances this reaction and iron absorption. Acid pH is also needed to ionise calcium carbonate and transform it into ionised form to be absorbed.
3. In addition to the above-mentioned nutritional benefits, the gastric microenvironment has a relevant role as an antimicrobial defence barrier thus protecting the gastrointestinal tract from various ingested germs. The acid gastric pH is one of the most relevant non-specific defence mechanisms of the body [1]. In vitro studies have shown that pH 3 or below causes a bacterial depletion that lasts for 15 min, and bactericidal properties are kept when pH rises up to 4 [2]. Studies conducted in rats and subsequently confirmed in humans revealed that gastric juice is almost sterile, having a bacterial colony count below 10^5/ml [3]. Additionally to the chemical bactericidal properties, the acid causes closure of the pylorus inhibiting gastric motility, and this allows the gastric alimentary content to be kept for a considerable period of time exposed to these conditions. Therefore it potentiates the bacterial clearance and sterilisation of alimentary contents that passes into the gut where mucosal permeability is much higher.
4. Acid pH inhibits the growth of nitrites and other N-containing compounds generated from protein digestion. N-containing products are transformed into nitrates that are also

secreted by the oral glands. Its conversion into nitrites involves some toxicity and may have a role in gastric epithelium metaplasia. This experimental evidence seems to have clinical confirmation from studies of gastric metaplasia performed in adults [4]. Thus, production of nitrous compounds in neutral pH may have some carcinogenic effect as seen in adults with chronic atrophic gastritis and persistent hypochlorhydria [5].

Maintenance of pH below 4.0 is due to the secretion of gastrin by the parietal cells. This is an important secretagogue produced by G cells, part of the pyloric glands located in the antrum. Emotional factors, initiation of the cephalic phase of digestion or any other vagal stimulus, as well as the presence of proteins in the gastric lumen, initiate the secretion of gastrin. Due to this mechanism, whenever there is a decrease in the production of acid, be it disease or ingestion of inhibitors of the parietal cells, there is a compensatory hypergastrinaemia. The production of gastrin is the strongest stimulus for the secretion of hydrochloric acid. Fortunately it is accompanied by the secretion of mucus that is essential to keep homoeostasis in the mucosal barrier.

Disturbance or variation of the gastric acidity can be divided into hyperproduction of acid causing a reduction of the pH, termed hyperchlorhydria, or reduction of the secretion, causing hypo- or achlorhydria. This is defined as a persistent pH above 6.5 after maximum stimulation with pentagastrin, synthetic analogue of the gastrin hormone. In paediatrics hyperchlorhydria may present as gastro-oesophageal reflux and oesophagitis, duodenal ulceration or gastritis, representing disruption of the mucosal barrier. In hypochlorhydria pH is usually between 4.0 and 6.5 and may be due to several causes as discussed below.

Causes of Hypochlorhydria in Children

Helicobacter pylori

Hypochlorhydria had much attention in the 1980s due to the identification of a cause for a well-known disease, epidemic hypochlorhydria affecting the adult population [6]. The hypothesis of a gram-negative bacillus similar to *Campylobacter* can be the causing agent for this condition and lasting for several months gained consistency after identification of *Helicobacter pylori* (Hp) [7]. The identification of this agent led to the award of the Nobel Prize in 1982. *Helicobacter pylori* became one of the most important digestive pathogens due to its ubiquitous nature and the large spectrum of effects that it may cause. It is an infective agent transmitted by enteral route, acquired early in infancy with compensatory hypergastrinaemia and has a worldwide distribution, especially in areas with low sanitary conditions. In paediatrics this is the most common cause for hypochlorhydria, being apparently as prevalent as malnutrition in some areas of the world. Infection is usually acquired in childhood and persists throughout life if not eradicated. Actual numbers of prevalence vary in different series and countries, being estimated as 20 % in population below 20 years in developed countries but also reported to occur in up to 85 % in children of 9 years of age [8]. In developing countries prevalence is also very high. Following infection with Hp and ensuing gastritis, there is a state of hypochlorhydria that may last for 8 months or more, and then pH subsequently becomes normal to previous acidity level. In adults chronic infection transforms the acute gastritis into chronic atrophic gastritis of the gastric body and antrum leading to irreversible hypochlorhydria and its consequences. The impact of gastric infection by Hp is mediated by inflammatory responses that are host dependent. Interleukin 1β (IL-1β) and TNF-α are potent inhibitors of acid secretion, and its variation leads to interindividual differences. Hypochlorhydria associated to Hp infection is dependent on the IL-1β polymorphisms in the population, with higher inhibition of secretion in carriers of genotypes IL-1B-511 C/T and T/T (strong producers of IL-1β) opposite to carriers of genotype IL-1B-511 C/C (weak producer of IL-1β) [9]. Variation of infecting Hp strains (like *cag*-positive strains that are more aggressive) is also associated with different degrees of hypochlorhydria in the host [10].

Other Infections

As mentioned above, hypochlorhydria favours proliferation of pathogens in the gastrointestinal tract. However, some infections, particularly in the mucosa of the gut, reduce acid secretion and may lead to hypo- or achlorhydria. Experimental studies in awake dogs have shown that stimulation with lipopolysaccharides from *Pseudomonas aeruginosa* causes reduction of acid secretion [3]. Infection with *Taenia taeniaeformis* in rats led to reduction of parietal cell mass, and it was postulated that this direct action on the gastric mucosa might facilitate the passage of the organism into the small intestine to adhere and proliferate. The hypothesis that a parasitic infection may cause transient hypochlorhydria in humans was confirmed with exposure to *Diphyllobothrium latum* and *Trypanosoma cruzi* by mechanisms yet unknown. In humans and experimental animal models in dogs, the transient inhibition of gastric secretion was observed after raising the body temperature to 39 °C by exposure to heated environment. In some infections there seems to be a reduction of acid secretion that returns to normal after the acute event.

Use of Inhibitors of Acid Secretion

Some diseases like duodenal ulcer or reflux oesophagitis are caused by the aggression of gastric acid on the mucosa and often require the use of medication to control it. The knowledge of pharmacological blockage of the acid was very well documented in adults with Zollinger-Ellison syndrome that evolves with hypergastrinaemia and hypochlorhydria induced by proton-pump inhibitors (PPIs). This type of induced hypochlorhydria has differences from the one occurring in patients with atrophic gastritis. Under the effect of PPIs, gastric pH undergoes some circadian variations, keeping values below 3.0 at certain times of the day (nadir) as opposed to atrophic gastritis where achlorhydria is permanent. In paediatric practice reduction of acid secretion is frequently induced by the use of H_2 blockers, as ranitidine, or PPIs like omeprazole or lansoprazole. Apart from situations of established acid-induced disease, these drugs are also commonly used in stress situations like extensive burns, complex surgery or intensive care units to prevent ulceration due to increased acid or reduced resistance of the mucosa. In infants, one of the main indications for inducing gastric hypochlorhydria is gastro-oesophageal reflux disease (GERD), although the real benefit of this measure was recently questioned [11].

Autoimmune Gastritis

Autoimmune disease in paediatrics, particularly thyroid disease, Graves' disease or lymphocytic thyroiditis, has been addressed by many studies evaluating the presence of antibodies against parietal cells. Recent papers mention a prevalence of these antibodies in 14–21 % in autoimmune disease [12, 13]. However, autoimmune atrophic gastritis in children is mostly associated with production of autoantibodies secondary to autoimmune disturbance, particularly thyroid disease, diabetes mellitus or coeliac disease. Segni et al. demonstrated that autoimmune gastritis is an early event in children with autoimmune thyroid disease: having evaluated endoscopy in patients with hypergastrinaemia and anti-parietal cell antibodies, it was shown that gastric atrophy was present in 50 % of the subjects [14]. Greenwood et al. reported two cases of autoimmune lymphocytic gastritis as part of polyglandular autoimmune disease with mucosal atrophy, loss of parietal cells, anti-parietal cell antibodies and achlorhydria [15]. In children with autoimmune disease, the presence of anti-parietal cell antibodies and hypergastrinaemia may be early indicators of gastric atrophy and, presumably, hypochlorhydria.

Congenital Genetic Diseases

Mucolipidosis type IV (ML-IV) is a recessive autosomal disease due to the mutation of gene MCOLN1 and one of the congenital causes for constitutional gastric acid deficiency. It is a storage disease where the cellular secretory vesicles fail regeneration pathway ending up included in the lysosome, as lamellar deposits in electronic microscopy. There is progressive/degenerative neurologic disease with amaurosis and loss of

motor competences due to involvement of the white matter, optic nerve and epithelium of the cornea. Various other tissues like the kidney epithelium and pancreatic and hepatobiliary acinar tubes are also affected with typical vacuolisation [16, 17]. In the parietal cell, there may be an inactive ATPase coenzyme protein leading to scarce secretory granules and reduction in the production of hydrochloric acid. Changes observed in the parietal cell resemble those seen in animals treated with omeprazole [18]. In a recent series, 28 patients with ML-IV aged 2–25 years, all had achlorhydria and hypergastrinaemia [19]. In older patients, it was possible to identify atrophic gastritis as well as hyperplasia of enterochromaffin cells (ECC), consistent with long-standing evolution and constitutional nature of the condition.

Gastrectomy in Infancy

Although this is a very rare situation, partial or total surgical resection of the stomach as in gastric primary tumours prevents production of gastric acid and the above-mentioned acidic microenvironment and its benefits.

Watery Diarrhoea, Hypokalaemia and Achlorhydria Syndrome

This syndrome was first described in the 1950s and is characterised by watery diarrhoea, hypokalaemia and achlorhydria (WDHA). We now know that approximately 76 % of cases have hypochlorhydria rather than achlorhydria, and it has been proposed that the condition be renamed as WDHH. In children this syndrome was described in 64 patients occurring between 2 months and 9 years. There is an M:F ratio of 1:1.5 and is generally associated with neurogenic tumours, ganglioneuroma and ganglioneuroblastoma being more frequent, particularly abdominal thoracic or cervical [20–22]. The syndrome is derived from increased secretion of VIP (vasoactive intestinal polypeptide) and sometimes neurotensin (present in the brain and gastrointestinal tract) and other pancreatic polypeptides. However, there are reports of paediatric cases of WDHA without neoplasia as opposed to adults that always have a primary tumour producing VIP [23]. This polypeptide promotes relaxation of the lower oesophageal sphincter, gastric body and antrum and reduction of the production of gastrin and gastric juice with subsequent hypochlorhydria. Exogenous infusion of VIP and synthetic analogues replicates this effect in experimental models. Reversion of the effect has been clinically demonstrated in children after infusion of somatostatin [23]. Any pancreatic primary or secondary neuroendocrine tumour may virtually cause WDHA syndrome that causes intractable diarrhoea in children, dehydration and failure to thrive. Treatment of choice is surgical resection of the primary tumour if present or somatostatin.

Transient Hypergastrinaemia

Achlorhydria resulting from secondary hypergastrinaemia and transient hyperplasia of G cells was described in a child of 23 months of age with fundic gastritis, watery diarrhoea and failure to thrive. Despite normal tests of secretory function in response to pentagastrin, no cause was identified, and it resolved spontaneously 2 years later without further treatment [24].

Consequences of Hypochlorhydria

What may we expect from hypochlorhydria? Which are the main paediatric groups affected by reduction of acid secretion?

Assuming that infection with Hp is very prevalent, is acquired early in life and will continue if not treated, we may certainly classify this as the largest group in terms of achlorhydria in childhood that may evolve into adulthood. Next in terms of frequency are the patients with GERD being treated with PPIs followed by the children and adults with autoimmune disease that may have associated gastritis. There are many publications associating Hp and nutritional, metabolic, immunological consequences following the hypochlorhydric status induced by the infection.

Gastrin regulation of secretion by the parietal cells and its effect in enterochromaffin is regulated by a negative feedback system. Inhibition of secretion leads to a rise in secretin in plasma with

proliferation of enterochromaffin cells, as shown in rats. In humans, proliferation of ECC with production of gastric carcinoids follows a period of sustained hypergastrinaemia (>500 pg/ml) as in atrophic chronic or autoimmune gastritis, but it is unlikely that this process may evolve entirely during childhood [25–28].

As previously mentioned, persistent hypochlorhydria favours the proliferation of bacteria producing nitrous compounds that convert into nitrites and facilitate carcinogenesis of the gastric epithelium. At the same time at neutral pH, ascorbic acid loses stability leading to low intra-gastric levels of vitamin C. This prevents nitrites (derived from ingested nitrates) from transforming into nitric oxide and causes a higher exposure to metaplastic nitric compounds [25, 29]. More than half of patients with common variable immunodeficiency (CVID) have hypochlorhydria and atrophic gastritis, and there have been rare cases of gastric carcinoma in children with this immune disorder [30, 31]. Studies have shown that the concentration of nitrites in the gastric juice of patients with CVID is much higher than those with isolated chronic gastritis [32]. Carcinoma may occur in 5–10 % of these patients which is a prevalence 50 times above the general population, providing support to the mentioned pathophysiology, similar to adults with atrophic gastritis where increased cell turnover favours epithelial metaplasia.

Nutritional Consequences

Malabsorption of vitamin B12 is clearly associated with chronic gastritis and hypochlorhydria. In infancy malnutrition and infection with Hp have parallel incidences, with reciprocal effect [33]. Various paediatric cohorts have shown that Hp infection causes hypochlorhydria of variable magnitude [34–39]. It is also well known that malnutrition favours hypochlorhydria, and this decreases nutrient absorption. In a series throughout the world, a convergence between Hp infection and short stature has been observed, as well as iron-deficiency anaemia and bone mineralisation defects [8, 39–42]. Iron-deficiency anaemia seems to correlate directly with Hp infection in areas where oral intake of iron seems adequate in the absence of prevalent intestinal parasitic infections (this factor induces important bias studies in developing countries) [39]. Hp infection causes hypochlorhydria and decreases iron absorption as mentioned above, leading to iron deficiency. In three cases correction of iron deficiency was only achieved after eradication of Hp [43]. The absorption of folic acid is also compromised due to a rise in pH partly because vitamin C is less stable [44].

Vitamin A is formed from its precursor β-carotene in ingested food. Bioavailability depends on several factors, namely, ingestion of fresh foods. Tang et al. have sown that hypochlorhydria and achlorhydria affect and reduce its bioavailability [45].

Hypocalcaemia and Hp infection were identified in clinical studies in adults. The rate of hip fracture and osteoporosis correlated with the prolonged use of PPIs, and this seems to provide additional evidence relating to reduced calcium absorption and decreased acid secretion [46, 47].

Infectious Consequences

Hypochlorhydria reduces the potent natural antibacterial filter and may favour bacterial proliferation not only within the stomach but throughout the gastrointestinal tract [48, 49]. In vitro studies using chemical simulation of gastric juice have demonstrated that gastric juice has a bactericidal effect over *E. coli* O157:H7, which is a rather frequent agent in paediatric practice [50]. Elevation of gastric pH may be an important facilitator of infection in humans through agents like *Vibrio cholerae*, *Campylobacter jejuni*, *Giardia lamblia*, *Serratia* and several strains of *Salmonella* [1, 2, 39, 51, 52]. In a study among children from Peru, the presence of cholera was significantly associated with infection with Hp in children below 10 years of age in Peru, and the presence of Hp was the sole independent factor even correcting for low social and sanitary conditions [53]. In the same series, the use of antacids was not associated with cholera, and this may correspond to better health care and access to potable water.

In a hospital setting, there was an increased risk of diarrhoea by *Clostridium difficile* among

inpatients after intake of PPIs, and other recent series report a higher incidence of pneumonia in this subgroup of patients [54–56]. For a long time, there has been a perception that immunocompromised patients being treated with inhibitors of acid secretion are more prone to infection, especially in adults. The increased risk of nosocomial infections among patients in intensive care units taking PPIs was recently taken into ambulatory setting: it was also observed that patients without co-morbidities taking antisecretory drugs also had an increased risk for pneumonia. However, paediatric studies on this issue are very rare. The use of omeprazole in preterm newborns has been associated with an increased risk of necrotizing enterocolitis and potential systemic infections [57]. Naturally these complex patients have a number of other factors in intensive neonatal units that need separate assessment besides hypochlorhydria and changes in the intestinal microbiota.

An interesting study was performed by Canani et al. in a paediatric population on chronic treatment with PPIs for GERD [58]. A significant increase in the incidence of pneumonia and gastroenteritis in the treatment group was observed, and hypochlorhydria was the independent risk factor; however, this was a small study group. Additional paediatric studies are needed because empirical anti-secretory treatment is widely prescribed for long periods in small infants hoping to abolish signs and symptoms presumably associated with GERD. However, there is some evidence that the symptoms usually associated with GERD not only persist but also seem to have little relation with PPI intake and reduction of acid secretion, raising the hypothesis that non-acid reflux may contribute to the clinical picture that prompts for therapy [11]. Strict selection of high-risk patients for treatment with PPIs may minimise the above-mentioned complications.

Immunological Consequences

Protein digestion started in the stomach has benefits beyond nutrition. Hydrolysis of proteins may have immune consequences that were unknown until recently. Identification of adults with chronic gastritis developing de novo immunogenicity to alimentary antigens that were previously tolerated prompted for research in this area. Reduction of proteolysis adds an allergenic potential to ingested proteins. Mechanisms of alimentary intolerance, especially IgE mediated, are mainly related to the size of macromolecules presented to the intestinal mucosa, although we know that some intact proteins may be found in the small intestine and even in the bloodstream [59]. It is possible to simulate gastric juice in vitro in a way to promote proteolysis of food fragments that would otherwise be allergenic [60]. If pH rises in this controlled setting, this hydrolytic capacity is compromised, thereby increasing sensitising risk. The same experiment was simulated in experimental animal models after injection of omeprazole [61]. Untersmayr et al. have demonstrated that the lack of proteolytic potential increases in patients under treatment to inhibit gastric secretion along with increased de novo production of IgE [62]. Perception that gastric hypoacidity may be the first obstacle to modulation of food tolerance has a prominent role in paediatrics as the incidence of alimentary allergy is twice that found in adults given the increase in tolerance with age. In this context prevention of situations that evolve with hypochlorhydria *may* play an important role in prevention of food allergy.

Conclusion

Hypochlorhydria in infancy and childhood seems to be a far more common phenomenon than usually recognised. If we associate infection with Hp to transient achlorhydria and chronic gastritis, we may realise that a substantial number of older children, adolescents and adults may have a considerable reduction of acid secretion. In small infants there is a subgroup with feeding or swallowing difficulties to which PPIs are often prescribed empirically, assuming that there is GERD. Prescription of PPIs in children became as common as antipyretics in some communities.

Consequences of reducing acid secretion may be deleterious or even outgrow potential benefits. Among those there is reduced absorption of iron, calcium and vitamins as well as exposure to ingested bacteria increasing the

risk of infection (not only gastrointestinal). The role of allergenic sensitisation, although paediatric studies are lacking, may also be considered. Finally, there may be a small increase in the risk of malignancy that may evolve slowly from child to adulthood although very rare in children.

Medically induced hypochlorhydria especially for prolonged periods should only be undertaken after clear analysis of benefits versus potential risks. Further paediatric studies may shed additional light into this discussion.

Gastric Bleeding and Perforation 122

Jürgen Schleef

Introduction

Gastric bleeding and perforation are rare events in children. Upper GI pathology represents only about 20 % of all episodes of intestinal bleeding or perforation [1]. The clinical appearance is often more severe and acute than in the lower GI tract. Both bleeding and perforation of the stomach might occur in all age groups ranging from preterm patients to adolescents. Aetiology and cause of bleeding and perforation differ significantly from age to age. Causes can be iatrogenic (tube, probe, medical therapy), malformative (vascular malformation, stenosis, atresia) and acquired (tumorous, secondary to infections and hepatic disease). In all cases, a precise history, a clinical workup and a diagnostic approach should be performed. In acute cases, intensive care therapy and support should be the first step to ensure vital parameters and stable conditions for further investigations and therapeutic measures. Diagnostics should in all cases include a laboratory workup, radiological investigations and, if possible, endoscopy. A surgical exploration for diagnostic purposes can be necessary in rare situations. If general conditions are stable, a diagnostic laparoscopic approach might be the first choice.

Gastric Bleeding

Gastric bleeding forms an important part of upper GI bleeding. Usually this represents an emergency and needs in all cases immediate further investigation. Clinical gastric bleeding is usually a blood loss from the upper GI tract (haematemesis). The source of the bleeding can be elsewhere in the oropharynx, oesophagus, stomach or duodenum. It can be continuous, intermittent, acute or chronic. Therefore it is difficult to divide a clinical upper GI bleeding into locations, but it can be classified according to age groups as described by others [2, 3] (Table 122.1).

How to Approach a Paediatric Patient with Upper GI (Gastric Bleeding)?

As mentioned briefly, upper GI or gastric bleeding is not frequent in children. Nevertheless, it is always considered a severe condition, even if it is not serious at all in some situations (swallowed maternal blood).

Therefore, a precise history is extremely important in order to get information about the location of the bleeding. The patient's age is the most important fact, since especially in early life (the first days) of a healthy child, vomiting of ingested blood is the most frequent condition, which does not affect the patient at all, if there is no risk of aspiration of maternal blood [4]. A thorough exam of the oropharynx is important to

DOI 10.1007/978-3-642-11202-7_122

Table 122.1 Causes of gastric bleeding according to the age of the patient

Neonates	<2 years	>2 years
Swallowed maternal blood	Oesophagitis/gastritis	Oesophageal/gastric varices in portal hypertension (hepatic disease, post-op, biliary disease, portal thrombosis)
Haemorrhagic disorders of the newborn	Gastric ulcer	Gastric ulcers
Vitamin K deficiency	NSAID/drug-induced ulcer disease	Vascular malformations
Acute gastritis (stress, post-op, NICU patients)	Foreign body ingestion (e.g. batteries)	Bleeding induced by vomiting (Mallory–Weiss, Dieulafoy)
Gastroduodenal malformations (web, stenosis)	Vascular malformations	Bleeding from tumorous lesions
Maternal drugs	Swallowed blood from the naso-/oropharynx	Bleeding from gastrostomy sites
	Bleeding from gastrostomy sites	

exclude a bleeding with subsequent swallowing of blood mimicking a gastric bleeding. Sometimes small mucosal tears after repeated tube insertions can become a source of bleeding. The general conditions (other underlying problems like organ dysfunction and bleeding disorders) might not be already well studied and known. Red blood vomiting can be related to a stress situation with stress ulcers. Stress (NICU patients or patients being operated as a newborn) should always be considered as a risk factor. The general condition of the child at the time of bleeding is important since fever might indicate an infectious condition of an underlying disease. The history of the mother should always be known, since some kind of maternal medication (NSAID) or drug abuse can cause bleeding in the newborn. In newborns a history of continuous vomiting since birth might be a hint to a malformative condition at the level of the stomach outlet (web, pyloric stenosis) that can be the cause of bleeding [5].

In the elder group of children up to 2 years, the history should focus more on general medical conditions. Especially liver dysfunction (history of jaundice, previous surgery of biliary disease) can be an underlying condition for gastric bleeding from varices. The most frequent cause in this age group is oesophagitis and gastritis. Oesophagitis is probably the most common cause of upper GI bleeding and cannot be distinguished clinically from a gastric bleeding. The history of these children is often typical (regurgitation, dysphagia and failure to thrive). Many of these patients are syndromic or handicapped children. Drug therapy (NSAID, cortisone) can be another cause of bleeding. In some cases a history of foreign body ingestions should be evaluated, since swallowed batteries and cleaning tabs might cause local necrosis and severe damage to the mucosa. In some instances this can also lead to organ perforation and vascular damage.

In the elder groups of children and adolescents, causes are very similar. In this group general underlying conditions and diseases are usually well known, but the general conditions due to chronic organ failure are often not good and can be critical. For adolescents another typical and frequent condition can be due to recurrent vomiting, a Mallory–Weiss or Dieulafoy lesion of the stomach mucosa. Sometimes this can be due to acute alcohol intoxication or incidental drug abuse. In rare instances a gastric tumour in adolescents can be the cause of a gastric bleeding. This could be a lymphoma or a, in rare situations, a primary gastric cancer.

Physical Exam

The initial and quick physical exam of the patient is very important. In all patients with bleeding, you should look for signs of shock (skin colour, heart rate, blood pressure and capillary refill, grade of consciousness). The examination of the heart, nose and throat should be concentrated on erosions from caustics, oropharyngeal mucosal

erosions or lesions, fresh blood and clotted blood in the nose and throat. The thorax and abdomen should be inspected for scars or abnormal superficial vessels/caput medusa, which indicate previous surgery and portal vein occlusion (oesophageal atresia and reflux disease, biliary atresia and secondary liver disease). The palpation of the abdomen might indicate an enlarged liver or spleen as a clinical sign of hepatic disease or portal hypertension. Hyperperistalsis might be present in upper GI bleeding. If the abdomen is tender with a peritoneal irritation, a perforation might be considered. The evaluation of consistence and colour of the stool can be important. A serious gastric bleeding might lead to the loss of red and fresh blood through the anus, while black stool might be a sign of a more chronic upper GI bleeding [5].

Instrumental Examination

As mentioned before, the most common cause of upper GI bleeding in neonates is due to the ingestion of maternal blood. To avoid expensive and unnecessary exams, a simple Apt test can be performed to differentiate between maternal and foetal blood. By mixing the blood, aspirated from the gastric tube, with 1 % of sodium hydroxide, maternal blood will result in a brown-yellowish colour, while foetal blood (haemoglobin) will give a bright red colour. If this test confirms maternal blood in the stomach of the newborn, no further investigation is necessary.

The diagnostic in all other cases with upper GI/gastric bleeding is usually based on radiological exams and endoscopy. The first exam is a plain x-ray of the thorax and abdomen to rule out free abdominal air or pneumomediastinum. The next step is an ultrasound exam of the abdomen. Hepatic disease is often expressed with liver enlargement and portal hypertension as well as splenomegaly. A Doppler exam of the portal and hepatic vessels can be helpful to verify the presence of enlarged portal vessels, splenomegaly and pathological blood flow and direction. Abdominal masses, like lymphomas or tumours, can be recognized.

The most important diagnostic tool is usually an upper GI endoscopy. Under direct vision the mucosa of the oesophagus and stomach can be controlled, and eventual bleeding sources can be visualized. This exam can be difficult in patients with severe massive bleeding due to the lack of vision. Intensive cleaning of the gastric cavity with large amounts of cold water can usually resolve this problem. Endoscopy is not only diagnostic but can be combined with therapeutic manoeuvres under direct vision like sclerotherapy, clipping or coagulation of bleeding vessels or ligation of varices. In rare situations, where the source of bleeding cannot be clearly defined, further investigations might be necessary. These can be an angio-CT scan and sometimes also an angiography to verify vascular malformations. In very small children (preterm and newborns), these techniques might not be applicable since these children are very often too unstable for being transported. In these cases a symptomatic/medical therapy and some kind of bedside exam (plain x-ray, ultrasound and endoscopy) are the bases for the diagnosis.

Therapy

The treatment of gastric bleeding in all cases and age groups is based on a symptomatic and supportive approach and a specific treatment of the bleeding itself. The first approach consists of IV fluid infusion and stabilization of the circulation and vital parameters. Once the blood loss can be estimated, a blood transfusion and substitution of clotting and coagulation factor should be undertaken [6]. In stable condition further diagnostic should be performed. As mentioned above the most important exam is an endoscopy. If bleeding from the stomach is verified, different options could be selected.

In newborns, being on NICU care, the most frequent cause would be stress gastritis. In these cases, once the diagnosis is made by endoscopy, a treatment with omeprazole should start (2 mg/kg IV/day). This can be combined with ranitidine (1 mg/kg IV 4/day). If the child is too small or too unstable for endoscopic diagnostics, the

treatment should be started in any case. To treat a possible vitamin K deficiency, 1 mg of vitamin K IV should be administered. If the bleeding does not stop within 2 h, fresh frozen plasma has to be given. About 0.25–0.5 % of newborns present this deficiency causing bleeding in the first days of life. Once the bleeding is stopped, further investigation should be performed to rule out rare causes and malformations.

In the group of children in the first year of life, the most frequent causes of bleeding are reflux disease and oesophagitis. After endoscopy the treatment should be medicated with omeprazole and ranitidine. After the acute phase, children should receive a prophylactic therapy and further investigation. If a gastritis is present and resistant to the initial therapy, a *Helicobacter* infection should be ruled out [7]. Sometimes in this age group, also off-label therapies with NSAIDs can cause a bleeding. Finally, very rarely also Crohn's disease can be observed in the first year of life. Therefore biopsies should always be part of the initial endoscopic diagnostic.

In all other children, the most frequent cause is again diffuse peptic ulcer disease, very often correlated to *Helicobacter* infections. If the endoscopy confirms a single bleeding source (mucosal vessel), an endoscopic sclerotherapy or clipping or coagulation is the treatment of choice. If varices are identified, they should be ligated or clipped in the acute situation. A control endoscopy is always necessary to review the result of the initial treatment and to proceed with a prophylactic treatment. Naturally the further diagnostic should include an evaluation of the hepatic function and a possible associated portal hypertension. In these cases octreotide can be used. The dose suggested in the literature is 1 mcg/kg IV as an initial bolus followed by a continuous IV application (1 mcg/kg IV/h). The treatment has to continue 24 h after the bleeding has stopped and will then be reduced stepwise. This therapy is also an off-label therapy in children. Another therapeutic approach is by the application (off label) of vasopressin. The starting dose in the literature for children is 0.002–0.005 U/kg IV/min. The total doses should not be higher than 0.01 U/kg IV/min. The therapy continues 12 h after the bleeding has stopped and is consequently reduced within 48 h to zero. Recently in the literature, a therapy with a high-dose application of propranolol lowering the portal pressure is described as a chronic treatment strategy in these children. The doses are similar to the treatment in adult patients but should be adjusted under controlled hospital conditions individually [8].

A small group of patients will present with vascular malformations, causing bleeding from the stomach wall. In this case a precise diagnostic should be performed and, if possible, a sclerotherapy is the best therapeutic choice. Only in very rare situations, a surgical resection or ligation of vessels might be necessary [9].

In children presenting with gastric tumorous disease, the treatment of the bleeding should be symptomatic, followed by a specific oncologic therapy. There are rare cases where a surgical resection remains the only choice to resolve the bleeding.

Some children present following the ingestion of dishwasher agents or other cleaning products. Usually these cases do not show a severe bleeding and should be treated according to well-established protocols. Ingested foreign bodies, which might cause mucosal necrosis and subsequent bleeding and perforation (batteries), should be removed as soon as possible [10].

Conclusion

Gastric bleeding in children is rare. The approach is well standardized and orientated according to the age, the general condition of the child and other underlying disease. In the literature the incidents are not clear, but it should be a rare event. Mortality rates are not known, but in some cases children might die during the acute phase. Nevertheless, mostly the general condition and the presence of systemic (coagulopathies) or organic (portal hypertension and liver failure, malignant disease) diseases are conditioning the prognosis of the patient. Many conditions, leading to an acute event, can be prevented by prophylactic medical treatment (omeprazole and ranitidine) and control of portal hypertension and varicose

disease (Rex shunt, sclerotherapy or banding of varices, systemic propranolol treatment).

Gastric Perforation

A perforation of the stomach is a rare event in children and represents usually an acute and dramatic situation for the patient. Most of these cases do present with a "free perforation" into the abdominal cavity (pneumoperitoneum) and acute enlargement of the abdomen. The frequency of this event is not well known. It can appear in any age group, and the aetiology can be spontaneous or associated to inflammatory, tumorous and malformative conditions. Perforation can be further a complication of diagnostic (endoscopy with biopsies) or therapeutic procedures (dilatation, laser coagulation) or placement of NG tubes. Special entities are patients with complications and perforation associated with gastrostomies.

Diagnostics

As mentioned before gastric perforation is usually associated with an acute event and dilatation of the abdomen. The patient often presents with a shock situation and respiratory failure, especially in newborns. In a small group of patients with non-acute symptoms, the diagnosis of gastric perforation can be difficult. Generally in all patients after gastric surgery and tube placements with consecutive signs of an "acute abdomen", a gastric perforation should be suspected. The most important and usual first exam in these patients is an abdominal x-ray. Usually a pneumoperitoneum can be detected. If the location of the perforation seems to be unclear, a contrast study via an NG tube or a gastrostomy tube can be performed. A CT scan might be helpful to understand the anatomical relationship between the stomach wall and other organ structures. In unclear cases an endoscopy can be performed to understand the cause of a suspected perforation or lesion. This can be in some instances a tumour or inflammation.

Neonatal Gastric Perforation

In newborns a gastric perforation presents with increasing tenderness of the abdomen, which becomes increasingly irritated, associated by emesis and bilious gastric juice. It is important to detect this event as early as possible to avoid a septic shock and peritonitis in these small children followed by anuria and respiratory failure. The abdominal distension is worsening and compromising the respiratory situation. The most important exam is a plain x-ray of the abdomen [11].

In case of a pneumoperitoneum, a nasogastric tube should be placed, and the child should be prepared (resuscitation) for surgery as soon as possible. In some cases this should be performed in a NICU setting to avoid unnecessary transportation of the unstable and fragile patient. An upper abdominal laparotomy is performed and the gastric perforation identified. A limited debridement of the area of the perforation should be performed. The tissue borders should be viable and well perfused. The defect should be closed by a double-layer suture avoiding a stenosis or extensive resection of the stomach tissue. In all cases a complete inspection of the stomach is necessary to avoid the overseeing of a second perforation. This might occur in case of an anterior disruption due to a tube or probe placement, where the tear can also involve the posterior wall. Some authors use the omentum to cover the suture site. We do not perform a post-op drainage of the abdominal cavity in this case but only a lavage of the abdomen. An intra-gastric tube is left in place for decompression of the stomach. The post-op treatment consists of a broadband antibiotic therapy and intensive care support. Post-op mask ventilation with positive pressure should be strictly avoided. The factors, contributing to the prognosis of these children, are the grade of prematurity and associated problems, the length of the interval between the perforation and the detection, the extension of a possible peritonitis and the grade of respiratory complications. In this group of children, the mortality rate is around 50 % according to the literature.

The aetiology of this pathology is not clear in most cases [12]. Three aspects are usually

described and proposed: trauma, ischaemia and spontaneous perforation. The vast majority of these instances are due to iatrogenic trauma by tube placement. Another cause is an overdistension during positive-pressure ventilation especially by mask ventilation. Spontaneous perforations of the stomach have been observed within the first week of life. In these cases no specific clinical event or trauma can be identified besides prematurity and perinatal stress. Of all cases spontaneous perforation occurs in about 20%. Some authors describe a congenital defect with the absence of a part of the gastric muscle layers predisposing as a reason for perforation. A further possible cause is a distal obstruction in some cases (duodenal stenosis, duodenal web, jejunal stenosis). A recent retrospective study from Japan reports an incidence of 8.8% of 16,556 NICU which underwent surgery, but only 0.76% account for gastric perforation. The authors report in their survey a mortality rate of 36% over a 20-year period [12].

Factors affecting a negative outcome are in all major studies the delayed diagnosis, prematurity, acidosis and respiratory failure and peritonitis at the time of surgery. Some single reports do exist emphasizing a successful non-surgical treatment (drainage) of gastric perforation. No bigger series exist and experiences are too small and limited to give any further recommendation. This technique might be like in other intestinal perforations in newborns an alternative approach in the unstable and non-operable patient.

A particular situation can be seen in NICU patients with intratracheal high-pressure ventilation. An alveolar rupture might cause a pneumomediastinum and subsequent pneumoperitoneum mimicking a gastrointestinal perforation. This situation is usually unclear and might need an exploratory laparotomy (Fig. 122.1).

A rare cause for perforation might be a volvulus of the stomach, causing ischaemia and perforation (Fig. 122.2).

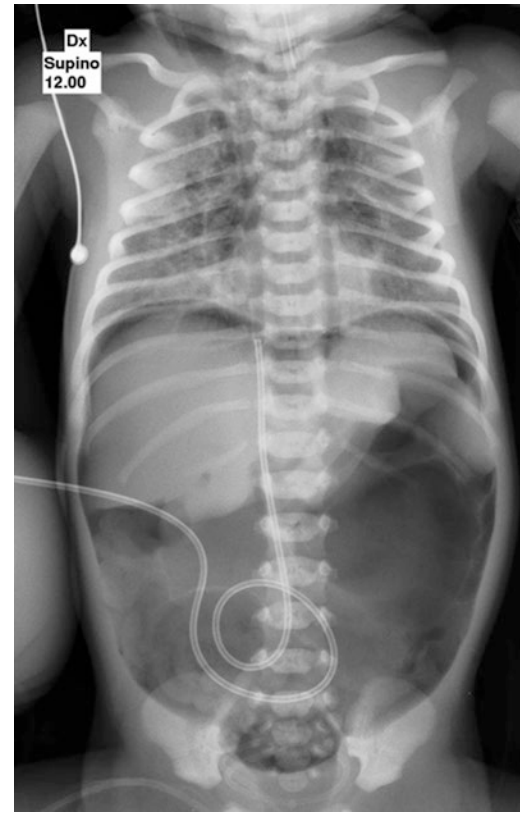

Fig. 122.1 X-ray study: preterm baby with pneumoperitoneum after high-pressure ventilation. The laparotomy excluded a perforation of the viscera

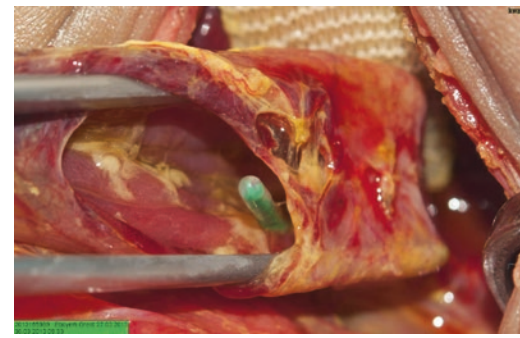

Fig. 122.2 Major perforation of the stomach at the larger curvature due to perinatal gastric volvulus (Case from Prof. Till, Graz, Austria)

Gastric Perforation in Elder Children

In elder children gastric perforation is a very rare event. It is mostly traumatic, iatrogenic and in rare cases due to an ulcer disease of the stomach. A bigger group of children with perforation of the stomach are belonging to children having complications of gastrostomy tube insertion or changing of gastrostomy buttons. It seems to be that gastric perforations due to trauma occur more frequently after meals and gastric dilatation. Usually this

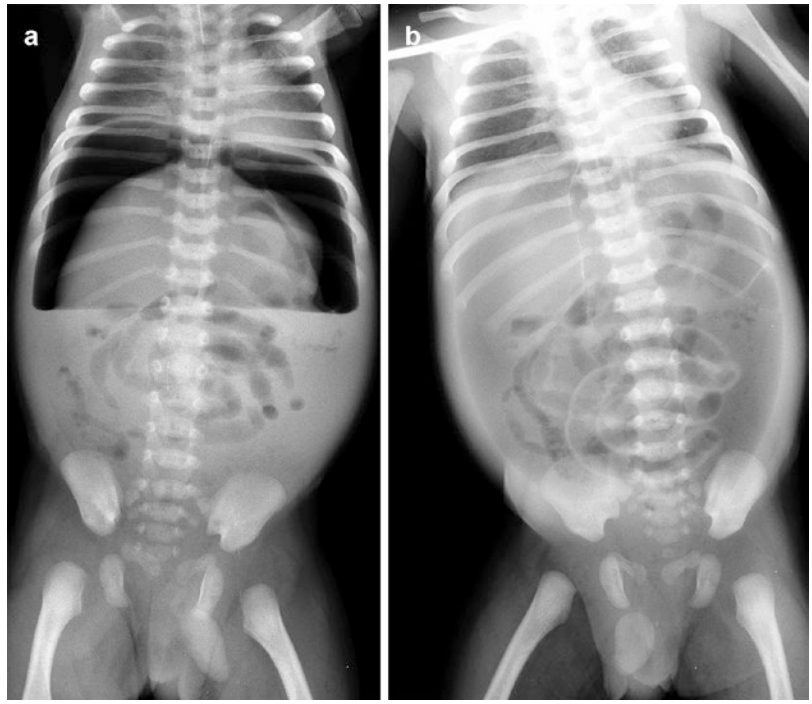

Fig. 122.3 "Battered child" (4-month-old boy) with gastric perforation (x-ray with massive pneumoperitoneum; (**a**) erect x-ray and (**b**) supine)

finding is associated with a blunt abdominal trauma and represents only 0.9–1.8 % of all abdominal traumas. The trauma can be due to an accident but also to a "battered child" syndrome. In all cases the clinical signs are the acute distension of the abdomen, pneumoperitoneum on abdominal x-rays and respiratory distress (Fig. 122.3). All these patients need a surgical exploration of the abdominal cavity, and further investigations are usually a loss of time. The therapeutic measures before surgery (resuscitation, broadband antibiotic therapy) were already mentioned before. In case of a suspicious trauma, caused by an accident or a second person, a thorough photographic documentation should be performed for further legal considerations. The site of rupture or perforation can be elsewhere but is more often described at the anterior part of the stomach wall. Therapy should include the excision of wound edges, lavage of the cavity and closure of the stomach, which need for some days an intraluminal decompression and drainage. The mortality rate in this group is lower than in the newborn population but determined by secondary injuries during trauma. A very important critical aspect is delayed diagnosis due to necrosis of the stomach wall and general peritonitis, causes by the spillage of gastric juice into the peritoneal cavity [13].

Fig. 122.4 CT scan of the upper abdomen. Two-year-old girl with ALL and massive systemic aspergillosis. The aspergilloma perforated from the spleen into the stomach. The child was admitted with gastric bleeding and during the gastroscopy, the perforation was detected

Infectious or tumorous lesions from adjacent organs can be responsible for a gastric perforation (Fig. 122.4). In these cases a CT scan or a study with water-soluble contrast media might be helpful to get the diagnosis.

Gastric Perforation Associated to Gastrostomies

Gastrostomies can be inserted by endoscopy (PEG), laparoscopy or laparotomy. One of the associated risks is a gastric perforation, in some cases overseen at the time of surgery. These perforations might happen during the blind puncture of the stomach during an endoscopy, causing a perforation and consecutive fistula between the stomach and other hollow organs (colon, small bowel). Sometimes the puncture can cause a laceration at the posterior part of the stomach (dorsal stomach wall), with a consecutive extravasation of gastric juice. This laceration might be overseen during the endoscopic gastrostomy placement. In some instances the gastrostomy tube is removed and substituted by a gastrostomy button without endoscopic control. In this case, even months after the PEG placement, the dilatation of the balloon outside the stomach wall can create a dehiscence of the stomach from the anterior wall and a consecutive fistula of the stomach into the abdominal cavity. If this problem is observed during an endoscopy, a new gastrostomy (PEG) catheter can be inserted, fixing the stomach again to the anterior abdominal wall, without major harm to the patient. If this problem is not recognized early, a peritonitis and pneumoperitoneum might occur later, presenting a patient in a serious clinical condition [14].

But even a laparoscopic assisted or open gastrostomy placement can cause later problems and gastric perforation. A gastrostomy constructed under tension might detach from the anterior abdominal wall and create a "free" intraperitoneal perforation. Sometimes traction sutures are used to fix the stomach in its position. If these traction sutures were tired due to too much traction, they could consecutively cut the stomach wall and create leakage of gastric juice (Fig. 122.5). In these patients, a peritoneal reaction and abdominal tension associated with vomiting might be the first clinical signs.

In all situations with a doubtful gastric perforation or leakage, a contrast study via the gastrostomy tube should be performed to rule out any extravasation of contrast media into the abdominal cavity. There are no clear numbers but some authors describe a rate of up to 2 % of perforation during or after gastrostomy placement.

Fig. 122.5 Five days after PEG insertion with push technique and T-bar fixation of the stomach. The T-bars "migrated" through the wall of the stomach and caused a gastric perforation with leakage of gastric juice into the abdomen

Conclusion

There is a high variety of causes and complications leading to gastric perforation in any age group. For the newborn group, some typical clinical situations might occur, while in the elder group, gastric perforation is very rare. For all groups and situations, some rules concerning diagnostic and therapeutic procedures can be established.

Manipulation with probes and tubes in the stomach and consecutive abdominal distensions and abdominal resistance should lead to diagnostic ruling out of the stomach perforation. Abdominal trauma and consecutive abdominal distension are clinical situations suspicious for a hollow organ perforation. If a pneumoperitoneum is detected, stomach perforation should be ruled out. The prognostic factors in all patients are the general conditions of the child and the presence of a peritonitis and sepsis.

Ménétrier's Disease

123

Ann Matthai

This is a rare acquired disorder of the stomach characterized by hyperplastic folds in the gastric fundus and body. It is a protein-losing gastropathy [1] resulting in hypoalbuminemia and accompanied by increased mucous secretion and hypochlorhydria. This was first described by a French pathologist Pierre Eugene Ménétrier in 1888 who noted hyperplastic changes in the gastric mucosa of some cadavers. Ménétrier's disease is seen in adults and children. Unlike pediatric disease, that in adults is progressive and more often associated with *Helicobacter pylori.*

Etiology and Pathogenesis

There have been many case reports of Ménétrier's disease in children associated with CMV infection. In one series coinfection with *H. pylori* was noted in one case. Recently Sheffield Children's Hospital had a case associated with swine flu.

The exact pathogenesis is not clear but pioneering work has been done by Coffey et al. in identifying the role of transforming growth factor alpha (TGFα) and epidermal growth factor receptor (EGFR) [2, 3].

A. Matthai

e-mail: annmatthai@yahoo.com

Transforming growth factor alpha (TGFα) is a 5.6 kd single-chain polypeptide that acts through binding to the epidermal growth factor receptor (EGFR). TGFα is produced in a wide range of normal as well as embryonic and neoplastic cells and tissues. TGFα and EGFR, but not EGF, are expressed in normal gastric mucosa. TGFα has a gastroprotective role, namely, inhibition of acid secretion and stimulation of mucous cell growth.

The normal oxyntic gland in the gastric mucosa has progenitor cells which give rise to surface mucous cells, parietal cells, chief cells, and neuroendocrine cells. In Ménétrier's disease there is expansion of the surface mucous cell compartment at the expense of parietal and chief cells. It is hypothesized that these changes are due to increased signaling of the epidermal growth factor receptor by TGFα. TGFα immunostaining in the gastric mucosa of four patients with Ménétrier's disease showed that in contrast to the normal pattern of TGFα immunostaining, in which TGFα appears most concentrated in parietal cells, there was intense staining in the majority of mucous cells. Transgenic mice, which overexpress TGFα in the gastric mucosa, exhibit a number of features characteristic of and consistent with the diagnosis of Ménétrier's disease, including foveolar hyperplasia and glandular cystic dilatation.

The most common symptoms are vomiting, abdominal pain, and edema. Anemia may be seen due to gastric blood loss, or reduced absorption

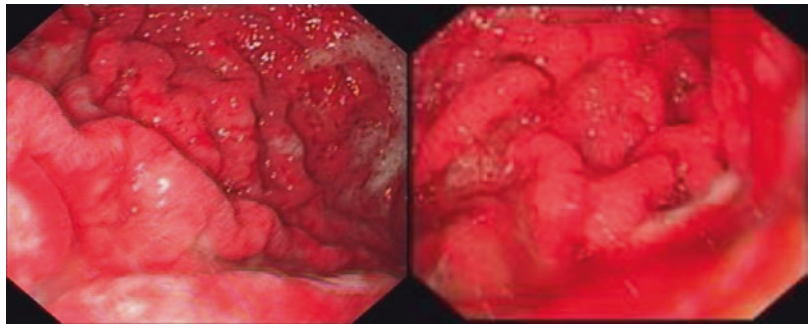

Fig. 123.1 Courtesy Department of Gastroenterology, Sheffield Children's Hospital

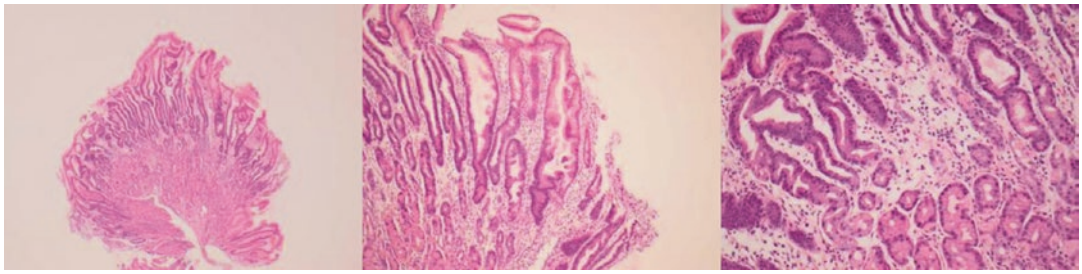

Fig. 123.2 The gastric mucosa with elongated hyperplastic crypts and focal cyst formation

of iron due to hypochlorhydria. Weight loss has also been noted.

The diagnosis is established by upper GI endoscopy which reveals giant gastric folds (Fig. 123.1), and histology demonstrates foveolar hyperplasia (expansion of mucous cells) and cystic dilatation of glands (Fig. 123.2). Ultrasound can detect hypertrophic gastric folds and point toward the diagnosis. Differential diagnosis includes Zollinger-Ellison syndrome where there is hyperplastic gastric folds but with high gastrin levels and hyperchlorhydria.

Treatment

Most cases in children need only supportive treatment and albumin infusions.

Omeprazole has been used in adults but it is not clear whether *H. pylori* eradication was more effective. Somatostatin analogue octreotide has been used successfully in children [4]. Eradication of *H. pylori* and treatment of CMV with ganciclovir have also resulted in resolution of long-standing disease in children [5]. Recently monoclonal antibody to EGF receptor has been tried successfully in adults [6, 7].

Prognosis in children is good as it is not progressive, and chronic cases have responded to treatment of underlying cause.

Inflammatory Bowel Disease and the Stomach

124

Robert Heuschkel

Introduction

Crohn's disease (CD) is known to occur in any part of the gastrointestinal (GI) tract, although it is the terminal ileum that was the site that initially identified the disease as a distinct clinical entity [1]. Similarly ulcerative colitis (UC) has traditionally been considered to involve only the large intestine, although the so-called backwash ileitis is a recognised feature of more extensive UC. The increasing reliance on endoscopic appearance and ability to develop tissue-based diagnostic algorithm has inevitably blurred the boundaries between apparently distinct clinical entities.

Gastroduodenal involvement in IBD was initially recognised in the late 1940s [2]; however the inflammatory changes in the upper GI tract have only recently been more formally documented [3–6].

The classical anatomical distributions of CD and UC suggest that study of the upper GI tract by endoscopic and histological techniques can help differentiate the two conditions. The presence of inflammation in the stomach does not however confirm a diagnosis of CD, as a number of researchers have reported upper GI tract changes in patients with UC [7–10]. Upper GI involvement remains more common in CD than UC [9]. The increasingly common diagnosis of indeterminate colitis (IC) – now known as IBD – unclassified (IBD-U) – is largely based on the increase in diagnostic oesophago-gastroduodenoscopies (OGDs), at which routine biopsies are now more frequently taken. Additional findings in the upper GI tract have surely provided more clinical information; however they have also complicated a previously straightforward classification. A diagnostic OGD is now strongly advocated in addition to an ileocolonoscopy [3, 6, 11, 12].

The ESPGHAN IBD working group recommended that all children suspected of having an inflammatory bowel disease should undergo upper GI endoscopy and colonoscopy with ileal intubation [11]. Radiological imaging of the small bowel has also been recommended in all cases except in definite UC.

The hard data remains limited, with the definitions of upper GI 'involvement' not being consistent. Varied terminology for endoscopic appearances of the gastric mucosa is used, and in some studies it is not made clear whether abnormalities refer to endoscopic or histological anomalies. In the absence of clear descriptive endoscopic terminology, retrospective studies suffer terribly from individual reporting bias. This may gradually be improving as standardised reporting tools are becoming more widely used.

DOI 10.1007/978-3-642-11202-7_124

Incidence and Epidemiology

The overall incidence of IBD in childhood is increasing in the paediatric age group [13].

A two-phase, 7-year retrospective study showed abnormalities on OGD in 64 % of children with CD and 50 % with UC; histological abnormalities were found in 81.6 % and 70.6 % of these cases, respectively [14]. Castellaneta et al. showed that upper GI inflammation was evident in 29/65 children with suspected IBD included in their study, of these 81.4 % had CD and the remainder had UC. They reported that inflammatory changes were most common in the stomach followed by the oesophagus and then duodenum [6].

In UC, as in CD, the stomach is most commonly affected within the upper GI tract [8, 9, 14].

Another retrospective study involving 196 children with Crohn's disease, only 25 children underwent an OGD for symptoms of upper GI involvement. Overall the group reported an incidence of upper GI abnormalities in only 5.1 %, with a male predominance of 8:2 [15]. The incidence of upper GI involvement was 40 % in the symptomatic group (10/25).

It appears there is a greater risk of having upper GI involvement in CD if a child has both small and large bowel disease (33 %, $p<0.05$). In a 15-year retrospective study involving 230 children with CD, with average follow-up of 6.6 years, 69 (30 %) had endoscopic upper GI involvement. There was no significant difference between sexes [4].

Clinical Features

The most common upper GI symptoms in Crohn's disease are epigastric pain (65 %), vomiting and weight loss [15], although dysphagia, aphthoid ulcers and pain on eating have also been reported [4]. It also appears that weight loss and hypoalbuminaemia are overrepresented in this group of patients. It is worth remembering that between 19 % (13 of 69) children with abnormalities did not exhibit any upper GI symptoms in this series and that others also report that there is no clear correlation between the severity of clinical symptoms and upper GI involvement [9].

Although gastroduodenal obstruction is a potential complication of persistent upper GI inflammation, none of the patients included in these studies had this complication during their relatively short follow-up period. Significant upper GI bleeding is even less common [15], but can be extremely severe and require emergency endoscopic intervention.

In their 2-year prospective study, Castellaneta et al. showed upper GI involvement was significantly higher in children with ileocolonic involvement compared to those with ileal or colonic involvement alone (71 % versus 36 %; $p<0.05$) [6]. Clinical symptoms suggestive of upper GI tract involvement were found in 56 % of 54 children included in this study. Of the symptomatic group, 33 % did not have inflammation of the upper GI tract. The common presenting symptoms recorded for children with upper GI involvement were epigastric pain, abdominal pain, nausea and/or vomiting and weight loss. Although these symptoms were significantly more common in children with upper GI involvement, in this series there was no significant correlation between low albumin levels or mouth ulcers and upper GI involvement in this cohort.

In another prospective study involving 31 children with CD, the authors reported that only 16 % had symptoms suggestive of upper GI involvement, 42 % had endoscopic findings, whilst there were histological changes in 87 % (granulomas in 39 % and nonspecific inflammatory changes in 48 %) [3]. This group concluded that there was no correlation between clinical, radiological and histological data.

Children with Crohn's disease and focally enhanced gastritis (FEG – see below) are more likely to have upper GI symptoms as compared to those without; however none of the children with FEG in UC had symptoms to suggest upper GI disease. GI symptoms alone did not indicate the presence of FEG in children with IBD [12].

Endoscopy

When IBD is confined to the colon, conventional colonoscopic and histological criteria alone may fail to establish a definitive diagnosis, and hence it is increasingly recommended, at least at diagnosis, to perform an OGD with biopsies.

The Porto criteria developed by the IBD working group of ESPGHAN strongly advocate upper endoscopy in all children with suspected IBD, irrespective of the presence or absence of upper intestinal symptoms. Not only does this provide potential diagnostic clues, but it also allows the detection of pathology. During upper GI endoscopy, biopsy samples must be obtained from inflamed and non-inflamed gastric mucosa to maximise diagnostic benefit [11].

Upper GI endoscopy may be helpful in distinguishing between CD and UC, even in patients who do not have symptoms suggestive of proximal gastrointestinal involvement [3, 4].

Upper GI endoscopic abnormalities are described in 54–64 % of children with Crohn's disease [6, 14], the antrum being the most common site of gastric disease, with about 20 % of children with CD having isolated gastric involvement on upper endoscopy. The most commonly observed mucosal abnormalities were gastric body erythema and oedema (79.3 %) along with antral mucosal nodularity (79.3 %); less common were polyps and ulcers. Upper endoscopic changes were also noted in 50 % of patients with UC [6].

In adults other gastroduodenal lesions in CD are also reported, e.g. aphthoid, serpiginous or longitudinal ulcers (in contrast to peptic ulcers, which are round or oval).

Furthermore, conventional endoscopic studies of the gastric mucosa do not exclude FEG, as around 70 % of children with FEG are found to have endoscopically normal gastric mucosa [12].

There is still significant confusion among clinicians in the reporting of endoscopic findings. A lack of standard and validated terminology has hampered the development of clear diagnostic features, with a huge range of descriptive terms being used to describe similar changes. In addition, some authors report 'oesophagitis/gastritis/duodenitis' as endoscopic findings, when these are clearly histological descriptions. Instead, endoscopists should accurately, systematically and rigorously document what is seen at endoscopy. Descriptive terminology with clear landmarks should be used – terms such as erythema, erosion and haemorrhage have clear definitions and are widely understood concepts that are easily reproducible.

Histological Findings in Gastric IBD

Nonspecific microscopic inflammation of the upper GI tract was found in 55 % of CD patients and 60 % of UC patients in a well-conducted, prospective study [7]. These authors also found *H. pylori* infection was present in gastric IBD patients with a frequency almost equal to that of children with recurrent abdominal pain. *H. pylori* was found in 19 % of children with UC and in 12 % of those with CD. Histological lesions were frequently seen in patients with normal endoscopic appearances, as 44 % of children with CD had nonspecific inflammation and 24 % had granulomas in the presence of a normal macroscopic mucosa [7]. In UC, 58.3 % had microscopic nonspecific inflammation with endoscopically normal mucosa, whilst none had granulomas. A definitive diagnosis of CD could not be made on the basis of nonspecific inflammation found in the stomach or upper GI tract.

Specific lesions such as giant cell granulomas or mucosal ulcers in the stomach help to confirm the diagnosis of CD where there is diagnostic dilemma.

It is estimated that microscopic findings at upper endoscopy may change a diagnosis to CD in 11–29 % cases [3, 6, 14].

Severe partial villous atrophy and increased intra-epithelial lymphocytes in the duodenum were reported in up 15 % of subjects.

In a study where pathologists were blinded to the clinical diagnosis, Tobin et al. found that in 45

children with IBD and 22 controls, endoscopic gastroduodenal ulceration, partial villous atrophy and an increase in intra-epithelial lymphocytes were equally common in UC and CD. Furthermore histological oesophagitis and duodenitis were not significantly more common in CD than UC. Mild gastric inflammation was seen in nearly 92 % cases with CD, whilst only 27 % had moderate-to-severe inflammation. Only 12 % of CD patients had gastric granulomas. Interestingly 4 of 11 patients with upper GI granulomas did not have colonic granulomas, re-emphasising that upper GI investigation can be crucial to achieve an accurate diagnosis. Of children with UC, 69 % had mild gastritis. Identification of non-caseating granulomas is almost always diagnostic of CD, but differentiation from other granulomatous gastritides is important. The group concluded that severe inflammation and other abnormalities occur in the proximal GI tract in both conditions [9].

In all cases of gastric inflammation where IBD is suspected, infection with *Helicobacter pylori* should also be definitively excluded [9].

A smaller retrospective review of five paediatric cases showed gastroduodenal inflammation in UC [8]. All of them had confirmed chronic active gastritis on histology, and none of them had non-caseating granulomas. All five children had been given a presumptive diagnosis of CD based on the presence of these changes together with pancolonic inflammation. All patients failed multiple medical regimens and finally required a proctocolectomy. Analysis of the resection specimen finally confirmed a diagnosis of UC in all.

In a 7-year retrospective study of children with IBD, a significant number of patients had endoscopic and histological abnormalities in the upper GI tract. As before, the stomach was the most common site affected histologically (86 % in CD and 78 % in UC). Inflammation was more severe in CD compared to UC; granulomas were more commonly detected in the stomach than elsewhere in the GI tract. Nine out of 23 patients had granulomas solely in the upper GI tract, which was the key to establishing a diagnosis [14].

Microscopic gastric lesions termed ‘focally enhanced gastritis’ (FEG) have been described as a common finding in CD [5, 12]. However this finding has also been described in other conditions. In a retrospective case-controlled study, FEG was present in 65.1 % with CD and 20.8 % children with UC as opposed to 2.3 % children without IBD and 2.6 % children with *H. pylori* [12].

Larger FEG foci harbouring neutrophilic infiltrates are more characteristic of children with IBD. The term ‘Crohn’s gastritis’ has been used to describe this pattern of gastric inflammation; however as very similar findings were seen in patients with UC, the term ‘Crohn’s gastritis’ is now obsolete, there being no truly pathognomonic features. Interestingly treatment with steroids or five ASAs does not affect the incidence of FEG [12].

Classical granulomas may not always be present in gastric Crohn’s disease. Griffiths et al. reported that only 3 out of 10 cases of gastric CD had typical granulomas [15]. Similarly Ruuska et al. reported in their prospective study that granulomas were found in the stomach in only 8 out of 32 cases of CD who had endoscopic or histological changes in the stomach [16]. Thus the absence of non-caseating granulomas in gastric biopsies does not exclude a diagnosis of CD. Nonspecific inflammation remains very common in both conditions. Others also suggested that recognition of a granuloma and/or focal gastritis in *Helicobacter pylori*-negative biopsies should prompt further investigation towards Crohn’s disease [5].

Despite these apparent similarities, a retrospective, 2-year, blinded case series was able to correctly identify 43 out of 56 patients with CD on the basis of gastric biopsies alone. They identified discrete patterns of inflammation on the gastric biopsy that were highly suggestive of CD although none were absolutely diagnostic; they concluded that a single well-formed granuloma on a background of otherwise normal histology or focal glandulitis/glandular abscess formation is enough to suggest a diagnosis of CD. They also indicated that eosinophilic infiltrates in the lamina propria were also specifically indicative of CD (in 19 cases with no false positives identified.) They identified *H. pylori* in 18 out of 56 patients with CD [17].

A larger paediatric study reported abnormal antral histology in almost similar proportions of

children and adolescents with Crohn's colitis and ulcerative colitis (92 % versus 75 %). Focal antral gastritis was more common in patients with Crohn's colitis than ulcerative colitis (52 % versus 8 %; $p = 0.013$). Granulomas were found in antral biopsies from 15 out of 25 patients with Crohn's colitis versus none in subjects with ulcerative colitis ($p < 0.001$). The colonoscopic diagnosis of five (14 %) patients (four indeterminate, one ulcerative colitis) was changed to Crohn's disease by the finding on gastric antral biopsy of granulomatous inflammation not found in colonic biopsies. Nonspecific antral gastritis was found to be common in all forms of chronic colitis [10].

Differential Diagnosis

It is more common to find eosinophilic infiltration in CD than in UC; however eosinophils may of course represent a primary disease process in their own right. Although some diagnostic confusion remains, eosinophilic gastritis/gastroenteritis should also be considered in the differential diagnosis of gastric CD. It can be difficult to make the latter diagnosis on mucosal biopsies alone; however a clinical history of atopy, blood investigations (peripheral eosinophilia, elevated serum IgE) and histological findings showing predominant eosinophilic infiltration of the glandular epithelium (as opposed to neutrophils in CD) should help distinguish eosinophilic disease from IBD [18].

It is also important to consider and exclude any associated or isolated bacterial or fungal infections of the stomach using specific staining on the biopsy samples [17]. In this retrospective blinded case series, 10 out of 56 cases thought to have gastric CD on initial histology had an alternative diagnosis on independent histologic review. One case each had actinomycosis (with granulomas/focal neutrophilic glandulitis/glandular abscess), chronic granulomatous disease (focal glandulitis/glandular abscess), gastric abscess of unknown aetiology and pseudopancreatic cyst with concurrent active gastritis, and six cases had focal active gastritis favouring an infectious pathology. This study concluded that gastric CD should be highly considered in *H. pylori*-negative biopsies showing the above changes.

Other Investigations

Low albumin levels, anaemia and elevated inflammatory markers can be found in CD patients with gastric involvement but do not occur any more or less than in other children with CD [15]. However the presence of any of these findings with even minor histological gastric abnormalities should prompt a thorough hunt for a diagnosis of CD. Particularly Lenaerts et al. showed that only 9 % of the children and adolescents with upper GI CD had normal albumin levels compared to about 30 % without upper GI disease [4].

Barium contrast radiology is only really sensitive at detecting anatomic abnormalities (stenosis/stricture) and hence is of very limited use in investigating gastric Crohn's disease. A simple barium contrast meal is commonly normal in gastric CD [7]; however it can occasionally show irregular antral mucosa and cobblestone appearance [15]. Other possible radiological findings include thickened mucosal folds, nodularity and rarely stenosis of gastric outlet/duodenum. Cross-sectional imaging (MRI/CT) has the advantage of being able to assess gastric wall thickness as a measure of local transmural inflammation, although ultrasound in experienced hands may also have a role to play.

Given the limited response that the gastric mucosa has to insult and the obvious lack of pathognomonic endoscopic features for any one condition, endoscopists must remain open-minded and cautious in the interpretation of their macroscopic findings. The temptation to provide immediate feedback for patients and families should be resisted until discussion with an expert pathologist has occurred. The clinico-pathological meeting has become an essential part of making a diagnosis in most paediatric gastroenterology units. This exchange between endoscopist and pathologist allows frequently

subtle endoscopic findings and histological appearances to be put into an appropriate clinical context. This prevents either endoscopic features per se or histological reports alone dictating the management plan for the child.

Summary

Upper gastrointestinal involvement is common in paediatric IBD. Endoscopic abnormalities are more prevalent in Crohn's disease, whilst histological abnormalities appear equally common in both conditions. Although the presence of granulomas on upper endoscopy has clear diagnostic value, all other endoscopic and histological findings in the stomach do not distinguish between Crohn's disease and ulcerative colitis. In fact the additional detail obtained at a diagnostic upper endoscopy for IBD may well make a definitive histological diagnosis more difficult. The ease and facility of endoscopic tissue samples make it more important than ever to have an active dialogue between clinicians and pathologists. Whilst more microscopic data may increase histological uncertainty, the clinical context remains key in making appropriate and timely treatment decisions.

Autoimmune Gastropathy

125

Ed Giles and Nicholas Croft

Introduction

Autoimmune gastropathy is a broad term encompassing an overlapping group of pathological effects in the stomach, including classical autoimmune gastritis, gastric atrophy, and gastritides associated with other diseases. There are many causes of gastropathy in children that may be considered autoimmune. Many of these are discussed in detail in other chapters of this book, such as gastritis associated with inflammatory bowel disease or gastritis associated with other systemic diseases.

Definition

There is no widely accepted unifying definition to make a diagnosis of autoimmune gastropathy or gastritis in children. Classic autoimmune gastritis (AG) is characterized by the presence of gastritis with autoantibodies directed against the parietal cell [1]. This condition, which is extremely rare in children, is a leading cause of vitamin B12 (cobalamin) deficiency in adults.

The term gastric atrophy (GA) is sometimes used interchangeably with autoimmune gastritis (AG) (see Table 125.1). GA refers to an endoscopic finding which is confirmed by histology, as described in adult pathology scoring systems and also applied to children. Histological changes are of corpus inflammation and atrophy, but these features may also be seen in other conditions and are therefore not specific [2]. GA in adults is associated with progression to metaplasia and risk of subsequent malignancy [1], but this significance is not certain in children. There is a lack of consistency in the degree of inflammation found in children with a diagnosis given of GA, reflecting lack of certainty about this condition in pediatric practice [3].

Etiology

The underlying cause of AG, like many autoimmune diseases, is unknown. The pathophysiology of parietal cell antibody (PCA)-positive AG appears to be T-cell mediated, with the H+K+-ATPase (proton pump) as the target autoantigen [4]. Parietal cells are lost from the gastric mucosa [5]. In adults, the natural history in adults appears to be slow but steady progression from atrophic gastritis to pernicious anemia over many years [6].

Pernicious anemia is a megaloblastic anemia due to vitamin B12 malabsorption caused by intrinsic factor deficiency [7]. Intrinsic factor is a glycoprotein produced by gastric parietal cells that binds dietary vitamin B12. The vitamin B12-intrinsic factor complex is absorbed in the

Table 125.1 Comparison of autoimmune gastritis (AG) and gastric atrophy

Findings	Autoimmune gastritis	Gastric atrophy
Clinical	Pernicious anemia (in long term)	Non-specific symptoms
Endoscopic	Atrophy spares antrum	Atrophy throughout stomach
Histology	Mononuclear cell infiltrate in submucosa and LP	Atrophic submucosa
Blood	+ve autoantibody to PC +/or IF	*H. pylori* serology association
Other	Schilling test positive	Schilling test negative

LP lamina propria, *PC* parietal cell, *IF* intrinsic factor

terminal ileum after binding to intrinsic factor receptors. The progression from autoimmunity to anemia is usually over decades. Childhood pernicious anemia is not associated with chronic gastric atrophy but is usually the result of a genetically determined failure to secrete intrinsic factor or secretion of a defective intrinsic factor [5]. In a rare case of antibody-positive pernicious anemia in a child, there was no evidence of gastritis [8].

It has been suggested that *Helicobacter pylori* could be implicated in the pathogenesis of autoimmune gastritis [9, 10]. Historically, it was believed that AG was a noninfective cause of gastric atrophy affecting the fundus and body of the stomach but sparing the antrum. This is in contrast to gastric atrophy, which was thought to be caused by *H. pylori* and affecting the whole stomach [7]. There has been a suggestion that in gastric atrophy with antral sparing, the autoimmunity may be triggered by molecular mimicry (i.e., after *H. pylori* infection) [11]. The type of gastric atrophy in *H. pylori* infection is related to lifestyle factors and also the particular antigen types of the bacteria [12]. However, a study looking at the relationship between H. pylori and autoimmune gastritis in over 200 children found only three patients with positive PCA, and there was no clear association between H. pylori serology and PCA antibody positivity [13]. The relationship between H. pylori and AG thus remains unclear, particularly in children.

Incidence

As there is no clear definition, the incidence of autoimmune gastritis in children is not known. However, it is relatively more common in patients with other autoimmune diseases. Juvenile patients affected with autoimmune thyroid disease show a 14–30 % prevalence of parietal cell antibodies (PCA), and some of these patients have endoscopic and histological features of AG [14, 15]. In a study of 177 patients in the pediatric age group, 6.8 % were PCA positive, but none of the patients had AG [16].

A review of the literature regarding the prevalence of gastric atrophy in children showed a range from 0 % to 70 %, although the higher figures seem to be isolated [3]. Most of the studies included are related to *H. pylori* infection, but even in this group, the incidence appears to be from 0 % to 4 %. Interestingly, in all the studies included, the vast majority of cases were older children, and there were only a handful of individual cases of gastric atrophy in young children.

Clinical Presentation and Management

Diagnosis

Clinical manifestations of AG are not well characterized in children. In adults, they relate to the symptoms of pernicious anemia, which are insidious, and are related primarily to the megaloblastic anemia. They also include neurological features of demyelination and many nonspecific gastrointestinal symptoms and signs.

Endoscopically, there may be gastric atrophy which spares the antrum, but this is not universally found [7]. Biopsy specimens show a mononuclear cellular infiltrate in the submucosa extending into the lamina propria between the

gastric glands [5]. Histological changes rely on appropriate biopsies being taken. The updated Sydney System advises five biopsies – two from the antrum, two from the body, and one from the incisura [2]. Unless there is a high degree of suspicion macroscopically on endoscopy, it is unlikely that all these biopsies would be routinely taken in pediatric practice, which may affect the prevalence data.

Blood tests are required, as autoimmune gastritis is classically characterized by gastric atrophy, achlorhydria, low serum pepsinogen I, and high serum gastrin (due to hyperplasia of gastrin-secreting cells) [17]. Autoantibodies to parietal cells and their secretory product, intrinsic factor, are present in both the serum and in gastric juice.

Previously pernicious anemia was diagnosed by the now largely obsolete Schilling test. This was measuring urinary vitamin B12 before and after administration of vitamin B12 with intrinsic factor. Now the autoantibodies are relied upon for diagnosis, although sensitivity and specificity of various different forms of tests varies [7].

Treatment

Given the rarity of the disease in children, there is little published on specific treatments. The mainstay of treatment for adults with autoimmune gastritis is treatment of the vitamin B12 deficiency with replacement injections [7]. Early studies suggested that immunosuppression, specifically prednisolone and azathioprine can be used to halt progression of the autoimmune disease to the clinical entity of pernicious anemia [18, 19].

Natural History

The classic progression from autoantibody production to gastritis and then to the development of pernicious anemia is over decades in adults. The risk of developing gastric cancer from gastric atrophy has been quoted at 0.1% per year, and surveillance is warranted [20]. Gastric carcinoma is exceedingly rare in pediatrics but has been reported in association with pernicious anemia [21]. Untreated pernicious anemia may lead to the neurological consequences of vitamin B12 deficiency, such as reversible ataxia [8].

Other "Autoimmune Gastropathies"

Celiac Disease

Celiac disease is diagnosed by classic histological changes in the distal duodenum and jejunum. The majority of pediatric patients are found to have gastritis, which is either lymphocytic (increased number of intraepithelial T-lymphocytes), or chronic gastritis, or both [22, 23] (Fig. 125.1). These histological features seem to resolve as the celiac disease is treated [22]. However, the findings have not been related to any particular clinical features or presentation of the disease. There is clearly overlap with the diagnosis of lymphocytic gastritis [24], which is described below.

Allergic Gastritis

In contrast to pure eosinophilic gastritis, this condition is part of the spectrum of allergic gastrointestinal disorders. Cow's milk protein is the allergen most commonly associated, although there is substantial crossover with soya bean allergy, as well as other allergens [25]. Symptoms include vomiting, irritability, and poor weight gain [26].

To confirm a diagnosis of food allergic gastritis would require a formal food challenge with associated endoscopic findings, although in practice the diagnosis is often suspected on history and treated with elimination of allergens in the diet [25]. If endoscopy is performed, histological findings are of eosinophilic infiltrate in the lamina propria, as well as increased numbers of lymphocytes, plasma cells, and neutrophils [2, 27]. The treatment is through elimination of the appropriate antigen in the diet, including sometimes in the diet of a breastfeeding mother. This can involve the use of a hypoallergenic infant formula [26]. The natural history of this condition is to resolve with age [28].

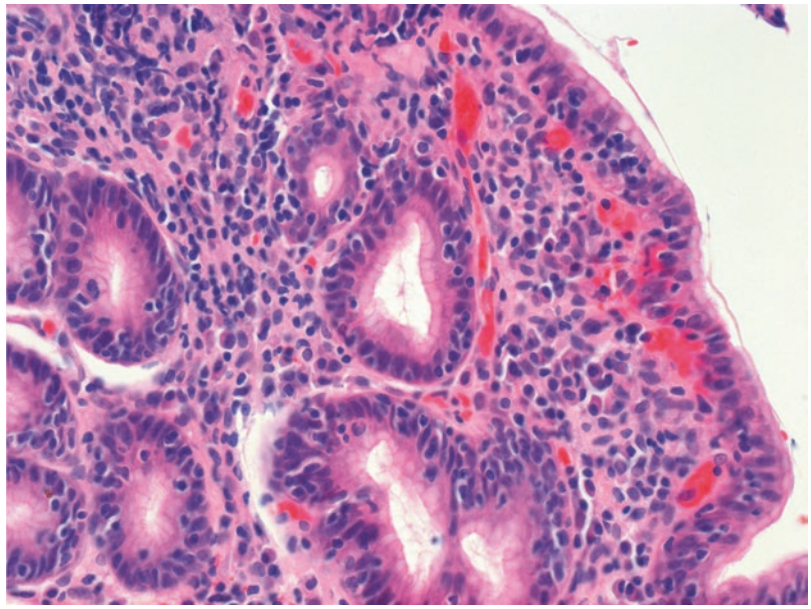

Fig. 125.1 High-power photomicrograph showing lymphocytic gastritis in association with celiac disease. There are clusters of lymphocytes in surface and gland epithelium, together with a chronic inflammatory cell infiltrate in the lamina propria (Image kindly provided by Professor Paola Domizio)

Eosinophilic Gastritis

This is a rare disorder even in adults and is usually grouped together with eosinophilic gastroenteritis [29], although it is likely they are distinct clinical entities. Eosinophils are seen in normal gastric biopsies making diagnosis even more difficult. The condition can either be primary or secondary to a systemic disease or infection, including to *H. pylori*. Primary or idiopathic eosinophilic gastritis is suggested to have an allergic etiology, and treatment is often directed at potential allergens or medications that alter the allergic response [30].

Ménérier's Disease

This is also a rare disorder characterized by a protein-losing hypertrophic gastritis. In children, the average age of presentation is 5 years. The clinical picture is an abrupt onset of edema, vomiting, abdominal pain, and anorexia [31]. Gastroscopy shows giant hypertrophy of the mucosal folds in the stomach [29]. Microscopic findings may include hypertrophic dilated gastric glands filled with mucous and an inflammatory infiltrate with the gastric mucosa [31]. Compared with adult Ménétrier's disease, in childhood the disease is usually self-limiting. CMV has been implicated as the cause in a third of pediatric cases [32].

Varioliform Gastritis

Exceptionally rare in children, this condition is most striking in innumerable prominent nodules on the fundus and proximal body of the stomach, which may have a central crater or erosion [27]. There is some evidence that there may be an allergic basis for this condition, with high total IgE levels and eosinophilia [33]. There is also overlap with lymphocytic gastritis as described below [34].

Lymphocytic Gastritis

This condition is defined by the recognition of >25 intraepithelial lymphocytes per 100 surface epithelial cells [29]. This is a histological

diagnosis with a lot of overlap with other conditions [22]. For example, approximately 50% of children with untreated celiac disease have lymphocytic gastritis [24], and it is also seen in varioliform gastritis [34].

Henoch-Schönlein Gastritis

Henoch-Schönlein purpura (HSP) is the most common systemic vasculitis in children. It is a vasculitis mediated by IgA deposition. It is diagnosed by criteria which include palpable purpura plus one of abdominal pain, arthralgia or arthritis, renal involvement, or IgA deposition [35]. These IgA deposits can develop anywhere in the gastrointestinal tract, but the small bowel is the most common [36]. If endoscopy is performed, gastritis may be found, but the features are usually nonspecific [25]. However, purpuric-type lesions may be seen in the stomach and histologically show a leukocytoclastic vasculitis, with immunostaining revealing IgA deposits [37]. These features are similar to what is seen in the skin lesions. HSP is usually self-limiting, and no medical treatment (including corticosteroids) has been shown to consistently affect the gastrointestinal manifestations [35].

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) can be acute or chronic, with acute occurring in the first 100 days following transplantation, during or soon after engraftment. It generally refers to damage to the skin, gastrointestinal tract, or liver which is graft T-cell-mediated targeting host antigens [38]. Acute GVHD of the GI tract usually presents with diarrhea which is secretory in nature and often of great volume [38]. Other clinical features include anorexia, nausea and vomiting, abdominal pain, and bleeding due to mucosal ulceration (and carry a worse prognosis) [39]. Given the multiple possible causes of gastrointestinal symptoms in this group of patients, endoscopy and biopsy are required to establish the diagnosis [40]. The classic histological feature is epithelial apoptosis [41]. This must be differentiated from the similar features of viral infections, particularly CMV, which can also cause pathology in this group of patients. Chronic GVHD has much more varied presentations, but typically affects the esophagus in the GI tract, and may present with strictures [25, 38]. There are no specific histological features of chronic GVHD [41].

Inflammatory Bowel Disease

Gastritis is a feature seen in both Crohn's disease and ulcerative colitis, but this will be discussed in great detail in. Crohn's disease is the most common cause of granulomatous gastritis.

Other Granulomatous Gastritides

Granulomata in the stomach are a rare finding and are usually a feature of Crohn's disease [42]. However, in an endemic area, *H. pylori* has been implicated as a leading cause, especially when found associated with ulceration [43]. Eradication of the *H. pylori* leads to resolution of the granulomata, but it is not clear why a small number of patients develop this feature [44].

Other causes included sarcoidosis, chronic granulomatous disease, tuberculosis, syphilis, histoplasmosis, parasitic infections, vasculitis-associated granulomata, tumors (including adenocarcinoma and lymphoma), lymphocytic gastritis, and foreign-body associated granulomata [27, 42]. Sometimes a diagnosis of idiopathic granulomatous gastritis is made, but it is uncertain whether this is a true clinical entity.

Systemic Disease Affecting the Stomach

126

Sue Protheroe

Introduction

The stomach is a complex organ that performs three basic physiological processes to contribute toward digestion, i.e., secretory activity, endocrine function, and motility. The stomach may respond to systemic disease with the development of macroscopic and microscopic mucosal changes such as gastritis or gastropathy secondary to vasculitis or infiltrative disease. Gastritis is defined as microscopic evidence of inflammation affecting the gastric mucosa and can be primary or secondary, based on the underlying etiology. Primary gastritis may be due to infection with the organism *Helicobacter pylori*. Secondary gastritis and ulceration may be clinically and often histologically distinct and gastric biopsy offers a relatively accessible source of information to support a clinical diagnosis. Gastric distension and emptying involve a number of complex interactions between myenteric, neurologic, and hormonal factors. Although symptoms related to gastric dysfunction such as nausea and vomiting are common in children, primary motility disorders of the foregut are relatively rare. Delayed transit disorders may be secondary to conditions that involve only the stomach (gastroparesis) or be part of a more generalized gastrointestinal motility disorder and reflect a disease process affecting one of more of the neurogenic, smooth muscle, or hormonal factors that regulate gastric emptying. The objective of this chapter is to review various systemic conditions affecting the stomach, highlighting where gastric biopsy can be useful to diagnose or evaluate a systemic disorder. Although there is no single satisfactory description of all systemic disease involving the stomach, an etiology-based classification (Table 126.1) provides a practical approach for directing both further investigations and unifies the findings of the endoscopist and the histopathologist when mucosal biopsy material is available. The overlapping nature of endoscopic or histological findings makes classification of some gastropathies into more than one category.

Systemic Vasculitis

Systemic vasculitides are a group of disorders with multiorgan involvement that can involve local or diffuse pathologic changes in the gastrointestinal tract [1]. The extent and clinical course of disease depend on the size and location of the affected vessel and the histological characteristics of the lesion (Table 126.2). Gastrointestinal clinical manifestations are diverse: nonspecific paralytic ileus, mesenteric ischemia, submucosal edema and hemorrhage, and bowel perforation or stricture.

Table 126.1 Systemic disease and the stomach

Pathophysiology of systemic disease affecting the stomach	Condition
Vasculitis	Henoch-Schonlein purpura, Kawasaki's disease, Beçhet's disease, rheumatoid arthritis, SLE, PAN
Granulomatous	Crohn's disease, vasculitis-associated inflammation, Wegener's granulomatosis, Churg-Strauss syndrome
Infectious and postinfectious disease	Infectious (tuberculosis, parasitic, histoplasmosis, syphilis, Whipple's disease, viruses (e.g., CMV, EBV, VZV)
Immune deficiency/dysregulation	Common variable immune deficiency, severe combined immune deficiency, X-linked agammaglobulinemia, chronic granulomatous disease
	Sarcoid
	Langerhans cell histiocytosis (LCH)
	Graft versus host disease
	Posttransplant lymphoproliferative disease
Autoimmune and autoinflammatory disease	Celiac disease
	Autoimmune enteropathy including IPEX
	Autoimmune hepatitis type 1 diabetes mellitus
	Autoimmune thyroiditis
	Autoimmune polyendocrine syndrome types 2 and 3
	Familial Mediterranean fever
Endocrine	Hypothyroidism, type 1 diabetes
Renal	Renal failure
	Cystinosis
Allergic	Cow's milk protein intolerance
Vascular	Hereditary hemorrhagic telangiectasia, portal hypertension
Stress related	Respiratory failure, hepatic failure, cardiac failure, multiorgan failure, sepsis, trauma, burns
Neoplasia	Gastrointestinal stroma tumor (GIST) in Carney's triad (gastric epithelioid stromal sarcoma, extra-adrenal paraganglioma, and pulmonary chondroma)
	Gastric lymphoma in primary immunodeficiency
	Non-Hodgkin's lymphoma/GIST (leiomyosarcoma) in HIV
Polyps	Juvenile polyposis syndrome
	Familial adenomatous polyposis
	Peutz-Jeghers syndrome
	Gardner's syndrome

Table 126.2 Vasculitis and the gastrointestinal tract

Size of vessel	Vasculitis
Large vessel	Giant cell arteritis
	Takayasu arteritis
Medium vessel	Kawasaki disease, PAN
Small vessel	Henoch-Schonlein purpura, Beçhet's, disease, SLE, RA, Wegener's granulomatosis
	Churg-Strauss syndrome

The most common vasculitides in children are self-limiting conditions: Henoch-Schönlein purpura and Kawasaki disease. Lifelong and chronic vasculitides (e.g., giant cell arteritis, Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, polyarteritis nodosa, and Takayasu arteritis) are rarely seen in children [2]. Nevertheless, the possibility of vasculitis should be considered whenever possible mesenteric ischemic changes occur in young patients at unusual sites (e.g., the stomach, duodenum, and rectum) and have a tendency to concomitantly involve the skin or genitourinary system. Clinical manifestations usually provide the diagnosis, but endoscopic findings in the stomach may help

establish the specific cause since radiologic findings in various types of vasculitis often overlap considerably and have limited value in making a specific diagnosis [3].

Henoch-Schlonlein Purpura

Henoch-Schlonlein purpura (HSP) is the most common childhood vasculitis comprising up to 90 % of all cases. Peak incidence is 4–6 years and 90 % occur before the age of 10. HSP is characterized by nonthrombocytopenic palpable purpura, arthritis or arthalgia, and gastrointestinal and renal involvement. Antigen-antibody (IgA) complexes activate the alternate complement pathway, resulting in inflammation and small vessel vasculitis without a granulomatous reaction [4]. The etiology is unclear but it is associated with infections (group A beta hemolytic streptococci, *Staphylococcus aureus*, *Mycoplasma*, human parvovirus B19), medications (clarithromycin, paracetamol), and vaccinations (pneumococcal, influenza). Cutaneous involvement is the most common presentation and is seen in 50 % of cases as the presenting sign and usually precedes gastrointestinal manifestation, although in one forth of cases, skin lesion occurs after gastrointestinal manifestations. Diffuse, abdominal pain colicky is the most common symptom, and nausea, vomiting hematemesis, melena, and hemochezia are secondary to mesenteric vasculitis which causes extravasation of blood into the interstitial spaces resulting in edema and hemorrhage. Rarely ileocecal intussusception, ischemic necrosis of the bowel, or massive gastrointestinal bleeding can occur. Positive fecal occult blood and raised stool α1-antitrypsin suggest mucosal injury even in the patients without gastrointestinal symptoms [4]. HSP is a clinical diagnosis, but when the presentation is atypical, if skin lesions are absent, or when gastrointestinal symptoms are severe or persistent, gastrointestinal mucosal biopsy may be helpful useful in early diagnosis [5]. The duodenum is most commonly involved, but changes noted in the gastric antrum include erythema, edema, petechiae, superficial, multiple ulcers, hemorrhage, hematoma-like protrusions, and ecchymotic lesions [6]. Histopathology shows preserved villous architecture and leukocytoclastic vasculitis with IgA deposition on immunofluorescence with neutrophilic and eosinophilic infiltrates. Crohn's disease and Wegener's granulomatosis can also present as leukocytoclastic vasculitis. High-resolution ultrasound can identify bowel wall abnormalities such as submucosal thickening and loss of differentiation [7]. Treatment of HSP reflects its self-limiting nature in 94 % of children and specific therapy is not usually required. Oral steroids are indicated in patients with severe colicky abdominal pain, renal, scrotal, and testicular involvement or severe rash. Early steroid therapy has been shown to decrease gastrointestinal symptoms within 2 days compared to 12.3 days in patients without steroids and may decrease recurrence of gastrointestinal bleeding or intussusception [8]. Although corticosteroids alleviate the symptoms, they seem not to alter the clinical course of extra renal symptoms during 6 months of follow-up [9].

Kawasaki's Disease

Kawasaki disease (KD) is a vasculitis of unknown etiology. The diagnosis is based upon the most frequent symptoms of fever and abnormalities in the oral mucosa, and the most important complication is the characteristic damage to coronary arteries. The essential lesion in Kawasaki's disease is an arteritis initially involving small arteries and later the medium and large vessels which can target the gastrointestinal tract. Complications secondary to necrosis of the intestines can affect the stomach, duodenum, jejunum, liver, and gall bladder causing acute hydrops [10, 11].

Juvenile Chronic Arthritis

Children with juvenile chronic arthritis (JCA) frequently presents with epigastric pain and dyspepsia which have largely been attributed to the use of nonsteroidal anti-inflammatory

drugs (NSAIDs), the mainstay of treatment in JCA. Macroscopic endoscopic lesions such as ulcers and infection by *Helicobacter pylori* have been frequently observed in this population who may be asymptomatic [12]. It is suggested that endoscopic evaluation of children with JCA receiving NSAIDs should be considered at least in symptomatic cases [13, 14]. Long-standing juvenile rheumatoid arthritis can be associated with amyloidosis, although the condition is rare in these under 15 years of age. Amyloid is deposited in the gastrointestinal tract and can be detected by rectal or gastric biopsy. Serial gastroduodenal mucosal biopsy specimens have been used to demonstrate removal and sustained decrease in amyloid deposits after therapy with agents such as anti-TNFα [15].

Systemic Lupus Erythematosus

Gastrointestinal vasculitis may contribute to morbidity and mortality in systemic lupus erythematosus (SLE) [16]. Dysphagia and heartburn are the most common manifestations. Since virtually all children with SLE require treatment with NSAIDs and/or corticosteroids, it is difficult to differentiate treatment-caused gastrointestinal manifestations and gastritis due to the disease itself [17]. However, immune complex deposition in the arteriolar walls has been observed in the inflammatory infiltrate in the stomach and duodenum from children during disease exacerbation [18]. Children with SLE on long-term NSAIDS may need to be maintained on long-term gastroprotective agents such as a proton pump inhibitors and use of specific COX-2 inhibitors which have fewer gastric side effects than conventional NSAIDs. Ischemic bowel ulcers, attributable to vascular lesions of SLE in children, can be complicated by perforation and secondary invasion by opportunistic organisms [17]. Invasive gastric mucormycosis, a rare but usually fatal fungal infection in SLE, occurred in a child with systemic lupus erythematosus who was successfully treated with aggressive antifungal therapy [17]

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) rarely presents in childhood. Upper gastrointestinal bleeding can occur due to ulcers in the stomach (Dieulafoy's lesions) [18, 19]. Multiple visceral aneurysms causing colitis and jejunitis have been reported in a child with PAN. The diagnosis was established with multidetector CT and CT angiography [20]

Beçhet's Disease

Beçhet's disease (BD) is a chronic multisystem vasculitis that can involve both the arteries and veins of almost any organ and is characterized by mucocutaneous, articular, neurological, gastrointestinal, and ophthalmological lesions. Pediatric Beçhet's is rare and is diagnosed in the presence of recurrent oral aphthosis plus one of the following: genital ulceration, erythema nodosum, folliculitis, pustulous/acneiform lesions, positive pathergy test, uveitis, venous/arterial thrombosis, and family history of BD [21]. Intestinal Beçhet's disease is less common and is characterized by discrete, deep punched-out ulcers, most commonly located in the ileocecal region, with a tendency to bleeding and perforation. In comparison with Crohn's disease, less inflammation is seen in the area surrounding an ulcer and granulomas are not seen [22]. Gastric involvement is thought to be rare, although in asymptomatic patients screened with routine endoscopy, abnormalities in the upper GI tract were noted including gastritis, gastric ulceration [23], and perforation [24]. Abnormalities might not be specific for the disorder since medications such as steroids or aspirin might aggravate ulcer formation.

Granulomatous Gastritis

Granulomatous gastritis is a notable feature in gastric biopsies. Histological identification requires consideration of potential causes (Table 126.3) and distinction from the common histological appearance of gastritis and gastric mucosal ulceration of Crohn's disease. Chronic

Table 126.3 Systemic diseases associated with granulomatous gastritis

Systemic diseases associated with granulomatous gastritis	
Inflammatory bowel disease	Crohn's disease
Infectious	*Helicobacter pylori*, mycobacterium tuberculosis, parasitic, histoplasmosis, syphilis, Whipple's disease
Vasculitis-associated inflammation	Wegener's granulomatosis, Churg-Strauss syndrome
Infiltrative/immunological	Sarcoid
	Langerhans cell histiocytosis
	Chronic granulomatous disease

active gastritis is not uncommonly found in ulcerative colitis [25].

Vasculitis-Associated Inflammation with Granulomata

Wegener's Granulomatosis

Wegener's granulomatosis (WG) is a systemic vasculitis, involving the respiratory tract and the kidneys [26]. The incidence of childhood WG during is comparable to reports in adults (6.39 cases/million/year) and it seems to be increasing. Typical histopathological features are a polymorphous vasculitis often associated with necrosis and granulomatous inflammation. Histological proof of necrotizing vasculitis is dependent on the depth of the biopsy and can be missed since the vessels that are usually affected in WG are present in the submucosa and may not be accessible on biopsy. Crohn's disease may be suspected due the histological findings of granulomatous gastritis in the presence of gastrointestinal and extra gastrointestinal symptoms, such as arthralgia, arthritis, and inflammatory changes in the eye and skin. Differentiation from Crohn's disease is supported by a positive test for antineutrophil cytoplasmic antibodies (ANCAs) with a cytoplasmic pattern (c-ANCA) and antigenic specificity for proteinase 3 (PR-3) [27]

Churg-Strauss Syndrome

Churg-Strauss syndrome is an allergic granulomatous vasculitis accompanied by asthma and eosinophilia. The lungs, skin, and nervous system are the most common sites of involvement. It is generally considered a disease of adults; occurrence in children has been reported infrequently [28, 29]. Widespread involvement of the gastrointestinal tract including gastric ulceration has been reported in adults [30].

Non-vasculitis-associated Inflammation with Granulomata

Sarcoid

Sarcoidosis is a systemic granulomatous immunological disorder of unknown etiology, with accumulation of activated lymphocytes and macrophages in any organ. The intrathoracic lymph nodes and the lung remain the most common sites of disease (90%). While gastrointestinal involvement is rare, gastric involvement is the most common [30] and can be a feature of systemic disease or in isolation. Generally the disease is asymptomatic, but pain in the epigastrium, nausea, vomiting, or hematemesis may be present. Endoscopic findings are variable: localized or diffuse hyperemia, single or multiple ulcers, with noncaseating granulomas [31]. Differentiation is required from the histological and endoscopical gastric pathologies resembling sarcoidosis (histoplasmosis, Crohn's disease). Steroids are the most appropriate treatment.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a rare disease caused by a clonal proliferation of specialized dendritic-like CD1a-positive (Langerhans) cells with an unknown cause. The

large mononuclear cells accumulate forming granulomata in various organs, mainly the lung, bone, or skin. LCH of the alimentary tract is rare, but gastric mucosal biopsies in an adolescent with multiorgan LCH and striking gastric polyposis have been reported [32]. Microscopically, the gastric mucosa was expanded by discrete granulomatous microaggregates of Langerhans cells, resulting in a close resemblance to other, more common nonnecrotizing granulomatous gastritides. Abdominal tuberculosis (TB) is infrequent in the Western world and occurs more frequently among at-risk populations, elderly patients and patients with HIV infection. Abdominal TB usually manifests itself as intestinal TB, peritoneal TB, and mediastinal lymphadenitis. Gastric TB is a rare manifestation; symptoms include nausea and vomiting, iron deficiency, and weight loss. Diagnosis is made by endoscopic biopsy of the affected area in the antral region, with granulomatous chronic gastritis suggesting tubercular origin [33] (Fig. 126.1). Chronic granulomatous disease (CGD) is an additional important cause of granulomatous gastritis (Sect. 126.6).

Infectious Disease

In addition to tuberculosis, Whipple's disease is a multisystem granulomatous infectious disease. It is caused by *Tropheryma whipplei* and is transmitted by the fecal-oral route, generally in children 2–4 years of age with other enteric pathogens. The bacteria rod-shaped gram-positive actinomycete accumulates within macrophages, preferentially in the intestinal mucosa causing diarrhea, abdominal pain, and malabsorption [34]. Disease manifestation seems to be linked to immunological abnormalities of macro-

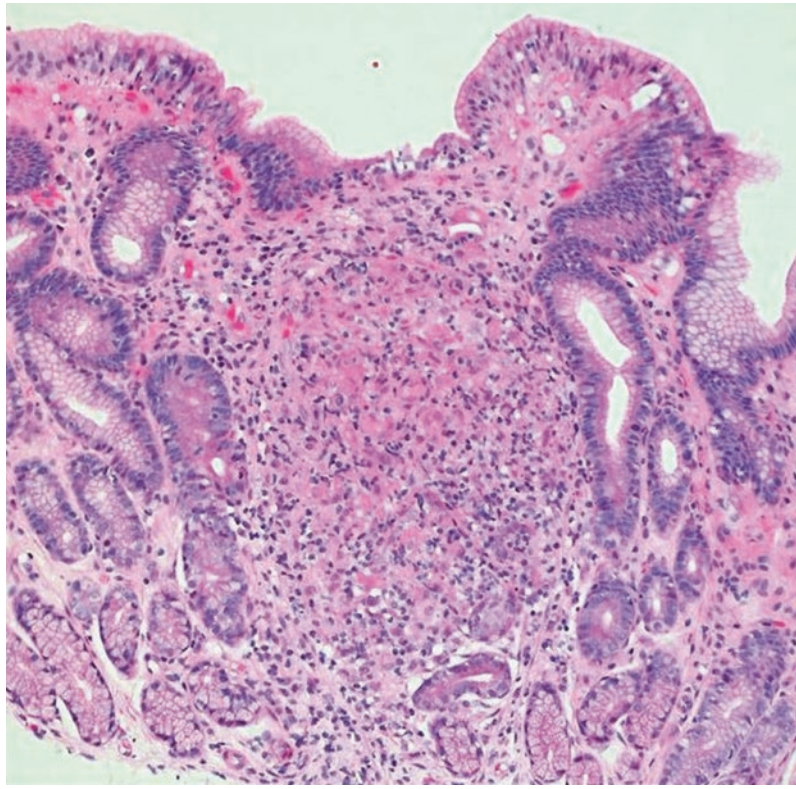

Fig. 126.1 *Mycobacterium tuberculosis*. Gastric biopsy of a child undergoing endoscopy for suspected celiac disease revealing granuloma. *Mycobacterium tuberculosis* infection and celiac disease diagnosed (H&E ×40)

phages. Gastric antral Whipple's may be found on biopsy as a granulomatous infection in the stomach with foamy macrophages with intracellular PAS-positive granules [35]. See following Sect. 126.6 for opportunistic and viral infections involving the stomach.

Immune Dysregulation

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is an uncommon primary immune deficiency with X-linked and autosomal recessive forms. CGD is caused by a defect in phagocyte production of oxygen metabolites resulting in recurrent infections with a narrow spectrum of bacteria and fungi as well as a common set of inflammatory complications most notably including inflammatory bowel disease in the majority of cases [36]. Patients often present with enterocolitis, while ulceration and infection associated with granuloma formation (abscesses) can occur anywhere from the mouth to the anus. CGD is known to present with gastric outlet narrowing or obstruction due to inflammatory thickening in the gastric antral wall which needs to be distinguished from other causes of pyloric narrowing such as peptic ulcer disease, Crohn's disease, and gastric tumor [37]. MRI has been used to monitor gastric wall inflammation [38]. CGD has been an important disease for the development of bone marrow transplantation and gene therapy [36].

Other disorders of neutrophilic function, e.g., leukocyte adhesion molecule deficiency I where hepatic and perirectal abscesses are characteristic, should be distinguished from CGD.

Other Immune Deficiencies (ID)

Immunoglobulin A (IgA) deficiency is the most common primary immunodeficiency, with decreased serum level IgA in the presence of normal levels of other immunoglobulin isotypes. Most individuals with IgA deficiency are asymptomatic and identified coincidentally but appears to be a risk factor for infections, allergic diseases, and autoimmune conditions [39]. IgA-deficient individuals have a tendency to develop infections such as giardiasis and disorders of the gastrointestinal tract, notably malabsorption, lactose intolerance, celiac disease, ulcerative colitis, and nodular lymphoid hyperplasia [40]. Common variable immune deficiency (CVID) is the second most prevalent primary ID but clinically the most important. Increased susceptibility to infections and diminished responses to protein and polysaccharide vaccines are apparent after 24 months of age and usually in young adulthood. CVID is a combination of humoral and cell-mediated deficiency, which explains not only why so many systems are affected but also why standard therapy in the form of intravenous immunoglobulin is not always effective [41, 42].

Gastointestinal tract CVID displays a wide spectrum of histologic patterns and can mimic celiac disease, lymphocytic gastritis, acute graft-versus-host disease, and inflammatory bowel disease. The diagnosis of CVID may be suspected on the basis of the lack of plasma cells in a gastric biopsy, present in about two-thirds of patients, lymphoid aggregates poorly formed granulomas, and an increase in apoptosis [43]. Intraepithelial neutrophils were found in a subset, accompanied by various infections [cytomegalovirus (CMV), *Helicobacter pylori*, and *Cryptosporidium*]. Children with X-linked agammaglobulinemia (XLAG) have high incidence of chronic gastrointestinal complaints, most commonly diarrhea. Patients with XLAG, like CVID, manifest a spectrum of abnormalities that resemble graft-versus-host disease with apoptotic bodies and lymphocytes in crypts in gastric biopsies [44]. The primary immunodeficiences (severe combined immunodeficiency (SCID), XLAG, CVID, Wiskott-Aldrich syndrome, and ataxia telangiectasia) are associated with an increased risk of high-grade gastric lymphomas. Symptoms may be nonspecific such as abdominal pain, gastric outlet obstruction, or bleeding. Tumors require resection followed by chemotherapy/radiotherapy.

HIV and Opportunistic Infections of the Stomach

Highly active antiretroviral therapy (HAART) has dramatically decreased opportunistic infections (OIs) in HIV-infected patients. However, gastrointestinal disease continues to account for a high proportion of presenting symptoms in patients with HIV infection. An abnormal endoscopic finding confirmed by histologic, microbiologic, or a combination of these studies was reported in 72 % of children. Thirty-five percent of children had an opportunistic pathogen identified endoscopically; 65 % of these pathogens were previously undiagnosed [45]. HIV-associated non-Hodgkin's lymphoma is mainly diagnosed with advanced disease. Intestinal infection with *Cryptosporidium* sp. and *Strongyloides stercoralis* can be identified in H&E tissue stained sections of nomal-looking gastric mucosa or abnormal mucosa with gastric hyperemia, edema, and erosions.

Viral Gastritis

Cytomegalovirus (CMV) infection of the stomach is described in immune-compromised and immunocompetent individuals and is the most common opportunistic infection of the stomach. It is commonly associated with nonspecific symptoms such as epigastric pain, nausea, and vomiting. Ulcerations, erosions, and mucosal hemorrhage may be seen endoscopically, although mucosa may appear normal. Cytomegalic cells in tissue biopsies are considered the gold standard for establishing a diagnosis of CMV disease. The availability of newer, rapid diagnostic techniques such as polymerase chain reaction (PCR) detection of CMV-DNA in the stools may facilitate diagnosis, as serology studies may be misleading. Usually, only supportive care is required, but treatment with ganciclovir may be considered for severe or prolonged cases. CMV is one of the agents associated with Menetrier's disease [46]. Menetrier's disease is an uncommon disease in childhood, characterized by gastric hypertrophy and hypoalbuminemia. The most common presenting symptoms are vomiting and edema in children with protein-losing gastropathy associated with cytomegalovirus (CMV) infection [46].

Posttransplant Lymphoproliferative Disease and Opportunistic Infections

While gastrointestinal lymphoma in congenital immunodeficiency disorders is rare, posttransplant lymphoproliferative disease (PTLD) of the gastrointestinal tract is not uncommon and is associated with high mortality in transplant recipients. PTLD can occur after every kind of organ transplantation, is associated with immune suppression and EBV infection, and is predominantly in the form of a B-cell lymphoma. Pediatric patients are often EBV-seronegative pretransplant which places them at high risk [47]. EBV infection and early PTLD can be subclinical or have nonspecific signs such as fever and malaise and can affect the lymph nodes, intestine, tonsils, adenoids, or eye. Gastrointestinal PTLD occurs mostly in the stomach and duodenum and may be multifocal. Pediatric patients with PTLD with abdominal involvement have increased mortality, and rates of life-threatening complications such as bleeding, perforation, or obstruction are high [48]. Endoscopy demonstrates diffuse or nodular polypoid lesions covered with erosive mucosa (Fig. 126.2).

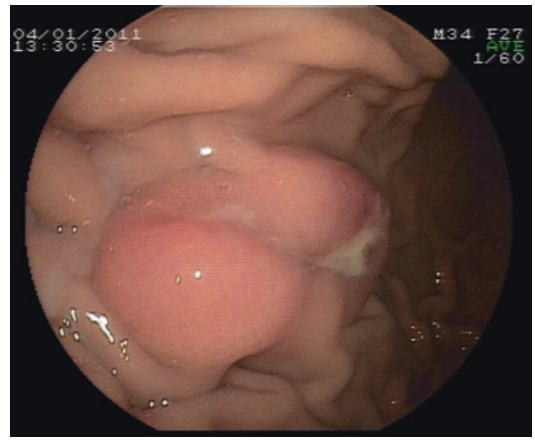

Fig. 126.2 Posttransplant lymphoproliferative disease. Gastric polypoid tumor detected in a child with upper gastrointestinal hemorrhage and fever post renal transplantation

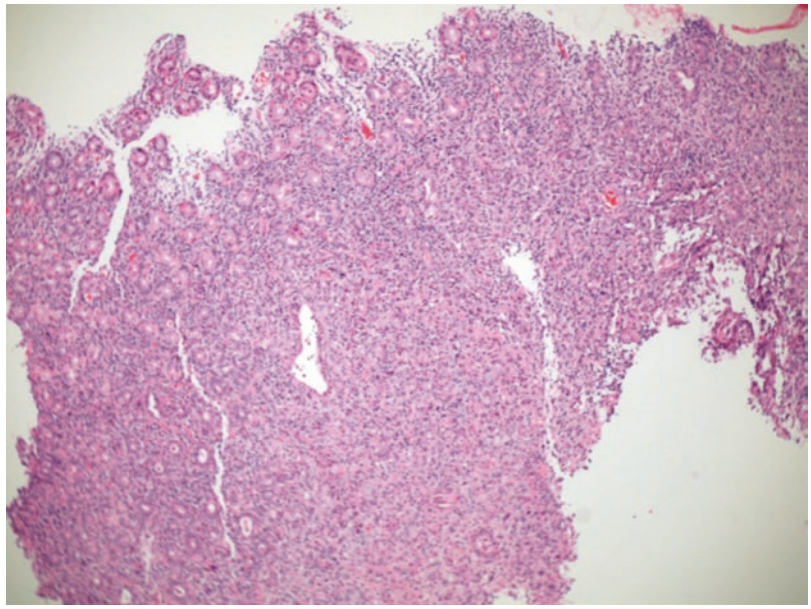

Fig. 126.3 Gastric posttransplant lymphoproliferative disease. Dense polymorphic B-cell lymphoid infiltrate expands the lamina propria (H&E ×4)

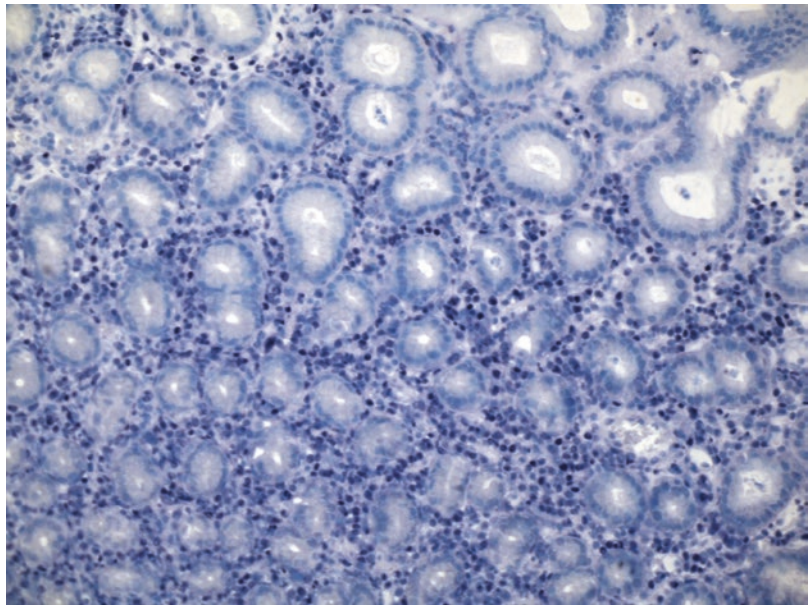

Fig. 126.4 Gastric posttransplant lymphoproliferative disease. Polymorphic B-cell posttransplant lymphoproliferative disorder – the majority of the lymphoid cells are EBER positive (EBER in situ hybridization ×20)

Mucosal biopsies reveal high-grade B-cell histology (monomorphic or polymorphic B-cell lymphoma, Burkitt lymphoma, or reactive plasmacytic hyperplasia if early [49] (Fig. 126.3). Epstein-Barr virus (EBV) in situ is demonstrated in mucosal biopsies (Fig. 126.4). Treatments include tapering of immunosuppression, viral monitoring, and antiviral interventions, surgery,

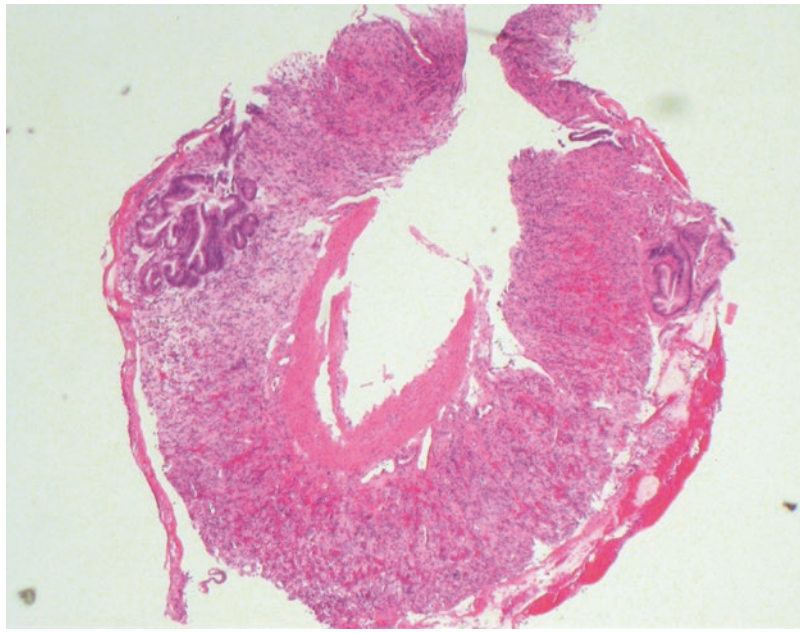

Fig. 126.5 Severe graft-versus-host disease. Complete surface epithelial denudation and subtotal loss of glands in gastric antral mucosa seen in a 14-year-old girl post bone marrow transplantation (H&E ×4)

autologous T-cell therapy, and anti-CD20 antibody (rituximab). Routine detection of increased EBV by quantitative polymerase chain reaction is used to determine the EBV viral load in the peripheral blood and is a marker for increased risk of PTLD.

In addition to CMV and EBV infections, varicella zoster-induced gastritis has been reported in the immunosuppressed posttransplant patient in the absence of herpetic skin lesions [50]. Herpetic lesions were demonstrated in the gastric antrum by endoscopy and emphasize the importance of viral-induced gastritis in the absence of skin lesions in differential diagnosis of abdominal pain in this group.

Graft-Versus-Host Disease

Accurate diagnosis of gastrointestinal graft-versus-host disease (GVHD) is important, as it contributes significantly to post-allogeneic stem cell transplant (SCT) morbidity and mortality [51]. Acute graft-versus-host disease is characterized by damage to the skin, liver, and gastrointestinal tract. Upper gastrointestinal tract disease presents with anorexia, vomiting, and dyspepsia and must be distinguished from drug or radiation toxicity. Endoscopic appearances may appear normal or show evidence of mucosal erosion, edema, and erythema and sloughing. Biopsy is required even if the mucosa appears normal, targeting the gastric fundus rather than antrum [50]. The diagnosis is made by finding mixed inflammatory infiltrate often with epithelial cell apoptosis (Fig. 126.5). Differentiation is required from the similar histological changes in viral infections such as CMV and toxicity of the pre-transplant conditioning regime. Capsule endoscopy (CE) is a novel and noninvasive means of investigating the small bowel in suspected GVHD, with a diagnostic yield of 88 % [49].

Autoinflammatory Diseases

Autoinflammatory diseases (or hereditary periodic fever syndromes) are a group of genetic disorders characterized by recurrent or persistent systemic inflammatory symptoms with

an underlying single causative gene defect [50]. They are classified as primary immunodeficiencies and must be distinguished from infectious diseases, autoimmune diseases, and other primary immunodeficiencies. Familial Mediterranean fever (FMF) is due to mutations in the Mediterranean fever (MEFV) gene and is best understood and characterized by recurring and self-limiting fever with a combination of severe abdominal pain due to peritonitis, serositis, pleurisy, arthritis, and a characteristic ankle rash. The flares typically last for up to 3 days at a time, and most patients are completely asymptomatic between attacks [51]. Gastric amyloidosis secondary to FMF in childhood has been demonstrated by deposits in endoscopic gastric biopsies, performed in view of abdominal pain [51].

Autoimmune Disease (Table 126.4)

Atrophic body gastritis or autoimmune gastritis (AG) is rare in children, but is seen in the context of other autoimmune conditions such as diabetes mellitis, autoimmune thyroiditis, and autoimmune polyendocine syndrome (APS) type 3 (a syndrome characterized by the combination of at least two autoimmune endocrinopathies) [52]. Parietal cell antibodies (PCA) are markers of AG which can be found in up to 30 % children with autoimmune thyroid disease who are positive for thyroid peroxidase antibodies (TPOAb) and in 25 % of children with type 1 diabetes mellitus (T1DM), but overt clinical AG disease is rare in children with T1DM [53]. AG results from immune-mediated destruction of specialized oxyntic glands, is restricted to the body and fundus, and shows lymphocytic infiltration of the gastric submucosa, with loss of parietal and chief cells and characteristic neuroendocrine hyperplasia [54]. The main immunological marker of AG is the presence of autoantibodies against the parietal cell (anti-parietal cell antibodies (PCA)) [55]. AG can lead to hypergastrinemia; gastrin levels reflect the degree of gastric atropy. PCA+ subjects are at increased risk for iron-deficiency anemia and atrophic gastritis, vitamin B 12 deficiency, and megaloblastic anemia. An 11-year-old boy has been reported with malabsorption and macrocytic anemia in the presence of autoimmune polyglandular syndrome (APS) type 2, which is characterized by Addison's disease, in association with autoimmune thyroid disease and/or type 1 diabetes mellitus [55].

Table 126.4 Autoimmune conditions associated with autoimmune gastritis

Organ specific autoimmune conditions associated with autoimmune gastritis	
Autoimmune gut/liver disorders	Celiac disease
	Autoimmune enteropathy including IPEX syndrome
	Autoimmune hepatitis
Autoimmune endocrine disorders	Type 1 diabetes mellitus
	Autoimmune thyroiditis
	Autoimmune polyendocrine syndrome types 2, 3

Concurrent autoimmune diseases are also common in patients with autoimmune hepatitis (AIH), an inflammatory liver disease that mainly affects females and is particularly aggressive in children. It is characterized histologically by interface hepatitis, biochemically by increased aspartate and alanine aminotransferase levels, and serologically by the presence of autoantibodies and increased levels of immunoglobulin G. It progresses rapidly unless immunosuppressive treatment is started promptly, when 80 % of patients achieve remission and long-term survival [56, 57].

Celiac disease is an autoimmune gluten-sensitive enteropathy. Lymphocytic gastritis is a histopathological finding with increased CD8+ intraepithelial lymphocytes in children with untreated celiac disease [58, 69]. IPEX syndrome is a systemic disorder characterized by a severe autoimmune enteropathy, insulin-dependent diabetes mellitus, eczema, hematological abnormalities, and eventually other endocrinopathies. The entire gastrointestinal tract can be involved and the gastric mucosa typically shows mild changes such as erythema and mucosal granularity; however, changes can be severe [60]. Histologically, the same inflammatory changes in the stomach are

observed as the small bowel, characterized by a massive mononuclear infiltrate of predominantly T lymphocytes (mainly CD4+), epithelial cell apoptosis, and crypt abscess formation which helps distinguish this immune-mediated enteropathy from other cases of protracted diarrhea and is in contrast to celiac disease with no or only a moderate increase of intraepithelial lymphocytes [61].

It is necessary to screen pediatric patients with organ-specific autoimmune diseases to estimate risk of accumulating coexistent autoimmune diseases, including autoimmune hepatitis, gastritis, type 1 diabetes, and especially autoimmune thyroiditis. Early detection of antibodies by screening at diagnosis of T1DM and regularly thereafter is advocated to take appropriate action to avoid morbidity of disease.

Other Endocrine Conditions

Zollinger-Ellison (ZE) syndrome is a rare condition characterised by a triad of severe ulcer disease, gastric acid hypersecretion, and a gastrinoma, which is usually found in the pancreas, but may be gastric or duodenal origin. ZE may be sporadic or occur in multiple endocrine neoplasia type I (MEN1)/(ZE) and, along with atrophic gastritis and pernicious anemia, is a chronic hypergastrinemic state, where the proliferative effects of gastrin on gastric enterochromaffin (ECL cells) can result in hyperplasia, dysplasia, and finally gastric carcinoid (ECL cell tumors) [62].

Patients with MEN1 develop parathyroid hyperplasia (causing hyperparathyroidism) and pancreatic endocrine tumors (PETs) as well as pituitary and adrenal adenomas.

Vascular Lesions

Hereditary hemorrhagic telangiectasia (HHT) is characterized by the presence of multiple arteriovenous malformations. Although infants are occasionally severely affected, the diagnosis usually suspected during adolescence or later with recurrent anemia because of epistaxis or gastrointestinal bleeding in relation to telangiectases in the stomach or small bowel. Initial clinical signs of HHT may be subtle; however early interventional treatment can prevent life-threatening complications of arteriovenous malformations. Accessible lesions in the stomach are suitable for treatment with endoscopic argon plasma coagulation. In severe anemia and minimal epistaxis or moderate anemia but overt gastrointestinal bleeding, capsule endoscopy [63] detected gastric and small bowel telangiectasia in adults. Recently, a combined syndrome of hereditary hemorrhagic telangiectasia (HHT) and juvenile polyposis syndrome (JPS) was described due to mutations in the SMAD4 gene [64]. JPS is an autosomal dominant condition characterized by multiple juvenile polyps in the gastrointestinal tract with a lifetime cancer risk of 39 %.

In the congenital blue rubber nevus syndrome, multiple giant cutaneous and gastrointestinal venous malformations are associated with intestinal hemorrhage and iron-deficiency anemia. Lesions occur in the esophagus, stomach, duodenum, and colon. Systemic complications include thrombosis and calcification, as well as consumptive coagulopathy and thrombocytopenia [65]. Endoscopy is the technique for diagnosis and also allows immediate therapeutic measures such as argon plasma coagulation, laser photocoagulation, sclerotherapy, or band ligation. In addition, pharmacological treatments based on corticosteroids, interferon-α, vincristine, or octreotide have been described [66].

Portal Hypertensive Gastropathy

Portal hypertensive gastropathy is commonly observed in children with portal hypertension [67]. Children with biliary atresia, the most common cause of childhood cirrhosis, have a high risk of portal hypertension in the first year of life which presents with chronic or acute bleeding. Upper gastrointestinal endoscopy is undertaken when there are clinical or ultrasonic signs of portal hypertension to determine the presence and size of gastroesophageal varices. Characteristic endoscopic mucosal appearances are a mosaic-

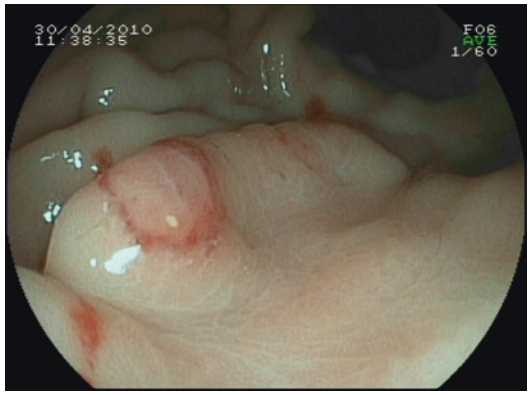

Fig. 126.6 Portal hypertensive gastropathy. Mosaic-like appearance of gastric mucosa with red marks secondary to intramural bleeding in child with biliary atresia

Fig. 126.7 Hemorrhagic renal gastropathy with multiple erosions. Gastric antrum in child with chronic renal failure and painless upper gastrointestinal hemorrhage

like pattern of the gastric mucosa and cherry-red spots or red marks are often seen in severe portal hypertensive gastropathy (Fig. 126.6). Mucosal biopsies carry a risk of bleeding, so are not usually performed; however, histologically, dilation of the mucosal and submucosal capillaries and venules without inflammation is evident. A combination of esophageal varices, red markings, and gastric varices along the cardia is independent factors associated with bleeding and children should receive primary prophylaxis of bleeding, with modalities such as variceal banding, local injection therapy, TIPS, shunt surgery, and liver transplantation [68].

Miscellaneous Conditions

Renal Gastropathy

Feeding problems, anorexia, and vomiting are common in infants and children with chronic renal failure (CRF) and play a major role in the growth failure often found in this condition. Although dyspepsia and upper gastrointestinal bleeding with gastric erosions, antral gastritis, and/or ulcers appear to be relatively rare in children with renal failure compared to adults, symptoms have been reported in 40 % of children with CRF [69]. Hemorrhagic gastropathy is most common, while peptic ulcers are atypical but are likely to be painless and present with bleeding (Figs. 126.7 and 126.8). Mechanisms are multifactorial and may involve a complex disorder of gastrointestinal motility related to reduce renal clearance of hormones such as gastrin, cholecystokinin, and autonomic nervous system dysfunction secondary to uremia and acidosis [70]. Cystinosis is an autosomal recessive condition with multiorgan involvement, particularly renal damage, due to deposition of cystine crystals. Gastrointestinal symptoms may relate to cystine deposits or secondary to treatment with cysteamine (Cystagon TM) treatment, an agent which lowers intracellular cystine and reduces the rate of development of thyroid failure, progression of end-stage renal failure, and the need for transplant in children, as well as improving growth potential [71]. Cysteamine causes hypergastrinemia and ulcers; hence symptoms in affected children are often acid mediated and improve with omeprazole.

Cardiac Disease and Critical Illness

Abdominal pain and vomiting with gastritis can be the sole manifestation of myocarditis and a cardiac cause for vomiting should be considered if hypotension is refractory to rehydration therapy [72]. Gastroesophageal reflux and dysmotility are common in children with congenital

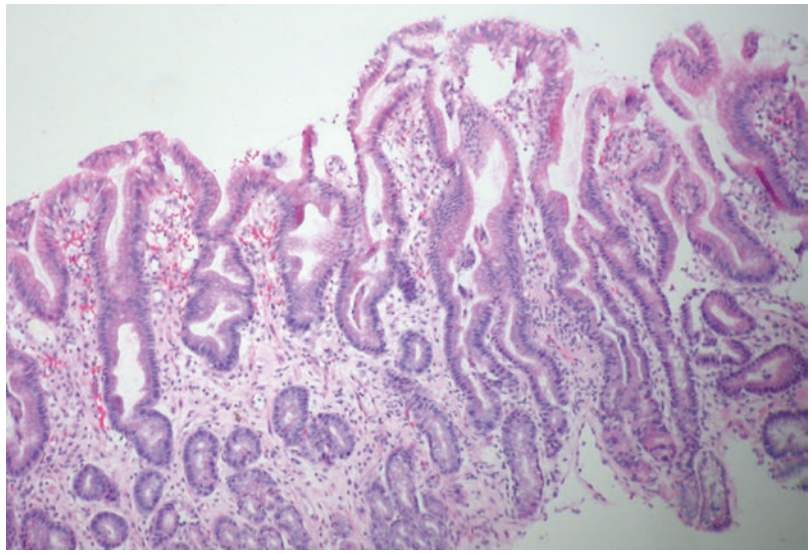

Fig. 126.8 Renal gastropathy. Chronic inflammation with reactive changes without *H.pylori* infection. Mild increase in cellularity, focal hemorrhage, telangiectasia, and foveolar hyperplasia (H&E ×4)

cardiac disease [73]. Critically ill children, including preterm infants who experience severe physiological stress such as respiratory failure, hepatic failure, multiorgan failure, sepsis, head injury, hypotension, trauma, burns, and the use of corticosteroids, are at risk of developing stress-related mucosal disease of the stomach and bleeding. Patients at high risk of stress-related bleeding should receive acid suppression.

Motor Disorders of the Stomach

Gastrointestinal motor dysfunction may result from disorders at every anatomic level of extrinsic innervation. A number of systemic diseases are associated with motility disorders of the stomach (Table 126.5) that interfere with both the normal receptive function (where the proximal stomach relaxes to accommodate a meal) and the propulsive function (where gastric contents are emptied into the pylorus by forceful gastric contractions coordinated with contractions of the duodenum) [74].

When delayed gastric emptying occurs in the absence of mechanical obstruction, the term idiopathic gastroparesis is used. The motor mechanisms associated with gastroparesis are not completely understood, but may involve degenerative myopathic (smooth muscle) or neuropathic processes, where involvement of the autonomic system is the relevant mechanism and gastric enteric neurons, and/or interstitial cells of Cajal may be affected.

Vomiting is common in children with disorders of the central nervous system (CNS) such as cerebral palsy. This is usually ascribed to gastroesophageal reflux (GER), but may represent a wider problem of foregut dysmotility related to abnormal modulation of the enteric nervous system (ENS) by the CNS or to involvement of the enteric nervous system by the same process affecting the brain [75]. Following fundoplication, many patients with CNS disorders continue to have symptoms possibly related to gastric dysrhythmias, the effects of which may be unmasked by fundoplication.

Conditions Associated with Gastroparesis

Down's syndrome (DS) is the most common chromosomal abnormality and up to 77 % of DS children have associated gastrointestinal abnormalities, which may be structural or functional in nature. This suggests that developmental disor-

Table 126.5 Systemic disease and gastroparesis

Mitochondrial disorders	
Cardiac and renal disease	

ders of the ENS are probably fundamental to the functional gastrointestinal disturbances encountered in patients with DS [76]. Feeding abnormalities have been reported in female patients with Rett's syndrome [77]. Oropharyngeal dysfunction and gastric dysmotility including diminished peristalsis or atony were apparent on videofluoroscopy. Children may warrant early diagnostic evaluation and intervention strategies to improve nutritional status. Delayed gastric emptying commonly occurs in preterm infants with immaturity of the gastrointestinal tract. Noonan's syndrome is a common dysmorphic syndrome in which failure to thrive and gastrointestinal symptoms are frequent. Electrogastrography (EGG) showed fasting frequency gradient loss along the stomach fundus and pylorus with antral postprandial frequency loss, reminiscent of 32–35-week preterm patterns [78]. Feeding problems appear to be the result of delayed gastrointestinal motor development and resolve as gut motility matures. Symptoms of dyspepsia, nausea, or vomiting observed in hypothyroidism usually resolve with treatment of the thyroid disease [79]. In children with insulin-dependent diabetes mellitus complicated by dyspeptic symptoms and gastroparesis, domperidone is superior to cisapride in reversing gastric emptying delay and gastric electrical abnormalities, as well as in improving dyspeptic symptoms and diabetic metabolic control [80]. The mechanisms involved include autonomic neuropathy, acute hyperglycemia, and abnormalities in gastrointestinal hormones and neuropeptides. Dysmotility of the upper gastrointestinal tract has been reported in children with Hirschsprung's disease. Adult patients with Hirschsprung's disease have an abnormal pattern of gastric emptying, indicating persisting involvement of the upper gastrointestinal tract [81]. Gastric dysmotility is commonly reported in patients with cystic fibrosis [82, 83]. Real-time ultrasonography has demonstrated significantly prolonged gastric emptying time and reduced antral distension in patients with CF and that H2 receptor blockers are more effective than prokinetics in improving dyspeptic symptoms and gastric emptying and distention [84].

Gastroparesis may develop in apparently health children and the symptoms may be preceded by flu-like illness or rotavirus infection [85]. Gastric emptying was delayed in children with acquired gastroparesis evaluated with scintigraphy, and antroduodenal manometry confirmed postprandial antral hypomotility. All children recovered within 6–24 months. A number of other infectious organisms have

been reported to cause gastroparesis including Epstein-Barr virus and varicella and may be seen in autonomic nervous system dysfunction of Guillain-Barré syndrome.

Mitochondrial Disease/Cyclical Vomiting

Mitochondrial disorders usually present with neurological symptoms or myopathic features. Although gastroparesis may occur as part of a mitochondrial disorder, only in a minority are they an early sign [86]. Abnormalities in gastrointestinal motility were reported as an early presenting sign of disorder of the mitochondrial electron transport chain enzymes of oxidative phosphorylation (OXPHOS) [87]. Mitochondrial dysfunction and disease-associated mitochondrial deoxyribonucleic acid sequence variants are believed to be present in most cyclic vomiting syndrome cases; these variants are rarely identifiable on "standard" mitochondrial deoxyribonucleic acid testing. Variants of cyclical vomiting have been reported in Kearns-Sayre syndrome [88].

Complex regional pain syndrome type I (CRPS-I), previously known as reflex sympathetic dystrophy (RSD), is characterized by gastrointestinal dysmotility, migraine, cyclic vomiting and chronic fatigue, abnormally intense and prolonged pain, allodynia, and autonomic nervous system changes (i.e., swelling, skin color and temperature changes, and altered perspiration) that usually appear following a "noxious" trigger such as trauma or surgery. Maternally inherited mitochondrial disease may be a cause CRPS-I, especially in children who present with other manifestations of dysautonomia [89]. Familial dysautonomia (FD) is an autosomal recessive disorder characterized by autonomic and sensory neuropathy, affecting the ocular, gastrointestinal, pulmonary, orthopedic, vasomotor, and neurologic systems. Lack of tears and sweating, orthostatic hypotension, and internuclear ophthalmoplegia are characteristic. The gastrointestinal problems include dysphagia, gastroesophageal dysmotility, gastroesophageal reflux, constipation, and vomiting crises [90, 91]. Maintenance of satisfactory nutrition and quality of life may be a challenge in patients with persistent or progressive gastroparesis. Gastrojejunostomy or jejunostomy may be the treatment of choice [92].

Disorders Affecting Gastroduodenal Smooth Muscle

Systemic Sclerosis

Upper gastrointestinal endoscopy in patients with systemic sclerosis without symptoms of gastrointestinal tract involvement reveals reflux esophagitis and gastritis in the majority of patients [93]. Dysmotility appears to be due to accumulation of extracellular matrix in the submucosa and muscularis that gives thicker gastric antral wall as visualized by endoscopic ultrasound (EUS) of the esophagus [94]. Abnormal gastric emptying has been identified in patients with polymyositis or dermatomyositis but is seldom symptomatic.

Myotonic and Muscular Dystrophy

Myotonic dystrophy is associated with dysmotility which has considered to be due to esophageal rather than gastric dysmotility. However, gastric emptying may be abnormally delayed in myotonic dystrophy patients, even in absence of dyspeptic symptoms [95]. Although muscular dystrophy (MD) (including Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD)) affects primarily striated muscles, smooth muscle cells of the gastrointestinal tract may also be involved. Gastric emptying was reduced in children early in the course of the disease, when gastrointestinal symptoms are absent and skeletal muscle symptoms are minimal [96]. Gastric volvulus is an uncommon condition in the pediatric age group. The cause of gastric volvulus may be idiopathic or secondary to a congenital condition and has been reported due to ligamentous laxity in Ehlers-Danlos syndrome (EDS). These are a heterogeneous group of inherited connective tissue disorders characterized clinically by skin fragility, skin hyperextensibility, joint hypermobility, and excessive bruising. Recent advances in the molecular analysis of EDS have identified defects responsible for EDS

such mutations in the collagen genes I and IV [97, 98].

Spinal muscular atrophy is a neurodegenerative disease that requires multidisciplinary medical care [99]. Weakness may affect several organ systems: respiratory, due to restrictive lung disease; gastrointestinal, in terms of dysphagia and constipation; and orthopedic, with progressive deformities Progressive respiratory muscle weakness with bulbar involvement is the main cause of morbidity and mortality in type I and severe type II spinal muscular atrophy. Since noninvasive positive-pressure ventilation techniques allow longer survival, gut motility problems are emerging that may be challenging to manage [100].

Management of Gastroparesis

The main goals of treatment for gastroparesis are to alleviate symptoms, to maintain adequate fluids and nutrition, and to resume sufficient oral intake of liquids and solids. Intake may be modified to provide small-volume, low-fat, low-fiber liquid nutrition. If dysmotility is progressive continuous rate, enteral gastric feeds are often necessary and jejunal feeds or parenteral nutrition in the presence of foregut dysmotility. Prokinetic drugs such as metoclopramide, erythromycin, and the selective 5-HT4 agonist tegaserod are used to improve gastric motility. Ondansetron and alimemazine may be used when nausea and retching are debilitating symptoms [104]. Surgical procedures such as fundoplication, placement of gastrostomy or gastrojejunostomy feeding tubes [100], gastric electrical stimulation [110 Hyman P], or botulinum toxin A injected into the pyloric sphincter [105] are employed for patients with chronic intractable nausea and vomiting secondary to gastroparesis unresponsive to dietary and medical treatment.

Allergic Disorders

Allergic gastrointestinal motility disorders are common in infancy and early childhood. Cow's milk protein allergy may present with a range of motility problems including gastroesophageal reflux and gastric dysrhythmia/delayed gastric emptying [101]. The exact mechanisms of delayed-onset allergy in motility disorders are being unraveled with a focus on interaction of inflammatory cells such as mast cells and eosinophils with the enteric nervous system [102]. In the human stomach, studies have demonstrated that mast cells degranulate minutes after cow's milk exposure, with associated disruption of normal gastric peristalsis [102]. The ability of the stomach to distend and contract rhythmically is reduced which manifest as inability to accommodate large volumes and delayed gastric emptying [103]. Complete exclusion of the causative antigen, cow's milk with replacement with a partially hydrolyzed, or amino acid formula is recommended.

Gastric Neoplasia

Gastric polyps may represent an underappreciated clinical abnormality in Menke's disease. An infant with Menke's disease presented with gastrointestinal bleeding from solitary gastric polyps. Histopathologic examinations showed submucosal vascular ectasia with mucosal hyperplasia, edema, and ulceration [106]. Hyperplastic esophagogastric polyps occur in the context of neurofibromatosis type 1 (NF-1) [107]. Histologically these polyps show hyperplastic gastric foveolar and/or squamous epithelium with inflamed stroma. Familial adenomatous polyposis (FAP) is the most common inherited polyposis syndrome characterized by the development of hundreds of colorectal adenomatous polyps [109]. 50% had gastric fundal gland polyposis, hamartomatous gastric polyps, and Peutz-Jeghers syndrome (PJS), e.g. in a 2-year-old with STK11 gene, illustrating the importance of considering early screening, along with close clinical review for detection of complications [108].

Mucosa-Related Gastropathology: The Upper Gastrointestinal Tract and the Microbiome

127

Doron D. Kahana and Timothy Van Natta

Extending Our View of Self

Microbiome in Health and Disease

Over the past two decades, we have learned a lot about the biological continuum of life. New molecular techniques allow the detection of microbial DNA in organs that were previously deemed uninhabitable, such as the esophagus and stomach. Many bacteria are fastidious, slow growing, and difficult to cultivate, and thus prior studies overlooked a large number of bacteria. Advancement in genomic analysis of bacterial 16S ribosomal DNA (rDNA) by high-throughput pyrosequencing technique has opened the door to the detection of thousands of microbial species living within us, providing a new perspective on our place in the universe. Turns out, our health is dependent not only on the health of human cells but also the health of the sum collection of all microorganisms living within our body, otherwise called the *microbiome*. With this understanding, a new *germ theory* of disease has emerged, one where disease is not secondary to a single, specific microbe, but rather to the interaction and crosstalk between microbes and their host organism.

The classic germ theory of disease, initially developed by Robert Koch in the nineteenth century, described an infectious disease as the direct consequence of a single pathogen (e.g., tuberculosis, anthrax, HIV) [1]. The new germ theory of disease denotes a process of an aberrant microbial community triggering a host immune response, resulting in inflammation and consequent tissue damage (e.g., IBD, diabetes, heart disease, cancer) [2]. This new theory of disease requires that we further our understanding of the symbiotic relationship between microbes and humans as commensals and hosts.

The microbiome is the aggregate biological load of our entity, more prokaryotic than eukaryotic, with microbial cells outnumbering our own by about tenfold. Microbial genes (*metagenome*) outnumber human genes by two orders of magnitude. Thus, we can consider ourselves as a composite of many creatures, with a genome that is an amalgam of many more than just human genes. The microbiome endows our bodies with physiologic capacities that evolution did not bestow upon us; the symbiotic relationship between our body and microbes forms a barrier that protects us from invaders and maintains homeostatic balance with our environment. Commensal bacteria partake in many immunological tasks, such as induction of oral tolerance, training of the adaptive immune system, and stimulation of mucosal products, including

secretory immunoglobulin (Ig) A. A state of normal microbial communities is termed *eubiosis* and of abnormal communities is termed *dysbiosis*.

The human gastrointestinal (GI) tract is predominantly a bacterial ecosystem, although archaea, yeast, protozoa, viruses, and parasites may be found. Microbial cell densities in the colon are the highest recorded for any known ecosystem (10^{11}–10^{12}/ml contents). The vast majority of the phylotypes belong to two divisions of bacteria—*Bacteroidetes* (48 %) and *Firmicutes* (51 %). *Proteobacteria*, *Verrucomicrobia*, *Fusobacteria*, *Cyanobacteria*, and *Spirochaetes*, among others, share the remaining 1 %. The stomach and duodenum harbor lower numbers of microorganisms, typically less than 10^3 bacterial cells per gram, as acid, bile, and pancreatic secretions kill most ingested microbes; moreover, propulsive motor activity in the intestine (i.e., migrating motor complex, MMC) impedes colonization of the lumen. A progressive increase in numbers of bacteria is normal along the jejunum and ileum, from approximately 10^4 per gram of intestinal contents proximally to 10^7 distally, with a predominance of Gram-negative aerobes. This is in contrast to the colonic predominance of obligate anaerobes such as *Clostridia* and *Bacteroides*, which are adept at metabolizing proteins, producing short-chain fatty acids (SCFA) and excreting toxins, such as ammonia, amines, and phenols. The putrefaction of proteins is associated with several disease mechanisms, most notably the pathogenesis of hepatic encephalopathy in patients with liver failure, treatment of which is often mediated via modulation of the enteric flora (i.e., with antibiotics, prebiotics, and probiotics) [3].

Several other disorders are directly associated with changes in the composition and/or metabolic function of the enteric flora [4, 5]. Perhaps the most clinically demonstrable entities are antibiotic-associated diarrhea and *Clostridium difficile* colitis. Other disease states are indirectly related to changes in the intestinal ecology; notably, the initiation of colon cancer may occur through microbial production of by-products that act as carcinogens and pro-carcinogens (e.g., indoles, nitrites). High consumption of fat and red meat, particularly processed and cured meat, is believed to trigger the genetic mechanism of colorectal cancer, while consumption of fruits and vegetables, whole grain cereals, fish, and calcium is associated with reduced risk [6]. Dietary and genetic factors interact through the microbiome and influence carcinogenesis via modulation of the metabolic activity of colonocytes [7].

Microbiota and Inflammation

Much of our current understanding of the function of the microbiome comes from studies of *gnotobiotic* animal models, such as mice. The word "gnotobiotic" stems from the Greek words "gnosis" and "bios," meaning "known life"; gnotobiotic animals are reared in a germ-free (GF) laboratory environment and introduced a defined microbiota for experimental reasons. Comparison of GF and normal mice has shown that intestinal microbiota help regulate host energy homeostasis [8]. Some microbes are more efficient at extracting energy from indigestible components of our diet, namely, *fiber* such as cellulose, resistant starch, oligosaccharides, and various glycoproteins. Obesity, for example, has been associated with an increased number of colonic *Firmicutes*, which are particularly efficient in extracting calories from food [9]. By-products of carbohydrate fermentation, specifically short-chain fatty acids (e.g., butyrate, acetate, propionate) and carboxylic acids (e.g., lactic acid), are metabolized on the mucosal level and in the liver and are capable of salvaging several hundreds of calories per day in a healthy human colon [10, 11]. Microbiota can synthesize molecules that are used by their host as nutrients, such as quinones (vitamin K), niacin, biotin, pantothenic acid, folic acid, and cyanocobalamins (vitamin B12) [12]. They also metabolize *xenobiotics*, which are synthetic chemicals, such as antibiotics and other drugs, influencing their bioavailability and contributing to their steady-state metabolism. Lastly, microbiota impact enterocytes and colonocytes directly, through an intricate and evolutionarily conserved

manner, affecting gene expression of various proteins (e.g., nutrient transporters, mucoid glycoproteins) [13, 14].

It is no surprise that an aberrant microbiota, or *dysbiosis*, can induce disease. Dysbiosis can manifest as the colonization of a single, potential pathogen, such as *Helicobacter pylori* or *C. difficile*, which can become virulent and predispose the host to inflammation and disease. Dysbiosis can also manifest as an aberrant ecology that lacks diversity or *mutualism*, such as in the case of inflammatory bowel disease (IBD), in which the inflammatory response is exaggerated and dysregulated toward an aberrant community of microbes, and not just a single pathogen [15]. In Crohn's disease (CD) and ulcerative colitis (UC), mucosal T lymphocytes are believed to overreact against antigens that are commonly found on commensal bacteria and yeast, such as the outer membrane protein C (Omp-C) of *E. coli* and the flagella component CBir-1. Patients with IBD have a measurable alteration in their bacterial communities compared to healthy controls, and the loss of oral tolerance to a range of dietary antigens is strongly implicated in aggravating of the disease [16]. Gut microbiota are believed to invoke other medical conditions beyond IBD, such as diabetes mellitus, rheumatoid arthritis, asthma, and cardiovascular disease [17].

Intestinal microbiota interact with mucosal epithelial cells in a fashion that creates crosstalk between luminal contents and host innate and adaptive immune responses [18, 19]. Mutualism between host and commensals is vital to health, with activation of innate host defense mechanisms resulting in end-organ inflammation and damage. On the molecular level, our immune system recognizes and engages conserved molecular patterns in the environment via *pattern-recognition receptors* (PRR), such as Toll-like receptors (TLR) and nucleotide-binding oligomerization domain (NOD) receptors. PRR have been shown to be extremely important in mediating inflammation and repair [20]. They converge signals that result in regulation of transcription factors, such as nuclear factor-kappa B (NF-kB), which regulate the transcription of genes responsible for the synthesis of inflammatory molecules (e.g., tumor necrosis factor, cytokines, leukotrienes). Intestinal cells express PRR and thus can function as antigen-presenting cells, activating innate immunity. And so the entire intestinal epithelial layer is an immune organ, alive with bacteria feasting on food matter, other bacteria, or their host. It is only natural for a host to evolve toward mutualism with its microbiome.

Microbial impact on the immune system is mediated via organized lymphoid structures within the small intestinal mucosa—the gut-associated lymphoid tissue (GALT). GF animals have been shown to have low density of GALT and low levels of circulating Ig [21]. Following exposure to microbes, the number of mucosal lymphocytes expands, germinal centers and Ig-producing cells appear, and there is a significant increase in serum Ig levels. Commensal bacteria elicit a different cytokine response than pathogenic bacteria, involving induction of regulatory pathways of the immune system (e.g., transforming growth factor (TGF)-β and interleukin (IL)-10) [22]. For example, *Lactobacillus* strains have been shown to downregulate the spontaneous release of tumor necrosis factor alpha (TNF-α) by inflamed tissue and balance the inflammatory response induced by *Escherichia coli* [23]. It is now known that mutualism helps shape host cellular differentiation and proliferation, especially on the epithelial layer. Mucosal injury, for example, is further sustained in the absence of bacteria or with disruption of the communication channel, as noted in TLR-4 knockout mice models of IBD [24].

Further evidence supports the vital role of microbes in the development and balance of the immune system. An important example is embodied by the *hygiene hypothesis*, which claims that the increased incidence of allergy and immune-mediated diseases noted in Westernized societies may, to some extent, be explained by aberrant microbial exposure early in life [25, 26]. The hypothesis suggests that inability to form mutualism between host and microbes can lead to a maldeveloped immune system showing exaggerated immune responses, such as with asthma, atopic dermatitis, allergic rhinitis, multiple sclerosis, and others. The hygiene hypothesis is supported

by epidemiological studies noting lower allergy and asthma rates in developing countries relative to their developed counterparts. Moreover, therapeutic benefit with the use of probiotics to treat atopic disease has been reported [27]. And although the evidence is circumstantial and does not prove causation, animal data is more convincing of an immune dysregulatory link.

In summary, we must extend our view of self beyond human cells, even beyond human genes, and include the vast microbial world that engulfs our body. Its relation to health and disease is a new concept in the evolution of medicine, and we must consider the effects our biology and environment have on a delicate symbiotic balance.

Microbiota of the Esophagus and Stomach

Reflux Esophagitis and Barrett Esophagus

The anatomic junction between the distal esophagus and stomach endures the constant threat of gastric content reflux. Stomach contents are corrosive and can cause inflammatory changes in the stratified squamous epithelium of the esophagus, including hyperplasia of the basal layer and necrotic erosions. The correlation between gastric reflux and esophageal adenocarcinoma is clinically supported by the observed increased incidence of both the cancer and gastroesophageal reflux disease (GERD). Since the 1970s, we have witnessed a sixfold increase in the incidence of esophageal cancer following a similar increase rate in the prevalence of GERD [28–30]. Barrett esophagus (BE), considered to be the precursor condition to esophageal adenocarcinoma, is found in up to 12 % of patients undergoing endoscopy for symptoms of GERD [31, 32]. And although all cases of adenocarcinoma are believed to be preceded by BE, only 5 % of patients with BE appear to develop adenocarcinoma [33].

Recent studies have shown that up to 100 different commensal bacterial species may reside in the normal distal esophagus at any given time [34]. Similar to the rest of the gut, members of at least five phyla are represented: *Firmicutes* (majority), *Bacteroidetes* (second most common), *Actinobacteria*, *Proteobacteria*, and *Fusobacteria* (Table 127.1). Other phyla, such as *Spirochaetes* and *Deferribacteres*, are present in the oral cavity but not commonly identified in the distal esophagus, indicating that environmental conditions are different in the two anatomical areas. Although molecular detection technique cannot distinguish colonizing or living bacteria from naked bacterial genomes, studies suggest that the esophageal microbiota is a relatively stable and unique community and not merely composed of organisms in transit.

The presence of *H. pylori* in esophageal samples of some patients with GERD confirms that gastric bacteria can be brought into the distal esophagus by reflux. *H. pylori* colonization of the esophagus is less likely, so its presence is believed to be migratory. Several studies of patients with BE report prominent changes in ecological communities of the esophagus relative to normal controls [36, 38, 39]. Patients with BE are known to have a high prevalence of esophageal motility disturbances, and weak LES pressure and poor contractility contribute to GERD and delayed clearance of refluxate [35]. These motility disturbances may predispose to bacterial overgrowth in the distal esophagus, leading to further disturbance of the LES and further increase of reflux; thus, a positive-feedback loop is formed, between reflux and mucosal injury.

Yang et al. conducted a study of patients with GERD and BE compared to controls and classified the esophageal microbial community into two enterotypes: type 1 was rich in facultative anaerobic Gram-positive *Firmicutes*, especially *Streptococcus* phylotypes (79 %); type 2 was composed of only 30 % *Streptococcus* and was characterized by a greater number of obligate anaerobes, such as *Bacteroidetes* phylotypes (e.g., *Prevotella* 13 %) and Gram-negative *Proteobacteria* (e.g., *Haemophilus* 6 %, *Neisseria* 5 %). Enterotype II microbial community showed a significant association with GERD (odds ratio, OR >15) [36] (Fig. 127.1). The authors conclude that enterotype 2 microbiota might play a causative role in GERD. They argue that abnormal

lower esophageal sphincter (LES) pressure and esophageal acidification during transient LES relaxation are critical and that the etiology of abnormal LES function is incompletely understood and might actually stem from esophageal dysbiosis [37].

Macfarlane et al. corroborated the above finding and also identified bacterial species that produce nitrosamines in patients with BE [38]. The authors provided evidence to support the hypothetical correlation between the presence of bacteria that promote nitrosamine production and consequent tissue metaplasia and dysplasia. Esophageal biopsies and aspirates were collected from 14 individuals, 7 with known BE and 7 without BE but with upper GI symptoms. Bacteria were cultivated and measured by PCR, with 46 bacterial species belonging to 16 genera identified; 18 species from 7 subjects without BE and 38 species from 7 patients with BE, and 10 species common to both groups. Similar to the study by Yang, Macfarlane found that the normal esophageal community consists of a majority of lactobacilli and streptococci (*Firmicutes*) and that patients with BE had higher counts of Gram-negative anaerobic bacteria, such as *Prevotella* (*Bacteroidetes*) and *Neisseria* (*Proteobacteria*). Lactobacilli were only detected in mucosal samples from the control group; conversely, *Fusobacterium*, *Megasphaera*, *Neisseria*, and *Campylobacter* species were only detected in patients with BE. Interestingly, yeast (e.g., *Candida* and *Saccharomyces*) were found in aspirates from both groups, but only BE patients had yeast present within the mucosa. Moreover, high levels of *Campylobacter* species (*Proteobacteria*), which reduce nitrate and manufacture nitrosamines, were reported to colonize 4 of 7 (57 %) patients with BE and none of the control subjects. *Campylobacter concisus* was

the most prevalent nitrosamine-producing species detected and occurred in the highest numbers.

Osias et al. in a study using only cultivation and staining techniques noted the prominence of *Firmicutes*, specifically streptococcus species, and reported that patients with BE had higher counts of bacteria than non-BE patients [39]. Moreover, an association was measured between progressively higher bacterial count and higher grades of mucosal dysplasia ($P=0.028$). Thus, consistently among the above three studies, there appears to be a putative role for bacteria in the development of chronic inflammation and BE, with progression to dysplasia and cancer.

In summary, patients with BE harbor a unique, mucosal community of bacteria and yeast that is different from control subjects. It is more diverse and contains a higher density of microbes, fewer streptococci and lactobacilli, and other Gram-positive facultative aerobes, and more Gram-negative anaerobic and microaerophilic bacteria, such as *Prevotella*, *Neisseria*, and *Campylobacter*. The capacity of species like *Campylobacter* to produce nitrosamines makes them ideal candidates for pathogenic activity in BE. Nitrate reduction and production of nitrosamines from nitrites and secondary amines, which often exist in the form of protein, can occur only under strongly acidic conditions, which is consistent with the environment of patients with GERD and BE. These chemicals are known to be highly carcinogenic and might be the responsible agents for the disease-to-cancer axis in GERD.

Megaesophagus and Esophageal Atresia

Achalasia of the LES and esophageal motor disturbances, such as in Chagas disease, induce progressive dilatation of the organ, causing megaesophagus and resulting in poor content evacuation and chronic stasis. Stagnated contents provide a medium for bacterial growth, which likely contribute to some of the comorbidities of megaesophagus, such as recurrent aspiration pneumonia and chronic pulmonary infections, as well as infectious complications related to esophageal perforation during surgical or endoscopic procedures [40, 41]. As noted above, bacterial overgrowth is believed to favor development of epithelial dysplasia, the first step in the development of cancer, and indeed cancer is 33 times more frequent in patients with megaesophagus than in the general population [42, 43].

Pajecki et al. conducted a prospective study of the bacterial content of 15 patients with Chagas megaesophageal disease, age range 24–74 years (mean 49.1), and compared them to a control group of 10 patients evaluated by upper endoscopy for general dyspeptic complaints [44]. While both groups showed a predominance of aerobic Gram-positive and anaerobic bacteria, cultures were positive much more frequently on aspirates from diseased esophagus than from controls (93 % vs. 40 %, $p<0.05$). *Streptococcus* (Gram-positive, lactose-fermenting, aerobic Firmicute) appeared in all positive cultures in both groups; *Veillonella* (Gram-negative, anaerobic Firmicute) was identified in 73.3 % of the patients with megaesophagus versus none of the control patients. Concentrations of microbes were 10^1–10^2 in the control group and 10^1–10^5 in the megaesophagus group, with statistical significance observed for specific organisms.

The finding of *Streptococcus* is consistent with other studies of esophageal and oropharyngeal microbiota; thus, it is likely an important component of the microbiota in the esophagus as well as oropharynx. With stasis of contents, as with megaesophagus, swallowed microorganisms proliferate and thrive on stagnant food matter, creating an environment with low oxygen content that is propitious for anaerobic, Gram-negative bacteria, such as *Veillonella*, which is abnormal for the esophagus. It is believed that such colonization predisposes patients to worse respiratory infections due to aspirative phenomena of more harmful anaerobes. This is corroborated by the finding of pulmonary disease in 34 % of patients with Chagas megaesophagus on autopsy [45]. A different study reported a high incidence of *Mycobacterium fortuitum* in a similar cohort of patients [46].

The increased prevalence of esophageal squamous cell carcinoma in patients with Chagas disease may be related to increased concentration of microbial by-products within the esophagus, such as nitrosamine compounds from protein putrefaction, as well as stasis of dietary carcinogens within the esophagus [47].

Data on the microbial composition of patients with esophageal atresia (EA) is extremely sparse. A study by Bayston et al. in 1984 of the fecal flora in neonates with EA is the only available microecological study of patients with EA [48]. It reported that in feces of newborns with EA, culture technique isolated *Staphylococcus albus* (aka *S. epidermis*) most frequently, as well as klebsiella, enterococci, and clostridia. Relevant information for our purposes was that no bifidobacteria were found in fecal cultures or seen on Gram stain until after the neonates received their first feed (which was often delayed and introduced after placement of a gastrostomy tube). Bifidobacteria are an important constituent of the microbiome and the predominant bacteria in nursing infants; data have implicated their importance for immune development and possible prevention of inflammatory and atopic disorders [49, 50]. An important message from Bayston's study is that neonates with EA may not be able to make enteric vitamin K, so an additional dose at 2 or 3 weeks of age was recommended, particularly if further surgery is planned. Interestingly, the authors mentioned the implication of neonatal dysbiosis on immune development, with possible impairment of the opsonization and complement system and increased risk for infectious complications. Moreover, the authors recommended against prophylactic or empiric antibiotics, as these were shown in their study to eradicate the intestinal flora and further delay proper colonization.

Children with EA are now reaching adulthood in larger numbers, and many of them experience functional problems with both GI and respiratory systems after the initial postoperative period [51]. Several series on long-term follow-ups of adolescents and young adults with EA after surgical repair reported persistent respiratory symptoms in a large number of patients, including bronchitis, brassy or chronic cough, pneumonia, and wheezing [52, 53]. Almost a quarter of the children with EA are found to have clinically relevant tracheomalacia; more than two-thirds experience recurrent respiratory tract infections in the first 5 years of life; and about a fourth require prophylactic antibiotics [54]. The morbidity from respiratory disease appears to abate as patients get older, but approximately 40 % of adolescents and 10 % of adults continue to have respiratory symptoms [55, 56]. Wheezing appears to be the most frequent symptom beyond childhood, with 22 % of adolescents and 16 % of adults reporting asthma; airway hyperresponsiveness to histamine is reportedly increased in 40–78 % of patients. Airway remodeling likely contributes to airway obstruction, with an obstructive defect measured in 30–57 % of subjects. However, bronchial biopsies performed in children with EA demonstrated a thickened basal membrane, similar to asthma; thus, both inflammatory processes and intrinsic airway remodeling are likely to contribute to the obstructive phenomenon noted in patients with a history of EA. The role of changes in the microbiome (i.e., the delayed neonatal colonization of bifidobacteria in lieu of delayed feeding) as possible contributor to inflammatory processes has not been investigated.

In summary, megaesophagus and EA are conditions that result in esophageal dysmotility, stasis of food, and propensity for aberrant microbial communities. Patients with megaesophagus are clinically noted to be prone to respiratory infections and esophageal cancer with dysbiosis possibly playing a causal role. Recurrent respiratory infection and other respiratory symptoms, such as cough and wheezing, are also noted in patients with EA. It is unknown whether esophageal stasis and/or dysbiosis contributes to these symptoms, although the delayed colonization of the GI tract due to delayed feeding in these patients is hypothetically an indirect connection.

Gastritis and Gastric Cancer

It is well recognized nowadays that *H. pylori*, a proteobacterium, is a significant player in the human gastric microbial ecosystem. *H. pylori* is

believed to be indigenous to the stomach and has coevolved with humans for at least 50,000 years [57]. In the past, traditional methods for cultivating gastric aspirates or mucosal biopsies have identified firmicutes, proteobacteria, actinobacteria, and fusobacteria, as well as low abundance of yeast. Newer molecular methods have led to data suggesting that *H. pylori* is a common gastric colonizer and recognize a native population of bacteria present in the stomach, normally in low concentrations of 10^1–10^3 CFU/mL. A study by Bik et al. on patients with symptomatic upper GI disease reported the presence of 128 bacterial phylotypes among 8 phyla, with *H. pylori* sequences present in 19 of 23 patients tested; 12 of the 19 also tested positive for *H. pylori* using conventional methods [58]. This latter group demonstrated a relative lack of non-proteobacteria phylotypes, especially bacteroidetes, compared with *H. pylori*-negative subjects, meaning that *H. pylori* and other proteobacteria had become dominant colonizers. The authors conclude that their findings confirm the presence of distinct bacterial communities that have adapted to the specific habitat in the stomach.

These findings were corroborated by Maldonado-Contreras et al. who also reported marked differences in the structure of the gastric bacterial community according to *H. pylori* status [59]. The authors used gene microarray PhyloChip technology to analyze the 16S rRNA of gastric aspirates of 12 immigrant patients from rural Venezuela, South Asia, and Africa and found *H. pylori* in 8 of them. The communities of all subjects were dominated by only four phyla: *Proteobacteria*, *Firmicutes*, *Actinobacteria*, and *Bacteroidetes*. As previously noted, *H. pylori* status was associated with increased abundance of proteobacteria and decreased abundance of actinobacteria, bacteroidetes, and firmicutes. *H. pylori* was found in patients even without GI disease, which is important because it underscores the likelihood that certain bacterial virulence factors or host defense mechanisms are likely responsible for the disease state that follows *H. pylori* infection. Interestingly, not all host response mechanisms to *H. pylori* are pathogenic, and evolutionary advantage may be conferred to colonizers of *H. pylori*, such as protection against tuberculosis [60].

In a molecular profiling study of gastric microbiota in patients with non-*H. pylori* gastritis and without exposure to nonsteroidal anti-inflammatory drugs (NSAID), Li et al. reported that 70.5 % of all microbial clones belonged to five genera, specifically *Streptococcus*, *Prevotella*, *Neisseria*, *Haemophilus*, and *Porphyromonas* [61]. Interestingly, the overall microbial complexity of patients in this study was remarkably similar to the patients in the Bik study, despite vastly different geographic locations and patient ethnicities. Li compared the microbiota of the antrum to that of the body in patients with and without gastritis and concluded that the samples were quite similar. Moreover, cultivation of the same streptococcal phylotypes identified through molecular 16S rRNA sequencing helped the authors conclude that these bacteria are true residents in the stomach mucosa. The question of causality remains, though, as it is unclear whether the increase in streptococcus abundance is causative for non-*H. pylori*, non-NSAID gastritis or secondary to inflammation caused by another trigger. A second unanswered question is whether streptococcus phylotypes predispose the antral mucosa to colonization and invasion by *H. pylori*, which can lead to cancer.

Gastric cancer is a global health concern—the fourth most common cancer and the second leading cause of cancer-related deaths worldwide [62]. Research has shown that *H. pylori* is a major associative agent in gastric cancer, and eradication of *H. pylori* has been shown to decrease the incidence of gastric cancer, although the causative mechanism is still not yet fully understood [63]. In antral-predominant gastritis, the production of gastric acid is increased (i.e., *hyperchlorhydria*), a condition associated with a higher risk of developing duodenal ulcers but believed to be protective against gastric cancer. In contrast, body-predominant gastritis leads to lower production of gastric acid (i.e., *hypochlorhydria*) and may lead to atrophic gastritis, a condition known to increase the risk for gastric cancer. Incidentally, the hypochlorhydic environment has been shown suitable for growth of nitrogen-

reducing bacteria capable of producing carcinogenic nitrosamine compounds. This raises the question of whether bacteria other than *H. pylori* contribute to the development of gastric cancer.

A study by Dicksved et al. looked at ten patients with non-cardiac gastric cancer and five dyspeptic control patients with normal gastric mucosal morphology [64]. Eight out of the ten cancer patients were positive for *H. pylori* by conventional testing (three by culture); none of the controls were positive for *H. pylori*. Analysis by restricted fragment length polymorphism (RFLP) yielded 102 phylotypes of bacteria clustering into the regular phyla of *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, *Proteobacteria*, and *Fusobacteria*. As in the esophagus, members of the *Firmicutes* were most highly represented, with the majority corresponding to *Streptococcus*, *Lactobacillus*, and different *Clostridia*, such as veillonella. Notably, the study was unable to discern differences in total abundance of bacteria between cancer patients and controls, and no significant differences were measured in diversity indices between these two groups. The authors did suggest that the phylotypes of control patients appeared to be clustered, suggesting that these bacterial communities were more similar to each other than to those of cancer patients. Moreover, cancer patients were separately measured to have significantly different communities from each other. Interestingly, *H. pylori* was only detected in one of the cancer patients. The study did not measure nitrosamine compounds in gastric aspirates or distinguish the presence of nitrate-reducing bacteria, so further conclusions cannot be made. Another major deficit in this study and others is the lack of data on gastric aspirate pH, which might show some correlation with gastric bacterial communities. It is interesting to note that microbial dysbiosis is suggested in other forms of GI cancers, such as colorectal cancer, with significant elevation measured in the population of bacteroides and prevotella [65]. *Bacteroides fragilis*, for example, has been implicated in carcinogenesis due to its ability to produce a metalloprotease that disturbs host immune responses [66].

In summary, studies confirm the presence of distinct bacterial communities residing in the stomach. The role of bacteria in gastritis and cancer is still under scrutiny, and although *H*. pylori is an important player in gastric inflammation and dysplasia, other bacteria, virulence factors, and host response mechanisms are all prime targets for further research.

Consequences of Gastric Acid Suppression

Acid Suppression and Bacterial Overgrowth

Decreased acid secretion predisposes patients to increased bacterial counts in gastric and duodenal fluid. The ability to secrete acid into the stomach evolved secondary to conferred survival advantage for those species that possessed it. Medical acid suppression in humans and experimental animals is not associated with immediate morbidity. Rather, clear clinical benefits are noted with acid suppression therapy for multiple conditions, such as when used in conjunction with antibiotics for eradication of *H. pylori* or to minimize progression of BE [67]. Yet, interrupting the acidic environment in the stomach does appear to carry long-term complications, including bacterial overgrowth and its consequent events, such as increased risk for enteric and non-enteric infections, nutrient malabsorption, and deconjugation of bile acids.

The relationship between gastric pH and gastric bacterial counts is strong, with increased pH directly correlated to increased bacterial concentration in stomach aspirates [68]. Normal gastric pH is in the 1–2 range and associated with median gastric bacterial counts less than 10^3 CFU/ml; as the pH rises above 5–6, bacterial counts reach a plateau of about 10^7 CFU/ml (Fig. 127.2). Gastric acid also influences the composition of the microflora of the small intestine, and early studies on patients with peptic ulcer disease requiring acid-reducing surgery, such as vagotomy or antrectomy, noted jejunal aspirates with an increase in bacterial counts from 10^3 CFU/mL preoperatively to 10^8 postoperatively.

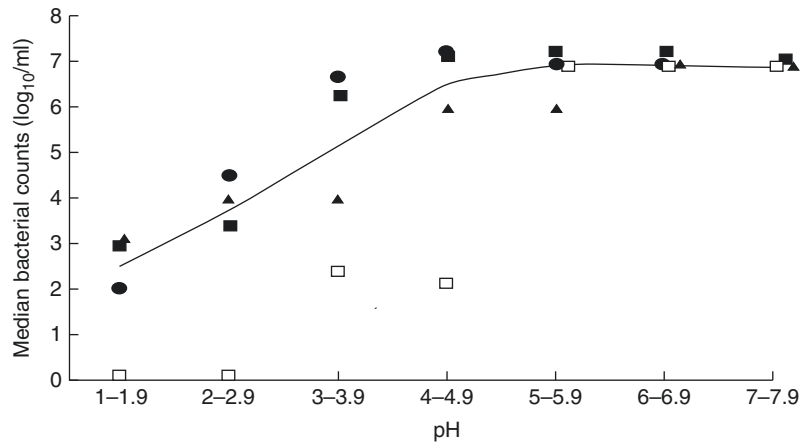

Fig. 127.2 Relationship between gastric luminal pH and bacterial counts in the gastric juice from four studies in which simultaneous measurements of bacterial numbers ad pH were made. The *curve* indicates the median value from the studies at each pH range (Reprinted, with permission, from Yeomans et al. [68])

Discussion of small intestinal bacterial overgrowth (SIBO) is outside the realm of this book, but since some of the more serious complications of gastric acid suppression involve SIBO, a few brief comments are in order. First, aspiration of jejunal fluid and standard cultivation techniques have been the gold standard in diagnosing SIBO, which in the past often failed to produce growth, leading to incorrect conclusions. Justesen et al. reported in a 1984 study on 51 children without gastrointestinal disorders that a consistent population of jejunal microbiota was present in 26 (51 %) of tested subjects. Cultivation of aspirates yielded, in decreasing frequency, growth of *Streptococcus viridans*, *Veillonella parvula*, *Haemophilus parainfluenzae*, lactobacillus, corynebacterium, actinomyces, bacteroides, *Haemophilus influenzae*, neisseria, *Staphylococcus aureus*, and candida [69]. The concentration of growth ranged from $<10^1$ CFU/mL in 37 % of samples (i.e., sterile) to $10^{8–9}$ in one sample, with a median concentration in the range of 10^4–10^6. The growth concentration of the main species isolated was similar for the majority of subjects, from 5.0×10^4 CFU/ml (e.g., lactobacillus) to 2.0×10^3 (e.g., peptococcus).

Today, most definitions of normal small intestinal flora describe population numbers to be $\leq 10^4$ CFU/mL, but certainly greater than normal growth concentrations in the stomach and esophagus. Jejunal aspirates with growth greater than 10^4 are considered abnormal, and the symptomatic patient may be diagnosed with SIBO and treated accordingly [70]. Several host defense mechanisms prevent excessive colonization of the proximal small intestine, including gastric acid and digestive enzyme production, antegrade peristalsis, mucosal protection, and immune factors, such as secretory immunoglobulin (Ig) A. In most patients, SIBO is not caused by a single bacterial strain but rather represents an increase of "normal" communities of bacteria. Select bacteria implicated in SIBO include microaerophilic and facultative anaerobic bacteria that sneak in from the oropharynx, such as streptococcus, *Escherichia coli*, staphylococcus, and klebsiella, as well as resident anaerobes, such as bacteroides, lactobacillus, and clostridium [71]. Recent studies using pyrosequencing methods report that over 50 % of bacterial species in the proximal intestine belong to strains that have yet to be cultivated [72]. Indeed, poor diagnostic correlation has been noted between jejunal aspirate testing, breath testing, and pyrosequencing technique, an observation requiring further study of current definitions and clinical implications of SIBO [73].

The bacterial profile in the small intestine in response to acid suppression is similar to the bacterial profile produced by bacterial overgrowth in the stomach, compromising largely of oropharyngeal flora. SIBO is known to cause deconjugation of bile acids, a process that interferes with digestion and nutrient absorption. A study by Theisen et al. of 30 patients treated with 40 mg of omeprazole for 3 months reported a markedly increased concentration of unconjugated

bile acids in gastric aspirates, in direct correlation with measured bacterial counts [74]. Also, bacteria can produce various toxic molecules that carry systemic adverse effects, such as ammonia, D-lactate, peptidoglycans, and even ethanol. These molecules upregulate systemic inflammation and may contribute to certain clinical conditions (e.g., hepatic encephalopathy, steatohepatitis). Bacterial overgrowth in the small intestine may also impact the morphological structure of the bowel, with associated inflammatory changes and villous atrophy resulting in nutrient malabsorption.

The proton pump inhibitors (PPI) produce profound effects on the production of gastric acid. Although the safety profile for this class of medications has been excellent, studies on the long-term complications of PPI intake are emerging, and they are significant. Specifically, PPI appear to result in malabsorption of nutrients (e.g., iron, calcium), and studies suggest that chronic intake increases the risk for bone disease in older patients (e.g., osteopenia) [75]. Certain micronutrients require an acidic environment for dissolution and conversion to isoforms with increased bioavailability. Calcium disintegration and dissolution, for example, decreases from 96 % at pH 1 to 23 % at pH 6.1. O'Connell et al. conducted a randomized, double-blind, placebo-controlled study on calcium absorption, comparing placebo to omeprazole 20 mg daily for 1 week in a community-dwelling population of women ≥65 years of age. Subjects were given labeled ^{45}Ca at a dose of 500 mg per day, and blood samples were measured at baseline and 5 h after calcium ingestion. Omeprazole was found to markedly decrease fractionated calcium absorption from 9.1 % with placebo to 3.5 % with omeprazole (Fig. 127.3) [76].

Available studies do not show a clear correlation between PPI treatment and increased nitrosamine compounds in gastric fluid, although rising bacterial counts in the stomach are believed to result in increased nitrate-reducing strains (e.g., peptococcus, klebsiella, escherichia, and helicobacter). One study demonstrated increased urinary excretion of nitrosamine compounds in patients on PPI therapy [77]. As already noted, the contribution of nitrosamine formation to gastric cancer is not fully understood, but it is important to mention that cancer rates have increased alongside the increased intake of dietary nitrates (e.g., animal protein) [78].

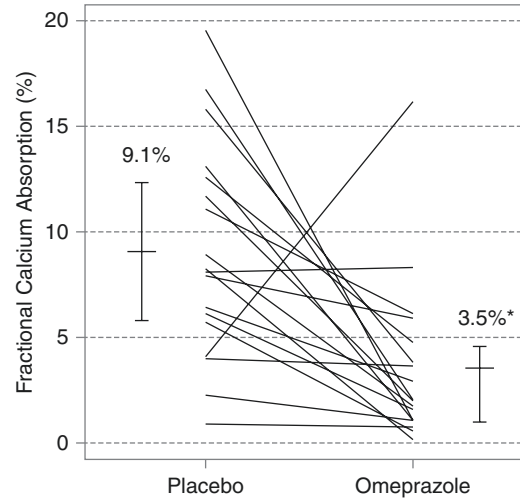

Fig. 127.3 Fractional calcium absorption for each subject ($N=18$) after 1 week of placebo versus omeprazole 20 mg. The 25–75th percentile bars and means are depicted for each treatment period. The difference between placebo and omeprazole was statistically significant, $P=0.003$* (Adapted with permission from O' Connel et al. [78])

Acid Suppression and Risk for Infection

The interplay between bacteria and the chemical milieu of the stomach is strongly implicated in the risk for infections. Many bacteria, such as *Salmonella typhimurium*, a leading cause of gastroenteritis worldwide, cannot survive pH <4; other bacteria, such as *E. coli* 0157:H7, are able to survive a very low pH [79]. Some bacteria have evolved to combat gastric acid, such as *Yersinia enterocolitica* and *H. pylori*, both of which produce a urease enzyme that hydrolyses urea to carbon dioxide and ammonia, producing an ammonia cloud or basic buffer zone around the organism.

Clinical evidence has been slow to accumulate, but data now appear to suggest that PPI

therapy is associated with increased risk for enteric infections, such as salmonella, campylobacter, *Vibrio cholera*, and *C. difficile*. Leonard et al. reviewed 25 studies that included a total of 29,748 patients who received acid suppression therapy and concluded that enteric infection rates were significantly higher than case controls [80]. Specifically, the odds ratio of *C. difficile* infection in patients receiving acid-suppressive drugs was 1.95 (95 % CI 1.48–2.58) times higher on acid suppression versus controls, with a higher risk conferred for PPI over H2-receptor antagonists (H2RA); the odds ratio of acquiring other enteric infections (e.g., salmonella, campylobacter, shigella) was 2.55 (95 % CI 1.53–4.26) times higher than case controls. Dial et al. reported that the incidence of *C. difficile* infection in patients, as documented in the General Practice Research Database in the United Kingdom, increased by an OR of 2.9 (95 % CI 2.4–3.4) with current use of PPI and 2.0 (95 % CI 1.6–2.7) for H2RA [81]. The authors concluded that extra caution should be practiced in caring for those at increased risk for developing enteric infections, such as travelers, hospitalized patients, children, and the elderly.

The risk for non-enteric infections, specifically respiratory infections, is also increased with acid suppression. Hypochlorhydria (pH >4) is an abnormal environment for the stomach, and the bacterial overgrowth that ensues has been shown to cause significant respiratory disease if aspirated. Achlorhydric stomachs contain large numbers of intestinal *coliforms*, rod-shaped Gram-negative bacteria (e.g., citrobacter, enterobacter, klebsiella, serratia, and escherichia), as well as streptococcus and staphylococcus [82]. Studies on PPI use note that the severity of bacterial overgrowth is directly related to the amount of time gastric pH is >4. Therefore, it is possible that clinical benefit may be derived from pulse administration of PPI in asymptomatic patients who can tolerate intermittent dosing (e.g., post-EA repair).

A landmark study by Laheij et al. reviewed the records of 364,683 individuals living in The Netherlands, as part of the Integrated Primary Care Information project, a database study of patient records in primary care setting, and reported that patients taking acid-suppressive drugs developed pneumonia 4.47 (95 % CI 3.82–5.12) times more often compared to those who never used acid-suppressive drugs [83]. The study identified and reviewed 5,551 first occurrences of pneumonia over 7 years; 185 cases occurred in individuals taking acid-suppressive drugs. The adjusted increased relative risk of pneumonia in individuals taking acid-suppressive drugs was 1.27 (95 % CI, 1.06–1.54); the adjusted attributable risk was 42 % for PPI and 37 % for H2RA. Overall, 1.05 pneumonia cases per 100 person-years of PPI exposure and 0.86 pneumonia cases per 100 person-years of H2RA exposure could be attributed directly to the use of acid-suppressive drugs. This roughly translated to one case of pneumonia for every 226 patients treated with PPI and every 508 patients treated with H2RA. A dose response trend was observed in the subgroup of patients taking PPI, consistent with previous studies; this again raises the notion that pulse administration of PPI may have clinical relevance to the risk for infection.

A more recent Danish study by Gulmerz et al. reported that the OR associated with current use of PPI and community-acquired pneumonia was 1.5 (95 % CI 1.3–1.7) relative to case controls. The study reviewed 7,642 cases of community-acquired pneumonia in patients who were discharged from hospital and compared to 34,176 control subjects, matched to age and sex. Initiating PPI therapy showed a strong association with pneumonia with an OR of 5.0 (95 % CI 2.1–11.7) [84]. Other studies have corroborated this correlation, but to a different extent and some with skepticism. A meta-analysis by Johnstone et al. of six case-control studies, for example, concluded that the overall OR of 1.36 (95 % CI 1.12–1.65) was precluded by data heterogeneity, confounding factors and bias [85]. However, the most recently available meta-analysis, which included 23 randomized controlled trials, as well as 5 case-control and 3 cohort studies, concluded that acid suppression does indeed result in greater overall risk of acquiring pneumonia [86].

Clinical studies evaluating the risk for respiratory infections with acid suppression in

mechanically ventilated patients are lacking. A review of the subject by Vakil noted the paucity of data and concluded that available studies are outdated in the era of intravenous PPI, which raise gastric pH but also decrease gastric volume substantially [87]. Despite hard data either way, it appears that limiting acid-suppressive therapy to patients who are at serious risk for gastric ulcers has been emphasized in recent guidelines [88]. And extra caution is prudent in patients who are immunocompromised and have asthma or chronic obstructive lung disease, as these populations may be most vulnerable to acid suppression.

In summary, acid suppression results in bacterial overgrowth in the stomach and proximal small intestine. The clinical consequences of acid suppression and bacterial overgrowth are both nutritional and infectious. Bile acid deconjugation and decreased micronutrient dissolution in gastric juice may result in the malabsorption of vital nutrients, such as calcium and iron. Infectious consequences are both enteric and non-enteric, with a clear association with acid suppression and gastric pH. Clinicians must be cautious in prescribing long-term acid suppression, especially in vulnerable patient populations, such as hospitalized, ventilated, or immunocompromised patients, those with asthma or chronic lung disease, travelers, children, and the elderly. Clinical practice may extrapolate from studies that show that the risk of infections is directly related to the amount of time gastric pH is >4 and administer acid blockers in pulses, allowing for intermittent return of gastric acidity. Future studies should consider new generation, intravenous acid blockers that result in decreased gastric volume.

Conclusion

The microbiome is the sum collection of all microbes living within our individual body and an essential component of our being. It defines life as a continuum of biology that requires mutualism among organisms. It follows that many modern diseases are consequent not only to the breakdown of host biology, but also to a host response to alterations in the microbiome. In the upper gastrointestinal tract, the esophagus inhabits large numbers of firmicutes, mostly streptococcus, and a shift to bacteroidetes and nitrosamine-producing proteobacterial anaerobes appears to contribute to the disease process of reflux esophagitis and Barrett esophagus. Chagas disease megaesophagus is notable for a shift in the microbiota with increased prevalence of veillonella (Gram-negative, anaerobic clostridium). Although no data are available on the esophageal microbiota in cases of esophageal atresia, the common occurrence of respiratory disease in this patient population cannot be ignored, and future research may support a dysbiotic microecology that predisposes to respiratory disease. *H*. pylori, a major associative agent in gastric cancer, appears to dominate gastric ecology whenever present, favoring the growth of proteobacteria in expense of firmicutes and bacteroidetes. In general, acid suppression therapy results in increased bacterial counts in the stomach, leading to increased concentration of potentially dangerous strains, the deconjugation of bile acids, and an environment that is prone to nutrient malabsorption. Moreover, acid suppression appears to be associated with increased rates of both enteric and non-enteric infections, with a substantial risk for respiratory infections in vulnerable populations. Thus, the microbiome of the upper GI tract is a vibrant and important microecology with numerous functions, and its perturbance carries a risk for disease, from infections to inflammation and cancer.

Functional Gastropathology

Duodeno-Gastric Reflux and Duodeno-Gastro-Oesophageal Reflux

128

Rok Orel

Introduction

Reflux of duodenal juice, containing bile and pancreatic secretions into the stomach, is called duodeno-gastric reflux (DGR). When contents of duodenal juice are mixed with contents of the stomach and reflux in the oesophagus, we are speaking of duodeno-gastro-oesophageal reflux (DGER). As bile is most commonly used for the detection of both DGR and DGER for research and clinical practice, the term "bile reflux", although being to some extent erroneous since it neglects other refluxate components, is often used synonymously for DGR and DGER.

Only a few studies have been published about DGR and DGER in children, and to the best of my knowledge, no such studies were done in infants. Therefore, a majority of data about physiology, pathology and clinical importance of DGR and DGER in this chapter derive from the results of studies made in experimental animal models and in adult patients. Moreover, a lot of knowledge about the importance of these refluxes came from studies performed in patients with partial or total gastrectomy who represent an in vivo model with excessive reflux of duodenal juice because of disrupted pyloric anti-reflux barrier. With total gastrectomy, no acid and pepsin secretions interfere with harmful effects of duodenal juice components and represent an ideal possibility for studying duodeno-oesophageal reflux.

Duodeno-gastric reflux is a physiological phenomenon. In healthy people, it occurs sporadically during phase II and III of the interdigestive migrating motor complexes (MMC) of the antrum and is regularly present postprandially [1] and during the night [2]. Beside the motility of stomach, pylorus and duodenum, the amount and concentration of bile, pancreatic and duodenal secretions as well as food intake and its composition are likely to determine the duration and quantity of DGR. Postprandial DGR is provoked by a great amount of bile and pancreatic secretions in the duodenum after a meal and enhanced duodenal motor activity. Lipid-rich meals are probably associated with higher reflux rates and a higher concentration and total amount of duodenal juice in the stomach when compared to protein-rich meals [3]. At the end of the antral phase III, reflux of bicarbonate and immunoglobulins IgA, but not bile, from the duodenum aided by duodenal retro-peristalsis may play an important physiological role in the chemical and immunological restitution of the gastric mucosal barrier function after the exposure to high acid and pepsin concentrations [4]. In this physiologic

DGR, bile reflux is prevented by deviation to the gallbladder, probably by a phase III-associated occlusion of the sphincter of Oddi [5]. In view of the presumed role of MMC phase III as a gastrointestinal housekeeper, a role of gastric phase III in clearing of duodenal contents from the stomach seems likely [1].

The extent and duration of physiologic DGR in healthy persons show great interpersonal and intrapersonal day-to-day variability. The results of DGR detection are mostly dependent on the methods that were used. Even measurements with bilirubin monitoring system Bilitec 2000, probably the most accurate method for the DGR detection, which is explained in details in the section about the methods for DGR and DGER measurement, show very wide normal ranges. The median duration of bile presence in the stomach, the most frequently used marker for DGR, varied from 1.4 to 24.0 % of the day in healthy adults with an upper normal quartile cut-off levels from 7.8 to 72.0 % [6–12]. A comparison of gastric bilirubin exposure between proximal and distal sites within the stomach shows very big similarity that indicates that the duodenal refluxate is well mixed and evenly distributed within the stomach rather than concentrated more in the antrum and prepyloric area [9]. Since duodenal refluxate is relatively frequently present in the stomach, it is obvious that during gastro-oesophageal reflux episodes, it can reflux into the oesophagus.

Therefore, DGER can also be regarded as a part of normal physiology, although it does not appear regularly in all healthy people. Reflux episodes in healthy people are most common postprandially, and in healthy volunteers, more DGER was found during daytime than during the night. The median percentage of time with bile in the oesophagus in studies in healthy adults varied from practically none to up to 19.6 % [6, 13–16]. The amount of DGER may increase with ageing as more DGER was found in older volunteers [6]. For that reason, the adult normal values should not be directly extrapolated to children. Although the amount of DGER in healthy children has not been evaluated because of ethical reasons, the percentages of total time, upright time and supine time with bile in the oesophagus measured in children with gastro-oesophageal reflux symptoms but without reflux oesophagitis are comparable to those measured in healthy young adults (Table 128.1) [17]. After a reflux episode, refluxed material is cleared from the oesophagus by peristalsis and by washing with saliva end oesophageal gland secretions. Using simultaneous measurement of volume reflux by intraluminal impedance technique, acid reflux by pH monitoring and bile reflux by bilirubin absorptiometry with Bilitec 2000, we found out that volume bolus is cleared fast, followed by slower normalisation of oesophageal pH, whilst bile clears from the oesophagus as the last (unpublished observation). That can be explained by the fact that bolus clearance depends mostly on peristalsis, but the clearance of small amounts of refluxed material is the result of washing by saliva. Whilst acid can be chemically neutralised by relatively alkaline salivary and oesophageal glands' secretions faster than the washing process are finished, acid reflux episodes seem to finish faster than bile reflux episodes.

Table 128.1 Results of DGER measurement by Bilitec 2000 in children without oesophagitis

Bilirubin absorbance ≥0.14	Mean (SD)	95th percentile
% total time	0.3 (0.93)	1.17
% upright time	0.45 (1.44)	1.77
% supine time	0.13 (0.8)	0.5

Methods for Detection and Measurement of DGR and DGER

Several methods have been used in the past for the detection of DGR and DGER; however, each of them has its own strengths and shortcomings.

The observation of bile in the stomach or oesophagus during endoscopy is a poor indicator because of the intermittent nature of DGR and DGER and its clinical significance has never been demonstrated. Therefore, the endoscopy has a low accuracy and a low predictive value, and even histological picture of the mucosa, although suggestive of bile reflux, is not pathognomonic [18].

Aspiration studies with chemical analysis of aspirate contents produced a lot of scientifically important information but are inappropriate for everyday medical practice. Whilst using single aspiration yields a high rate of false-positive and false-negative results, frequent or even continuous sampling overcomes this drawback but may induce refluxes by creating pressure gradient [19].

Detection of bile acids, bilirubin or other constituents of duodenal juice in mouth saliva has been applied as a marker for DGER [20], but this method has not been validated enough and its accuracy is very questionable.

Scintigraphy is another possible method to detect DGR and DGER. A radioactive marker, for example, iminodiacetic acid (HIDA), which is rapidly eliminated through the liver and the bile ducts into the duodenum, is given to patients. Intermittent imaging of abdomen with gamma camera reveals refluxes as the appearance of the marker in the gastric or oesophageal area. Although non-invasive, it is relatively insensitive, because of the overlap of other organs and patient movement and especially due to the intermittent nature of refluxes, particularly the oesophageal one [21].

Detection of DGR and DGER by pH monitoring is based on the assumption that these refluxes cause an increase of pH over 7 because of alkaline nature of the duodenal juice. A term "alkaline reflux" was used as a synonym for DGR and DGER [22]. Simultaneous pH monitoring in oesophagus and stomach was frequently used in an effort to relate alkaline shifts in the stomach to those in the oesophagus [21]. However, detection of DGR and DGER with more objective methods revealed that these refluxes infrequently cause an increase in pH over 7. Moreover, the majority of bile reflux episodes take place at acidic or neutral pH [23–25]. Therefore, a pH of less than 7 does not exclude DGR and DGER. A pH above 7 may be caused by other factors, such as saliva, food, bicarbonate secreted by oesophageal submucosal glands, etc. [21]. DGR and DGER can therefore not be detected by pH monitoring alone, and the term "alkaline reflux" is a misnomer for describing refluxes of duodenal juice into the stomach and the oesophagus.

A fiberoptic spectrophotometer, Bilitec 2000, detects DGR and DGER independently of pH and can be used in an ambulatory setting [26]. This system utilises the optical property of bilirubin, the main biliary pigment, that has a characteristic spectrophotometric absorption band with a peak between 390 and 460 nm. The basic working principle of the instrument is that absorption of light near these wavelengths implies the presence of bilirubin and, therefore, represents bile reflux. In vitro validation experiments using Bilitec in differing dilutions of a bilirubin solution revealed a linear correlation between absorbance and bilirubin concentration, but in acidic environment ($pH < 3.5$), the bilirubin concentration can be underestimated by at least 30 % [27, 28]. It has been shown that bilirubin absorbance also correlates with the concentration of bile acids; however, this relationship was weaker in vivo [29]. In clinical practice, the method is not used for measuring bilirubin concentrations but to detect the presence or absence of bile in the stomach or in the oesophagus. For that purpose, threshold values of absorbance have been set on experimental basis to be sensitive and specific enough for bile detection. Absorbance ≥ 0.14 is usually applied for DGER detection, but different threshold values, ranging from ≥ 0.14 to ≥ 0.30, are used for DGR [6, 30]. By increasing the threshold value, the specificity of the method increases, but its sensibility decreases. The results are expressed as percentage of time of the recording with the presence of DGR or DGER. Ingested substances, in particular heavily coloured foods, may absorb light at the same wavelengths as bilirubin, thus interfering with the accuracy of the method and generating false-positive measurements. For that reason, a special "white diet" is recommended during monitoring [14, 31, 32]. Another drawback of the method is a possibility that a particle of food or other substance obstructs the tiny gap between fiberoptic probe and reflecting cap at its end (Fig. 128.1) and causes the disappearance of the signal [26]. Despite its limitations, bilirubin spectrophotometry represents the most practical and accurate method for DGR and DGER detection for both experimental and clinical purposes.

Fig. 128.1 The tip of a fiberoptic spectrophotometer Bilitec 2000

Multichannel intraluminal impedance is a method that enables detection of volume reflux independently of its pH. Usually, it is used simultaneously with pH monitoring so reflux episodes can be recognised as acid, weakly acid and alkaline [33]. However, impedance cannot detect a chemical composition of the refluxed material and is therefore inappropriate for the detection DGR and DGER.

In the future, new technologies using biosensors specific for bile acids or other reflux constituents seem a promising practical tool for DGR and DGER measurement. Such a biosensor could be devised using molecular imprinting technology (MIP) based on recognition characteristics of polymers that have complimentary size, shape and binding site to specific substrates and have already been applied to recognise steroids such as cholesterol and bile acids which share the same four-ring structure as other steroids [34].

Mechanisms of Inflammation and Oncogenesis Produced by the Duodenal Refluxate Constituents

Numerous studies using animal models or tissue culture experimental models revealed that duodenal juice constituents play an important role in the development of inflammation and oncogenesis in the stomach and the oesophagus.

Trypsin and perhaps other pancreatic proteases cause tissue damage and release of intracellular inflammation mediators [35]. Trypsin is thought to digest intercellular substances and surface structures that contribute to the maintenance of cohesion between cells, causing the dilution of intercellular spaces and the shedding of epithelial cells [36–38]. It has been shown that trypsin induces the expression of pro-inflammatory cytokines on epithelial cells through the activation of specific receptors, protease-activated receptors (PARs). Human oesophageal cells stimulated with trypsin produce interleukin-8 and prostaglandin E_2 [39]. Trypsin's activity depends on pH and is optimal in the pH range from 5 to 8.

Another important component of duodenal juice is lysolecithin that is formed when pancreatic phospholipase A hydrolyses the lecithin in bile. Studies have demonstrated that in the presence of acid, lysolecithin is able to injure oesophageal mucosa, causing almost complete tissue breakdown [36, 40].

Bile salts are normal duodenal juice components. Human liver converts an average of 0.78–1.29 mmol (300–500 mg) of cholesterol into bile acids daily. These primary bile acids, cholate and chenodeoxycholate, are synthesised by hepatocytes in a ratio of 2–1. Secondary bile acids, deoxycholic acid and lithocholic acid, are formed from primary bile acids as metabolic by-products of intestinal bacteria, most importantly *bacteroides* and *bifidobacteria*, by deconjugation and 7α-dehydroxylation. Prior to secretion into bile, 98% of bile acids are conjugated with taurine or glycine in a ratio of about 3–1. Bile acid synthesis is regulated by feedback inhibition from reabsorbed bile acids from the gut reaching the liver via the portal vein. Bile acids have to be deconjugated by intestinal bacteria before absorption and are reconjugated in the liver before re-entering the bile. This enterohepatic circulation maintains a composition of human bile consisting of 54% cholic, 31% chenodeoxycholic, and 15% deoxycholic acid, of which about 80% is conjugated with taurine and 20% with glycine [41]. Damaging effect of bile salts on the mucosa is dependent on their conjugation state. The conjugation state depends mostly on the pH. When the pH is equal to the pKa, the bile acid is half ionised and half protonated, the ionised half being soluble [40].

Although the mechanism by which bile acids damage the mucosa is not fully understood, available studies suggest more hypotheses. The first is that bile acids damage mucosal cells by their detergent property and solubilisation of their lipid membranes [38]. This theory is supported by studies in gastric mucosa in which bile acid mucosal injury was correlated with the release of phospholipids and cholesterol into the lumen [42]. The second hypothesis suggests that bile acids gain entrance across the mucosa because of their lipophilic state, causing intramucosal damage by disorganising membrane structure and interfering with cellular metabolism [38]. Once bile acids have penetrated the mucosal barrier, they are trapped inside the cells by intracellular ionisation that results in severalfold increase in their intracellular concentration [43, 44]. The unionised lipophilic forms predominate at more acidic pH for conjugated bile acids (i.e. pKa 1.9) and at more neutral pH for unconjugated bile acids (i.e. pKa 5.1) [38]. As the damage caused by bile salts depends on their solubility, conjugated bile salts cause mucosal damage under acidic and unconjugated under neutral and alkaline conditions [36, 37]. Moreover, by dissolution of cell membranes and tight junctions, bile acids open the doors to other harmful substances such as acid, pepsin and pancreatic enzymes [45].

It is known that bile acids can also stimulate cell proliferation and promote tumorigenesis and are therefore implicated in the development of Barrett's oesophagus, gastric and oesophageal squamous cell carcinoma and adenocarcinoma [35, 46–50]. Damaged mucosal cells produce inflammatory mediators such as cytokines, which recruit inflammatory cells to the site of inflammation. These cells produce free radicals whose primary role is to remove the damaged cells, but they may also induce genetic mutations. Bile acids are known to induce oxidative stress and DNA damage [51, 52]. They can induce up-regulation of superoxide-generating NADPH oxidase NOX5-S expression and increase in cell proliferation depend on activation of TGR5 receptor (a bile acid receptor) and Cαq protein which is involved in hydrogen peroxide production [53]. Whilst most of these changes will lead to cell death, others may confer a survival advantage and lead to a clonal expansion of the premalignant, Barrett's or malignant cell type [54].

One of the characteristics of premalignant and especially malignant cells is also their loss of differentiation. The vitamin A derivate retinoic acid is an inducer of differentiation, and there is evidence that bile acids compete for one of its nuclear receptors [55]. Cyclooxygenase (COX) is the enzyme responsible for the rate-limiting step in the production of prostaglandins. Whilst COX-1 is constitutively expressed in the normal gastric and oesophageal mucosa and has a protective function, the role of COX-2 includes inflammation, cell adhesion, blocking apoptosis, invasion, angiogenesis and metastasis and is induced by inflammatory and cancerous processes [54]. Bile acids have been shown to stimulate production of COX-2 and prostaglandins such as prostaglandin E_2 which may play an important role in cell metaplasia, dysplasia and tumorigenesis [56, 57]. They can also activate mitogen-activated protein (MAP) kinase and NF-κB pathways, thereby increasing cell proliferation and decreasing cell apoptosis [53].

Experimental studies suggest that bile acids can directly induce DNA changes which may lead to mutations and may be thus implicated in the initiation of carcinogenesis [58]. Many chromosomal losses and gains were detected by a high-resolution oligonucleotide comparative genomic hybridisation in the neoplastic cells developed by experimental reflux of duodenal juice [59]. Moreover, by entering cellular nucleus and binding to nuclear receptors, bile acids may induce the expression of oncogenes. For example, the proto-oncogene C-myc is up-regulated and expression is increased by exposure to bile acids [60].

In conclusion, duodenal juice contents as pancreatic enzymes, lysolecithin and conjugated and unconjugated bile acids are implicated in mucosal damage, inflammation, metaplasia and malignant alteration through different mechanisms; however, their detrimental effect depends on pH. In acidic conditions, conjugated bile acids and lysolecithin can damage mucosa in synergism with hydrochloric acid and pepsin from the

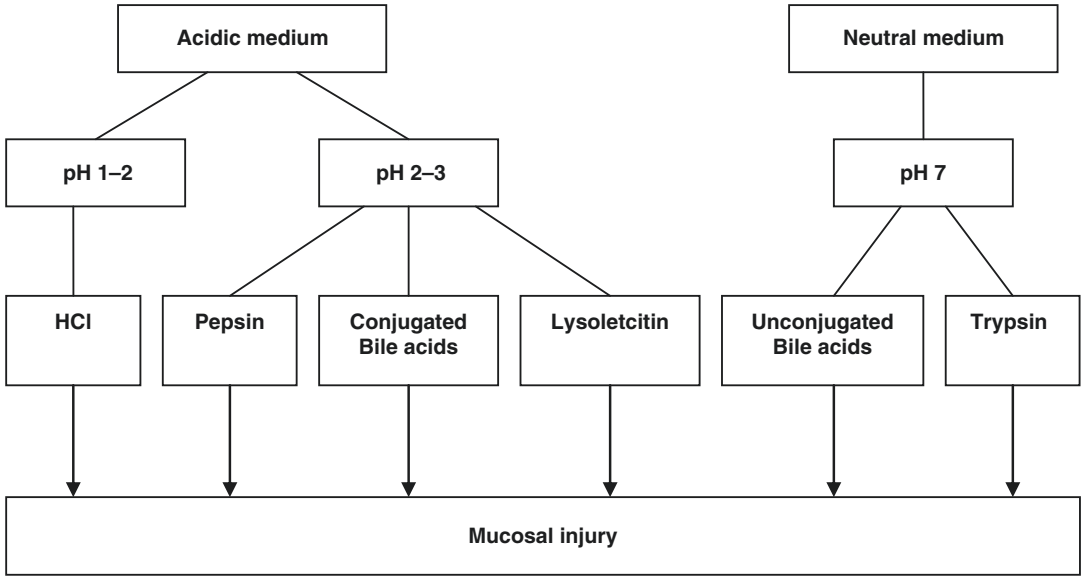

Fig. 128.2 A schematic representation of pH dependence of different agents responsible for mucosal injury

gastric juice. At neutral or alkaline pH, unconjugated bile acids and pancreatic trypsin can damage gastric and oesophageal mucosa (Fig. 128.2).

Clinical Presentation

Excessive DGR and DGER have been suggested to be involved in the pathogenesis of several foregut diseases such as chemical gastritis, functional dyspepsia, reflux oesophagitis, Barrett's oesophagus and gastric and oesophageal carcinoma. Symptoms are non-specific such as upper abdominal pain or discomfort, postprandial fullness, regurgitation and, occasionally, bile vomiting. Therefore, the objective diagnostic methods are necessary to prove pathologic amount of reflux as well as its connection with the disease.

A lot of knowledge about the importance of DGR and DGER has arrived from observations in surgical patients. In patients after partial or total gastrectomy with gastroduodenostomy (Billroth I), gastrojejunostomy (Billroth II) or reconstruction with biliary diversion (Roux-en-Y), excessive DGR had been documented by objective measurements with intragastric bilirubin spectrophotometry, caused by the loss of pyloric sphincter functioning as a physiologic barrier to retrograde flow of duodenal contents into the stomach [10, 61, 62]. Not only dyspeptic symptoms but also remnant gastritis, gastric ulcerations, gastric stump carcinoma, gastro-oesophageal reflux disease and oesophageal adenocarcinoma have been attributed to excessive DGR in these patients [10].

Moreover, excessive DGR with its consequences has also been discovered in patients who underwent cholecystectomy, endoscopic sphincterotomy or other hepatobiliary operative procedures [63–65]. In contrast with healthy subjects in whom DGR was present most often postprandially, in cholecystomised patients, bile is present in stomach also during fasting [65]. This profile may be explained by the surgical loss of the normal gallbladder reservoir for bile, which is then excreted into the duodenum at the same rate it is secreted by the liver. Thus, after cholecystectomy, more bile enters the duodenum when fasting and less after eating compared with subjects with a normal gallbladder. The more constant presence of bile in the duodenum creates conditions predisposing to increased duodeno-gastric bile reflux. Moreover, a number of motility abnormalities were noted after cholecystectomy [66]. Phase II in the antrum, the "clearance" wave, was found to occur at a significantly slower

rate. Also, there was less build-up to phase III of the interdigestive migrating motor complex, with a lengthened phase I and reciprocally shortened phase II. Furthermore, the phase III front migrates down the duodenum at half the speed that it does in healthy subjects. This may slow clearance of the increased proximal duodenal pool of biliary secretions, which is then available to reflux into the stomach where it is ineffectively cleared [66]. In children operated for choledochal cyst, excessive DGR was found following hepaticoduodenostomy but not following Roux-en-Y hepaticojejunostomy [67].

In contrast to this, serious gastric pathology caused by primary excessive DGR without previous gastrointestinal surgery is relatively rare. It has been postulated that DGR produces consistent histological changes in the gastric mucosa, so-called chemical or reactive gastropathy or bile reflux gastritis. The histological feature most strongly associated with DGR was intestinal metaplasia at the gastric antrum. DGR was also positively associated with the severity of glandular atrophy, chronic inflammation, lamina propria oedema and foveolar hyperplasia. As a result, a histological index, the bile reflux index (BRI), was derived. Evaluation studies showed that its values above a threshold 14 have a sensitivity of 70 % and a specificity of 85 % for a bile acid concentrations >1.00 mmol/l, which is the upper limit of physiological reflux [68]. Increased DGR has been incriminated in the genesis of symptoms in patients with functional dyspepsia. Although in some studies significantly increased DGR has been found in these patients compared to controls [10], other groups found the role of DGR to be minor since its amount during fasting was normal and only slightly increased after eating [65]. In patients with dyspeptic symptoms with pathologic amount of DGR, the mucosal lesions such as active inflammation, chronic inflammation, intestinal metaplasia, atrophy and *Helicobacter pylori* infection in the whole stomach were more severe than those in dyspepsia patients without DGR, and the bile reflux time was well correlated with the severity of pathological changes [69]. However, the relationship between *H. pylori* infection and DGR remains controversial. Some data suggest that *H. pylori* may induce DGR, and therefore both may act synergistically on the gastric mucosa, causing chronic gastritis, which may lead to the carcinoma sequence [68, 70, 71]. On the other hand, there are reports proposing that DGR decreases *H. pylori* colonisation and even suggesting to use bile acids for the treatment of *H. pylori*-related gastritis [72, 73]. However, by comparing the amount of DGR before and after *H. pylori* eradication [74], and the presence of *H. pylori* infection in patients with and without DGR [75], no causative relationship could be proved between DGR and *H. pylori* infection. Primary DGR has been rarely reported as a proposed mechanism of gastric pathology in children unresponsive to classical antacid therapy [76].

The principal role of acid reflux of gastric juice in the development of reflux oesophagitis, Barrett's oesophagus and oesophageal cancer has been well established. First ideas about the importance of DGER came from the observations in patients with atrophic gastritis, pernicious anaemia and following gastrectomy who developed oesophagitis despite practically absent gastric acid secretion [77–79]. Although DGER can be a consequence of excessive DGR, it can appear from either increased or normal gastric exposure to duodenal contents [80]. Therefore, pathologic DGR can be an important mechanism but is not a prerequisite for increased DGER. In contrast with paucity of convincing clinical evidence that DGR can produce serious pathology in intact (non-operated) stomach, numerous quality clinical studies elucidated the importance of DGER in oesophageal pathology, both in adults and children.

Some but not all of the studies using gastric or oesophageal aspiration and chemical analysis of the aspirate showed an increase in the presence of bile acids in gastro-oesophageal reflux (GERD) patients in comparison with healthy controls [45]. The differences in the results can be partially explained by different techniques of sampling and particularly by different methods of chemical analysis. In addition, particularly increased bile acid concentration was found amongst patients with Barrett's oesophagus, with

the highest concentrations amongst those with complicated Barrett's oesophagus (stricture, ulcer, dysplasia) [81, 82]. However, even in studies which found increased amounts of bile acids in GERD patients, their concentration seldom exceeded 1.0 mmol/l, the concentration regarded high enough to produce oesophageal mucosal lesions [83].

Although it is clear today that increase of pH above 7 cannot be regarded as a marker of DGER, oesophageal pH monitoring was used in the past to trace for "alkaline reflux". Several groups published their findings of significantly higher amounts of both acid and alkaline reflux in patients with complicated oesophagitis, Barrett's oesophagus and complicated Barrett's oesophagus [84]. These investigators went on to suggest that prolonged exposure of oesophageal mucosa to duodenal contents alone may promote the development of complicated Barrett's oesophagus and even adenocarcinoma.

Most of the knowledge about the clinical importance of DGER in oesophageal pathology arrives from studies using simultaneous oesophageal pH monitoring and bilirubin spectrophotometry with Bilitec 2000. These studies again pointed out the importance of DGER in the development of Barrett's oesophagus as in the majority of them patients with Barrett's oesophagus had a significantly greater exposure to both acid and duodenal contents than patients with reflux oesophagitis or healthy controls [14, 85, 86]. Moreover, it seems that patients with long segment and complicated Barrett's oesophagus have particularly increased exposure to DGER [82, 87]. In comparison with patients with short segment Barrett's oesophagus, they have similar acid reflux but significantly greater reflux of duodenal contents. With some exceptions that did not find significant differences in GERD between controls and patients with reflux oesophagitis [14], a gradual increase of both acid reflux and DGER has been proven across the GERD spectrum, being the lowest in healthy persons and in patients without oesophagitis, higher in patients with reflux oesophagitis and the highest in patients with Barrett's oesophagus [15, 86, 88]. Barrett's oesophagus is a rare disorder in children; therefore, paediatric studies did not include patients with Barrett's oesophagus. However, both acid reflux and DGER exposure were found to increase stepwise with the severity of oesophagitis. They were lower in children with GERD symptoms but without reflux oesophagitis compared with children with reflux oesophagitis, and children with severe oesophagitis (Los Angeles grades C and D) had more refluxes than those with mild oesophagitis (Los Angeles grades A and B) (Fig. 128.3) [17].

Duodeno-gastro-oesophageal reflux may cause symptoms, although symptom episodes in patients with GERD seem to be more often related to acid reflux episodes [89, 90]. There is a growing evidence that pathologic amounts of DGER without pathologic acid reflux can result in erosive reflux oesophagitis both in adults [91–94] and children [17, 95]. In my experience, a majority of children without oesophagitis has no pathologic refluxes. Isolated pathologic acid reflux or isolated DGER cause mild oesophagitis, and a combination of both cause severe oesophagitis (Fig. 128.4) [17]. However, in some patients with reflux oesophagitis or even Barrett's oesophagus, the results of both pH monitoring and bilirubin spectrophotometry can be normal [96].

Duodeno-gastro-oesophageal reflux may play an important role in the pathophysiology of proton pump inhibitor-refractory GERD [97, 98]. Although pathologic acid reflux, pathologic DGER or a combination of both were found in adults and children not responsive to the therapy with proton pump inhibitors (PPIs), acid exposure did not differ according to the presence of oesophagitis, but patients with substantial oesophagitis had significantly higher DGER exposure than those without oesophagitis [98, 99]. DGER may also participate in the development of more severe forms of GERD in children with additional risk factors like neurological and developmental disorders, cystic fibrosis and operated anomalies of upper gastrointestinal tract. Significantly higher gastric bilirubin levels were found in children with cystic fibrosis when compared with healthy subjects that may result in exaggerated DGER [100].

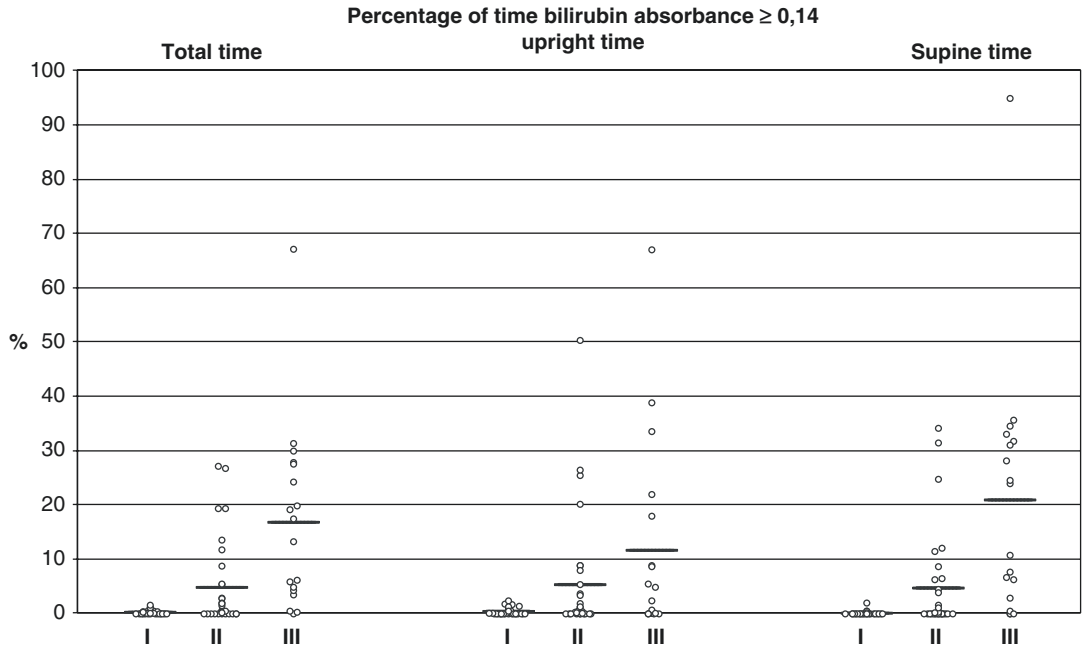

Fig. 128.3 Results of 24 h DGER monitoring with fiber-optic spectrophotometer expressed as mean and individual values in children without oesophagitis (I), with mild to moderate oesophagitis (II) and with severe oesophagitis (III) for percentages of total time, upright time and supine time with bilirubin absorbance ≥0.14 [17]

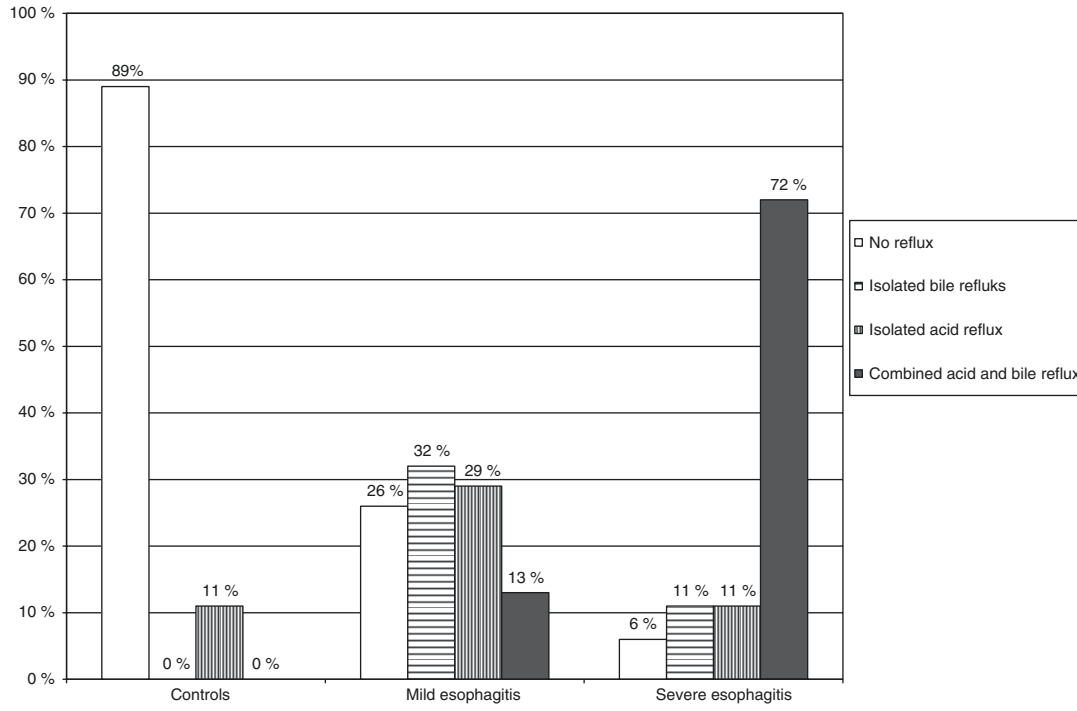

Fig. 128.4 Percentage of patients with no pathologic reflux and with three different patterns of pathologic reflux (isolated bile reflux, isolated acid reflux and combined acid and bile reflux) in the groups of children without oesophagitis, with mild to moderate oesophagitis and with severe oesophagitis [17]

As DGER or its effects may extend beyond the oesophagus, it may cause or contribute to a variety of supra-oesophageal manifestations. Pathological DGER was found in patients with unexplained excessive throat phlegm [101]. Significant higher prevalence of symptoms and findings of laryngeal damage including laryngeal neoplastic lesions was reported in patients after gastric surgery with presence of bilirubin and bile acids, indirect markers of DGER, in saliva [20]. Moreover, pathological acid reflux and especially excessive "alkaline" reflux were found to be elevated and could be implicated into the pathogenesis of neoplastic lesions of the pharynx and larynx [102].

Simultaneous oesophageal pH monitoring and bilirubin spectrophotometry explained the exact relationship between DGER and oesophageal pH. Firstly, these studies revealed that DGER rarely coincide with so-called alkaline shift (a rise of pH over 7), suggesting that the term "alkaline reflux", previously often used synonymously with DGER, is a misnomer [24, 88]. Secondly, DGER appears across the whole oesophageal pH spectrum. Whilst some studies found DGER episodes most frequently between oesophageal pH 4 and 7 [14, 24], the others discovered the majority in an acidic environment (pH < 4) [15]. It was shown that in children, DGER episodes most frequently begin at pH between 6 and 7, the pH of an empty oesophagus. However, after the beginning of an episode, oesophageal pH may change. The pH of the refluxate depends on the proportions of acid gastric juice, food and duodenal juice in it. It is interesting that in children without oesophagitis, relative duration of DGER was longest between pH 5 and 6, in children with mild oesophagitis between pH 4 and 5, whilst in those with severe esophagitis, it was between pH 2 and 4 [25]. From these observations, one can hypothesise that the lower the pH at which DGER occurs, the more severe the oesophageal damage, resulting from simultaneous effects of gastric and duodenal juice components.

Therapy

Both pharmacological and surgical therapies of excessive DGR and DGER have been profoundly studied.

Specific aims of treating DGR and DGER with medications can be directed at three components: decreasing gastric acid secretion, promoting motility and gastric emptying and neutralising or binding bile acids and making them less injurious to the gastric and oesophageal mucosa [103].

Acid suppression, particularly with PPIs, is the mainstay of treatment of gastric and oesophageal diseases. Several clinical studies revealed that treatment with PPIs and even H_2-blockers dramatically decreases not only acid reflux but also reflux of duodenal juice into the oesophagus, both in adults [88, 104–107] and children [108] (Fig. 128.5). The proposed mechanism is reduction of the volume of gastric secretions, with less fluid available in the stomach for any DGR to mix with and thence to reflux into the oesophagus. This mechanism may also explain the reduction in DGR to the upper part of the stomach, a prerequisite for DGER [104]. Moreover, some studies showed that acid suppression therapy can influence gastric and duodenal motility by increasing antral phase III MMC, which have the role of "street sweeper" and clean the duodenal reflux contents from stomach. MMC III is evoked by a presence of bile and pancreatic juice and neutralisation of acid in the duodenum but can be inhibited by acidic pH. Therefore, PPIs may also decrease DGR and DGER through increasing MMC III due to increased duodenal pH [107]. The second proposed mechanism seems more likely since studies using combined oesophageal pH monitoring and intraluminal impedance revealed that therapy with PPIs does not affect volume reflux into the oesophagus [109]. It should not be forgotten that several DGER components such as conjugated bile acids and lysolecithin are most dangerous to the oesophageal mucosa at acidic pH when their harmful effect is synergistic with gastric acid and pepsin. Their activity can be neutralised by rising oesophageal refluxate pH with acid suppression therapy.

Cisapride promotes the release of acetylcholine from the myenteric plexus and thereby improves gastric emptying and increases lower oesophageal sphincter pressure. Several studies showed that cisapride relieves symptoms in both adult [110] and paediatric [98, 111] patients with excessive duodenal reflux. However, the results of studies using objective

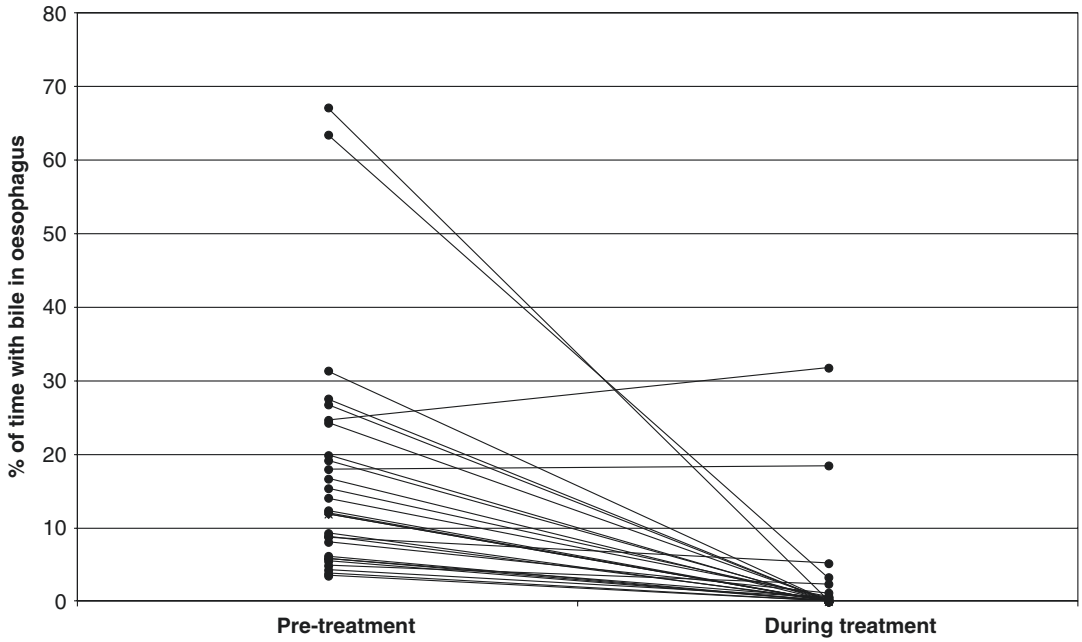

Fig. 128.5 The effect of therapy with omeprazole on duodeno-gastro-oesophageal reflux in children [108]

measurements of DGR or DGER for assessment of the efficacy of cisapride are conflicting. Significant decrease of DGER was observed during therapy with cisapride in a placebo-controlled trial in postgastrectomy patients [110], but not in patients with gallstones and intact stomach [112]. Cisapride is not available any more, as it has been withdrawn from the market because of its interactions with many other drugs and serious side effects.

Domperidone, a peripheral dopamine (D_2) receptor antagonist, acts as an antiemetic and prokinetic agent through its effects on the chemoreceptor trigger zone and motor function of the stomach and small intestine, thus promoting gastric emptying by augmenting gastric peristalsis and improving antroduodenal coordination. Domperidone was effective both in amelioration of symptoms and in decreasing nocturnal bile reflux into the stomach in patients with functional dyspepsia [113].

Erythromycin, an antibiotic with prokinetic properties, almost completely normalised DGR in all patients with pathological DGR after biliary surgery [114].

Baclofen, the gamma-aminobutyric $acid_B$ ($GABA_B$) agonist, inhibits the occurrence of transient lower oesophageal sphincter relaxations that are the main pathophysiological mechanism underlying the gastro-oesophageal reflux. In a study in patients with DGER refractory to PPIs, baclofen reduced both the number and the duration of DGER episodes significantly [115].

Cholestyramine is a basic anionic exchange resin that binds bile salts. In an uncontrolled study, cholestyramine helped some patients with mild bile reflux gastritis [116], but this finding was not confirmed in a later randomised, double-blind study [117].

Aluminium hydroxide but not magnesium hydroxide antacids absorb conjugated bile acids and lysolecithin with an affinity and capacity comparable with cholestyramine. Their efficacy in symptom relief of bile reflux gastritis was equivalent to cholestyramine but not better than placebo [117].

Ursodeoxycholic acid (UDCA) is potentially effective by changing the composition of the refluxed bile, which may be less noxious to the gastric and oesophageal mucosa. In a placebo-controlled study in patients with bile reflux gastritis, a therapy with UDCA resulted in significant amelioration of symptoms but had no effect on the macroscopic and microscopic appearance of the gastric mucosa [118].

Sucralfate is the basic aluminium salt of sulphated sucrose that adheres to exposed proteins

in damaged mucosa, protecting them from acid, pepsin and bile acids. In a placebo-controlled study in patients with bile reflux gastritis, sucralfate lowered the gastric inflammatory cell scores but was not associated with improvement of symptoms [119].

Remnant chemical gastritis as a consequence of excessive DGR after subtotal gastrectomy can probably be prevented by choosing reconstructive procedures which decrease retrograde flow of duodenal juice and particularly bile into the stomach. Studies revealed that Roux-en-Y reconstruction is better than Billroth I or II [120, 121]. With Roux-en-Y operation, a 45–60 cm-long isoperistaltic limb of jejunum is created between partially resected stomach and jejunal limb draining the pancreatic biliary system [103]. The Roux-en-Y operation was shown to preserve the cardia and the position of the remnant stomach better than other procedures. In patients after resection of the extrahepatic bile duct, Roux-en-Y hepaticojejunostomy was more effective in prevention of excessive DGR than hepaticoduodenostomy [67]. The Roux-en-Y anastomosis is also a successful therapy for patients with intractable symptoms of remnant gastritis and documented increased DGR after other gastric operations [122, 123]. However, side effects include ulceration, delayed gastric emptying and dumping [103]. Duodenal switch is an operation in which the stomach and proximal 5–7 cm of the duodenum are left intact. The jejunum is divided about 25 cm distal to the ligament of Treitz. The distal limb is anastomosed end to end to the proximal portion of the duodenum, and the proximal limb of the jejunum is anastomosed end to side to the distal jejunum. This may be the preferred operation in patients with excessive DGR and intact stomach as complications are markedly reduced compared to Roux-en-Y operation [103, 124]. However, such aggressive surgery is nowadays not a realistic therapeutic option in patients and especially in children with pathology due to excessive DGR and DGER without previous gastric or biliary operation. Exceptions to this rule are patients with severe gastro-oesophageal reflux disease refractory to pharmacological therapy who may benefit from anti-reflux surgery. Several studies showed that DGER adequately decreases after Nissen fundoplication [125, 126].

Gastric Pacing

129

Marc Christopher Winslet

Introduction

Gastric pacing is used in the treatment of gastroparesis. Although fewer children are affected than adults, their symptoms are equally debilitating. Children often require hospital admission and parenteral feeding, and they suffer disruption to their schooling. The diagnosis, however, may not be as easy to make in children, either because it might be seen as part of another condition or because of its lack of recognition amongst practitioners [13].

Stimulation of the stomach has been considered a possible treatment for the symptoms of gastroparesis for approximately 50 years. Initially the generated stimulus mirrored the natural frequency of gastric motility in a hope to entrain the stomach, so-called gastric pacing. Animal studies produced a combination of stimulus frequency and energy that could produce the optimum motility, called gastric electrical stimulation (GES). The theory was applied to a young insulin-dependent diabetic woman with encouraging results. In 2000, an implantable unit became widely available which has gained US Federal Drug Administration (FDA) approval, but not UK National Institute for Health and Care Excellence (NICE) approval.

Gastroparesis

Gastroparesis is a disorder defined by objective evidence of delayed or disordered stomach emptying in the absence of mechanical obstruction.

The most common symptoms are severe nausea and vomiting, but others include early satiety, postprandial fullness, bloating, abdominal discomfort, epigastric pain and/or weight loss. In adults, the commonest causes are diabetes, idiopathic and surgery, in particular with vagotomy. In children, postviral illness is the usual cause and should be self-limiting, taking several months to resolve [11]. The next commonest causes in children are idiopathic, which tends to be longer lasting and more severe, and also following surgery. Rarely, it is due to an autoimmune illness, or as part of a paraneoplastic process. Diabetic gastroparesis can be recognised in children, as seen in three cases of insulin-dependent diabetic children aged between 10 and 15 years [23].

Diagnosis

Once neoplastic and obstructive causes have been excluded, gastroparesis can be confirmed

using scintigraphy, ultrasonography, ^{13}C-breath testing, magnetic resonance imaging, swallowed-capsule telemetry, antroduodenal manometry and electrogastrography (EGG) [21]. Scintigraphy is considered the gold standard investigation, but is not always available. It should be performed with a calorie- and nutritional-standardised solid meal labelled with technetium-99m sulphur-colloid bound to egg, rather than a liquid meal, as liquids may have normal gastric emptying times. Measurements are taken at 2 h and 4 h post-ingestion, and can be expressed as percentage remaining within the stomach at these times. Ultrasonography can be very useful in children as it is less invasive and only requires the ingestion of a standardised meal, although the quantity ingested may vary according to age. It requires a skilled ultrasonographer to undertake measurements of various parameters of the stomach. Antroduodenal manometry can provide information on whether the delayed gastric emptying is due to antral or duodenal causes, and also whether a neurological or muscular disease may be causing it. EGG is a noninvasive technique and was introduced in 1921 by Alvarez. By placing electrodes cutaneously on the long axis of the stomach, it is able to measure the slow wave, generated by the stomach's pacemaker, the interstitial cells of Cajal. The slow wave is not directly associated with contractile activity, but with the spatial and temporal organisation of gastric contractions [16]. It has been found that 75 % of patients with gastroparesis have an abnormal EGG, and also experience more severe symptoms. A study from 2004 [17] investigated GES using EGG on 15 patients with gastroparesis. It was shown to enhance the slow-wave amplitude and propagation velocity and resulted in a significant improvement in nausea and vomiting but did not entrain the gastric slow wave or improve gastric emptying. There appears to be no difference in myoelectrical activity in children compared to adults from age, gender or body mass index (BMI), as measured in 55 children aged between 6 and 18 [16]. EGG has demonstrated antral hypomotility in diabetic children [6].

Treatment

Coincidental with treating the symptoms of gastroparesis, the electrolyte imbalances that it may produce must also be treated. Hyperglycaemia induces delayed gastric emptying and reduces the efficiency of prokinetics, so normoglycemia should be aimed for. Dietary changes aim for an easily digestible meal which can be emptied quickly using liquid [11] or soft, frequent, low-fat, low-fibre meals and high-calorie liquid supplements [4]. First-line pharmacotherapy treatments use prokinetic agents such as erythromycin, metoclopramide and domperidone and antiemetics including phenothiazines, antihistamines and 5-HT receptor agonists.

Local treatments for gastroparesis have employed the injection of Botox into the pylorus, as pylorospasm has been observed in diabetic gastroparesis, but a double-blind controlled crossover study found no improvement over placebo. Until the advent of gastric stimulation, via pacing, the next progressive step in the management of gastroparesis was surgery employing the palliative procedures of venting gastrostomy, and pyloroplasty for gastric emptying, and providing enteral nutrition with a feeding jejunostomy [14, 22]. When all other treatments fail, a subtotal gastrectomy, or as a last resort, total gastrectomy can be used, but these carry higher morbidity and mortality rates [10]. To date there has only been one report of a paediatric Billroth I procedure in a 15-year-old for intractable nausea who had undergone three attempts at repair of a congenital diaphragmatic hernia [15].

Gastric Electrical Stimulation

History

Gastric pacing was first documented as a treatment for ileus in 1963 [3]. The desire to create a series of contractions that mimicked the normal gastric pattern was based on the assumption that it was the prolonged gastric emptying that produced the debilitating symptoms of intractable

vomiting and nausea [20]. The technique began with the temporary placement of electrodes connected to an externally housed generator unit. The stimuli produced were of high energy and a frequency comparable to intrinsic contractions, namely, three per minute. In 1997 the first case of stimulation at a higher frequency was published. The background research for choosing this frequency was based upon a canine model which studied varying combinations of frequency and energy of the generated pulses [7]. They found the frequency which produced the largest motility index and entrained the stomach was four times the physiologic rate. These results were then applied to a human case by the same research group [8] using pulses of width 300 μs, current of 2 mA and a frequency of 12 cycles per minute. The subject chosen was a 29-year-old insulin-dependent diabetic woman with symptomatic gastroparesis, and the results showed improvement in her symptoms, as evidenced by recurrence with electrode malfunction and reimprovement when another of the simultaneously placed electrode pairs were used to continue pacing. Also gastric entrainment occurred, in addition to an improved gastric emptying rate, although she remained on cisapride throughout the study. A year later, a study on nine patients with severe gastroparesis had a series of 4 mA currents applied with a width of 300 ms and a frequency of 10 % higher than that recorded at baseline [19]. This showed a significant improvement in symptoms, and all nine patients' stomachs were entrained, and had reduced gastric emptying times, with a mean time of 5 min (range 1–10 min) A preliminary report from a trial 2 years previously using a frequency of 12 cycles per minute also showed symptom improvement, but there was no data for gastric emptying times [12]. Again a further study from 1998 revealed immediate improvement in nausea and vomiting, with the possibility of the delayed effect of improved gastric emptying time using the same stimulation characteristics. It is thought that this high-frequency, low-energy combination may exert its effects via neuronal activity rather than true pacing of the slow wave [24] and direct muscle contraction; thus, it is referred to as gastric electrical stimulation. An implantable system was produced, and in 2000 the Enterra™ Therapy System was approved for use in the USA.

How It Works

How the technique brings about a reduction in symptoms is unknown, but is thought to involve a neuronal pathway. The stimulation impulses are too weak to excite gastric smooth muscles, but are able to excite gastric nerves. The possibility that it may exert its effects through a placebo-like action has been disproved by a multicentre double-blind, randomised crossover trial on adults [2]. This year-long trial initially randomised 33 patients (17 diabetic and 16 idiopathic) to a month of the stimulator setting to its 'on' or 'off' mode, followed by a further month in the opposite mode (i.e. 'off' or 'on'). To complete the study, all the pacemakers were set to 'on' for the remaining months to achieve 6- and 12-month follow-up. The results were measured by recording all symptoms using a total symptoms score (TSS; bloating, early satiety, epigastric pain, nausea, postprandial fullness and vomiting, combined with a 5-point severity score for each symptom) and gastric emptying by a low-fat test meal and scintigraphy. They found that there was a significant decrease in vomiting frequency and total symptom score throughout the study regardless of cause, and no association between changes in symptoms and gastric emptying. For children, there is no equivalent trial, and thus far there has only been one published case series of gastroparetic children receiving an implanted GES [13] for intractable nausea.

Implantation

The gastric electrical stimulator generates low-energy stimuli at a frequency of 12 cycles/min (high frequency) that restore myoelectrical activity.

The pacemaker itself looks very much like a cardiac pacemaker, with a similar-sized generator unit. The device is implanted at surgery under a general anaesthetic, using either an upper midline laparotomy or laparoscopic approach. Two electrodes are placed through the serosal surface of the stomach, 1 cm apart, approximately 10 cm from the pylorus, corresponding to the site of the intrinsic pacemaker. During the operation the electrodes, which are attached to button-like pads, are stitched into place using a non-absorbable suture, and a gastroscopy is performed to ensure that their tips have not perforated the mucosa. A lead is attached to each electrode, and the wire is passed through the rectus muscle on either side of the abdomen and into a subcutaneous pocket created to house the generator unit. It is important to make sure that the leads are treated with care and that there are not excessive lengths within the abdominal cavity. The subcutaneous pocket is closed independently of the midline mass closure. The functioning of the unit needs to be checked at various points during the operation to ensure that no dislodgement of the leads has occurred, and also just before and after abdominal closure.

A laparoscopic approach can be used instead of an upper midline laparotomy. The number of ports varies by surgeon preference, employing either three ports (two 5 mm, and one 10 mm port which later is enlarged to house the stimulator) [13], or four (three 5 mm and one 10 mm) [5].

Results: Children

The only published case series in children [13] has only nine cases. Eight were female and one male, and eight were suffering with nausea. Five had idiopathic gastroparesis, two were idiopathic/postviral, and one was postsurgical following operations for oesophageal atresia with tracheoesophageal fistula with her last operation, a redo ileocolic anastomosis 1 year previously. All underwent gastric emptying studies with scintigraphy and EGGs for temporary pacing. The temporary pacing for 2–7 days was performed using endoscopically placed wires which were brought out through the mouth and connected to the stimulator unit. The last five cases also had biopsies taken to analyse for the interstitial cells of Cajal. Results of this small series showed that both nausea and vomiting were reduced with the use of both temporary and permanent pacemakers, and as seen in the adult reports, there was no improvement in gastric emptying times. As seen in adult reports, patients who have abnormal or fewer interstitial cells of Cajal have a poorer prognostic outcome with the pacemaker. In one of the patients, the pacemaker failed within 2–4 months, and in another there was progression of multiple autoimmune diseases (lupus, diabetes mellitus and hypothyroidism). Seven children were able to return to schooling.

Results: Adults

Gastric pacing using high-frequency, low-energy impulses has produced consistent results from different centres. Total symptom scores recorded pre- and post-investigation have shown improvement in vomiting, early satiety, bloating, postprandial fullness, nausea and epigastric pain; however, gastric emptying appears not to be significantly improved by this procedure. There appears to be no direct correlation between gastric emptying times and symptomatic improvement [1, 10, 17]. In a subset of a pacing trial (Gastric Electromechanical Stimulation (GEMS) study group), the nutritional aspect of pacing was considered. Twelve patients between 19 and 48 years (eight women and four men) had their weight, BMI, albumin, cholesterol, complete blood count and route of nutrition recorded at baseline, 12 months, 24 months and 5 years. The weight and BMI increased to a statistically significant level, but although their biochemistry improved, it was not to a significant level beyond 6 months.

There are few studies providing long-term data, but it has shown that symptoms remained significantly lower up to 3 years following insertion, and patients retained their weight gain [18].

Complications of Pacemakers

The commonest complication of pacemakers is infection within the pocket necessitating its removal, and can occur at any time following implantation [1, 10, 18]. This may be due to malnutrition, the systemic complications of diabetes and the wound being situated near a stoma site. In one instance, trauma to the skin overlying the pacemaker resulted in its extrusion and removal [13]. Other rarer complications are small bowel volvulus around the leads, and the pacemaker switching itself off. This latter complication manifested itself by patients returning to hospital complaining that their symptoms had returned. It is thought to have been caused by electromagnetic fields produced by strong magnets such as the ones found in airport scanners, department stores and loudspeakers [9].

Conclusion

GES has produced some fairly consistent results from nearly a decade of data from the implantable unit. Patients do experience fewer debilitating gastrointestinal symptoms and admissions to hospital, are less dependent on jejunal feeding and parenteral nutrition and have a better quality of life.

The question surrounding how it mediates its effects remains to be answered, and there is still very little data regarding the use of the device in children. In addition, there are no long-term follow-up results for the only published case series of nine children.

More long-term research needs to be undertaken, including the effects on children.

Dermatology and the Oesophagus 130

Sue Protheroe

Diseases of the skin and oesophagus coexist more frequently than could be expected by chance. This could be explained by similar functions and origin of both these organs. They both provide a protective layer and interface with the external environment being first point of contact with infective, irritant, or allergenic agents. Both the organs are lined by stratified squamous epithelium that contains immunocompetent antigen-presenting cells. Structurally, the oesophageal wall is composed of four layers: innermost mucosa, submucosa, muscularis propria, and adventitia. Oesophageal mucosa is nonkeratinized stratified squamous epithelium except at the gastroesophageal junction (GEJ), where squamous epithelium joins the columnar epithelium of the gastric cardia. Unlike the remainder of the GI tract, the oesophagus has no serosa. The basal cell layer (BCL) makes up approximately 20 % of the epithelial layer and is lined by lamina propria (LP), which is a thin layer of connective tissue.

Several types of interaction between the skin and the oesophagus are possible. The awareness of association between these organs is important as it not only helps in establishing a diagnosis but also helps in anticipating and recognising complications associated with them.

The common interactions include:

1. Dermatological manifestations of a primary gastrointestinal (GI) disease
2. Oesophageal involvement in a primary skin disease
3. A common pathology affecting both organs (Table 130.1)

Recognition of this association between oesophageal and skin disease is important in identifying the common pathology. Early Diagnosis is possible when identifying dysphasia in children with personal or family history of a skin condition. The correct diagnosis of such conditions relies on the ability of the gastroenterologist to recognise the underlying dermatologic disorder (Table 130.2).

Since the neuromuscular anatomy of the proximal and distal portions of the oesophagus is different, various diseases can affect either the skeletal or smooth muscle portions of the oesophagus. The upper third consists of muscularis propria, and the upper oesophageal sphincter (UES) is skeletal muscle and innervated by the central nervous system via vagal and the recurrent laryngeal nerves. There often are overwhelming symptoms of dysphagia and odynophagia because of involvement of striated muscle of the oesophagus or oropharynx. Muscular diseases affecting the striated muscle include muscular dystrophies (myotonic and oculopharyngeal, the former presenting more

often in children, although relatively rare) and inflammatory myopathies (e.g. dermatomyositis, polymyositis, and inclusion body myositis).

The distal third of the oesophagus and lower oesophageal sphincter is composed of smooth muscle which is aligned in a circular fashion. Smooth muscle is innervated by the autonomic nervous system which involves neurons in the myenteric plexus of the wall. Scleroderma causes abnormalities of the autonomic nervous system, microvasculature, and immune system and causes smooth muscle atrophy and fibrosis. The middle third of the oesophagus is a mixture of both types of muscle (transition zone).

Collagen Vascular Diseases

Systemic sclerosis (SSc) or scleroderma is a connective tissue disease and one of the most important secondary motor disorders to affect the oesophagus. The proximal one-third of the oesophagus, with its striated muscle, is spared. SSc causes abnormalities of the autonomic nervous system, microvasculature, and immune system. Atrophy of the smooth muscle layers of the muscularis propria characterises oesophageal involvement. It is accompanied by varying degrees of tissue fibrosis and chronic inflammatory infiltration in numerous visceral organs, prominent fibroproliferative vasculopathy, and humoral and cellular immune alterations. Juvenile systemic sclerosis, although rare, accounts for 5% of all cases [55]. It is more likely to occur in children between 10 and 16 years, is common in females as compared to males, and is equally distributed across all races [18].

Skin disease is in the form of skin tightness and induration with hypo- or hyperpigmentation. The skin of the hands may be oedematous or swollen early in the disease and precedes the indurated sclerotic stage. In the sclerotic phase, the skin may appear tight and shiny, with a characteristic loss of hair, decreased sweating, and loss of the ability to make a skin fold. This process of thickening generally begins distally on the fingers and progresses proximally in a continuous symmetrical fashion.

The gastrointestinal tract is frequently affected in diffuse and limited disease. Although any part of the gastrointestinal tract can be involved,

oesophageal disease occurs in nearly all patients. Patients may have no symptoms and simply present with features of the connective tissue disorder. Oesophageal involvement leads to reflux symptoms including heartburn and acid regurgitation reported in up to 50 %. Smooth muscle atrophy and fibrosis of the distal two-thirds of the oesophagus result in diminished peristalsis. The extent of the resulting hypomobility can vary from occasional uncoordinated contractions to complete paralysis [1]. Reflux, seen in 40 % of the cases, is a result of low pressure in lower oesophageal sphincter and disturbed peristalsis. This causes reflux oesophagitis and dysphagia in 1.5–13 %, though the severity of these symptoms is not related to degree of oesophagitis [14]. Dysphagia is possibly due to hypotensive oesophageal contractions or non-peristaltic contractions, but it more commonly relates to superimposed stricture formation or oesophageal inflammation, which results in loss of compliance of the distal oesophagus.

The x-ray findings in scleroderma oesophagus may sometimes be confused with achalasia as both may show a dilated oesophagus with narrowing at the GEJ. However, endoscopic and manometric findings can differentiate the two quite easily [17]. Manometric studies in juvenile localised scleroderma reveal that oesophageal involvement occurs even in the absence of specific symptoms [24]. Candida oesophagitis is a complication of SSc not seen with non-SSc reflux and is due to poor emptying of the oesophagus, immunosuppressive therapy, and acid suppression predispose [21]. Long-term complications include strictures, found in 17–29 % of adults. Most patients with oesophageal involvement with scleroderma have associated Raynaud's phenomenon. Respiratory symptoms may also occur, owing either to direct lung involvement with scleroderma or to aspiration.

Treatment of gastroesophageal reflux in SSc includes behavioural modification and medical therapy, mainly with proton pump inhibitors and prokinetic agents. Surgical intervention has only a limited role in management [44].

Systemic lupus erythematosus (SLE) is an autoimmune connective tissue disease of the small vessels. It is more common in girls with the peak age of incidence between 14 and 17 years. Dysphagia occurs in up to 13 % of adults with SLE and heartburn in up to 50 %. Oesophagitis with ulceration has been observed in 3–5 % and oesophageal perforation may rarely occur. Reduced oesophageal motility has been demonstrated in up to 72 % of adults with SLE [11], and although the motility disorder is mostly mild, aperistalsis has been reported up to a fourth of the patients [25]; the symptoms of dysphagia is worsened by gastroesophageal reflux and secondary candidiasis.

Treatment of dysphagia is systemic control of inflammation with corticosteroids and non-steroidal anti-inflammatory agents. The use of prokinetic agents and proton pump inhibitors has also been shown to be helpful in reducing symptoms [27].

Dermatomyositis

Inflammatory myopathies are acquired muscle diseases which include polymyositis and dermatomyositis. The dysphagia associated with these myopathies primarily affects the skeletal muscle-activated oropharyngeal phase of swallowing and may precede weakness of the extremities or present as the sole symptom [63].

Dermatomyositis is an idiopathic inflammatory microangiopathy affecting the skin and muscles characterised by progressive proximal symmetrical weakness, elevated levels of muscle enzymes, and cutaneous lesions. The pathognomonic features include heliotrope rash, a symmetrical erythematous rash involving the periorbital region, and Gottron papules: papules and plaques found over bony prominences, particularly the metacarpophalangeal joints, the proximal interphalangeal joints, and the distal interphalangeal joints. Other skin changes include malar erythema, violaceous erythema, and poikiloderma. Gastrointestinal involvement is seen in 5 % of children and up to 40 % during the course of the disease due to underlying vasculopathy or impairment of muscle function. Dysphagia is the most common symptom.

One-third of affected children have oesophageal disease [47], which mainly involves the striated muscles of the oesophagus (as in the rest of the body), but up to two-third of affected patients have dysfunctional motility in the distal oesophagus, implying involvement of smooth muscles as well [26]. Vasculitis also leads to inflammatory changes.

Dysphagia as a result of abnormal motility and reflux may be the presenting feature of the disease, but the diagnosis may not be apparent until the dermatologic disease is clearly observed [64]. There is a direct correlation between GI symptoms and the severity of peripheral skeletal muscle weakness [21]. Vascular changes can cause ulcerations in the oesophagus rarely leading to perforation [16].

Barium contrast studies reveal a dilated oesophagus with reduced peristaltic movements and gastroesophageal reflux in 30–50 % of cases [34]. Oesophageal manometry can also be used in selected cases.

A variety of medical, rehabilitation, and interventional treatments are used to manage inflammatory myopathies-associated dysphagia. Medical treatment emphasises control of the disease process, whereas rehabilitation focuses on swallowing compensation techniques, exercises, and diet modification. Most commonly used pharmacological agents are systemic corticosteroids. Other medications used for this purpose include azathioprine, methotrexate, cyclophosphamide, cyclosporine, mycophenolate mofetil, tacrolimus, rituximab, IVIG, or plasmapheresis [64].

Graft-Versus-Host Disease

The oesophageal epithelium, like skin and mucous membranes, is a target organ in chronic graft-versus-host disease.

Graft-versus-host disease (GVHD) is an immune-mediated disease resulting from a complex interaction between donor and recipient adaptive immunity. The main effectors in GVHD are immune-competent donor T cells in the grafted organ.

GVHD can be acute if it occurs within the first 100 days or chronic, if it occurs after this period. Acute GVHD occurs in 35–50 % of children after haematopoietic stem cell transplant and less frequently after solid organ transplant. The three main organs involved include skin, liver, and gastrointestinal tract. The earliest manifestation is skin GVHD which is in the form of a maculopapular rash that often starts with the palm and sole but can involve any part of the body.

The gastrointestinal involvement of acute GVHD is in the form of enterocolitis. It can sometimes affect the oesophagus presenting as anorexia, dyspepsia, food intolerance, nausea, and vomiting in children [5] due to desquamative oesophagitis with web formation. Mucosal oedema, hyperaemia, and widespread sloughing are seen, and severe cases may present with bullous lesions of the oesophagus.

Diagnostic endoscopy and disruption of webs should be performed carefully to avoid perforation. Treatment should be directed toward suppressing the underlying immunologic disorder and at preventing acid-peptic reflux.

Chronic GVHD presents 100 days after the transplant. Skin changes are the commonest presentation and can be lichenoid and sclerodermatous [6]. Lichenoid type, characterised by epidermal atrophy and irregular acanthosis, predominates early in the course of chronic GVHD. Sclerodermatous form appears late, usually 6–12 months after transplant. It is insidious in onset and can be in the form of localised plaques on the trunk or over pressure areas or widespread involvement.

Involvement of the oesophagus in chronic GVHD is seen in about a quarter of the patients and presents as dysphagia, weight loss, and retrosternal pain. Oesophagitis and desquamation of the mucosa can lead to development of webs and strictures. Strictures though not common can be seen in 7 % of children with dysphagia symptoms [56]. Prompt recognition of oesophageal disease and institution of immunosuppressive therapy dramatically alters the natural history of this disease [39]. The radiographic findings of 14 symptomatic patients with chronic GVHD involving the oesophagus were reviewed and found to

Fig. 130.1 Graft-versus-host disease. Desquamation and fibrosis are seen characteristically in chronic GVHD

have webs, ring-like narrowing, and tapering strictures in the mid- and upper oesophagus [39].

Endoscopic examination is the most important investigation and shows mucosal desquamation most pronounced in the upper part. Changes of chronic inflammation and resultant strictures or webs can also be seen. A fifth of the patients with oesophageal symptoms could have normal endoscopic appearances, and the diagnosis is confirmed by characteristic histological changes on biopsy [62]. The specific histological features of oesophageal involvement include the presence of epithelial single-cell necrosis which may or may not be accompanied by increased inflammation and reactive epithelial changes or loss. Ulceration and submucosal fibrosis reflect long-standing disease but are not specific features of oesophageal GVHD [48] (Fig. 130.1).

Acute GVHD of GI tract responds promptly to immunosuppressive therapy. The most commonly used treatment is systemic corticosteroids. For children who are refractory to treatment with steroids, alternatives used are infliximab, rituximab, and antithymocyte globulin (ATG). Maintenance of nutrition is just as important as immunosuppressive therapy, and early immunosuppression and nutritional therapies have shown to be associated with improved outcome [18]. Response to immunosuppression is not effective in children with chronic GVHD, and various steroid-sparing agents are used to minimise the side-effects of long-term corticosteroid therapy. Management of oesophageal strictures is by dilatation, although the risk of recurrence of stricture remains high [36].

Oro-Oculo-Genito-Cutaneous Syndromes

Behcet's Disease

Behcet's disease (BD) is a multisystem disorder characterised by aphthous ulcers, genital ulcers, and eye lesions. The primary lesion is vasculitis which mainly involves the small vessels. The pathogenesis of BD is unknown, genetic susceptibility may be present, and the disease may be triggered by infection. It is more common in males of Asian or Mediterranean descent, and only 1–2 % of the affected patients with BD are in the paediatric age group [45]. Neutrophilic hyperfunction and infiltration of lesions by neutrophils is characteristic. This forms the basis of tests which is formation of a neutrophil-rich pustule at the site of needle prick to the skin. Painful recurrent oral ulcers are the most common-presenting feature with other symptoms being genital ulcers, posterior uveitis, and skin lesions. Skin lesions are in the form of erythema multiforme, papulopustular lesions, ulcers, erythema nodosum, thrombophlebitis, or necrotizing vasculitis.

Gastrointestinal involvement is seen in 50 % of cases and mainly involves the small or the large bowel. Oesophageal involvement is rare and is in the form of ulceration, erosions, and widespread oesophagitis [41]. Ulcers are typically longitudinal and present in the middle part of the oesophagus. They are usually deep tunnelling ulcers and can lead to stricture formation. Histology shows features of nonspecific inflammation with neutrophilic infiltration.

Treatment is with immunosuppressive medications like systemic corticosteroids though steroid-sparing agents like azathioprine, cyclosporine, and anti-TNF agents are increasingly

being used [35]. 5-ASA medications, by virtue of their anti-inflammatory effects, are also effective in treating oesophageal disease associated with Behcet's disease [60].

Stevens-Johnson Syndrome (SJS)

SJS is an inflammatory disorder that predominantly involves the skin and mucous membranes and is triggered by an allergic reaction to certain drugs such as sulphonamides, tetracycline, amoxicillin, and ampicillin. Skin involvement starts as erythematous macular rash which is followed by epidermal detachment which involves up to 10 % of the total skin surface area. Ocular involvement at the onset of disease is frequent and can range from acute conjunctivitis, eyelid oedema, erythema, crusts, and ocular discharge to conjunctival membrane or pseudomembrane formation or corneal erosion. The Nikolsky sign is positive if mechanical pressure induces epidermal detachment, but is not specific for SJS. Abnormal laboratory findings may include an elevated sedimentation rate, hypoalbuminemia, elevated liver enzyme levels, microscopic haematuria, and mild leukocytosis. Mucosal involvement in the form of erythema and erosions is seen in up to 90 % of cases. The commonest site involved is the oral and genital mucosa, and in some cases the respiratory and gastrointestinal tracts are also affected [50].

Oesophageal disease manifests as dysphagia and retrosternal pain. Lesions involve the mucosal lining of the entire oesophagus, with blistering of the epithelium and formation of large ulcers. There is sloughing of mucosa which can cause gastrointestinal bleeding. Usually there is complete healing of the lesions of the gastrointestinal tract, but rarely there can be cicatrisation with formation of stricture [12].

Treatment is in the form of withdrawal of the causative agent and supportive therapy in the form of nutrition and fluid and electrolyte management. There is some data supporting the use of intravenous immunoglobulin, though they are not in general use currently in the treatment of SJS [49].

Hyperkeratotic Disorders

Acanthosis Nigricans

Acanthosis nigricans (AN) is caused by factors that stimulate epidermal keratinocyte and dermal fibroblast proliferation. In the benign form of acanthosis nigricans, this factor is probably insulin or insulin-like growth factor (IGF). Other proposed mediators include epidermal growth factor receptor [EGFR] or fibroblast growth factor receptor [FGFR]. Familial and syndrome forms of AN have been identified. Many syndromes share common features, including obesity, hyperinsulinism, and craniosynostosis.

Acanthosis nigricans is more common in people with darker skin pigmentation, with prevalence in whites less than 1 % in whites less than 1 % [42], but has no sex predilection [58]. Patients usually present with an asymptomatic area of darkening and thickening of the skin. Lesions begin as hyperpigmented macules and patches and progress to palpable plaques. Histological examination reveals hyperkeratosis, papillomatosis, with minimal or no acanthosis, or hyperpigmentation. The dermal papillae project upward as finger-like projections, with occasional thinning of the adjacent epidermis.

Acanthosis can also involve the oesophagus which is in the form of granular nodules through the length of the oesophagus. Small irregular lining of the oesophagus can be seen in upper GI contrast, and endoscopy shows multiple papillary-protruded lesions with white apices in the entire oesophageal mucosa. Histological features of these lesions are epithelial hyperplasia and papillomatosis [40]. AN increases the risk of developing oesophageal carcinoma in adulthood.

Darier's Disease (Keratosis Follicularis)

Keratosis follicularis is an autosomal dominant inherited disease characterised by hyperkeratotic papules in seborrheic regions. The underlying defect resides with a disorder of cytoskeletal

tonofibrils and desmosomes. A mutation in the long arm of chromosome 12 (ATP 2A2 gene) has been implicated [52]. Abnormal keratinocyte-keratinocyte adhesion and aberrant epidermal keratinisation are the primary histological features of keratosis follicularis. Electron microscopy reveals loss of desmosomes, breakdown of desmosome-keratin intermediate filament attachment, and perinuclear aggregates of keratin intermediate filaments. It usually presents in the first or second decade of life and both sexes are equally affected [45]. The severity of disease can vary considerably between individuals with some being asymptomatic and others having extensive lesions. The skin lesions are characterised by hyperkeratotic papules and plaques primarily in seborrheic areas of the face, neck, and trunk. Small palmoplantar pits are very characteristic of Darier's disease.

Mucosal lesions are detected in approximately 15 % of patients and are found most commonly in the oral cavity or anogenital region. They are in the form of white papules with a central depression [9]. Though rare there are few reported cases of involvement of oesophageal mucosa and association with malignant change in adulthood [2].

Lichen Planus

Lichen planus is a subacute to chronic mucocutaneous disorder of unknown aetiology which in its classical presentation involves the oral cavity and skin. It affects both genders with equal frequency and can affect any age group. Cutaneous lichen planus is characterised by eruptions of violaceous, scaling papules and plaques. These plaques typically are intensely pruritic and are most commonly localised to the extensor surfaces of the forearms and legs. Lichen planus of the mucosal surfaces may include lesions of the perineum, pharynx, and oesophagus. Mucosal involvement coexists with skin lesions in approximately 30–50 % of patients, but can occur as the sole manifestation of disease [3]. Involvement of the oesophagus by lichen planus is a well described and is seen in up to 25 % of cases [8]. Correct diagnosis of oesophageal lichen planus is critical to distinguish from other more common causes of oesophagitis because of its tendency to cause persistent dysphagia and stricture formation.

Early symptoms are mainly of dyspepsia and heartburn. If left untreated, it develops into dysphagia resulting from oesophagitis and stricture formation. Due to lack of recognition of association between skin and oesophageal lesions, diagnosis is usually delayed, and patients are treated with antireflux medications [30]. Recognition of oesophageal lichen is important to prevent complications like stricture formation. Stricture dilatation, without concomitant medical treatment, can exacerbate extra-oesophageal disease in a Koebner-like phenomenon [20]. There is also a potential risk of malignant transformation to squamous cell carcinoma.

Endoscopic features of lichen are in the form of hyperkeratotic papules, nonspecific oesophagitis, and strictures in late stages. The risk of malignant transformation is currently unknown but may parallel that of oral lesions at approximately 1–3 %.

Histology shows band-like inflammatory infiltrate with a predominance of mature T cells and parakeratosis (Fig. 130.2).

Treatment is with immune-suppressive agents like corticosteroids, cyclosporine, and azathioprine. Retinoids have also been used for cutaneous lesions. Although most patients in the literature who have oesophageal lichen planus have been reported to show clinical improvement with these agents, relapse can be expected when treatment is discontinued [8].

Plummer-Vinson or Paterson-Kelly syndrome presents as a classic triad of dysphagia, iron-deficiency anaemia, and oesophageal webs and, although rare, has been described in children and adolescents [43]. Other signs may be glossitis, cheilitis (scaling and fissures at corners of mouth due to riboflavin deficiency), and nail changes. Patients are at an increased risk of postcricoid squamous cell carcinoma [4].

The pathogenesis of this condition is not known and may be due to iron and nutritional

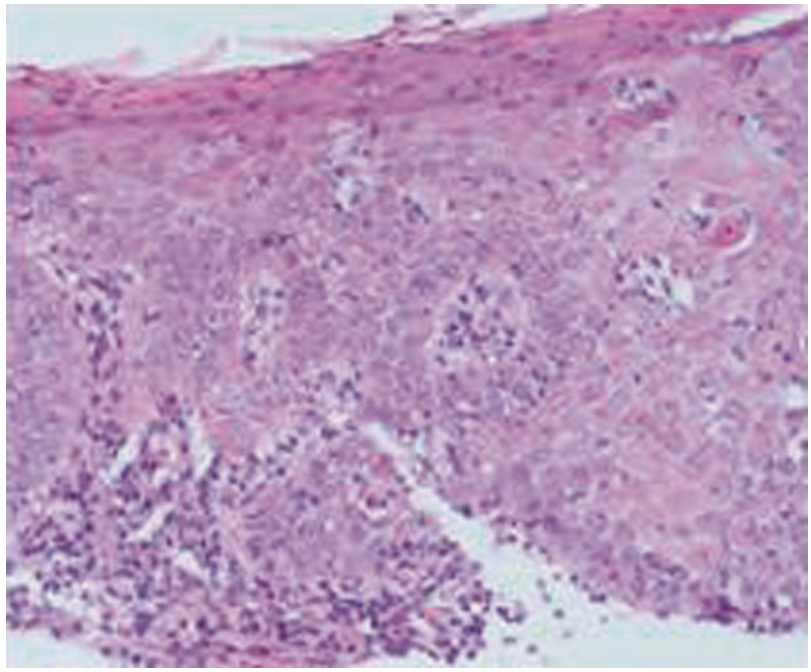

Fig. 130.2 Lichen planus. Squamous epithelium of the oesophagus showing lymphocytic infiltration and Civatte bodies

deficiencies and autoimmune factors in genetically predisposed individuals. The most important aetiological factor is iron deficiency and resulting anaemia, possibly based on decreased constricting power of the pharyngeal musculature due to impaired oxidative metabolism in the striated musculature, but other possible factors are malnutrition and perhaps autoimmunity. The dysphagia is worsened by formation of webs.

Treatment is with iron supplementation to correct deficiency. This usually is adequate to correct dysphagia except in cases with webs where oesophageal dilatation may be required. These patients would also need periodic monitoring for oesophageal carcinoma. The incidence of this condition is reducing which may be due to better diets and the treatment of sideropenic anaemia with inorganic iron salts [13].

Sweet's syndrome, also known as febrile neutrophilic dermatosis, can occur in children and has been reported in adult patients with underlying malignancy, including adenocarcinoma of the oesophagus [59].

Bullous Disorders

Epidermolysis Bullosa

Epidermolysis bullosa (EB) is a group of inherited disorders characterised by the formation of blisters spontaneously or after minor skin trauma. An estimated 5,000 and 12,500 people are affected in the United Kingdom and United States, respectively [19]. It results from the mutations of genes encoding for structural proteins located at the junction between the epidermis and the dermis. In normal individuals, there are "anchors" between the two layers that prevent them from moving independently from one another. In people born with EB, the two skin layers lack the anchors that hold them together, and any action that creates friction between the layers (like rubbing or pressure) will create blisters and painful sores.

There are three major types of EB, simplex, dystrophic and junctional. These vary from relatively mild to incapacitating, crippling, and sometimes fatal disorders. Within these there are

over 20 different subtypes of EB, each with their own characteristic symptoms.

The transmission of EB can be dominant or recessive, with recessive form being associated with more severe diseases. It is divided into three categories, epidermolysis bullosa simplex, junctional epidermolysis bullosa, and dystrophic epidermolysis bullosa.

The skin lesions in the recessive form start within the first few months of life. They are in the form of tense, fluid-filled blisters, erosions, or crusts. Areas prone to blistering due to pressure, trauma, or excessive heating include the fingers, hands, elbows, feet, legs, and diaper area. Scarring is often seen associated with these lesions [33].

EB frequently involves the gastrointestinal (GI) tract and may lead to poor dentition, oesophageal strictures, malabsorption, severe constipation, and anal fissures. The commonest areas involved are oral cavity, the oesophagus, and anal margin. Oral lesions with resultant scarring cause microstomia [28].

Oesophageal injury is due to the mechanical shearing force of the ingested food. It mainly affects the upper third and is in the form of bullous lesions which can easily rupture. Where there is rupture of bullae, the healing is with scar formation, and this can result in structuring of the oesophagus. There is also associated mucosal damage because of reflux secondary to low pressure in lower oesophageal sphincter. As the skin lesions are characteristic of EB, endoscopy does not add to the diagnosis and can cause further damage by mechanical trauma.

The mainstay of treatment of oesophageal disease is supportive. It is important to minimise trauma which is why soft diet is recommended. Gastrostomy feeding is an effective way of reducing damage and should be considered early in treatment. In view of associated gastroesophageal reflux, antireflux treatment helps minimise mucosal damage. Identification of strictures can be done by upper GI contrast studies and treatment is by balloon dilatation. Those who require frequent dilatations remain on ranitidine or omeprazole for indefinite periods [10]. Gene therapy in the form of transplantation of genetically modified epidermal stem cells to improve the adhesion properties of primary keratinocytes is being investigated as a definitive treatment [37].

Pemphigus

It is a chronic intraepidermal vesiculobullous autoimmune disease involving the skin and mucous membrane. The two main types are pemphigus vulgaris (PV) and pemphigus foliaceus (PF). Childhood pemphigus is a rare disease [15] and constitutes a minority of all the immunobullous disorders in childhood [29]. The mean age of onset in children is 12 years. Mucosal involvement is the first feature followed by cutaneous bullae. Oral mucosa is most commonly involved with blisters and erosions present in 50–70 % of patients [42]. Other mucosal surfaces involved may be the conjunctiva, oesophagus, anus, and genital and nasal mucosa. The primary skin lesion of pemphigus is flaccid vesicles on erythematous or normal skin which breaks easily to form erosions and crust.

Oesophageal disease presents as dysphagia and odynophagia. Typical mucosal lesions are in the form of flaccid bullae and erosions, and the mucosal lining may be detached. Histological examination shows severe inflammation and acantholysis of cells [53]. Strictures can form with long-standing disease and usually present in third to fourth decade of life [53].

The treatment is with high-dose systemic steroids. Other therapies include erythromycin, chloroquine, methotrexate, sulfapyridine, azathioprine, and hydroxychloroquine. A majority of children remain in remission either off medication or low maintenance dose within 1 year regardless of the type of therapeutic intervention used [14].

Crohn's Disease

Crohn's disease (CD) can involve any part of the gastrointestinal tract and is characterised by transmural inflammation of the affected part of

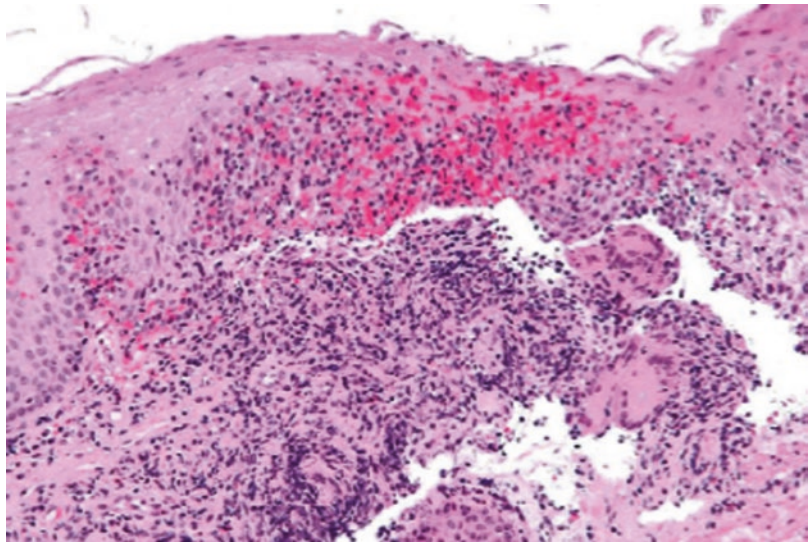

Fig. 130.3 Oesophageal involvement in Crohn's disease

the gut. The incidence of inflammatory bowel disease in the UK according to the British Paediatric Surveillance Unit (BPSU) was 5.3 per 100,000 children, of whom 60 % had CD. Oesophageal involvement is seen in 16 % of children with CD [54] (Fig. 130.3). Approximately, 7–24 % of affected children experience extraintestinal manifestations, of which dermatologic lesions are the second most common [57]. Symptoms of oesophageal disease include odynophagia, dysphagia, and heartburn. Aphthous ulceration is the usual finding of oesophageal CD with biopsies showing characteristic inflammation with or without granulomata. Sometimes linear serpiginous ulcers with cobblestoned mucosa can also be seen. Dermatologic lesions commonly associated with CD and may be as high as 34 % [23] and include erythema nodosum, pyoderma gangrenosum, and cutaneous CD. Less common manifestations are oral-facial granulomatosis, and inflammatory erythema nodosum, an acute, nodular, erythematous eruption seen in the extensor aspects of the lower legs, occurs in as many as 15 % of patients with CD [32]. Pyoderma gangrenosum is seen mainly in ulcerative colitis but also in some cases with CD. It is characterised by a deep ulceration with a violaceous border that overhangs the ulcer bed. These lesions of pyoderma gangrenosum most commonly occur on the legs, but may occur anywhere on the body.

Treatment of these dermatologic conditions is empiric and involves primarily topical and systemic corticosteroids and immunomodulatory agents. Miscellaneous associations include finger clubbing and vitiligo. Cutaneous manifestations secondary to disease complications include vitamin and micronutrient deficiency as a result of malabsorption – stomatitis, glossitis, angular cheilitis (iron and vitamin B), purpura (vitamin C and K), and acrodermatitis enteropathica (zinc). Cutaneous manifestations due to treatment include drug eruptions.

Infections

Human herpesvirus oesophagitis is a well-known infectious complication of patients with an impaired immune system and has also been described as a self-limiting illness in immunocompetent patients [51]. Reactivation of varicella-zoster virus (VZV) as herpes zoster is a well-recognised cause of morbidity in the HIV-infected host: other described complications are ocular, neurological, and chronic atypical skin lesions [22]. No cases of oesophagitis and spontaneous oesophageal perforation caused by VZV have been reported.

Herpes Simplex Oesophagitis

Herpes oesophagitis is more common in immunocompromised children but is an underrecognised condition in the immunocompetent child [6, 65]. It presents either as a primary herpes simplex virus (HSV) infection or reactivation. Fever, odynophagia, vomiting drooling, irritability, and retrosternal pain are presenting features. These symptoms may not be diagnostic, leading to a difficult and delayed diagnosis, unless exposure to HSV disease has been described or skin and/or oropharyngeal lesions are recognised. Endoscopy typically shows erythema and ulcers mainly in the distal and mid-oesophagus, but at times, the disease affects the entire oesophagus. Appearances can mimic the burns caused by caustic soda ingestion in children. Herpes oesophagitis is manifested by the development of small vesicles that subsequently rupture to form discrete superficial ulcers on the mucosa. In immunocompetent patients, the host response promotes healing of the ulcers, but in patients who are severely immunocompromised, the condition may progress from discrete areas of ulceration to a diffuse hemorrhagic oesophagitis or perforation. Histological examination shows inflammation with intranuclear inclusions present in about half of the cases [7]. Culture and PCR are the most specific tests for diagnosis and should be performed in all suspected cases [38].

Treatment of herpes oesophagitis in immunocompromised individuals is with acyclovir. In immunocompetent patients, its role is doubtful, and there is some adult data supporting its use as it reduces the duration and severity of symptoms [31].

Other causes of herpes virus oesophagitis in patients with human immunodeficiency virus (HIV) infection have been reported due to cytomegalovirus (CMV) and herpes simplex virus types 1 and 2 (HSV 1/2).

Varicella Zoster

Typically, varicella-zoster infection remains cutaneous, although visceral involvement has been described especially in immunocompromised patients. Varicella oesophagitis is a rare complication. In immunocompetent children, it is self-resolving, but in immunocompromised individuals, it can cause blistering lesion which can form ulcers [61].

Fig. 130.4 Oesophageal candidiasis

Oesophageal Candidiasis (Fig. 130.4)

Opportunistic oesophageal infections may occur in HIV-positive patients, who may manifest other skin lesions like Kaposi's sarcoma [46]. Kaposi's sarcoma is a neoplastic disorder of endothelial cell proliferation that occurs most frequently in the skin associated with the HIV virus, and gastrointestinal lesions are common.
